HANDBOOK OF ECONOMIC GROWTH

PHILIPPE AGHION AND STEVEN DURLAUF, EDITORS
ELSEVIER, 2005

Here is a list of chapters that are available online in working paper form. Thanks to Mark Feldman for reorganizing the list to match the order of the published handbook. Apologies for any errors or omissions; please let me know about them and I will correct them promptly.

Last updated March 14, 2006 by Chad Jones <chad@econ.berkeley.edu>.

The published version of the Handbook of Economic Growth is here. (Your university must have a subscription to the Handbooks for this to work.)

Ch 00 Reflections on Growth Theory (Not available online, to my knowledge.)
Robert M. Solow

Ch 01 Neoclassical Models of Endogenous Growth: The Effects of Fiscal Policy, Innovation and Fluctuations
Larry E. Jones and Rodolfo E. Manuelli

Ch 02 Growth with Quality-Improving Innovations: An Integrated Framework
Philippe Aghion, Harvard University and Peter Howitt, Brown University

Ch 03 Horizontal Innovation in the Theory of Growth and Development
Gino Gancia, CREI and Fabrizio Zilibotti, Institute for International Studies and University College London.

Ch 04 From Stagnation to Growth: Unified Growth Theory
Oded Galor, Hebrew University at Jerusalem and Brown University

Ch 05 Poverty Traps
Costas Azariadis, UCLA and John Stachurski, University of Melbourne

Ch 06 Institutions as the Fundamental Cause of Long-Run Growth
Daron Acemoglu, MIT, Simon Johnson, MIT, and James Robinson, UC Berkeley

Ch 07 Growth Theory through the Lens of Development Economics
Abhijit Banerjee, MIT and Esther Duflo, MIT

Ch 08 Growth Econometrics
Steven Durlauf, University of Wisconsin, Paul Johnson, Vassar College, and Jonathan Temple, University of Bristol

Ch 09 Accounting for Cross-Country Income Differences 
Francesco Caselli, Harvard University

Ch 10 Accounting for Growth in the Information Age
Dale Jorgenson, Harvard University

Ch 11 Externalities and Growth
Peter Klenow, Stanford University, and Andres Rodriguez-Clare, IADB

Ch 12 Finance and Growth: Theory and Evidence 
Ross Levine, University of Minnesota

Ch 13 Human Capital and Technology Diffusion
Jess Benhabib, NYU and Mark Spiegel, FRBSF

Ch 14 Growth Strategies
Dani Rodrik, Harvard University

Ch 15 National Policies and Economic Growth: A Reappraisal
William Easterly, NYU

Ch 16 Growth and Ideas 
Charles I. Jones, University of California at Berkeley

Ch 17 Long-term Economic Growth and the History of Technology
Joel Mokyr, Northwestern

Ch 18 General Purpose Technologies
Boyan Jovanovic, NYU and University of Chicago and Peter L. Rousseau, Vanderbilt

Ch 19 Technological Progress and Economic Transformation 
Jeremy Greenwood, University of Rochester and Ananth Seshadri, University of Wisconsin

Ch 20 The Effects of Technical Change on Labor Market Inequalities
Andreas Hornstein (Richmond Fed), Per Krusell (Princeton), and Gianluca Violante (NYU)

Ch 21 A Unified Theory of the Evolution of International Income Levels
Stephen Parente, University of Illinois and Edward Prescott, University of Minnesota

Ch 22 A Global View of Economic Growth

Jaume Ventura, CREI Pampeu Fabra

Ch 23 Trade, Growth and the Size of Countries
Alberto Alesina, Harvard University, Enrico Spolaore, Brown University, and Romain Wacziarg, Stanford University

Ch 24 Urbanization and Growth
J. Vernon Henderson, Brown University

Ch 25 Inequality, Technology, and the Social Contract
Roland Benabou, Princeton University

Ch 26 Social Capital
Steven N. Durlauf and Marcel Fafchamps

Ch 27 The Effect of Economic Growth on Social Structures
Francois Bourguignon, The World Bank

Ch 28 Economic Growth and the Environment: A Review of Theory and Empirics
William Brock, University of Wisconsin and M. Scott Taylor, University of Wisconsin

Neoclassical Models of Endogenous Growth: The Effects of Fiscal Policy, Innovation and Fluctuations*

Larry E. Jones
University of Minnesota and
Federal Reserve Bank of Minneapolis

Rodolfo E. Manuelli
University of Wisconsin

August, 2004

1 Introduction

Despite its role as the centerpiece of modern growth theory, the Solow model is decidedly silent on some of its basic questions: Why is average growth in per capita income so much higher now than it was 200 years ago? Why is per capita income so much higher in the member countries of the OECD than in the less developed countries (LDC) of the world? The standard implementation of the Solow model really has no answers for these questions except, perhaps for differences, across time and across countries in the production possibility set. This is typically summarized by differences in Total Factor Productivity (TFP). The fundamental reasons for why TFP might be different in different countries, or in different time periods is left open for speculation. If these differences are supposed to be due to differences in innovations, it is not made clear why access to these innovations should be different, nor is it noted that these innovations themselves are economic decisions– they have costs and benefits, and are made by optimizing, private agents.

This basic weakness in the Solow model (and its followers) was the driving force behind the development of the class of endogenous growth models. This literature has been wide and varied, with the models developed ranging from perfectly competitive, convex models to ones featuring a range of types of market failures (e.g., increasing returns, external effects, imperfectly competitive behavior by firms, etc.). But, a common feature that has been emphasized throughout is knowledge, or human capital, and its production and dissemination. In come cases, this has been

*Draft of a chapter for the forthcoming Handbook of Economic Growth edited by S. Durlauf and P. Aghion.

directly treated in the modeling, in others it has been more tangential, an important consideration for quantitative development, but less so for qualitative work. That this focus is essential follows from the fact that the Solow model already accurately reflects the quantitative limits of using models with only physical capital. (That is, capital's share is determined by the data to put us in the Solow range, technologically.) Although they differ in their details, in the end, what this class of models points to as differences in development are differences in social institutions across time and countries. Thus, countries that have weaker systems of property rights, or higher wasteful taxation and spending policies, will tend to grow more slowly. Moreover, these differences in performance can be permanent if these institutions are unchanging. As a corollary, those countries who developed these growth enhancing institutions more recently (and some still have not), have levels of income that are lower than those in which they were adopted earlier, even if current growth rates show only small differences.

In this paper we limit ourselves to studying neoclassical models. By this we mean models with convex production sets, well behaved preferences and a market structure that is consistent with competitive behavior. Therefore, we do not review the large literature that adresses the role of externalities and non-competitive markets. As it turns out, most of the basic ideas behind this literature can be expressed in simple, convex models of aggregate variables without uncertainty. These are the models that are the first focus of this chapter. They have proven both highly flexible and easy to use. With them, we can give substance to statements like those above that property rights and other governmental institutions are key to long run growth rates in a society. Most of this branch of the literature is well known by now, and much of it appears on standard graduate macro reading lists. Accordingly, our discussion will be fairly brief.[1] One important, and as of yet unresolved issue, is the size of the growth effects of cross-country differences in fiscal policy. Thus, our review of the standard convex model is complemented with a discussion of the more recent findings about the quantitative effects of taxes (and government spending) on growth. Even though the theoretical effects of social institutions are well understood, this is less true of the recent work on perfectly competitive models of innovation, and so, comparatively more space is used to discuss that ongoing development. As a second focus, one issue that comes immediately to light in studying this class of models is the possibility that uncertainty per se might have an impact on long run performance. This points to the possibility that instability in property rights and institutions might change the incentives for investment. That is, how are the time paths of savings, consumption and investment affected by uncertainty in this class of models? How does this compare with how uncertainty affects decisions in the Solow model (i.e., Brock and Mirman

[1] Other authors have also presented comprehensive surveys of this literature (see Barro and Sala-i-Martin (1995), Jones and Manuelli (1997), and Aghion and Howitt (1998) for examples). Our aim is to complement those presentations, rather than repeat them, and hence, our focus is somewhat distinct.

(1972) vs. Cass (1965) and Koopmans (1965))?

Much less is known about the answers to these questions at the present time and that knowledge that does exist is much less widespread. For this reason, we present a fairly detailed discussion of the properties of stochastic, convex models of endogenous growth. To this end, we study models in which technologies and policies are subject to random shocks. We characterize the effects of differential amounts of uncertainty on average growth. We show that increased uncertainty can increase or decrease average growth depending on both the parameters of the model and the source of the uncertainty. A separate, but related topic, is the business cycle frequency properties of these models. This is left to future work.

In section 2, we lay out the basics of the class of neoclassical (i.e., convex) models of endogenous growth. We show how differences in social institutions across time and across countries can give rise to different performance, even over the very long run. We also lay out some of the interpretations of the model, including human capital investment and innovation and knowledge diffusion sectors, that lend richness to its interpretation. Section 3 discusses properties of the models when uncertainty is added, and shows how this can affect the long run growth rate of an economy.

2 Endogenous Growth: Infinite Lifetimes

Historically, the engine of growth as depicted in Solow's seminal work on the topic (1956) was the assumption of exogenous technical change. Thus, initially, growth models aimed at being consistent with growth facts, but gave up on the possibility of explaining them. Moreover, this approach has weaknesses in two distinct areas. First, it is difficult using the exogenous growth model to explain the observed long run differences in performance exhibited by different countries. Second, the productivity changes that are assumed exogenous in the Solow model are, in fact, the result of conscious decisions on the part of economic agents. If this is the case, it is then important to explore both the mechanism through which productivity changes as well as the factors that can give rise to the observed long run differences if we are to understand these phenomena. In this section we briefly review the basic optimal growth model as initially analyzed by Cass (1965) and Koopmans (1965). We then discuss the nature of the technologies consistent with endogenous growth and the role of fiscal policy in influencing the growth rate. We conclude with an analysis of the role of innovation in the context of convex models of equilibrium growth.

2.1 Growth and the Solow Model

In the simplest time invariant version of the Solow model, it can be shown that the per capita stock of capital converges to a unique value independent of initial conditions. It is then necessary to assume some exogenous source of productivity growth in order to account for long run growth. In Solow (1956), it is assumed that

labor productivity grows continually and exogenously. In response, the capital stock (assumed homogeneous over time) is continually increased allowing for a continual expansion in the level of output and consumption. The literature on endogenous growth has concentrated on replacing this assumed exogenous productivity growth by an endogenous process. If this change in productivity of labor is thought to arise from the invention of techniques consciously developed, the literature on endogenous growth can then be thought of as explicitly modeling the decisions to create this technological improvement (see Shell (1967) and (1973)). For this to go beyond a reinterpretation of the Solow treatment, it must be that the technology for discovering and developing these new technologies does not have itself a source of exogenous technological change. Because of this, these models all feature technologies that are time stationary.

The consumer problem in the simple growth model is given by

$$\max_{\{c_t\}} \sum_{t=0}^{\infty} \beta^t u(c_t)$$

subject to

$$\sum_{t=0}^{\infty} p_t(c_t + x_t) \leq W_0 + \sum_{t=0}^{\infty} p_t r_t k_t, \tag{1a}$$

$$k_{t+1} = (1 - \delta_k)k_t + x_t, \tag{1b}$$

where c_t is the level of consumption, x_t is investment, k_t is the capital stock, p_t is the price of consumption (relative to time 0), and r_t is the rental price of capital, all in period t, and W_0 is the present value of wealth net of capital income. The first order condition for (an interior) solution to this problem is just

$$u'(c_t) = \beta u'(c_{t+1})[1 - \delta_k + r_{t+1}]. \tag{2}$$

If, as is standard in the literature, the instantaneous utility function, $u(c_t)$, is assumed strictly concave, growth —defined as a situation in which $c_{t+1} > c_t$— requires

$$\beta[1 - \delta_k + r_{t+1}] > 1. \tag{3}$$

Condition (3) is fairly general, and must hold *independently of the details of the production side* of the economy. Thus, if the economy is going to display long run growth, the rate of return on savings must be sufficiently high.

What determines the economy's rate of return? In the standard Solow growth model —and in many convex models— firms can be viewed as solving a static problem. More precisely, each firm maximizes profits given by

$$\Pi_t = \max_{k,n} c + x - r_t k - w_t n,$$

subject to

$$c + x \leq F(k, n),$$

where F is a concave production function that displays constant returns to scale.

Since in equilibrium the household offers inelastically one unit of labor, the rental rate of capital must satisfy

$$r_t = f(k_t), \tag{4}$$

where $f(k) = F(k, 1)$, and k is capital per worker.

It is now straightforward to analyze growth in the Solow model. The equilibrium version of (2) is just

$$u'(c_t) = \beta u'(c_{t+1})[1 - \delta_k + f(k_{t+1})]. \tag{5}$$

If the *productivity of capital* is sufficiently low as the stock of capital per worker increases, then there is no long run growth. To see this, note that if $\lim_{k\to\infty} f'(k) = \underline{r}$, with $1 - \delta_k + \underline{r} < 1$, there exists a finite k^* such that $1 - \delta_k + f(k^*) = 1$. It is standard to show that the unique competitive equilibrium for this economy (as well as the symmetric optimal allocation) is such that the sequence of capital stocks $\{k_t\}$ converges to k^*. Given this, consumption is also bounded. (Actually, it converges to $f(k^*) - \delta_k k^*$.)

Can exogenous technological change 'solve' the problem. The answer depends on the nature of the questions that the model is designed to answer. If one is content to generate equilibrium growth, then the answer is a clear yes. If, on the other hand, the objective is to understand how policies and institutions affect growth, then the answer is negative.

To see this assume that technological progress is labor augmenting. Specifically, assume that, at time t, the amount of effective labor is $z_t = z(1 + \gamma)^t$. In order to guarantee existence of a balanced growth path we assume that the utility function is isoelastic (see Jones and Manuelli (1990) for details), and given by $u(c) = c^{1-\theta}/(1-\theta)$. Let a $\hat{}$ over a variable denote its value relative to effective labor. Thus, $\hat{c}_t \equiv c_t/(z(1+\gamma)^t)$. In this case, the balanced growth version of (2) is

$$(1 + \gamma)u'(\hat{c}_t) = \hat{\beta} u'(\hat{c}_{t+1})[1 - \delta_k + f'(\hat{k}_{t+1})]$$

where $\hat{\beta} = \beta(1 + \gamma)^{1-\theta}$.[2]

Standard arguments show that the equilibrium of this economy converges to a steady state $(\hat{c}, \hat{k})$. Thus, this implies that, asymptotically, consumption is given by $c_t = (1 + \gamma)^t z\hat{c}$. Thus, even though there is equilibrium growth, the growth rate is completely determined by the exogenous increase in labor augmenting productivity.

[2]Existence of a solution requires that $\beta(1 + \gamma)^{1-\theta} < 1$, which we assume.

2.2 A One Sector Model of Equilibrium Growth

As we argued before, the critical assumption that results in the economy not growing is that the marginal product of capital is low. The modern growth literature has emphasized the analysis of economies in which the marginal product of capital remains (sufficiently) bounded away from zero. This induces positive long-run growth in equilibrium. As we will show, how fast output grows in these models depends on a variety of factors (e.g., parameters of preferences). Because of this, these models have the property that the rate of growth is determined by the agents in the model.

Throughout, there will be one common theme. This mirrors the point emphasized above, that for growth to occur, the interest rate (either implicit in a planning problem or explicit in an equilibrium condition) must be kept from being driven too low. This follows immediately from the discussion above.

In terms of key features of the environment that are necessary to obtain endogenous growth there is one that stands out: it is necessary that the marginal product of *some* augmentable input be bounded strictly away from zero in the production of some augmentable input which can be used to produce consumption.

Since we are dealing with convex economies, the arguments in Debreu (1954) apply to the environments that we study. Thus, in the absence of distortionary government policies, equilibrium and optimal allocations coincide. Thus, for ease of exposition, we will limit ourselves to analyzing planner's problems.

The planner's problem in the basic one sector growth model is given by

$$\max_{\{c_t\}} \sum_{t=0}^{\infty} \beta^t u(c_t),$$

subject to

$$\begin{aligned} c_t + x_t &\leq F(k_t, n_t), \\ k_{t+1} &\leq (1-\delta_k)k_t + x_t, \end{aligned}$$

where c_t is per capita consumption, k_t is the per capita stock of capital, x_t is the (nonnegative) flow of investment, and n_t is employment at time t. Since we assume that leisure does not yields utility, the optimal (and equilibrium) level of n_t equals the endowment, which we normalize to 1. The Euler equation for this problem is just (5) given that. as before, we set $f(k) = F(k, 1)$. It follows that if $\lim_{k\to\infty} \beta[1-\delta_k+f(k)] > 1$, then $\limsup_t c_t = \infty$. Thus, there is equilibrium growth. This result does not depend on the assumption of just one capital stock. More precisely, in the case of multiple capital stocks, the feasibility constraint is just

$$\begin{aligned} c_t + \sum_{i=1}^{I} x_{it} &\leq f(k_{1t}, ..., k_{It}), \\ k_{it+1} &\leq (1-\delta_{ik})k_{it} + x_{it}. \end{aligned}$$

In this case, the natural analogue of the assumption that the marginal product of capital is bounded is just that there is a homogeneous of degree one function —a linear function— that is a lower bound for the actual production function. However, it turns out that all that is required is that there exist a ray that has bounded marginal products. Formally, this corresponds to

Condition 1 (G) *Assume that* $f(k_1, ..., k_I) \geq h(k_1, ..., k_I)$*, where* h *is concave, homogeneous of degree one and* C^1 *for all* $(k_1, ..., k_I) \in \mathbb{R}^I_+$*. Moreover, assume that there exists a vector* $\hat{k} = (\hat{k}_1, ..., \hat{k}_I)$*,* $\hat{k} \neq 0$*, such that if* $\hat{k}_i > 0$*,*

$$\beta[1 - \delta_k + h_i(\hat{k})] > 1, \qquad i = 1, ..., I$$

The basic result is the following (see Jones and Manuelli (1990))

Proposition 2 *Assume that Condition G is satisfied. Then, any optimal solution* $\{c_t^*\}$ *is such that* $\limsup_t c_t^* = \infty$.

As Jones and Manuelli (1990) show, the planner's solution can be supported as a competitive equilibrium. An extension to multiple goods is presented by Kaganovich (1998) and it is based on similar insights. It is clear that Condition G does not rule out decreasing returns to scale. This, in turn implies that this class of models is consistent with a version of the notion of conditional convergence: relatively poor countries are predicted to grow faster than richer countries, with the consequent closing of the income gap. Put it differently, theory suggests that, with a finite amount of data, it is difficult to distinguish an endogenous growth model from a Cass-Koopmans exogenous growth model. The main difference lies in the tail behavior of the relevant variables (output or consumption), and not in the balanced (or unbalanced) nature of the equilibrium path.

2.3 Fiscal Policy and Growth

In this section we describe the effects of taxes and government spending on the long run growth rate. Consider the problem faced by a representative agent

$$\max \sum_{t=0}^{\infty} \beta^t u(c_t, 1 - n_t)$$

subject to

$$(1+\tau^c)c_t + (1+\tau^x)p_t x_{kt} + (1+\tau^h)q_t \leq w_t(1-\tau^n)(n_{ct}h_t + n_{kt}h_t) + (1-\tau^k)r_t k_t + T_t + \Pi_t,$$

where τ^j represent tax rates, c_t is consumption, x_{kt} is investment in physical capital, q_t are market goods used in the production of human capital, $n_{it}h_t$ is effective labor

—the product of human capital and hours— allocated to sector i, k_t is the stock of capital, T_t is a government transfer, and Π_t are net profits.

Accumulation of human capital at the household level satisfies

$$h_{t+1} \leq (1-\delta_h)h_t + F^h(q_t, n_{ht}h_t),$$

where F^h is homogeneous of degree one, concave and increasing in each argument.

The economy has two sectors: producers of capital and consumption goods. Output of the capital goods industries satisfies

$$x_t \leq F^k(k_{kt}, n_{kt}h_t),$$

where F^k is homogeneous of degree one and concave.

Feasibility in the consumption goods industry is given by

$$c_t \leq F^c(k_{ct}, n_{ct}h_t),$$

where F^c is increasing and concave. It is not necessary to assume that this production function displays constant returns to scale.

It is illustrative to consider several special cases. Throughout, we assume that the utility function is of the form that is consistent with the existence of a balanced growth path. Specifically, we assume that $u(c,\ell) = (cv(\ell))^{1-\theta}/(1-\theta)$. Moreover, since our emphasis is on the role of taxes and tax-like wedges between marginal rates of substitution and transformation, we assume that lump sum transfers, T_t, are adjusted to satisfy the government budget constraint.

Case I: One Sector Model with Capital Taxation We assume that the consumer supplies one unit of labor inelastically. In this case $F^c = F^k = Ak + \hat{F}(k)$, where $\hat{F}(k)$ is strictly concave and $\lim_{k\to\infty} \hat{F}'(k) = 0$. For now we ignore human capital and set $F^h \equiv 0$. It follows that the balanced growth rate satisfies

$$\gamma^\theta = \beta[1 - \delta_k + \frac{1-\tau^k}{1+\tau^x}A].$$

Thus, in this setting, increases in the effective tax on capital, $(1-\tau^k)/(1+\tau^x)$ unambiguously decrease the equilibrium tax rate. Thus, unlike exogenous growth models, government policies affect the growth rate. Moreover, this simple example illustrates the size of the impact of changes in tax rates on the long run growth rate depend on the intertemporal elasticity of substitution $1/\theta$. More precisely the elasticity of the growth rate with respect to τ^k is given by

$$\frac{\partial\gamma}{\partial\tau^k}\frac{\tau^k}{\gamma} = -\frac{1}{\theta}\frac{\frac{\tau^k}{1+\tau^x}A}{1-\delta_k+\frac{1-\tau^k}{1+\tau^x}A}.$$

It follows that, other things constant, high values of the intertemporal elasticity of substitution result in large changes in predicted growth rates in response to changes in tax rates. Thus, even an example as simple as this one illustrates that the quantitative predictions of this class of models will heavily depend on the values of the relevant preference (and technology) parameters.

Case II: Physical and Human Capital: Identical Technologies In this section we assume that $F^c = F^k$, and $F^h = q$. This implies that all three goods —investment, consumption and human capital— are produced using the same technology and, in particular, the same physical to human capital ratio. As in the previous section, τ^k and τ^x do not play independent roles. Thus, to simplify notation, we will set $\tau^x = 0$. However, the reader should keep in mind that increases in the tax rate on capital income are equivalent to increases in the tax rate on purchases of capital goods.

In this case, the balanced growth conditions are

$$\gamma^\theta = \beta[1 - \delta_k + (1 - \tau^k)F_k(\kappa, n)] \tag{6a}$$

$$\frac{c}{h}\frac{v'(1-n)}{v(1-n)} = \frac{1-\tau^n}{1+\tau^c}F_n(\kappa, n) \tag{6b}$$

$$(1 - \tau^k)F_k(\kappa, n) - \delta_k = \frac{1-\tau^n}{1+\tau^h}F_n(\kappa, n)n - \delta_h \tag{6c}$$

$$\frac{c}{h} + (\gamma + \delta_k - 1) = F(\kappa, n). \tag{6d}$$

There are several interesting points. First, increases in the tax rate on consumption goods (i.e. sales or value added taxes) are equivalent to increases in the tax rate on labor income. Second, the relevant tax rate to evaluate the return on human capital is $(1 - \tau^n)/(1 + \tau^h)$. Thus, it is possible that increases in τ^n —as observed in the U.S. between the pre World War II and the post WWII periods— if matched by decreases in τ^h (corresponding, for example, to expansion in the quantity and quality of free public education) have no effect on the physical capital - human capital ratio, κ. Third, it is possible to show that increases in τ^k, τ^n, τ^h or τ^c result in lower growth rates. Last, without making additional assumptions about preferences and technology, it is not possible to sign the impact of changes in tax rates on other endogenous variables.

Case III: Physical and Human Capital: Different Factor Intensities In this case, we assume that only human capital is used in the production of human capital. Thus, $F^h = A_h n_h h$. This is the technology proposed by Uzawa (1964) and popularized in this class of models by Lucas (1988). For simplicity, we only consider capital and labor taxes. The relevant steady state conditions are (6a), (6b), and (6d). However, (6c) becomes

$$\gamma^\theta = \beta[1 - \delta_h + A_h n] \tag{7}$$

In this version of the model, changes in labor income taxes, reduce growth through their impact on hours worked (relative to leisure). However, if total work time is inelastically supplied, i.e. $v(\ell) \equiv 1$, the growth rate is pinned down by

$$\gamma^{\theta} = \beta[1 - \delta_h + A_h].$$

Thus, in this setting (which corresponds to Lucas (1988) model without the externality, and to Lucas (1990)), taxes have no effect on growth. Increases in the tax rate on capital income simply change physical capital - human capital ratio and they leave the after tax rate of return unchanged. The reason for this extreme for of neutrality is that even though taxes on labor income reduce the returns from education, they also reduce the cost of using time to accumulate human capital (the value of time decreases with increases in taxes), and the two changes are identical. Thus, the cost-benefit ratio of investing in education is independent of the tax code.

2.3.1 Quantitative Analysis of the Effects of Taxes

Since the development of endogenous growth theory there have been several studies of the implications of substituting lump-sum taxes for a variety of distortionary taxes. Jones, Manuelli and Rossi (1993), analyze the optimal choice of distortionary taxes in several models of endogenous growth. In the case that physical and human capital are produced using the same technology and labor supply is inelastic, they find that for parameterizations that make the predictions of the model consistent with observations from the U.S., the potential growth effects of drastically reducing (eliminating in most cases) all forms of distortionary taxation is quite high. For their preferred parameterization the increase in growth rates is about 3%. They study a version of the model in which $F^c = F^k \neq F^h$., and the functions F^k andF^h are both of the Cobb-Douglas variety, but differ in the average productivity of capital. Jones, Manuelli and Rossi estimate the capital share parameter to be equal 0.36 in the consumption sector, and to be somewhere in the 0.40-0.50 range in the human capital production sector.[3] They also allow labor supply to be elastic. Their findings suggest that switching to an optimal tax code result in increases in yearly growth rates of somewhere between 1.5% and 2.0% per year. These are substantial effects.

The third experiment that they consider involves the endogenous determination (by the planner) of the level of government consumption. In this case, they revert back to the one sector version of the model, and they explore not only the consequences of changing the intertemporal elasticity of substitution, but they allow for varying elasticity of substitution between capital and human capital. For their preferred characterization, they also find growth effects of about 2% per year. Moreover, as in the other experiments, the predictions are quite sensitive to the details of the model

[3]Jones, Manuelli and Rossi (1993) calibrate this share. Since they study the sensitivity of their results to changes in other parameters (e.g. the intertemporal elasticity of substitution), the market goods share is not constant across experiments.

—in particular, to the choice of the intertemporal elasticity of substitution, and the degree of substitutability between capital and human capital.

Stokey and Rebelo (1995) undertake a thorough review of several models that estimate the growth impact of tax reform. They argue that in the U.S. tax rates in the post WWII period are significantly higher than in the pre WWII era. This conclusion is based on the increase in the revenue from income taxes as a fraction of GDP in the early 1940s. To reconcile the models with this evidence, they conclude that the human capital share in the production of human capital must be large, and that this sector must be lightly taxed. This description is close to the Case III above and, as argued before, it results in no growth effects[4]. Thus, in agreement with Lucas (1990) —and using a very similar specification of the human capital production technology— they conclude that changes in tax rates cannot have large growth effects.

This conclusion depends on several assumptions. First, that the U.S. evidence shows an increase in the general level of taxes after WWII. Second, that even if there is a tax increase, the additional revenue is used to finance lump-sum transfers. Third, that the balanced growth path is a good description of the pre and post WWII economy.

Measuring changes in the relevant marginal tax rates is a difficult task. Barro and Sahasakul (1986) using tax records compute average marginal tax rates for the U.S. economy. Their estimates, consistent with the Stokey and Rebelo assumption, show an increase in the 1940s. Even though the evidence about changes in the tax rate consistently points to an increase, the implications of this result for the model are not obvious. Consider, first, the uses of tax revenue. If, for example, additional income tax revenues (at the local level) are used to finance local publicly provided goods (e.g. education), then Tiebout-like arguments suggest that the 'tax effect' of a tax increase is zero. In the U.S. a substantial increase in government spending corresponds to increases in expenditures on education and, hence, the possibility of individuals sorting themselves to buy the 'right' bundle of publicly provided private goods cannot be ignored. A second quantitatively important public spending program in the post WWII era is Social Security. To the extent that benefits are dependent on contributions, the statutory tax rate on labor income used to finance social security overstates the true tax rate.[5] In this case, tax payments purchase the right to an annuity whose value is dependent on the payment. Finally, in a model with multiple tax rates an increase in a single tax does not imply, necessarily, a decrease in the growth rate. For the U.S. the evidence on the time path of capital income taxes is mixed. In a recent study, Mulligan (2003) argues that the tax rate on capital income has steadily fallen in the last 50 years. Similarly, Prescott and McGrattan (2003) and (2004) find that a decrease in the tax rate on corporate income —one form of

[4]The results are continuous in the parameters. Thus, for market goods share close to zero, as Stokey and Rebelo prefer, the growth effects are small.

[5]In a pay-as-you-go system, even if the share of total payments that an individual receives is sensitive to his contributions, the same effect obtains.

capital income— is instrumental in explaining the increase in the value of corporate capital relative to GDP. Overall, we find that the quantitative evidence on the time path of the relevant tax rates to be difficult to ascertain. More work is needed, with an emphasis on matching model and data.

The next section considers the effects of endogenous government spending and transitional effects.

2.3.2 Productive Government Spending

A Simple Balanced Growth Result In this section we study a simple one sector model that provides a role for productive government spending. Our discussion follows the ideas in Barro (1990). Assume that firm $i's$ technology is given by

$$y_{it} \leq A k_{it}^{\alpha} h_{it}^{\eta} G_t^{1-\alpha-\eta},$$

where k_{it} and h_{it} are the amounts of physical and human capital used by the firm, and G_t is a measure of productive public goods that firms take as given. The government budget constraint is balanced in every period, and it satisfies

$$G_t = \tau^k r_t K_t + \tau^h w_t H_t,$$

where τ^k and τ^h are the tax rates on capital and income, and r_t and w_t are rental prices. For simplicity we assume that the instantaneous utility function is given by

$$u(c) = \frac{c^{1-\theta} - 1}{1-\theta}.$$

We also assume that the technologies to produce market goods and human capital are identical. In this case, it is immediate to show that the equilibrium is fully described by

$$\begin{aligned} \delta_h - \delta_k &= A^{1/(\alpha+\eta)}(\alpha\tau^k + \eta\tau^h])^{(1-\alpha-\eta)/(\alpha+\eta)}[\eta(1-\tau^h)\kappa^{\alpha/(\alpha+\eta)} - \alpha(1-\tau^k)\kappa^{-\eta/(\alpha+\eta)}], \\ \gamma^{\theta} &= \beta[1 - \delta_k + \alpha(1-\tau^k)A^{1/(\alpha+\eta)}(\alpha\tau^k + \eta\tau^h)^{(1-\alpha-\eta)/(\alpha+\eta)}\kappa^{-\eta/(\alpha+\eta)}], \end{aligned}$$

where κ is the physical capital - human capital ratio.

Some tedious algebra shows that the growth rate is not a monotonic function of the tax rates. In general, there is no growth when taxes are either too low (not enough public goods are provided) or too high (the private returns to capital accumulation are too low). For intermediate values of the tax rates, growth is positive (if A is sufficiently high). Thus, in general, increases in tax rates need not result in lower growth if they are accompanied by changes in government spending. Thus, a variant of the model with endogenous government spending (or endogenous taxation and optimally chosen government spending) has potential to reconcile positive growth effects associated with the removal of distortions with the U.S. evidence.

What does the U.S. evidence show? In the U.S. there is a substantial increase in the ratio of government spending to GDP in the post WWII period on the order of 15%. Even ignoring defense related expenditures, the size of the federal government relative to output is close to 5% in the pre WWII period, and it increases steadily in the post war to reach about 20% of income. Of course, not all forms of government spending are productive, but if the trend in the productive component follows the trend in overall spending, ignoring changes in government spending result in biased estimates of the effects of distortions.

The Barro model is silent about the reasons why the desired ratio of (productive) government spending to GDP would increase. For this, it is necessary to have a model of the collective decision making mechanisms which is clearly beyond the scope of this chapter.

Progressive Taxes and Transition Effects Our discussion of the assumptions that suffice for sustained growth clearly shows that homogeneity of degree one is not necessary. In both theoretical and applied work it is common to appeal to linearity in order to ignore transitional dynamics (see, Bond, Wang and Yip (1996)) and Ladron de Guevara, Ortigueira and Santos (1997)) for analysis of the dynamics of endogenous growth models). However, when taking the model to the data, the assumption that the economy is on the balanced growth path may not be appropriate.

In this section we describe the results of Li and Sarte (2001). The basic insight from their model that is relevant for our discussion is that in the presence of heterogeneity in individual preferences and nonlinearities in the tax code, shocks to the tax regime (they consider an increase in the degree of progressivity of the tax code) that ultimately result in a decrease in the growth rate can have basically no effects for several decades.

The basic model that they consider is one in which goods are produced according to the following technology

$$Y_t \leq AK_t^{\alpha} L_t^{1-\alpha} G_t^{1-\alpha},$$

where K_t is capital at time t, L_t is the flow of labor, and G_t is a measure of productive public goods. All individuals have isoelastic preferences given by $u(c) = (c^{1-\theta} - 1)/(1-\theta)$, but they differ in their discount factors, β_i. Li and Sarte assume that each type has mass $1/N$, where N is population. The tax code is nonlinear. Given aggregate income Y, and individual income y_i, the *tax rate* is given by a function $\tau(z)$, where z is the ratio of individual to average income. In this application, Lin and Sarte assume that

$$\tau(\frac{y_i}{Y}) = \zeta(\frac{y_i}{Y})^{\phi}.$$

Note that the case of proportional taxes —the case discussed so far— corresponds to $\phi = 0$. In this setting, higher values of ϕ are interpreted as corresponding to more progressive tax codes. Individual income is defined as the sum of capital and labor income. Government spending is financed with revenue from income taxes. Li and

Sarte show that the equilibrium is the solution to the following system of equations

$$\begin{aligned}
\gamma^{\theta} &= \beta_i\{1-\delta+[1-(1+\phi)\zeta(\frac{y_i}{Y})^{\phi}]\alpha A^{1/\alpha}(\frac{G}{Y})^{(1-\alpha)/\alpha}, \qquad i=1,2,...I,\\
\frac{G}{Y} &= \sum_{i=1}^{I}\zeta(\frac{y_i}{Y})^{1+\phi}\frac{1}{N},\\
1 &= \sum_{i=1}^{I}\frac{y_i}{Y}\frac{1}{N}.
\end{aligned}$$

In this model, changes in the progressivity of the tax code affect the rate of return —this is the standard effect— as well as the distribution of income. It is this last effect that generates the slow adjustment. It is possible to show that an increase in ϕ decreases long run growth, γ.

Li and Sarte explore the dynamic effects of a one time increase in ϕ that result in a decrease in the growth rate of 1.5%. On impact, output growth increases because since the distribution of income does not adjust immediately, government revenues increase and this, in turn, increase output. As the low discount factor individuals adjust their relative income (an increase in progressivity affects them more than proportionally), government revenue (and spending decrease. For parameter values that are designed to mimic the U.S. economy, Li and Sarte find that the half-life of the adjustment is over 40 years. Thus, any test for breaks in the growth rate as suggested by models in which convergence is immediate would conclude (incorrectly) that the tax increase has no effects on growth.

It is difficult to evaluate how appropriate the Li and Sarte model is to study the impact of tax reform in the U.S. economy. However, it casts doubt on the approach by Stokey and Rebelo which ignores transitional dynamics. Models that rely on changes in tax rates that, in turn, affect the distribution of income, are consistent with the view that the effects of those changes are not monotone, and that the full impact may not be felt for decades.

2.4 Innovation in the Neoclassical Model

One of the things that seems unsatisfactory to many economists in the presentation up to this point is the starkness with which the technological side of the model is described. As we argued above, the key in improving over the Solow model is to explicitly consider decisions made by private agents about investments they make that cause technology to improve. This both endogeneizes the growth process envisaged by Solow and breaks away from another key assumption of the exogenous growth literature, that technological change happens without any resource cost. But, much of the detail that one thinks about as being an important part of the innovation process seems to be missing from the simple convex models of growth described above. The idea that innovation is carried out by specialized researchers who pass

on their newfound knowledge to production line workers is just one example of this. Indeed, one question is whether or not that kind of structure is consistent with convex models of growth at all.

Because of this, in this section we describe a variant of the models presented in the last section that is more directed at identifying innovation as a special activity. The purpose of this exercise is not to fully exhaust the possibilities, but rather to show the reader that more is possible with the class of convex models than one might first think. In particular, since the model we will analyze is convex, standard price taking behavior is consistent with equilibrium behavior. In this sense, the example we will present is similar to the ideas developed by Boldrin and Levine (2002).

There are many models of innovation that do not have convex technology sets (e.g., see the surveys in Barro and Sala-i-Martin (1995) and Aghion and Howitt (1998)). In this setting, standard price taking behavior is either not consistent with equilibrium in those settings or they must include external effects. Because of this, all policy experiments in those models mix two conceptually distinct aspects of policy, the desire to correct for monopoly power and/or external effects and the distortionary effects of 'wedges' (e.g. taxes). This, in turn, implies that the answers to questions about the effects of alternative policies on both the incentives to innovate and overall welfare depends on the details of the specifications of external effects (e.g., do other researchers learn new innovations for free after one month, or one decade) and/or market power (e.g., is there only one researcher at the frontier and so a monopoly analysis is in order, or are there two, or many). Thus, one thing that a convex model of innovation has to add is answers to some of these questions which are less dependent on those details.

2.4.1 Notation

We will follow the notation above as closely as is possible. We assume that there are two types of labor supply available, researchers and workers. Each individual of each type has his own level of knowledge. We will assume that there is a continuum of identical households each with some researcher time and some worker time to supply to the market. These are given by L_1 researcher hours per household, and L_2 worker hours per household, where $L = L_1 + L_2$ is total labor supply within the household. We will assume that L_1 and L_2 are fixed, with no ability to move hours between them. (In this sense, it might be easier to think of the household as being made up of L_1 researchers and L_2 workers.)

Each household has the level of knowledge H_t that they can use with researcher hours during period t. Thus, if households are symmetric, H_t symbolizes the absolute frontier of what 'society' knows at date t. Similarly, the level of knowledge for the average worker hour at date t is denoted by h_t. This will represent the average knowledge of those workers that work in the final goods sector below.

Final consumption at date t is denoted by c_t. We abstract from physical capital

to simplify.

Production Functions We will assume that:

$$\begin{aligned} H_{t+1} &= H_t + A_H L_{1t}^H H_t, \\ h_{t+1} &= (1-\delta_h)h_t + A_h(L_{1t}^h H_t)^\alpha (L_{2t}^h h_t)^{1-\alpha}, \\ c_t &= A_c L_{2t}^c h_t, \\ L_{1t}^H + L_{1t}^h &= L_1, \\ L_{2t}^h + L_{2t}^c &= L_2. \end{aligned}$$

This formulation is equivalent to one in which quality adjusted labor of the form $Z = LH$, (resp. $Z = Lh$) is employed in each activity.

The idea here is that $I_H = A_H L_{1t}^H H_t$ is new research and development or innovation, increasing H corresponds to learning more at society's highest level. Note that we have assumed that there is no depreciation– the level of frontier knowledge does not go backward (positive depreciation is easily included). If no innovation is done, $L_{1t}^H = 0$ for all t, $H_{t+1} = H_t$ for all t, that is, the frontier is static. In this case, h_t would also be bounded, and hence the level of output would be bounded above. In this sense, innovation is necessary for growth to occur in this model.

Similarly, we think of the $I_h = A_h(L_{1t}^h H_t)^\alpha (L_{2t}^h h_t)^{1-\alpha}$ technology as Education and/or Worker Training. This is where family members at the frontier spend part of their time educating the workers from the family on the use of new techniques. The more time researchers spend in I_h, the less time they have to spend in I_H, and hence workers are better prepared and more productive, but the frontier moves out more slowly. Note that increasing $L_{2t}^h h_t$, holding $L_{1t}^h H_t$ constant increases total output of worker productive knowledge (new h) but lowers the average product of frontier knowledge workers in educating (bigger classes give more total new training, but less output per student). Symmetrically, the more time that production line workers spend learning new knowledge, the less time they have available for production of current consumption goods.

Preferences We assume that each researcher/worker supplies one unit of labor to the market inelastically and that each has preferences of the form:

$$U(c) = \sum_t \beta^t u(c_t),$$

where $u(c) = c^{1-\sigma}/(1-\sigma)$. This model, although different in detail, shares one common critical feature with those above: linearity in the reproducible factors.

2.4.2 Balanced Growth Properties of the Model

Like many Ak, style models, this one has the feature that it converges to a Balanced Growth Path. Indeed if the initial levels of relative human capitals (H_0/h_0) are right

the economy is on the BGP in every period. Standard techniques can be used to characterize this BGP. After some algebra, we find:

$$\gamma^{\sigma} = \beta\left[1 + A_H L_1\right]$$

This equation gives γ as a function of the basic parameters σ, β, A_H, and L_1. By construction, the comparative statics of growth rates with respect to the deep parameters of the model are identical to what one would find in an Ak model. The one difference is the inclusion of the endowment of researcher hours, L_1, note that γ is increasing in L_1. That is, if one country had a higher proportion of researchers in its population, output would grow faster.

Since γ does not depend on the other parameters of the model, it can be shown that the only way income taxes affect growth rates here is through their effect on the R&D sector. That is, if we have a linear income tax (at rate τ) either on income generated in all sectors, or on income generated only in the H sector the growth rate will fall to:

$$\gamma_{\tau}^{\sigma} = \beta[1 + (1-\tau)A_H L_1]$$

In particular, if income from the h and/or c sectors are taxed, but that from the H sector is not, there are no effects on growth. This is reminiscent of the Lucas (1988) model and the 2-sector model in Rebelo (1991).

The amount of time spent on R&D on the BGP is given by:

$$\begin{aligned} L_1^H &= \frac{\left[\left(\beta\left[1 + A_H^*\right]\right)^{1/\sigma} - 1\right]}{A_H^*} L_1 = \frac{\left[\left(\beta\left[1 + A_H L_1\right]\right)^{1/\sigma} - 1\right]}{A_H L_1} L_1 \\ &= \left[\left(\beta\left[1 + A_H L_1\right]\right)^{1/\sigma} - 1\right] / A_H \end{aligned}$$

Thus, if we compare two countries with different discount factors, but identical in other respects, the one with the higher β will devote a higher fraction of its researcher time to innovation and a lower percentage to teaching. This causes worker productivity in the consumption sector to be lower at first (and consumption as well), but growing faster and hence, eventually overtaking the low β country.

As a second point, note that increases in A_h do not change γ (and neither do changes in A_c). Thus, in this case, L_1^H is not affected and so the time series of H_t will be identical. This implies that h_t must be higher. Thus, wages of both researchers and workers will be higher. This is similar in spirit to the result in Boldrin and Levine (2002) that improvements in the copying technology raises the value of being an innovator. Since the only 'copying' being done here is the passing on of new knowledge to final goods workers, this is analogous in this setting.

These are simple comparative statics exercises which are meant only to show that much intuition about the process of innovation, and its comparative statics properties with respect to incentives can be illustrated in this class of models.

There are many interesting extensions of the analysis that one could imagine. These include heterogeneity among households (e.g., some researcher households, some worker households), the inclusion of uncertainty about the results of researcher time (and the questions that this raises about ex post hold up problems when one researcher is the 'first' discoverer), the training of researchers by other researchers when they have different H_t 's, the inclusion of more than one good or process, what types of Industrial Organization are possible through decentralizations of the allocation as a competitive equilibrium (e.g., firms specializing in R&D vs. each firm having an R&D division), etc.

But, the reader can see that much of the analysis will go through unchanged. Notable exceptions are when there are assumed to be external effects in the learning process. The simplest example of this here would be to assume that $h = H$ no matter what L_2^h is. In this case, unless this is completely internalized within a firm (i.e., there are no spillovers across firms) the Planner's problem will not be implementable as a competitive equilibrium.

2.4.3 Adding a Non-Convexity

Most models of innovation differ from the one outlined above in that they assume that there is a non-convexity in the innovation technology. There are two ways to include this in the specification above, and the differences between them highlight a key question about innovation.

These are:

$$H_{t+1} = H_t + A_H L_{1t}^H H_t if L_{1t}^H \geq L^*,\ H_{t+1} = H_t\ if\ L_{1t}^H < L^* \tag{8}$$

and

$$H_{t+1} = H_t + A_H (L_{1t}^H - L^*) H_t\ if\ L_{1t}^H \geq L^*,\ H_{t+1} = H_t\ if\ L_{1t}^H < L^*. \tag{9}$$

Although these two specifications look similar, they differ in one key aspect. The technology in (8) is convex anytime R&D is 'active' (i.e., $L_{1t}^H \geq L^*$). The technology in (9) has constant marginal costs when R&D is active, but features a set-up cost as well (given by L^* denominated in labor units). Technology (9) is the specification that is most commonly employed in the R&D literature while that in (8) is similar in spirit to that used in Boldrin and Levine. Because of this difference, all of the analysis outlined above can be used if the technology is that given in (8) so long as in the solution to the planner's problem we have that $NL_{1t}^H \geq L^*$ for all t where N is the number of households. That is, the allocation can be supported as a competitive equilibrium with price taking behavior, etc. There are some restrictions on the implicit Industrial Organization in the equilibrium however. For example, if $NL_{1t}^H = L^*$ for all t it follows that there can be at most one R&D firm in any equilibrium (or one firm with an R&D division). This, were it true, would cause serious concern for the price-taking assumption in the decentralization.

One interesting implication of this model is that whether or not the solution to the planning problem above (without the non-convexity) describes the competitive allocation depends on the size of the country, N. Thus, large countries would, in equilibrium, conduct R&D while small countries would not. Adding in a fourth sector in which researchers in large countries could train researchers in small countries would be a natural extension in which R&D was done in large countries, these researchers train high H workers from small countries (e.g., in Engineering schools), those newly trained 'researchers' return to their home countries where they subsequently train production line workers, etc.

This description of equilibrium cannot be true for (9), however. Price taking behavior in this setting implies that prices for the rental of new knowledge equal their marginal cost of production. This implies that there is no way to recover the set up cost of researchers spending L^* hours. Thus, there can be no competitive equilibrium. It follows that there must be some monopoly rent generated somewhere to decentralize any allocation. Typically this will be accompanied by inefficiencies and incorrect incentives to conduct R&D.

3 Fluctuations and Growth

3.1 Introduction

In this section we describe the existing results on the effects of 'volatility,' both in technologies and policies, on the long-run growth rate. We start with a brief summary of the empirical research in this area, and we then describe some simple theoretical models that are useful in understanding the empirical results. We end with the description of some recent work based on the theoretical models but aimed at evaluating their ability to *quantitatively* match the growth observations. As before, we ignore models based on aggregate non-convexities, and with non-competitive market structures.

3.2 Empirical Evidence

A relatively small (but growing) empirical literature has tried to shed light on the relationship between 'instability' and growth. This literature has concentrated on estimating reduced form models that try to capture, with varying degrees of sophistication, how 'volatility' (defined in a variety of different ways) affects long-run growth.

Kormendi and Meguire (1985) is probably the earliest study in this literature. They consider a sample of 47 countries with data covering the 1950-1977 period. Their methodology is to run a cross-country growth regression with the average (over the sample period) growth rate as the dependent variable, and a number of control variables, including the standard deviation of the growth rate (one measure of instability), as well as the standard deviations of policy variables such as the inflation

rate and the money supply. Kormendi and Meguire find that the coefficient of the volatility measure (the standard deviation of the growth rate) is *positive* and significant. Thus, a simple interpretation of their results is that more volatile countries —as measured by the standard deviation of their growth rates— grow at a higher rate.

Grier and Tullock (1989) use panel data techniques on a sample of 113 countries covering a period from 1951 to 1980. Their findings on the effect of volatility on growth are in line with those of Kormendi and Meguire. They find that the standard deviation of the growth rate is *positively,* and significantly, associated with mean growth rates.

Ramey and Ramey (1995) first report the results of regressing mean growth on its standard deviation on a sample of 92 countries as well as a subsample of 25 OECD countries, covering (approximately) the 1950-1985 period. They find that for the full sample the estimated effect of volatility is negative and significant, while for the OECD subsample the point estimate is positive, but insignificant. In order to allow for the variance of the innovations to the growth rate to be jointly estimated with the effects of volatility, Ramey and Ramey posit the following statistical model

$$\gamma_{it} = \beta X_{it} + \lambda \sigma_i + u_{it} \tag{10}$$

where X_{it} is a vector of variables that affect the growth rate and

$$u_{it} = \sigma_i \epsilon_{it}, \qquad \epsilon_{it} \sim N(0,1). \tag{11}$$

The model is estimated using maximum likelihood. The control variables used were the (average) investment share of GDP (Average I/Y), average population growth rate (Average γ_{Pop}), initial human capital (measured as secondary enrollment rate, H_0), and the initial level of per capita GDP (Y_0). They study separately the full sample (consisting of 92 countries) as well as a subsample of 25 OECD (more developed) economies. Their results are reproduced in columns (1) and (3) of Table I.

Table I: Growth and Volatility I

Variables	(1) (92−*Country*) N = 2,184	(2) (92−*Country*) N = 2,184	(3) (*OECD*) N = 888	(4) (*OECD*) N = 888
Constant	0.07 (3.72)	0.08 (3.73)	0.16 (5.73)	0.16 (4.48)
σ_i	−0.21 (−2.61)	−0.109 (−1.22)	−0.39 (−1.92)	−0.401 (−1.93)
Average I/Y	0.13 (7.63)	0.12 (6.99)	0.07 (2.76)	0.071 (2.67)
Average γ_{Pop}	−0.06 (−0.38)	−0.115 (−0.755)	0.21 (0.70)	0.230 (0.748)
H_0	0.0008 (1.18)	0.0007 (1.03)	0.0001 (2.00)	0.0001 (1.954)
Y_0	−0.009 (−3.61)	−0.009 −3.53)	−0.017 (−5.70)	−0.017 (−4.7445)
$\sigma_{\ln(I/Y)}$	-	−0.023 (1.81)		0.007 (0.22)

Note: t-statistics in parentheses
Source: Columns (1) and (3) Ramey and Ramey (1995)
Columns (2) and (4), Barlevy (2002)

For both sets of countries, Ramey and Ramey find that the standard deviation of the growth rate is *negatively* related to the average growth rate. However, for the OECD subsample, the coefficient is less precisely estimated (even though the point estimate is larger in absolute value). Ramey and Ramey also consider more 'flexible' specifications that try to capture differences across countries in the appropriate forecasting equations. Considering the most parsimonious version of their model, the estimated effect of volatility on growth is still positive. However, the strength of the estimated relationship is reversed: for the OECD subsample the point estimate is four times the size of the estimate for the full sample and highly significant.

In more recent work, Barlevy (2002) reestimates the Ramey and Ramey model with one change: he adds the standard deviation of the logarithm of the investment-output ratio ($\sigma_{\ln(I/Y)}$) as one of the explanatory variables. Barlevy hypothesizes that this variable can capture non-linearities in the investment function. His results, using the same basic data as Ramey and Ramey are in columns (2) and (4) of Table I.[6] For the full 92-country sample, the introduction of this measure of investment volatility halves the size of the coefficient of σ_i, and it is no longer significant at conventional levels. The coefficient on $\sigma_{\ln(I/Y)}$ is *negative* and significant (at 5%). For the OECD sample, the addition of $\sigma_{\ln(I/Y)}$ does not affect much the estimate of the effect of σ_i on growth. However, Barlevy points out that this is finding is not robust, since eliminating two outliers, Greece and Japan where high volatility of the investment share seems to be due to transitional dynamics, implies that neither the volatility of the growth rate nor $\sigma_{\ln(I/Y)}$ are significant.[7]

[6] We thank Gadi Barlevy for providing us the estimated coefficient for the control variables.
[7] The point estimates are negative but insignificant.

One possible explanation for the differences in the estimates of the effects of volatility on growth found in Kormendi and Meguire, Grier and Tullock and Ramey and Ramey, is —as pointed out by Ramey and Ramey and Barlevi— that Kormendi and Meguire and Grier and Tullock include among their explanatory variables the standard deviations of policy variables that could be proxying for $\sigma_{\ln(I/Y)}$.

Kroft and Lloyd-Ellis (2002) also start from the basic statistical model of Ramey and Ramey but offer a different way of decomposing volatility. They hypothesize that uncertainty can be split into two orthogonal components: uncertainty about changes in regime (e.g. expansion-contraction) and fluctuations within a given regime. To this end, they generalize the empirical specification of the Ramey and Ramey statistical model to account for this. They assume that

$$\gamma_{ist} = \beta X_{it} + \lambda_w \sigma_{iw} + \lambda_b \sigma_{ib} + \upsilon_{ist}, \tag{12a}$$

$$\upsilon_{ist} = \sigma_{iw}\epsilon_{it} + \mu_{is}, \qquad \epsilon_{it} \sim N(0,1), \tag{12b}$$

$$\mu_{is} = \begin{cases} \mu_{ie} & \text{with probability } p_i = \frac{T_{ie}}{T} \\ \mu_{ir} & \text{with probability } 1 - p_i \end{cases} \tag{12c}$$

Kroft and Lloyd-Ellis interpret the standard deviation of the random variable μ_{is}, σ_{ib} —which they assumed observed by the economic agents but unobserved by the econometrician— as a measure of variability *between* regimes, while σ_{iw} is viewed as the *within-regime* variability. Kroft and Lloyd-Ellis estimate their model by maximum likelihood using the same sample as Ramey and Ramey. The results are in Table II

Table II: Growth and Volatility II

Independent Variable	92-Country Sample (2,208 observations)	OECD Sample (888 observations)
Constant	0.00132 (0.022)	0.095 (1.89)
Within-phase volatility (σ_{iw})	2.63 (4.69)	0.90 (1.44)
Between-phase volatility (σ_{ib})	−2.65 (−6.35)	−1.11 (−2.33)
Average investment share of GDP	−0.01 (−0.26)	−0.004 (−0.073)
Average population growth rate	0.58 (1.24)	0.28 (0.62)
Initial human capital	0.001 (0.66)	−0.00001 (−0.096)
Initial per capita GDP	0.002 (0.25)	−0.0008 (−1.30)

Note: t-statistics in parentheses.
Source: Kroft and Lloyd-Ellis (2002).

The major finding is that the 'source' of volatility matters: Increases in σ_{iw} — the within phase standard deviation— have a positive impact on growth for the full sample. For the OECD, the coefficient estimate is still positive but about one third of the size. The effect of the between-phase volatility, σ_{ib}, is negative in both cases.

However, the effects are stronger for the full sample. It is not easy to interpret the phases identified by Kroft and Lloyd-Ellis in terms of a switching model because their estimation procedure assumes that the econometrician can identify whether a particular period corresponds to either a recession or an expansion.[8]. Kroft and Lloyd-Ellis also use the same controls as Ramey and Ramey. However, they find that, when the two variances are allowed to differ, none of the control variables is significant. It is not clear why this is the case. One possibility is that the 'phases' that they identify are correlated with the control variables (this seems like a likely situation in the case of investment). Another possibility is that the control variables, in the Ramey and Ramey formulation, capture the non-linearity associated with the regime shift and that, once the shifts are taken into account, the control variables have no explanatory power. In any case, this illustrates a point that we will come back to: the fragility of the "growth" regressions suggest that better theoretical models are necessary to more provide restrictions that will allow to identify the parameters of interest.

The results of Ramey and Ramey and Kroft and Lloyd-Ellis are consistent with the existence of nonlinearities in the relationship between measures of instability and growth. Fatás (2001) estimates a number of different specifications of the relationship between instability and growth. His approach is to run standard cross country regressions. His data set is taken from the most recent version of the Heston-Summers sample and includes 98 countries with information covering the period 1950-1998. His estimates (see Table III) support the view that the effect of volatility on growth is nonlinear. Using Fatás' basic estimate —shown in column (1) of Table III— the pure effect of volatility is *negative* with a coefficient of -2.772 indicating that a one standard deviation increase in volatility reduces the growth rate by over 2.5%. However, the interaction term, corresponding to the variable Volatility * GDP is positive and equal to 0.340. According to these estimates, the net effect of σ_i on γ_i for the *richest* countries in the data is *positive* and greater than 0.3. For the less developed countries the estimate of the effect of volatility is *negative*. Columns (2) and (3) use other measures of non-linearity (initial per capita GDP and M3/Y, a measure of financial development), with similar outcomes: In all cases there is a significant effect, and increases in volatility are less detrimental to growth —and could even have a positive effect— the more developed a country is according to the proxy variables.

[8]Kraft and Lloyd-Ellis estimate the probabilites p_i as the fraction of the time that an economy spends in the recession "phase," defined as periods of negative output growth. Thus, not only is the process assumed to be *i.i.d.* but the transition probabilites are not jointly estimated with the parameters.

Table III: Growth and Volatility III			
Independent Variable	(1)	(2)	(3)
Volatility (σ_i)	−2.772	−1.700	−0.270
	(0.282)	(0.645)	(0.091)
GDP per capita (1960)	−2.229	−1.856	−0.953
	(0.235)	(0.422)	(0.220)
Human capital (1960)	0.037	0.040	0.026
	(0.015)	(0.018)	(0.017)
Average investment share of GDP	0.083	0.143	0.120
	(0.013)	(0.021)	(0.024)
Average population growth rate	−0.624	−0.562	−0.465
	(0.153)	(0.205)	(0.465)
Volatility * GDP	0.340	−	-

Martin and Rogers (2000) also study the relationship between the standard deviation of the growth rate and its mean, in a cross section of countries and regions. They study two samples —European regions and industrialized countries— and in both cases they find a *negative* relationship between σ_γ and γ. However, when they consider a sample of developing countries the point estimates are positive, but in general insignificant.

It is not easy to explain the differences between Ramey and Ramey, Fatás and Martin and Rogers. The period used to compute the growth rates (1962-1985 for Ramey and Ramey, 1950-1998 for Fatás and 1960 to 1988 for Martin and Rogers), and the set of less developed countries included (68 in Ramey and Ramey's study, and 72 in Martin and Rogers') are fairly similar. The two studies differ on their definition of the growth rate (simple averages in the Ramey and Ramey and Fatás papers, and estimated exponential trend in Martin and Rogers), and in the variables that are used as controls. However, it is somewhat disturbing that what appear, in the absence of a theory, as ex-ante minor differences in definitions can result in substantial differences in the estimates.

Siegler (2001) studies the connection between volatility in inflation and growth rates and mean growth for the pre 1929 period. Specifically, he uses panel data methods for a sample of 12 (presently developed) countries over the 1870-1929 period. He finds that volatility and growth are negatively correlated, and this finding is robust to the inclusion of standard growth regression type of controls.

Dawson and Stephenson (1997) estimate a model similar to (10) and (11) applied to U.S. states. They use the average (over the 1970-1988 period) growth rate of gross state product per worker for U.S. states as their growth variable, and its standard deviation as a measure of volatility. In addition, they include in their cross-sectional

regression the standard (in growth regressions) control variables (investment rate, initial level of gross state product per worker, labor force growth rate, and initial human capital). Dawson and Stephenson find that volatility has *no impact* on the growth rate, once the other effects are included. Unfortunately, they do not report the 'raw' correlation between mean growth and its standard deviation. Thus, it is not possible to determine if the lack of significance is due to the use of controls, or is a more robust feature of U.S. states growth performance.

Mendoza (1997) differs from the previous studies in terms of his definition of instability. Instead of the standard deviation of the growth rate, which, in general, is endogenous, he identifies instability with the standard deviation of a country's terms of trade. He estimates a linear model using a cross section of countries and finds a *negative* relationship between instability and growth. His sample is limited to only 40 developed and developing countries, and it only covers the period 1971-1991.

A fair summary of the existing results is that there is no sharp characterization of the relationship between fluctuations and growth. Variation across studies in samples or specifications yield fairly different results. Moreover, the findings do not seem robust to details of how the statistical model is specified.

Are the empirical findings of the channel through which uncertainty affects growth more robust? Unfortunately, the answer is negative. Ramey and Ramey find that volatility —measured as the standard deviation of the growth rate— does not affect the investment-output ratio. More recently, Aizenman and Marion (1999) find that volatility is negatively correlated with investment, when investment is disaggregated between public and private. Fatás estimates a non-linear model of the effect of volatility on investment. He finds that increases in volatility decrease investment in poor countries, but that the opposite is true in high income countries. Thus his findings are consistent with the view that changes in volatility affect mean growth rates through (at least partially) their impact upon investment decisions.

How should these empirical results be interpreted? Even though it is tempting to take one's preferred point estimate as a measure of the impact of fluctuations (or business cycles) on growth there are two problems with this approach. First, the empirical estimates are not robust to the choice of specification of the reduced form. Second, and more important in our opinion, is that from the point of view of policy design, the relevant measures of volatility is the —in general unobserved— volatility in *policies and technologies*. In most models, the growth rate (and its standard deviation) are endogenous variables and, as usual, the point estimate of one endogenous variable on another is at best difficult to interpret. One way of contributing to the interpretation of the empirical results is to study what simple theoretical models predict for the estimated relationships. In the next section we present a number of very simple models to illustrate the possible effects of volatility in fundamentals on mean growth. In the process, we find that it is very difficult to interpret the empirical findings. To put it simply, there are theoretical models that —depending on the sample— do not restrict the sign of the estimated coefficient of

the standard deviation of the growth rate on its mean. Moreover, the sign and the magnitude of the coefficient is completely uninformative to determine the effect of volatility on growth.

3.3 Theoretical Models

The analysis of the effect of uncertainty on growth can be traced to the early work of Phelps (1962), and Levhari and Srinivasan (1969) who studied versions of the stochastic consumption-saving problem that are similar to the linear technology versions of endogenous growth models. More recently, Leland (1974), studies a stochastic Ak model, and he shows that the impact of increased uncertainty on the consumption/output ratio depends on the size of the coefficient of risk aversion.

Even in deterministic versions of models that allow for the possibility of endogenous growth, existence of equilibria (and even optimal allocations) requires strong assumptions on the fundamentals of the economy (see Jones and Manuelli (1990) for a discussion). At this point, there are no general results on existence of equilibrium in stochastic versions of those models. In special cases, most authors provide conditions under which an equilibrium exists (see Levhari and Srinivasan (1969), Mendoza (1997), Jones et. al (2003a) and (2003b) for various versions). A recent, more general result is contained in de Hek and Roy (2001). These authors consider fairly general utility and production functions, but limit themselves to $i.i.d.$ shocks. It is clear that more work is needed.

In what follows, we will describe a general linear model and we will use it to illustrate the predictions of the theory for the relationship between mean growth rates and their variability. To simplify the presentation we switch to a continuous time setting. In order to obtain closed-form solutions we specialize the model in terms of specifying preferences and technology. Moreover, we will limit ourselves to $i.i.d.$ shocks. Generalizations of these assumptions are discussed in the section that presents quantitative results.

3.4 A Simple Linear Endogenous Growth Model

We begin by presenting a stochastic analog of a standard Ak model with a 'twist.' Specifically, we consider the case in which there are multiple linear technologies, all producing the same good. In order to obtain closed-form results we specify that the utility of the representative household is given by

$$U = E\left[\int_0^\infty e^{-\rho t}\frac{c_t^{1-\theta}}{1-\theta}dt\,|F_0\right]. \tag{13}$$

We assume that each economy has two types of technologies to produce consumption (alternatively, the model can be interpreted as a two sector model with goods

that are perfect substitutes). Output for each technology satisfies

$$\begin{aligned} dk_t &= ((A-\delta_k)k_t - c_{1t})dt + \sigma_k k_t dW_t + \eta_k k_t dZ_t^k, && \text{(14a)} \\ db_t &= ((r-\delta_b)k_t - c_{2t})dt + \sigma_b b_t dW_t + \eta_b b_t dZ_t^b, && \text{(14b)} \end{aligned}$$

where (W_t, Z_t^k, Z_t^b) is a vector of three independent standard Brownian motion processes, and k_t and b_t are two different stocks of capital. This specification assumes that each sector is subject to an aggregate shock, W_t, as well as sector (or technology) specific shocks, Z_t^j.

To simplify the algebra, we assume that capital can be costlessly reallocated across technologies, and we denote total capital by $x_t \equiv k_t + b_t$. Setting (without loss of generality) $k_t = \alpha_t x_t$ (and, consequently $b_t = (1-\alpha_t)x_t$) it follows that total capital evolves according to

$$\begin{aligned} dx_t &= [(\alpha_t(A-\delta_k) + (1-\alpha_t)(r-\delta_b))x_t - c_t]dt + \\ &\quad [(\alpha_t\sigma_k + (1-\alpha_t)\sigma_b)dW_t + \alpha_t\eta_k dZ_t^k + (1-\alpha_t)\eta_b dZ_t^b]x_t. \end{aligned} \qquad \text{(15)}$$

Given the equivalence between equilibrium and optimal allocations in this convex economy, we study the solution to the problem faced by a planner who maximizes the utility of the representative agent subject to the feasibility constraint. Formally, the planner solves

$$\max E\left[\int_0^\infty e^{-\rho t}\frac{c_t^{1-\theta}}{1-\theta}dt\,|F_0\right],$$

subject to (15).

Let the value of this problem be $V(x)$. Then, it is standard to show that the solution to the planner's problem satisfies the Hamilton-Jacobi-Bellman equation

$$\rho V(x) = \max_{c,\alpha}\left[\frac{c^{1-\theta}}{1-\theta} + V'(x)(\mu(\alpha)x - c) + \frac{V''(x)x^2}{2}\sigma^2(\alpha)\right],$$

where

$$\begin{aligned} \mu(\alpha) &= r + \alpha(A-r) - (\alpha\delta_k + (1-\alpha)\delta_b), && \text{(16a)} \\ \sigma^2(\alpha) &= (\alpha\sigma_k + (1-\alpha)\sigma_b)^2 + \alpha^2\eta_k^2 + (1-\alpha)^2\eta_b^2. && \text{(16b)} \end{aligned}$$

It can be verified that the solution is given by $V(x) = v\frac{x^{1-\theta}}{1-\theta}$, where

$$v = \left[\frac{\rho - (1-\theta)[\mu(\alpha^*) - \delta(\alpha^*) - \theta\frac{\sigma^2(\alpha^*)}{2}]}{\theta}\right]^{-\theta} \qquad \text{(17)}$$

and $\delta(\alpha) = \alpha\delta_k + (1-\alpha)\delta_b$.

The optimal decision rules are

$$\alpha^* = \frac{\frac{A-\delta_k-(r-\delta_b)}{\theta} - \sigma_b(\sigma_k - \sigma_b) + \eta_b^2}{(\sigma_k - \sigma_b)^2 + \eta_b^2 + \eta_k^2}, \tag{18a}$$

$$c = \frac{\rho - (1-\theta)[\mu(\alpha^*) - \delta(\alpha^*) - \theta\frac{\sigma^2(\alpha^*)}{2}]}{\theta} x. \tag{18b}$$

For the solution to be well defined it is necessary that $\rho - (1-\theta)[\mu(\alpha^*) - \delta(\alpha^*) - \theta\frac{\sigma^2(\alpha^*)}{2}] > 0$, which we assume. (In each case we make enough assumptions to guarantee that this holds.)[9]

It follows that the equilibrium stochastic differential equation satisfied by aggregate wealth is given by

$$\begin{aligned} dx_t = & [\frac{\mu(\alpha^*) - (\delta(\alpha^*) + \rho)}{\theta} - (1-\theta)\frac{\sigma^2(\alpha^*)}{2}]x_t dt + \\ & [(\alpha^*(\sigma_k - \sigma_b) + \sigma_b)dW_t + \alpha_k^* \eta_k dZ_t^k + (1-\alpha^*)\eta_b dZ_t^b]x_t, \end{aligned} \tag{19}$$

and the instantaneous growth rate of the economy, γ, and its variance, σ_γ^2, satisfy

$$\gamma = \frac{\mu(\alpha^*) - (\delta(\alpha^*) + \rho)}{\theta} - (1-\theta)\frac{\sigma^2(\alpha^*)}{2}, \tag{20a}$$

$$\sigma_\gamma^2 = (\alpha^*(\sigma_k - \sigma_b) + \sigma_b)^2 + \alpha^{*2}\eta_k^2 + (1-\alpha^*)^2\eta_b^2. \tag{20b}$$

One is tempted to interpret (19) as the theoretical analog of (10) by defining the stochastic growth rate as

$$\gamma_t = \frac{dx_t}{x_t}.$$

Given this definition, the discrete time —with period length equal to one— version of the stochastic process followed by the growth rate is

$$\gamma_t = \frac{\mu(\alpha^*) - (\delta(\alpha^*) + \rho)}{\theta} - (1-\theta)\frac{\sigma_\gamma^2}{2} + \varepsilon_t, \tag{21a}$$

$$\varepsilon_t = (\alpha^*(\sigma_k - \sigma_b) + \sigma_b)dW_t + \alpha^*\eta_k dZ_t^k + (1-\alpha^*)\eta_b dZ_t^b. \tag{21b}$$

This simple model driven by i.i.d. shocks has a stark implication: the growth rate is i.i.d. and is independent of other endogenous (or exogenous) variables, except through the joint dependence on the error term. Using panel data, it is relatively easy

[9] In endogenous growth models existence of an equilibrium is not always guaranteed. The main problem is that with unbounded instantaneous utility and production sets, utility can be infinite. For a discussion of some conditions that guaranteee existence see Jones and Manuelli (1990) and Alvarez and Stokey (1998). The key issue is that the return function is unbounded above when $0 < \theta < 1$, and unbounded below if $\theta > 1$. In this setting, it can be shown that $c > 0$ is equivalent to ensuring boundedness.

to reject this implication. This, however, is not an intrinsic weakness of this class of models. The theoretical setting *can* be generalized to include serially correlated shocks and a non-linear structure, which could account for "convergence" effects, and would provide a role for lagged dependent variables. However, generalizing the theoretical model comes at the cost of not being able to discuss the impact of different factors on the growth rate, except numerically.

What is the (simple) class of model that we study useful for? We view the class of theoretical models that we present as more appropriate to discuss the implications of the theory for cross section regressions since, in this case, the constant $\frac{\mu(\alpha^*)-(\delta(\alpha^*)+\rho)}{\theta} - (1-\theta)\frac{\sigma_\gamma^2}{2}$ can be correlated with other variables like the investment-output ratio.

Even though there is a formal similarity between (21) and (10)-(11), the theoretical model suggests that the simple approach that ignores that the same factors that affect σ_γ, also influence the true value of β in (10) can result in incorrect inference. Alternatively, the "deep parameters" are not the means and the standard deviation of the growth rates. They are the means and standard deviations of the driving stochastic processes. In terms of those parameters, the "true" model is non-linear.

Whether the model in (21) implies a positive or negative relationship between fluctuations and growth depends on the sources of shocks. At this general level it is difficult to illustrate this point, but we will come back to it in the context of specific examples.

It is not obvious how to define the investment ratio in this model. The change in cumulative investment in k, X_k, is given by,

$$dX_{kt} = \delta_k k_t dt + dk_t,$$

while the change in total output can be defined as[10]

$$dY_t = \mu(\alpha^*)x_t dt + \sigma_\gamma dM_t,$$

where M_t is a standard Brownian motion defined so that

$$\sigma_\gamma dM_t = (\alpha^*(\sigma_k - \sigma_b) + \sigma_b)dW_t + \alpha^*\eta_k dZ_t^k + (1-\alpha^*)\eta_b dZ_t^b.$$

In order to avoid technical problems, we consider a discrete time approximation in which the capital stocks change only at the beginning of the period. The investment-output ratio (for physical capital) is given by

$$z_t = \frac{\gamma + \delta_k + \sigma_\gamma \varepsilon_t}{\mu(\alpha^*) + \sigma_\gamma \varepsilon_t},$$

[10] This is not the only possible way of defining output. It assumes that the economy two sectors (or technologies). However, another interpretation of this basic framework considers b_t as bonds, and k_t as the only real stock of capital. We will be precise about the notion of output in each application.

where ε_t is the same noise that appears in (21). Since the previous expression is non-linear, we approximate it by a second order Taylor expansion to obtain

$$z_t = \frac{\gamma + \delta_k}{\mu(\alpha^*)} + \frac{\sigma_\gamma[\mu(\alpha^*) - (\gamma + \delta_k)]}{\mu(\alpha^*)^2}\varepsilon_t - \frac{\sigma_\gamma^2[\mu(\alpha^*) - (\gamma + \delta)]}{\mu(\alpha^*)^3}\varepsilon_t^2. \tag{22}$$

The mean investment ratio, which we denote z, is given by

$$z = \frac{\gamma + \delta_k}{\mu(\alpha^*)}[1 + \frac{\sigma_\gamma^2}{\mu(\alpha^*)^2}] - \frac{\sigma_\gamma^2}{\mu(\alpha^*)^2}. \tag{23}$$

Given this approximation, the model implies that the covariance between the growth rate and the investment-output ratio is

$$cov(\gamma_t, z_t) = \frac{\sigma_\gamma^2[\mu(\alpha^*) - (\gamma + \delta_k)]}{\mu(\alpha^*)^2}, \tag{24}$$

while the standard deviation of z_t is

$$\sigma_z = \frac{\sigma_\gamma[\mu(\alpha^*) - (\gamma + \delta_k)]}{\mu(\alpha^*)^2}\frac{(1 + \mu(\alpha^*)^2)^{1/2}}{\mu(\alpha^*)}. \tag{25}$$

Simple algebra shows that, given that the existence condition (17) is satisfied, $cov(\gamma_t, z_t) > 0$. Thus, in a simple regression, the investment ratio has to appear to affect positively growth. At this general level it is more difficult to determine if high σ_z economies are also high γ economies. The problem is that there are a number of factors that jointly affect γ and σ_z. In order to be more precise, it is necessary to be specific about the sources of heterogeneity across countries. We will be able to discuss the sign of this relationship in specific contexts.

We now use this 'general' model to discuss —in a variety of special cases— the connection between the variability of the growth rate of output and its mean

3.4.1 Case 1: An Ak Model

Probably the simplest model to illustrate the role played by differences in the variability of the exogenous shocks across countries is the simple Ak model. Even though it is a special case of the model described in the previous section, it is useful to describe the technology in a slightly different way. Let the feasibility constraint for this economy be given by

$$\int_0^t \hat{A}k_s ds + \int_0^t \sigma_y \hat{A}k_s dW_s \geq \int_0^t c_s ds + \int_0^t dX_{ks}.$$

The left hand side of this condition is the accumulated flow of output until time t, and the right hand side is the accumulated uses of output, consumption and investment. The law of motion of capital is

$$dk_t = -\delta_k k_t dt + dX_{kt},$$

where δ_k is the depreciation rate. Expressing the economy's feasibility constraint in flow form, and substituting in the law of motion for physical capital, the resource constraint satisfies

$$dk_t = [(\hat{A} - \delta_k)k_t - c_t]dt + \sigma_y \hat{A} k_t dW_t. \tag{26}$$

The planner's problem —which coincides with the competitive equilibrium in this economy— is to maximize (13) subject to (26). This problem resembles the more general model we introduced in the previous section if we set $\eta_b = \sigma_b = \eta_k = 0$, and

$$\begin{aligned} A &= \hat{A} - \delta_k, \\ \sigma_k &= \sigma_y \hat{A}. \end{aligned}$$

In addition, we need to make sure that the "b" technology is not used in equilibrium. A simple way of guaranteeing this is to view $r - \delta_b$ as endogenous, and to choose it so that, in equilibrium, $\alpha^* = 1$; that is, all of the investment is in physical capital. It is immediate to verify that this requires

$$r - \delta_b = \hat{A} - \delta_k - \theta \sigma_y^2 \hat{A}^2.$$

In this case is it follows that $x_t = k_t$ and the formulas in (20) imply that the mean growth rate and the variance of the growth rate satisfy

$$\begin{aligned} \gamma &= \frac{\hat{A} - (\rho + \delta_k)}{\theta} - (1 - \theta)\frac{\sigma_\gamma^2}{2}, \\ \sigma_\gamma^2 &= \sigma_y^2 \hat{A}^2. \end{aligned}$$

This result, first derived by Phelps (1962) and Levhari and Srinivasan (1969), shows that, in general, the sign of the relationship between the variance of the technology shocks, σ_y^2, and the growth rate is ambiguous:

- If preferences display less curvature than the logarithmic utility function, i.e. $0 < \theta < 1$, increases in σ_y are associated with decreases in the mean growth rate, γ.
- If $\theta > 1$, increases in σ_y are associated with increases in the mean growth rate, γ.
- In the case in which the utility function is the log (this corresponds to $\theta = 1$) there is no connection between fluctuations and growth.

The basic reason for the ambiguity of the theoretical result is that the total effect of a change in the variance of the exogenous shocks on the saving rate —and ultimately on the growth rate— can be decomposed in two effects that work in different directions:

- An increase in the variance of the technology makes acquiring future consumption less desirable, as the only way to purchase this good is to invest. Thus, an increase in variance of the technology shocks has a *substitution effect* that increases the demand for current (relative to future) consumption. This translates into a lower saving and growth rates.

- On the other hand, an increase in the variability of the exogenous shocks induces also an *income effect*. Intuitively, for concave utility functions, the fluctuations of the marginal utility decrease with the level of consumption. Thus, the (negative) effect of fluctuations is smaller when consumption is high. This income effect increases savings, as this is the only way to have a 'high' level of consumption (i.e. to spend more time on the relatively flat region of the marginal utility function).

The formula we derived shows that the relative strength of the substitution and income effects depends on the degree of curvature of the utility function: if preferences have less curvature than the logarithmic function, the substitution effect dominates and increases in the variance of the exogenous shocks reduce growth. If the utility of the representative agent displays more curvature than the logarithmic function, the income effect dominates and the relationship between fluctuations and growth is positive.

In this simple economy, the variance of the technology shock, σ_y^2, and the variance of the growth rate of output, σ_γ^2, coincide up to scale factor $\hat{A}$.[11] If one views the differences across countries as due to differences in σ_y^2,[12] the theoretical model implies that the true regression equation is very similar to the one estimated in the empirical studies. The only difference is that the theory implies that it is σ_γ^2, and not σ_γ, that enters the right hand side of (10). If we use this model to interpret the results of Ramey and Ramey (1995), one must conclude that the negative relationship between mean growth and its standard deviation is evidence that preferences have less curvature than the logarithmic utility, i.e. $0 < \theta < 1$. On the other hand, the Kormendi and Meguire (1985) findings suggest that $\theta > 1$.

In this simple example, the mean investment ratio —the appropriate version of (23)— is

$$z = \frac{\gamma + \delta_k}{\hat{A}}[1 + \sigma_y^2] - \sigma_y^2$$

As was pointed out in the previous section, the covariance between the investment-ratio and the growth rate is positive. In this example, the appropriate version of (25) is

$$\sigma_z = \sigma_y \left(\frac{\rho - (1-\theta)(\hat{A} - \delta_k - \frac{\theta}{2}\sigma_y^2 \hat{A}^2}{\theta} \right) \left(1 + \hat{A}^2\right)^{1/2}.$$

[11] In general, this is not the case.

[12] This is not necessary. In addition to differences in preferences —which we will ignore in this chapter— countries can differ in terms of $(\hat{A}, \delta_k)$ as well.

In this case, the increases in σ_y are associated with increases (decreases) in σ_z if $\theta <$ (>)1. Thus, if $\theta < 1$, the higher the (unobserved) variance of the technology shocks (σ_y^2), the higher the (measured) variances of both the growth rate, σ_γ^2, and the investment rate, σ_z^2, and the lower the mean growth rate. Moreover, in this stochastically singular setting the standard deviation of the growth rate and the investment rate are related (although not linearly). Thus, this simple model is consistent with the findings of Barlevy (2002) that the coefficient of σ_z is estimated to be negative, and that its introduction reduces the significance of σ_γ.

This simple model cannot explain the apparent non-linearity in the relationship between mean and standard deviation of the growth rate process which, according to Fatás (2001), is such that the effect of σ_γ on γ is less negative (and can be positive) for high income countries. In order to account for this fact it is necessary to increase the degree of heterogeneity, and to consider non-linear models.

Finally, the model can be reinterpreted as a multi-country model in which markets are incomplete and the distribution of the domestic shocks —the productivity shocks— is common across all countries.[13] More precisely, consider a market structure in which all countries can trade in a perfectly safe international bond market. In this case —which of course implies that mean growth rates are the same across countries— there is an equilibrium in which all countries choose to hold no international bonds, and the world interest rate is

$$r^* = \hat{A} - \delta_k - \theta\sigma_{y_i}^2\hat{A}^2.$$

If there is a common shock that decreases the variability of every country's technology shocks, this has a positive effect on the "world" interest rate, r^*, and an ambiguous impact on the world growth rate.

3.4.2 Case 2 : A Two Sector (Technology) Model

In the previous model, the variance of the growth rate is exogenous and equal to the variance of the technology shock. This is due, in part, to the assumption that the economy does not have another asset that can be used to diversify risk. In this section we present a very simple two-technology (or two sector) version of the model in which the variance of the growth rate is *endogenously* determined by the portfolio decisions of the representative agent. The main result is that, depending on the source of heterogeneity across countries, the relationship between σ_γ and γ need not be monotone. In particular, and depending on the source of heterogeneity across countries, the model is consistent with increases in σ_γ initially associated with increases in γ, and then, for large values of σ_γ, with decreases in the mean growth rate.

[13] It is possible to allow countries to share the same realization of the stochastic process. Even in this case, the demand for bonds is zero at the conjectured interest rate.

To keep the model simple, we assume that the second technology is not subject to shocks, and we ignore depreciation. Thus, formally, we assume that $\eta_b = \sigma_b = \eta_k = 0$. However, unlike the previous case, the "safe" rate of return r satisfies

$$A - \theta\sigma_k^2 < r < A.$$

This restriction implies that $\alpha^* \ \varepsilon \ (0,1)$, and guarantees that both technologies will be used to produce consumption. Since this model is a special case of the results summarized in (20) (we set the depreciation rates equal to zero for simplicity), it follows that the equilibrium mean growth rate and its variance are given by

$$\gamma = \frac{r-\rho}{\theta} + \left(\frac{A-r}{\theta\sigma_k}\right)^2 \frac{1+\theta}{2}, \tag{27a}$$

$$\sigma_\gamma^2 = \left(\frac{A-r}{\theta\sigma_k}\right)^2. \tag{27b}$$

How can we use the model to interpret the cross country evidence on variability and growth? A necessary first step is to determine which variables can potentially vary across countries. In the context of this example, a natural candidate is the vector (A, r, σ_k). Before we proceed, it is useful to describe the connection between γ and σ_γ implied by the model. The relationship is —taking a discrete time approximation—

$$\begin{aligned} \gamma_t &= \frac{r-\rho}{\theta} + \sigma_\gamma^2 \frac{1+\theta}{2} + \varepsilon_t, \\ \varepsilon_t &= \sigma_\gamma \omega_t, \qquad \omega_t \sim N(0,1). \end{aligned}$$

It follows that if the source of cross-country differences are differences in (A, σ_k) the model implies that —independently of the degree of curvature of preferences— the relationship between σ_γ^2 and γ is positive. To see why increases in σ_k result in such a positive association between the two endogenous variables σ_γ and γ, note that, as σ_k rises, the economy shifts more resources to the safe technology (α^* decreases) and this, in turn, results in a decrease in the variance of the growth rate (which is a weighted average of the variances of the two technologies). Since the 'risky' technology has higher mean return than the 'safe' technology, the mean growth rate decreases. The reader can verify that changes in A have a similar effects.

If the source of cross-country heterogeneity is due to differences in r, the implications of the model are more complex. Consider the impact of a decrease in r. From (27b) it follows that σ_γ^2 increases and this tends to increase γ. However, as (27a) shows, this also decreases the growth rate, as it lowers the non-stochastic return. The total effect depends on the combined impact. A simple calculation shows that

$$\frac{\partial\gamma}{\partial r} \lesseqgtr 0 \qquad \Leftrightarrow \qquad r \lesseqgtr \hat{r},$$

where

$$\hat{r} = A - \frac{\theta \sigma_k^2}{1+\theta}.$$

To better understand the implications of the model consider a "high" value of r; in particular, assume that $r > \hat{r}$. A decrease in r reduces σ_γ and, given that $r > \hat{r}$, it results in an increase in γ. Thus, for low σ_γ (high r) countries, the model implies a positive relationship between γ and σ_γ. If $r < \hat{r}$, decreases in the return to the safe technology still increase σ_γ, but, in this region, the growth rate decreases. Thus, in (σ_γ, γ) space the model implies that, due to variations in r, the relationship between σ_γ and γ has an inverted U-shape.

Can this model explain some of the non-linearities in the data? In the absence of further restrictions on the cross-sectional joint distribution of (A, r, σ_k) the model can accommodate arbitrary patterns of association between σ_γ and γ. If one restricts the source of variation to changes in the return r the model implies that, for high variance countries, variability and growth move in the same direction, while for low variance countries the converse is true. If one could associate low variance countries with relatively rich countries, the implications of the model would be consistent with the type of non-linearity identified by Fatás (2001).

3.4.3 Case 3: Aggregate vs. Sectoral Shocks

The simple Ak model that we discussed in the previous section is driven by a single, aggregate, shock. In this section we consider a two sector (or two technology) economy to show that the degree of sectoral correlation of the exogenous shocks can affect the mean growth rate. To capture the ideas in as simple as possible a model, we specialize the specification in (14) by considering the case

$$\begin{aligned} \sigma_k &= \sigma_b = \sigma > 0, \\ \eta_b &= 0,\ \eta_k = \eta, \\ \delta_k &= \delta_b = 0. \end{aligned}$$

Note that, in this setting, there is an aggregate shock, W_t, which affects both sectors (technologies) while the A sector is also subject to a specific shock, Z_t^k. Using the formulas derived in (18) and (20) it follows that the relevant equilibrium quantities are

$$\begin{aligned} \alpha^* &= \frac{A-r}{\theta \eta^2}, \\ \gamma &= \frac{r-\rho}{\theta} - (1-\theta)\frac{\sigma^2}{2} + \left(\frac{A-r}{\theta\eta}\right)^2 \frac{1+\theta}{2}, \\ \sigma_\gamma^2 &= \sigma^2 + \left(\frac{A-r}{\theta\eta}\right)^2. \end{aligned}$$

As before, it is useful to think of countries as indexed by (A, r, σ, η). Since changes in each of these parameters has a different impact, we analyze them separately.

- `An increase in` σ. The increase in the standard deviation of the economy-wide shock affects both sectors equally, and it does not induce any 'portfolio' or sectoral reallocation of capital. The share of capital allocated to each sector (technology) is independent of σ. Since increases in σ increase σ_γ (in the absence of a portfolio reallocation, this is similar to the one sector case), the total effect of an increase in σ is to decrease the growth rate if $0 < \theta < 1$, and to increase it if $\theta > 1$.

- `A decrease in` r. The effect of a change in r parallels the discussion in the previous section. It is immediate to verify that a decrease in r results in an increase in σ_γ. However, the impact on γ is not monotonic. For high values of r, decreases in r are associated with increases in γ, while for low values the direction is reversed. Putting together these two pieces of information, it follows that the predicted relationship between σ_γ and γ is an inverted U-shape, with a unique value of σ_γ (a unique value of r) that maximizes the growth rate.

- `An increase in` η. This change increases the 'riskiness' of the A technology and results in a portfolio reallocation as the representative agent decreases the share of capital in the high return sector (technology). The change implies that σ_γ and γ decrease. Thus, differences in η induce a positive correlation between mean and standard deviation of the growth rate.

- What is the impact of differences in the degree of correlation between sectoral shocks. Note that the correlation between the two sectoral shocks is

$$\nu = \frac{\sigma}{(\sigma^2 + \eta^2)^{1/2}}.$$

  In order to isolate the impact of a change in correlation, let's consider changes in (σ, η) such that the variance of the growth rate is unchanged. Thus, we restrict (σ, η) to satisfy

$$\sigma_\gamma^2 = \sigma^2 + \left(\frac{A - r}{\theta\eta}\right)^2,$$

  for a given (fixed) σ_γ. It follows that the correlation between the two shocks and the growth rate are

$$\begin{aligned} \nu &= \left(1 + (\frac{A - r}{\theta})^2 \frac{1}{\sigma^2(\sigma_\gamma^2 - \sigma^2)}\right)^{-1}, \\ \gamma &= \frac{r - \rho}{\theta} - \sigma^2 + \frac{1 + \theta}{2}\sigma_\gamma^2. \end{aligned}$$

Thus, lower correlation between sectors (in this case this corresponds to higher σ) unambiguously lower mean growth. If countries differ in this correlation then the implied relationship between σ_γ and γ need not be a function; it can be a correspondence. Put it differently, the model is consistent with different values of γ associated to the same σ_γ.

3.5 Physical and Human Capital

In this section we study models in which individuals invest in human and physical capital. We consider a model in which the rate of utilization of human capital is constant. Even though the model is quite simple it is rich enough to be consistent with **any** estimated relationship between σ_γ and γ.

We assume that output can be used to produce consumption and investment, and that market goods are used to produce human capital. This is equivalent to assuming that the production function for human capital is identical to the production function of general output. The feasibility constraints are

$$\begin{aligned} dk_t &= ([F(k_t, h_t) - \delta_k k_t - x_t - c_t)\, dt + \sigma_y F(k_t, h_t) dW_t, \\ dh_t &= -\delta_h h_t + x_t dt + \sigma_h h_t dW_t + \eta h_t dZ_t, \end{aligned}$$

where (W_t, Z_t) is a vector of independent standard Brownian motion variables, and F is a homogeneous of degree one, concave, function. As in the previous sections, let $x_t = k_t + h_t$ denote total (human and non-human) wealth. With this notation, the two feasibility constraints collapse to

$$\begin{aligned} dx_t &= ([F(\alpha_t, 1-\alpha_t) - (\delta_k \alpha_t + \delta_h(1-\alpha_t))]x_t - c_t)\, dt + \\ \sigma_y F(\alpha_t, 1-\alpha_t) x_t dW_t + & \quad \sigma_h (1-\alpha_t) x_t dW_t + \eta(1-\alpha_t) x_t dZ_t. \end{aligned} \tag{28}$$

As in previous sections, the competitive equilibrium allocation coincides with the solution to the planner's problem. The planner maximizes (13) subject to (28). The Hamilton-Jacobi-Bellman equation corresponding to this problem is

$$\rho V(x) = \max_{c,\alpha} \left[\frac{c^{1-\theta}}{1-\theta} + V'(x)[(F(\alpha, 1-\alpha) - \delta(\alpha))x_t - c_t] + \frac{V''(x)x^2}{2}\sigma^2(\alpha) \right],$$

where

$$\begin{aligned} \delta(\alpha) &= \delta_k \alpha + \delta_h(1-\alpha), \\ \sigma^2(\alpha) &= \sigma_y^2 F(\alpha, 1-\alpha)^2 + \sigma_h^2 (1-\alpha)^2 + \eta^2 (1-\alpha)^2 + \sigma_y \sigma_h F(\alpha, 1-\alpha)(1-\alpha). \end{aligned}$$

It can be verified that a function of the form $V(x) = v\frac{x^{1-\theta}}{1-\theta}$ solves the Hamilton-Jacobi-Bellman equation. The solution also requires that

$$\rho = \theta v^{-1/\theta} + (1-\theta)\{F(\alpha, 1-\alpha) - \delta(\alpha) - \frac{\theta}{2}\sigma^2(\alpha)\},$$

where α is given by

$$\alpha = \arg\max(1-\theta)\{F(\alpha, 1-\alpha) - \delta(\alpha) - \frac{\theta}{2}\sigma^2(\alpha)\}.$$

For any homogeneous of degree one function F, the solution is a constant α. Moreover, α does not depend on v. Existence requires $v > 0$, and this is just a condition on the exogenous parameter that we assume holds.[14]

The growth rate and its variance are given by

$$\begin{aligned} \gamma &= F(\alpha, 1-\alpha) - \delta(\alpha) - v^{-1/\theta}, \\ \sigma_\gamma^2 &= \sigma_y^2 F(\alpha, 1-\alpha)^2 + \sigma_h^2(1-\alpha)^2 + \eta^2(1-\alpha)^2 + \sigma_y\sigma_h F(\alpha, 1-\alpha)(1-\alpha) \end{aligned}$$

It follows that, for the class of economies for which the planner problem has a solution (i.e. economies for which $v > 0$, and $\gamma > 0$), the conjectured form of $V(x)$ solves the HJB equation, for any homogeneous of degree one function F. However, in order to make some progress describing the implications of the theory, it will prove convenient to specialize the technology and assume that F is a Cobb-Douglas function given by

$$F(x, y) = Ax^\omega y^{1-\omega}, \qquad 0 < \omega < 1.$$

The next step is to characterize the optimal share of wealth invested in physical capital, α, and how changes in country-specific parameters affect the mean and standard deviation of the growth rate. It turns out that the qualitative nature of the solution depends on the details of the driving stochastic process. To simplify the algebra, we assume that the human capital technology is deterministic (i.e. $\sigma_h = \eta = 0$), and that both stocks of capital (physical and human) depreciate at the same rate ($\delta_k = \delta_h$). As indicated above, we assume that the production function is Cobb-Douglas. The first order condition for the optimal choice of α is simply

$$\phi(\alpha)\hat{F}(\alpha)[1 - \theta\sigma_y^2\hat{F}(\alpha)] = 0,$$

where

$$\begin{aligned} \hat{F}(\alpha) &\equiv A\alpha^\omega(1-\alpha)^{1-\omega}, \\ \phi(\alpha) &= \frac{\omega}{\alpha} - \frac{1-\omega}{1-\alpha}. \end{aligned}$$

The second order condition requires that

$$-\omega(1-\omega)[\alpha^{-2} + (1-\alpha)^{-2}]\hat{F}(\alpha)[1 - \theta\sigma_y^2\hat{F}(\alpha)] - \theta\sigma_y^2\hat{F}(\alpha)^2\phi(\alpha) < 0.$$

Since $\hat{F}(\alpha) > 0$ in the relevant range, the solution is either $\phi(\alpha) = 0$, which corresponds to $\alpha^* = \omega$, or $\hat{F}(\alpha^*) = 1/\theta\sigma_y^2$. The latter, of course, does not result in a unique α^*[15].

[14] This is just the stochastic analog of the existence problem in endogenous growth models.

[15] In the case of the Cobb-Douglas production function there are two values of α that satisfy $\hat{F}(\alpha^*) = 1/\theta\sigma_y^2$

The nature of the solution depends on the size of σ_y^2. There are two cases characterized by

- *Case A*: $\sigma_y^2 \leq \frac{1}{\theta \hat{F}(\omega)}$.
- *Case B*: $\sigma_y^2 > \frac{1}{\theta \hat{F}(\omega)}$.

In *Case A*, the low variance σ_y^2 case, the maximizer is given by $\alpha^* = \omega$, since $1 - \theta\sigma_y^2 \hat{F}(\alpha) > 0$ for all feasible α. The second order condition is satisfied.

In *Case B*, there are two solutions to the first order condition. They correspond to the values of α, denoted α^- and α^+ that solve $\hat{F}(\alpha^*) = 1/\theta\sigma_y^2$. By convention, let's consider $\alpha^- < \omega < \alpha^+$. It can be verified that in both cases the second order condition is satisfied.[16] The implications of the model for the expected growth rate and its standard deviation in the two cases are

$$\begin{aligned}
\gamma_A &= \frac{\hat{F}(\omega) - (\rho + \delta)}{\theta} - \frac{1-\theta}{2}\sigma_y^2 \hat{F}(\omega)^2, \\
\sigma_{\gamma_A} &= \sigma_y \hat{F}(\omega), \\
\gamma_B &= \frac{1}{\theta}[\frac{1+\theta}{2}\frac{1}{\theta\sigma_y^2} - (\rho + \delta)], \\
\sigma_{\gamma_B} &= \frac{1}{\theta\sigma_y}.
\end{aligned}$$

It follows that for large σ_y^2, that is in *Case B*, the model predicts a positive relationship between mean growth and the standard deviation of the growth rate, while for small values of σ_y^2, *Case A*, the sign of the relationship depends on the magnitude of θ.

Much more interesting from a theoretical point of view is the fact that the model is consistent with two countries with different σ_y^2 to have *exactly the same* σ_γ. To see this, note that for any σ_γ in the range of feasible values —corresponding to the set $[0, \left(\frac{\hat{F}(\omega)}{\theta}\right)^{1/2}]$ in this example— there are two values of σ_y, one less than $\left(\frac{1}{\theta\hat{F}(\omega)}\right)^{1/2}$, and the other greater than this threshold that result in the same σ_γ. The relationship between σ_γ and γ is a correspondence. Figure 1 displays such a relationship in the small risk aversion case, $0 < \theta < 1$.

If the only source of cross-country heterogeneity are differences in the variability of the technology shocks, σ_y, the model implies that all data points should be in one of the two branches of the mapping depicted in Figure 1. By arbitrarily choosing the location of these points, the estimated relationship between σ_γ and γ can have any sign, and the estimated value says very little about the deep parameters of the model

[16] The reader can check that, in this case, the solution $\alpha^* = \omega$ does not satisfy the second order condition.

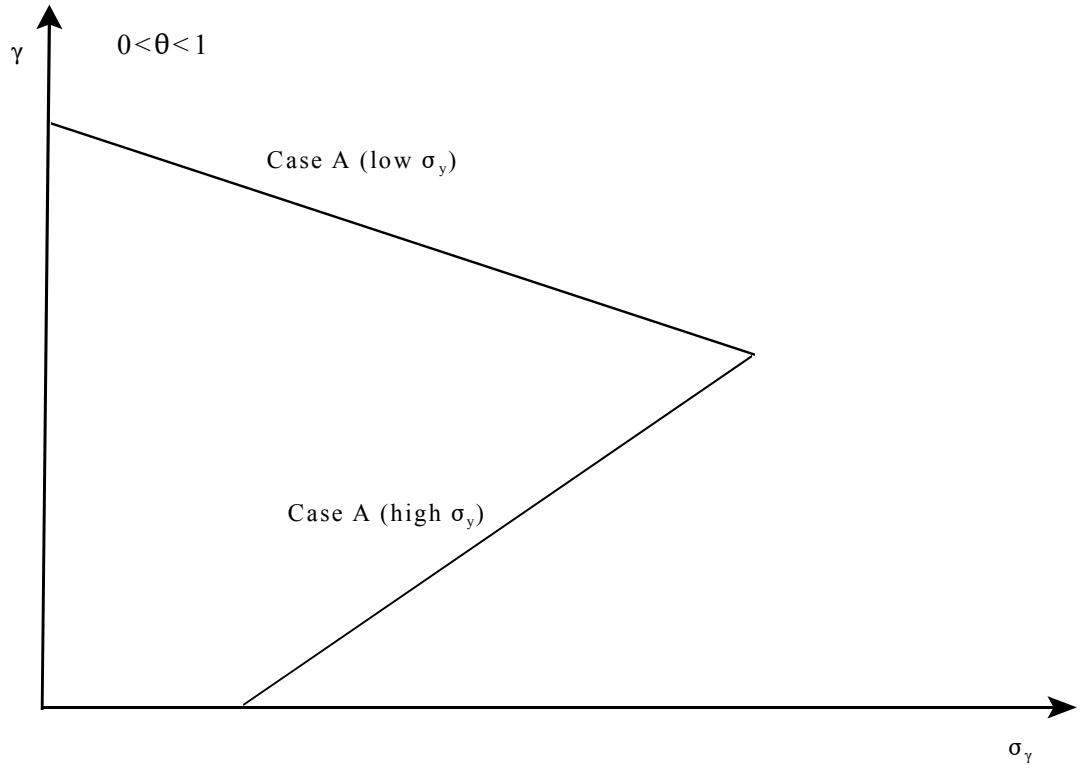

Figure 1: Figure 1: The mapping between σ_γ and γ. $[0 < \theta < 1]$

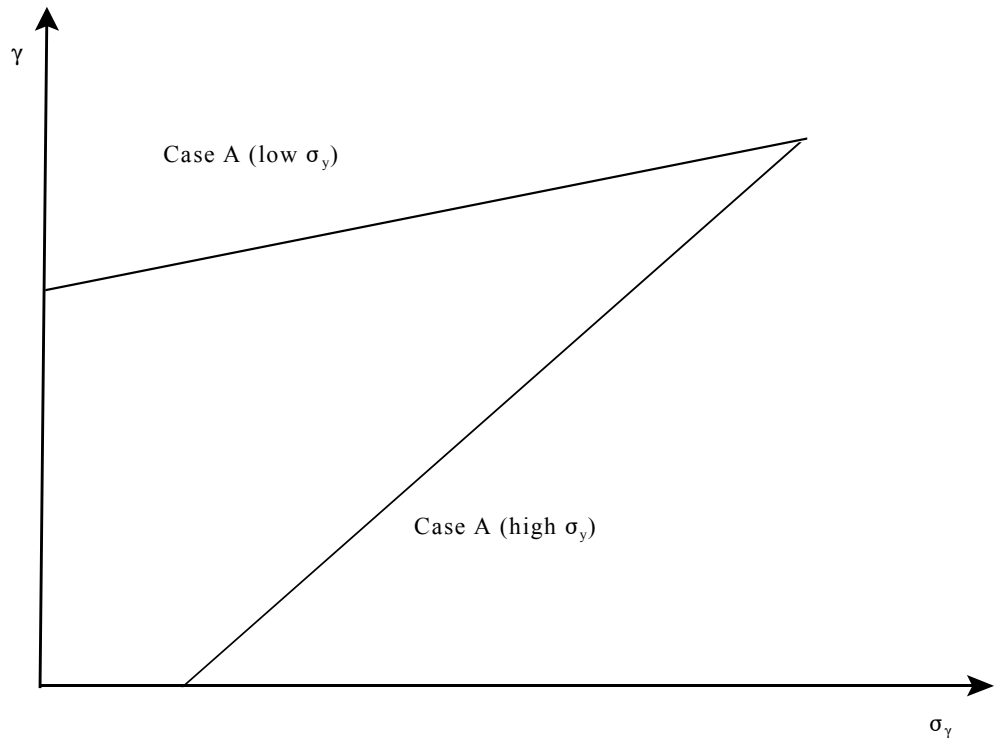

Figure 2: Figure 2: The mapping between σ_γ and γ. $[\theta > 1]$

or, more importantly, about the effects of reducing the variability of shocks on the average growth rate.

Does the nature of the result depend on the assumption $0 < \theta < 1$? For $\theta > 1$ the relationship between σ_γ and γ is also a correspondence, and hence that the model —in the absence of additional assumptions— does not pin down the sign of the correlation between σ_γ and γ.[17] In the case of $\theta > 1$, the size of θ matters only to determine which branch is steeper. I both *cases* A and B the relationship between the standard deviation of the growth rate and the mean growth rate is upward sloping. However, the low σ_y^2-branch is flatter (and lies above) the high σ_y^2-branch (see Figure 2).

Since we have studied a very simple version of this class of models, it does not seem useful to determine the relevance of each branch by asigning values to the parameters. In ongoing work, we are studying more general versions of this setup. However, even this simple example suggests that some caution must be exercised when interpreting the empirical work relating the variability of the growth rate and its mean. Unless

[17] At this point, we have not explored what are the consequences of adding the investment output ratio to the (theoretical) regression. However, to do this is a complete manner it seems necessary to model measurement errors, as the model is stochastically singular. We leave this for future work.

one can rule out some of these cases, theory gives ambiguous answers to the question that motivated much of the literature, i.e. Do more stable countries grow faster? Moreover, the theoretical developments suggest that progress will require to estimate structural models rather than reduced form equations.

3.6 The Opportunity Cost View

So far the models we discussed emphasize the idea that increases in the variability of the driving shocks can have positive or negative effects upon the growth rate depending on the relative importance of income and substitution effects. An alternative view is that recessions are "good times' to invest in human capital because labor —viewed as the single most important input in the production of human capital— has a low opportunity cost. In this section we present a model that captures these ideas. The model implies that the time allocated to the formation of human capital is independent of the cycle.[18] It also implies that shocks to the goods production technology have no impact on growth, but that the variability of the shock process in the human capital technology decreases growth.

As before, we concentrate on a representative agent with preferences described by (13). The goods production technology is given by

$$c_t + x_t \leq z_t A k_t^{\alpha} (n_t h_t)^{1-\alpha},$$

where n_t is the fraction of the time allocated to goods production, k_t is the stock of physical capital, and h_t is the stock of human capital. The variable z_t denotes a stationary process. To simplify the theoretical presentation we assume that capital depreciates fully. Thus, goods consumption is limited by

$$c_t \leq z_t A k_t^{\alpha} (n_t h_t)^{1-\alpha} - k_t.^{19}$$

Human capital is produced using only labor in order to capture the idea that the opportunity cost of investing in human capital is market production. The technology is summarized by

$$dh_t = [1 - \delta + B(1 - n_t)] h_t dt + \sigma_h [1 - \delta + B(1 - n_t)] h_t dW_t,$$

[18] The empirical relationship between investment in human capital and the cycle is mixed. Dellas and Sakellaris (1997) using CPS data for all individuals aged 18 to 22 find that college enrollment id procyclical. Christian (2002) also using the CPS but restricting the sample to 18-19 years olds (sa as to be able to control for family variables) finds no cyclical effects. Sakellaris and Spilimbergo (2000) study U.S. college enrollment of foreign nationals and conclude that, among those individuals coming from risch countries enrollment is countercyclical, while among students from less developed countries it is countercyclical. Moreover, college enrollment is only a partial measure of investment in human capital. Training (inside and outside business firms) is another (difficult to measure) component of increases in skill acquisition.

[19] This restriction makes it possible to derive the theoretical implications of the model in a simple setting.

where, as before, W_t is a standard Brownian motion.[20]

Given that the problem is convex[21] the competitive allocation solves the planner's problem. It is clear that, given $n_t h_t$, physical capital will be chosen to maximize net output. This implies that consumption is

$$c_t = A^* \hat{z}_t n_t h_t,$$

where $A^* = (A\alpha)^{1/(1-\alpha)}(\alpha^{-1} - 1)$ and $\hat{z}_t = z_t^{1/(1-\alpha)}$. We guess that the relevant state variable is the vector $(\hat{z}_t, h_t)$, and that the value function is of the form

$$V(\hat{z}_t, h_t) = v\frac{(\hat{z}_t h_t)^{1-\theta}}{1-\theta}.$$

Given this guess, the relevant Hamilton-Jacobi-Bellman equation is

$$\rho v \frac{(\hat{z}h)^{1-\theta}}{1-\theta} = \max_x \left\{ \frac{[\frac{A^*}{B}(\mu - x)\hat{z}h]^{1-\theta}}{1-\theta} + v(\hat{z}h)^{1-\theta}x - v(\hat{z}h)^{1-\theta}\theta\frac{\sigma_h^2}{2}x^2, \right\}$$

where $\mu \equiv 1-\delta+B$, and $x = 1-\delta+B(1-n)$. It follows that choosing x is equivalent to choosing n. The solution to the optimization problem is given by the solution to the following quadratic equation

$$x^2 = \frac{2(1+\mu\sigma_h^2)}{(1+\theta)\sigma_h^2}x + \frac{2(\rho-\mu)}{\theta(1+\theta)\sigma_h^2}.$$

In order to guarantee that utility remains bounded even in the case $\sigma_h = 0$ is is necessary to assume that $\rho - \mu > 0$. Simple algebra shows that the positive root of the previous equation is such that increases in σ_h decrease x. It follows that the stochastic process for h_t is given by

$$dh_t = xh_t dt + \sigma_h h_t dW_t$$

We now discuss the implications of the model for the growth rate of consumption (or output). Even though our results do not depend on the particular form of the z_t process, it is convenient to consider the case in which z_t is a geometric Brownian motion that is possibly correlated with the shock to the human capital. Specifically, we assume that

$$dz_t = z_t(\sigma_w dW_t + \sigma_m dM_t),$$

where M_t is a standard Brownian motion that is uncorrelated with W_t. Ito's lemma implies that

$$d\hat{z}_t = \frac{\alpha}{(1-\alpha)^2}\frac{\sigma_w^2+\sigma_m^2}{2}\hat{z}_t dt + \frac{\alpha}{(1-\alpha)}\hat{z}_t(\sigma_w dW_t + \sigma_m dM_t).$$

[20] A special case of this model in which utility is assumed logarithmic, and the goods production function is not subject to shocks is analyzed in De Kek (1999).

[21] Even though our choice of notation somewhat obscures this, the convexity of the technology is apparent by defining $h_{mt} = n_t h_t$ and $h_{st} = (1-n_t)h_t$, and adding the constraint $h_{mt} + h_{st} \leq h_t$.

In equilibrium, consumption (and net output) is given by

$$c_t = \frac{A^*}{B}(\mu - x)\hat{z}_t h_t.$$

Applying Ito's lemma to this expression, we obtain that the growth rate of consumption

$$\frac{dc_t}{c_t} = \frac{dh_t}{h_t} + \frac{d\hat{z}_t}{\hat{z}_t} + \frac{\alpha x}{(1-\alpha)}\sigma_h \sigma_w dt,$$

or, taking a discrete time approximation,

$$\begin{aligned}
\gamma_t &= x(1 + \frac{\alpha}{(1-\alpha)}\sigma_h\sigma_w) + \frac{\alpha}{(1-\alpha)^2}\frac{\sigma_w^2 + \sigma_m^2}{2} + \\
&\quad [(\frac{\alpha}{(1-\alpha)}\sigma_w + \sigma_h x)\tilde{W}_t + \frac{\alpha}{(1-\alpha)}\sigma_m \tilde{M}_t], \qquad (29a)\\
\gamma_t &= \gamma + \varepsilon_t, \qquad \varepsilon_t \sim N(0, \sigma_\gamma^2), \qquad (29b)\\
\sigma_\gamma^2 &= (\frac{\alpha}{(1-\alpha)}\sigma_w + \sigma_h x)^2 + (\frac{\alpha}{(1-\alpha)}\sigma_m)^2 \qquad (29c)
\end{aligned}$$

Equation (29a) completely summarizes the implications of the model for the data. There are several interesting results. To simplify the notation, we will refer to W_t as the aggregate shocks and to M_t as the idiosyncratic component of the productivity shock in the goods sector.

- The share of the time allocated to human capital formation —the engine of growth in this economy— is independent of the variability of the technology shock in the goods sector, as measured by (σ_w, σ_m).

- High (σ_w, σ_m) economies are also high growth economies. Thus, if cross-country differences in σ_γ are mostly due to differences in (σ_w, σ_m), the model implies a positive correlation between the standard deviation of the growth rate and mean growth.

- It can be shown that increases in σ_h result in *decreases* in $\sigma_h x$. Thus, if countries differ in this dimension the model also implies a positive relationship between σ_γ and γ.

- In the model, investment in physical capital (as a fraction of output) is α, independently of the distribution of the shocks. Thus, there is no sense that a regression that shows that variability does not affect the rate of investment provides evidence against the role of shocks in development.

- This lack of (measured) effect on both physical and human capital investment should not be interpreted as evidence against the proposition that incentives for human or physical capital accumulation matter for growth. It is easy enough to include a tax/subsidy to the production of human capital —consider a policy that affects B— and it follows that this policy affects growth.

3.7 More on Government Spending, Taxation, and Growth

In this section we consider a simple Ak model in which a government uses distortionary taxes to finance an exogenously given stochastic process for government spending. Our analysis follows Eaton (1981).[22]

The representative household maximizes utility —given by (13)— by choosing consumption and saving in either capital or bonds. However, given that tax policy is exogenously fixed, it is not the case that the rate of return on bonds is risk free. On the contrary, since the government issues bonds to make up for any difference between revenue and spending it is necessary to let the return on bonds to be stochastic.

The representative household problem is

$$\max U = E\left[\int_0^\infty e^{-\rho t}\frac{c_t^{1-\theta}}{1-\theta}dt\,|F_0\right]. \tag{30}$$

subject to

$$\begin{aligned} dk_t &= (r_k k_t - c_{1t})dt + \sigma_k k_t dW_t, && (31a)\\ db_t &= (r_b b_t - c_{2t})dt + \sigma_b b_t dW_t, && (31b)\\ c_t &= c_{1t} + c_{2t}, && (31c) \end{aligned}$$

where k_t is interpreted as capital and b_t as bonds. As before, it is possible to simplify the analysis by using wealth as the state variable. Let $x_t \equiv k_t + b_t$. With this notation, the single budget constraint is given by,

$$dx_t = [(\alpha_t r_k + (1-\alpha_t)r_b)x_t - c_t]dt + (\alpha_t\sigma_k + (1-\alpha_t)\sigma_b)x_t dW_t.$$

Since this problem is a special case of the "general" two risky assets model, it follows that the optimal solution is characterized by

$$\begin{aligned} \alpha &= \frac{\frac{r_k - r_b}{\theta} - \sigma_b(\sigma_k - \sigma_b)}{(\sigma_k - \sigma_b)^2}, && (32a)\\ c_t &= \underbrace{\frac{\rho - (1-\theta)[\alpha r_k + (1-\alpha)r_b - \theta\frac{(\alpha\sigma_k + (1-\alpha)\sigma_b)^2}{2}]}{\theta}}_{c} x_t. && (32b) \end{aligned}$$

The set of feasible allocations is the set of stochastic process that satisfy

$$\begin{aligned} dk_t &= (Ak_t - c_t)dt + \sigma A k_t dW_t - dG_t,\\ dG_t &= gAk_t dt + g'\sigma A k_t dW_t. \end{aligned}$$

Thus, the government consumes a fraction g of the non-stochastic component of output, and a fraction g' of the stochastic component. Taxes are levied on the

[22] For extensions of this model, see Turnovski (1995)

deterministic and stochastic components of output at (possibly) different rates. The stochastic process for tax revenue is assumed to satisfy

$$dT_t = \tau A k_t dt + \tau' \sigma A k_t dW_t.$$

In equilibrium, the parameters that determine the rate of return on capital (r_k, σ_k) are given by

$$\begin{aligned} r_k &= (1-\tau)A, \\ \sigma_k &= (1-\tau')\sigma A. \end{aligned}$$

The government budget constraint requires that the excess of spending over tax revenue be financed through bond issues. Thus,

$$B_t + dG_t - dT_t = p_t dB_t,$$

where $p_t B_t = b_t$ is the value of bonds issued. The stock of capital evolves according to

$$dk_t = ((1-g)A - \frac{c_t}{k_t})k_t dt + \sigma(1-g')Ak_t dW_t.$$

Note that

$$\frac{c_t}{k_t} = c\frac{x_t}{k_t} = c(1 + \frac{1-\alpha}{\alpha}) = \frac{c}{\alpha}.$$

Since, in equilibrium, it must be the case that, in all states of nature, the growth rate of private wealth and the growth rate of the capital stock are the same[23], it is necessary that

$$\alpha r_k + (1-\alpha)r_b - c = (1-g)A - \frac{c}{\alpha}, \tag{33a}$$

$$\alpha\sigma_k + (1-\alpha)\sigma_b = \sigma(1-g')A. \tag{33b}$$

The system formed by the four equations described in (32) and (33) provides the solution to the endogenous variables that need to be determined: c, α, r_b, σ_b. It is convenient to define the excess rate of return of capital, and the excess instant variability of capital as

$$\begin{aligned} \Delta_r &= r_k - r_b, \\ \Delta_\sigma &= \sigma_k - \sigma_b. \end{aligned}$$

Some simple but tedious algebra shows that

$$\begin{aligned} \alpha &= \frac{\sigma_\gamma - \sigma_k + \Delta_\sigma}{\Delta_\sigma}, \\ \Delta_r &= \theta\sigma_\gamma\Delta_\sigma \end{aligned}$$

[23] This, of course, depends on the fact that the solution to the individual agent problem is such that bonds and capital are held in fixed proportions.

Substituting in the remaining equations, and recalling that the instantaneous mean and standard deviation of the growth rate process is given by

$$\begin{aligned} \gamma &= \alpha r_k + (1-\alpha) r_b - c, \\ \sigma_\gamma &= \sigma(1-g')A, \end{aligned}$$

it follows that,

$$\gamma = \frac{(1-\tau)A - \rho}{\theta} - \left(\frac{1-\theta-\tau'+\theta g'}{1-g'} \right) \sigma_\gamma^2 \tag{34a}$$

$$\sigma_\gamma = \sigma(1-g')A. \tag{34b}$$

Equation (34a) summarizes the impact of both technology and fiscal shocks on the expected growth rate. Consider first the impact of variations in the tax regime on the relationship between the variability of the growth rate, σ_γ, and the average growth rate. If technology shocks, σ, are the main source of differences across countries in the standard deviation of the growth rate, then high variability countries are predicted to be low mean countries if $1-\theta-\tau'+\theta g' > 0$; that is, if a country has a relatively low tax rate on the stochastic component of income. This, would be the case if the base of the income tax allowed averaging over several periods. On the other hand, countries with relatively high tax rates on the random component of income display a positive relationship between the mean and the variance of their growth rates.

As in more standard models, high capital income tax countries (high τ countries) have lower average growth. Differences across countries in the average size of the government, g in this notation, have no impact on growth. Finally, cross country differences in the fraction of the random component of income consumed by the government, g', induce a positive correlation between γ and σ_γ. This is driven by the negative impact that increases in g' have on mean growth, and the equally negative effect that those changes have on σ_γ. Thus, high g' countries display low average growth rates, which do not fluctuate much.[24]

3.8 Quantitative Effects

In this section we summarize some of the quantitative implications various models for the relationship between variability and growth. Unlike the theoretical models described above, the quantitative exercises concentrate on the role of technology shocks in models with constant –relative to output– government spending.

[24] The impact of some variables in the previous analysis differs from the results in Eaton (1981) since our specification of the fiscal policy allows the demand for bonds (as a fraction of wealth) to be endogenous, and driven by changes in the tax code. Eaton assumes that the share of bonds, $1-\alpha$ in our notation, is given, and some tax must adjust to guarantee that demand and supply of bonds are equal.

Mendoza (1997) studies an economy in which the planner solves the following problem

$$\max_{\{c_t\}} \sum_{t=0}^{\infty} \beta^t \frac{c_t^{1-\theta}}{1-\theta}$$

subject to

$$A_{t+1} \leq R_t(A_t - p_t c_t),$$

where A_t is a measure of assets and p_t is interpreted as the terms of trade. Since this equation can be rewritten as

$$k_{t+1} = r_{t+1}(k_t - c_t),$$

where $k_t = A_t/p_t$ is the stock of assets (capital) measured in units of consumption, and $r_{t+1} = R_t p_t/p_{t+1}$ is the random rate of return, it is clear that Mendoza's model is a stochastic version of an Ak model. The rate of return, r_t is assumed to be lognormally distributed with mean and variance given by

$$\begin{aligned} \mu_r &= e^{\mu+\sigma^2/2}, \\ \sigma_r^2 &= \mu_r^2 e^{\sigma^2-1}. \end{aligned}$$

It follows that the standard deviation of the growth rate is $\sigma_\gamma = \sigma$. Mendoza studies the effect of changing σ from 0 to 0.15, holding μ_r constant. To put the exercise in perspective, the average across countries of the standard deviations of the growth rate or per capita output in the Summers-Heston dataset is 0.06. Thus, the model is calibrated at a fairly high level of variability. The results depend substantially on the assumed value of θ. For $\theta = 1/2$, the non-stochastic growth rate is 3.3%. If $\sigma = 0.10$, it decreases to 2.5%, while it is 1.6% when $\sigma = 0.15$. For $\theta = 2.33$ (Mendoza's preferred specification), the growth rate increases from 0.7% to 0.9% in the given range. For other values of the coefficient of risk aversion, the impact of uncertainty is also small. In summary, unless preferences are such that the degree of intertemporal substitution is large, increases in rate of return uncertainty have a small impact on mean growth rates.

Jones et. al (2003a) analyze the following planner's problem:

$$\max E_t\{\sum_t \beta^t c_t^{1-\theta} v(\ell_t)/(1-\theta)\},$$

subject to,

$$\begin{aligned} c_t + x_{zt} + x_{ht} + x_{kt} &\leq F(k_t, z_t, s_t), \\ z_t &\leq M(n_{zt}, h_t, x_{zt}) \\ k_{t+1} &\leq (1-\delta_k)k_t + x_{kt}, \\ h_{t+1} &\leq (1-\delta_h)h_t + G(n_{ht}, h_t, x_{ht}) \\ \ell_t + n_{ht} + n_{zt} &\leq 1. \end{aligned}$$

For their quantitative exercise, they specify the following functional forms

$$\begin{aligned} n_h &= x_z = 0, \quad n_z = n, \\ v(\ell) &= \ell^{\psi(1-\sigma)}, \\ F(k,z,s) &= sAk^{\alpha}z^{1-\alpha}, \\ G(h,x_h) &= x_h, \\ M(n,h) &= nh, \\ s_t &= \exp[\zeta_t - \frac{\sigma_\varepsilon^2}{2(1-\rho^2)}], \\ \zeta_{t+1} &= \rho\zeta_t + \varepsilon_{t+1}. \end{aligned}$$

The model is calibrated to match the average growth, in a cross section of countries, and its standard deviation. Jones et. al (2003) consider the impact of changing the standard deviation of the shock, s_t, from 0 to 0.15. The impact on the growth rate depends on the curvature of the utility function. For preferences slightly less curved than the log, the model predicts an increase in the growth rate of 0.7% an an annual basis, while for $\theta = 1.5$, the effects is an increase in the growth rate of 0.25%. However, the model predicts that σ_γ —which is endogenous— is unusually high (of the order of 0.10) unless $\theta \geq 1.5$.

Thus, Jones et. al (2003a) obtain results that are quite different from those of Mendoza (1997). There are two important differences between the models: First, while Mendoza (1997) assumes that shocks are *i.i.d.*, Jones et. al. (2003a) set the first order correlation parameter, ρ, to 0.95. Second, while Mendoza assumes a constant labor supply, Jones et. al allow for the number of hours to vary with the shock.

In order to disentangle the effect of the components of the standard deviation of the technology shock, Jones et. al. vary σ_ε and ρ in a series of experiments, where $\sigma_s = \sigma_\varepsilon/(1-\rho^2)^{1/2}$, where σ_ε is the standard deviation of the innovations. They find that changes in σ_ε appear quantitatively more important than those and ρ. Moreover, they also find that the relative variability of hours worked is very sensitive to the precise value of θ. Economies with high θ, and lower σ_γ in their specification, also display substantially less variability in hours worked. Even though it is not possible to determine on the basis of these two results which is the critical feature that accounts for the differences between the results obtained by Mendoza (1997) and Jones et. al (2003a), it seems that the assumption of a flexible supply of hours —which determines the rate of utilization of human capital— is a leading candidate.[25]

In a series of papers, Krebs (2003) and (2004) explores the impact of changes in uncertainty in models where markets are incomplete. Building on the work of de Hek (1999), Krebs (2003) studies the impact of shocks to the depreciation rate of the

[25] In subsequent work, Jones et. al (2003a) analyze the business cycle properties of the same class of models, and they show that are capable of generating higher serial correlation in the growth rate of output than similar exogneous growth models.

capital stock. Even though he assumes that instantaneous utility is logarithmic, he finds that increases in the standard deviation of the shock, decrease growth rates. This result is driven by the "location" of the shocks, and it does not require market incompleteness.[26] Quantitatively, Krebs (2003) finds that an increase in the standard deviation of the growth rate from 0 to 0.15 (a fairly large value relative to the world average) reduces growth from 2.13% to 2.00%. If the variability is increased to 0.20. the growth rate drops to 1.5%. However, these values are substantially higher than those observed in international data.[27]

The theoretical analysis of the impact of different forms of uncertainty on the growth of the economy is still in its infancy. Simple existing suggest that the sign of the relationship between the variability of a country's growth rate and its average growth rate is ambiguous. Thus, theoretical models that restrict more moments can help in understanding the effect of fluctuations on growth and welfare. The few quantitative studies that we reviewed have produced conflicting results. It seems that the precise nature of the shocks, their serial correlation properties and the elasticity of hours with respect to shocks all play a prominent role in accounting for the variance in predicted outcomes. Much more work is needed to identify realistic and tractable models that will be capable of confronting both time series and cross country observations.

4 Concluding Comments

In this chapter we briefly presented the basic insights about the growth process that can be learned from studying standard convex models with perfectly functioning markets. We emphasized three aspects of those models. First, the impact of fiscal policy on growth. A summary of the current state of knowledge is that theoretical models have ambiguous implications about the effect of taxes on growth. The key feature is the importance of market goods in the production of human capital. If, as Lucas (1988) assumes, no market goods are needed to produce new human capital, the impact of income taxes on growth is small (or zero in some cases). If, on the other hand, market goods are necessary to produce human capital then taxes play a more important role, and they have a large impact on growth. It seems that the next step is to use detailed models of the process of human capital formation and to explore the implications that they have for the age-earnings profile to identify the parameters of the production function of human capital. A first step in that direction is in Manuelli and Seshadri (2004).

A second important issue that features prominently in the discussion of the relative

[26] de Hek (1999) shows theoretically that increases in the variance of the depreciation shock decrease average growth even if markets are complete, and the shocks are aggregate shocks.

[27] Krebs (2003) does not have an aggregate shock. His model predicts that aggregate growth is constant. He calibrates his model to match the standard deviation of the growth rate of individual income.

merits of convex and non-convex models is the role of innovation. The standard argument claims that innovation is a one-off investment (with low copying costs) and hence that this technology is inconsistent with price taking behavior. In this chapter we elaborate on the ideas discussed by Boldrin and Levine (2002) and show that it is possible to reconcile the existence of a non-convexity with competitive behavior.

The last major theme covered in this survey is the relationship between fluctuations and growth. An important question is whether technological or policy induced fluctuations affect the growth rate of an economy. This is relevant for the time series experience of a single country(e.g. the discussion about the role of post-war stabilization policies on the growth rate of the American economy), as well as the prescriptions of international agencies for national policies. We discuss the empirical evidence and find it conflicting. It is not easy to identify a clear pattern between fluctuations and growth. To shed light on why this might be the case, we discuss a series of theoretical models. We show that the relationship between the growth rate and its standard deviation has an ambiguous sign. We also describe more precisely how one might identify the parameters of preferences and technologies that determine the sign of the relationship. This is one area of research in which more theoretical and empirical work will have a high marginal value.

Growth with Quality-Improving Innovations: An Integrated Framework*

Philippe Aghion† and Peter Howitt‡

September 20, 2004

1 Introduction

Technological progress, the mainspring of long-run economic growth, comes from innovations that generate new products, processes and markets. Innovations in turn are the result of deliberate research and development activities that arise in the course of market competition. These Schumpeterian observations constitute the starting point of that branch of endogenous growth theory built on the metaphor of quality improvements, whose origins lie in the partial-equilibrium industrial-organization literature on patent races. Our own entry to that literature was the pre-publication version of chapter 10 of Tirole (1988).

We argued in Aghion and Howitt (1998) that by using Schumpeter's insights to develop a growth model with quality-improving innovations one can provide an integrated framework for understanding not only the macroeconomic structure of growth but also the many microeconomic issues regarding incentives, policies and institutions that interact with growth. Who gains from innovations, who loses and how much all depend on institutions and policies. By focusing on these influences in a model where entrepreneurs introduce new technologies that render previous technologies obsolete we hope to understand why those who would gain from growth prevail in some societies, while in others they are blocked by those who would lose.

In this chapter we show that the growth model with quality-improving innovations (also referred to as the "Schumpeterian" growth paradigm) is not only versatile but also simple and empirically useful. We illustrate its versatility by showing how it sheds light on such diverse issues as cross-country convergence, the effects of product-market competition on growth, and the interplay between growth and the process of institutional change. We illustrate its simplicity by building our analysis around an elementary discrete-time model. We illustrate its empirical usefulness by summarizing recent papers and studies that test

*Draft of chapter for the forthcoming Handbook of Economic Growth.

†Harvard University

‡Brown University

the microeconomic and macroeconomic implications of the framework and that address what might seem like empirically questionable aspects of the earliest prototype models in the literature.

The paper is organized as follows. Section 2 develops the basic framework. Section 3 uses it to analyze convergence and divergence patterns in the cross-country data. Section 4 analyses the interaction between growth and product market competition. Section 5 deals with the scale effect of growing population. Section 6 analyzes the interplay between institutional change and technological change, and section 7 provides some concluding remarks and suggestions for future research.

2 Basic framework

2.1 A toy version of the Aghion-Howitt model

Asked by colleagues to show them the simplest possible version of the quality-ladder model of endogenous growth which they could teach to second year undergraduate students, we came out with the following stripped-down version of Aghion-Howitt (1992).

Time is discrete, indexed by $t = 1, 2, ...$, and at each point in time there is a mass L of individuals, each endowed with one unit of skilled labor that she supplies inelastically. Each individual lives for one period and thus seeks to maximize her consumption at the end of her period.

Each period a final good is produced according to the Cobb-Douglas technology:

$$y = Ax^{\alpha}, \tag{1}$$

where x denotes the quantity of intermediate input used in final good production, and A is a productivity parameter that reflects the current quality of the intermediate good.

The intermediate good is itself produced using labor according to a simple one-for-one technology, with one unit of labor producing one unit of the current intermediate good. Thus x also denotes the amount of labor currently employed in manufacturing. But labor can also be employed in research to generate innovations.

Each innovation improves the quality of the intermediate input, from A to γA where $\gamma > 1$ measures the size of the innovation. Innovations result from research investment. More specifically, there is an innovator who, if she invests z units of labor in research, innovates with probability λz and thereby discover an improved version of the intermediate input.

The innovator enjoy monopoly power in the production of the intermediate good, but faces a competitive fringe who can produce a unit of the same intermediate good by using $\chi > 1$ units of labor instead of one. For $\chi < 1/\alpha$, this competitive fringe is binding which means that χw_t is the maximum price the innovator can charge without being driven out of the market. Her profit is thus

equal to:

$$\pi_t = (\chi - 1) w_t x_t,$$

where $w_t x_t$ is the wage bill. This monopoly rent, however, is assumed to last for one period only, after which imitation allows other individuals to produce intermediate goods of the same quality.

The model is entirely described by two equations. The first is a *labor market clearing* equation, which states that at each period total labor supply L is equal to manufacturing labor demand x plus total research labor n, that is: $L = x_t + n_t$ for all t. The second is a *research arbitrage* equation which says that in equilibrium at any date t the amount of research undertaken by the innovator must equate the marginal cost of a unit of research labor with the expected marginal benefit. The marginal cost is just the manufacturing wage w_t. The expected benefit comes from raising the probability of success by $\lambda.1 = \lambda$, in which case she earns the monopoly profit π_t involved in producing the intermediate good for the final good sector. Thus the research arbitrage equation can be expressed as:

$$w_t = \lambda \gamma \pi_t. \qquad \text{(research arbitrage)}$$

where the factor γ on the right-hand side of the equation, simply stems from the fact that an innovation multiplies wages and profits by γ.

Using the fact that the allocation of labor between research and manufacturing, remains constant in steady-state, we can drop time subscripts. Then, substituting for π_t in the research arbitrage equation, dividing through by w, and using the labor market clearing equation to substitute for x, we obtain:

$$1 = \gamma(\chi - 1)(L - n)$$

which solves for the steady-state amount of research labor, namely:

$$n = L - \frac{1}{\gamma(\chi - 1)}.$$

The equilibrium expected rate of productivity growth in steady-state, is then simply given by:

$$g = \lambda n(\gamma - 1)$$

and it therefore depends upon the characteristics of the economic environment as described by the parameters λ, γ, χ, and L. In Section 2.3 below we interpret the comparative statics of growth with respect to all these parameters, and suggest preliminary policy conclusions.

The model is extremely simple, although at the cost of making some oversimplifying assumptions. In particular, we assumed only one intermediate sector, and that labor is the only input into research.. In the next sections we relax these two assumptions. We develop a slightly more elaborated version of the quality-ladder model that we then extend in several directions to capture important aspects of the growth and development process.

2.2 A generalization

There are three kinds of goods in the economy: a general-purpose good, a large number m of different specialized intermediate inputs, and labor. Time is discrete, indexed by $t = 1, 2, ...$, and there is a mass L of individuals, each endowed with one unit of skilled labor that she supplies inelastically.[1]

The general good is produced competitively using intermediate inputs and labor, according to the production function:

$$y_t = \left(\Sigma_1^m A_{it}^{1-\alpha} x_{it}^{\alpha}\right) (L/m)^{1-\alpha} \tag{2}$$

where each x_{it} is the flow of intermediate input i used at date t, and A_{it} is a productivity variable that measures the quality of the input. The general good is used in turn for consumption, research, and producing the intermediate inputs.

The expected growth rate of any given productivity variable A_{it} is:

$$g = E\left(A_{it}/A_{i,t-1}\right) - 1 \tag{3}$$

There is no i subscript on g because, as we shall see, all sectors are *ex ante* identical and hence will have the same productivity-growth rate. Likewise there is no t subscript because, as we shall also see, the system will go immediately to a constant steady-state expected growth rate.

Productivity growth in any sector i results from innovations, which create improved versions of that intermediate input. More precisely, each innovation at t multiplies the pre-existing productivity parameter $A_{i,t-1}$ of the best available input by a factor $\gamma > 1$. Innovations in turn result from research. If N_{it} units of the general good are invested at the beginning of the period, some individual can become the new "leading-edge" producer of the intermediate input with probability μ_{it}, where:[2]

$$\mu_{it} = \lambda f\left(n_{it}\right), \qquad f' > 0, f'' < 0, f\left(0\right) = 0,$$

and $n_{it} \equiv \frac{N_{it}}{\gamma A_{i,t-1}}$ is productivity-adjusted R&D expenditure in the sector. We divide by $\gamma A_{i,t-1}$, the targeted productivity parameter, to take into account the "fishing-out" effect - on average each quality improvement is harder to bring about than the previous one.

[1] The model we present here is a simplified discrete-time version of the Aghion-Howitt (1992) model of creative destruction, which draws upon Acemoglu-Aghion-Zilibotti (2002). Grossman and Helpman (1991) presented a variant of the framework in which the x's are final consumption goods and utility is log-linear. An early attempt at developing a Schumpeterian growth model with patent races in deterministic terms was presented by Segerstrom et al (1989). Corriveau (1991) developed an elegant discrete-time model of growth through cost-reducing innovations.

[2] More precisely, $f\left(n\right) = F\left(n, k\right)$ where k is some specialized research factor in fixed supply and F is a constant-returns function. Since there is free entry in research, the equilibrium price of k adjusts so that the expected profit of an R&D firm is zero. Since this price plays no role in the analysis of growth we suppress the explicit representation of k and deal only with the decreasing-returns function f. (Of course the constant-returns assumption can be valid only over some limited range of inputs, since F is bounded above by unity.)

Assume the time period is short enough that we may ignore the possibility of more than one successful innovator in the same sector. Then:

$$A_{it} = \left\{ \begin{array}{ll} \gamma A_{i,t-1} & \text{with probability } \lambda f(n_{it}) \\ A_{i,t-1} & \text{with probability } 1 - \lambda f(n_{it}) \end{array} \right\} \tag{4}$$

According to (3) and (4) the expected productivity-growth rate in each sector can be expressed as the product of the frequency of innovations $\lambda f(n)$ and the incremental size of innovations $(\gamma - 1)$:

$$g = \lambda f(n)(\gamma - 1) \tag{5}$$

in an equilibrium where productivity-adjusted research is the same constant n in each sector. We assume moreover that the outcome of research in any one sector is statistically independent of the outcome in every other sector.

The model determines research n, and therefore the expected productivity-growth rate g, using a research arbitrage equation that equates the expected cost and benefit of research. The payoff to research in any sector i is the prospect of a monopoly rent π_{it} if the research succeeds in producing an innovation. This rent lasts for one period only, as all individuals can imitate the current technology next period. Hence the expected benefit from spending one unit on research is π_{it} times the marginal probability $\lambda f'(n) / (\gamma A_{i,t-1})$:

$$1 = \lambda f'(n)(\pi_{it} / (\gamma A_{i,t-1}))$$

To solve this equation for n we need to determine the productivity-adjusted monopoly rent π_{it}/A_{it} to a successful innovator. As before, we assume that this innovator can produce the leading-edge input at a constant marginal cost of one unit of the general good. But she faces a competitive fringe of imitators who can produce the same product at higher marginal cost χ, where $\chi \in (1, 1/\alpha)$[3] is an inverse measure of the degree of product market competition or imitation in the economy.[4]. Thus her monopoly rent is again equal to:

$$\pi_{it} = (p_{it} - 1)x_{it} = (\chi - 1)x_{it}. \tag{6}$$

A monopolist's output x_{it} will be the amount demanded by firms in the general sector when faced with the price χ; that is, the quantity such that χ equals the marginal product of the $i$the intermediate good in producing the general good:

$$\chi = \partial y_t / \partial x_{it} = \alpha (m x_{it} / A_{it} L)^{\alpha - 1} \tag{7}$$

Hence:

$$\pi_{it} = \delta(\chi) A_{it} L / m \tag{8}$$

[3] It is easily verified that if there were no fringe then the unconstrained monopolist would charge a price equal to $1/\alpha$, but (**??**) implies that at that price the fringe could profitably undercut her.

[4] If no innovation occurs then some firm will produce, but with no cost advantage over the fringe because everyone is able to produce last period's intermediate input at a constant marginal cost of unity.

where

$$\delta(\chi) \equiv (\chi - 1)(\chi/\alpha)^{\frac{1}{\alpha-1}},\ \delta'(\chi) > 0.^{5}$$

Therefore we can write the research arbitrage equation, taking into account that $\gamma A_{i,t-1} = A_{it}$ because a monopolist is someone who has just innovated, as:

$$1 = \lambda f'(n)\,\delta(\chi)\,L/m \tag{9}$$

which we assume in this section has a positive solution.

The expected productivity growth rate is determined by substituting the solution of (9) into the growth equation (5). In the special case where the research-productivity function f takes the simple form:

$$f(n) = \sqrt{2n},$$

we have:

$$g = \lambda^2 \delta(\chi)\,(L/m)\,(\gamma - 1) \tag{10}$$

As it turns out, g is not only the expected growth rate of each sector's productivity parameter but also the approximate growth rate of the economy's per-capita GDP. This is because per-capita GDP is approximately proportional to the unweighted average of the sector-specific productivity parameters:[6]

$$A_t = \frac{1}{m}\sum_{i=1}^{m} A_{it}.$$

[5] To see that $\delta' > 0$ note that:

$$\chi \frac{d\ln(\delta(x))}{d\chi} = \frac{\chi}{\chi - 1} - \frac{1}{1-\alpha} > 0$$

where the last inequality follows from (**??**).

[6] To see this, note that GDP equals the sum of value added in the general sector and in the monopolized intermediate sectors. (There is no value added in the competitive intermediate sectors because their output is priced at the cost of the intermediate inputs. Also, we follow the standard national income accounting practice of ignoring the output (patents) of the research sector.) According to (7) the output of each monopolized sector ($i \in M_t$) at t is:

$$x_{it} = (\alpha/\chi)^{\frac{1}{1-\alpha}}\,(L/m)\,A_{it} \qquad (i \in M_t)$$

The output of each competitive sector ($i \in C_t$) at t is the amount demanded when its price is unity; setting $\chi = 1$ in (7) yields:

$$x_{it} = (\alpha)^{\frac{1}{1-\alpha}}\,(L/m)\,A_{it} \qquad (i \in C_t)$$

Substituting these into (2) and rearranging yields the following expression for per-capita GDP:

$$y_t/L = (\alpha/\chi)^{\frac{1}{1-\alpha}}\left(\frac{\#M_t}{m}\right)\left(\frac{1}{\#M_t}\sum_{i\in M_t} A_{it}\right) + \alpha^{\frac{1}{1-\alpha}}\left(\frac{\#C_t}{m}\right)\left(\frac{1}{\#C_t}\sum_{i\in C_t} A_{it}\right)$$

where $\#M_t$ is the number of monopolized sectors and $\#C_t$ the number of competitive sectors. By the law of large numbers, the fraction of sectors $\#M_t/m$ monopolized, i.e. the fraction in which there was an innovation at t, is approximately the probability of success in research in each sector: $\mu = \lambda f(n)$, and the fraction of sectors $\#C_t/m$ that are competitive is approximately $1 - \mu$. The average productivity parameter among monopolized sectors $\left(\frac{1}{\#M_t}\sum_{i\in M_t} A_{it}\right)$ is just γ times the average productivity parameter of those sectors last period; since innovations are spread randomly across sectors this is approximately γ times the average across all sectors last period: γA_{t-1}. Likewise the average productivity parameter

Since (a) all sectors have an expected growth rate of g, (b) the sectoral growth rates are statistically independent of each other and (c) there is a large number of them, therefore the law of large numbers implies that the average grows at approximately the same rate g as each component.

2.3 Alternative formulations

There are many other ways of formulating the basic model. We note two of them here for future reference. In the first one, as in the above toy model, the general good is used only for consumption, while skilled labor is the only factor used in producing intermediate products and research. The general good is produced by the intermediate inputs in combination with a specialized factor (for example unskilled labor) available in fixed supply. In this formulation, the growth equation is the same as (5) above, but with n being interpreted as the amount of skilled labor allocated to R&D. This version will be spelled out in somewhat more detail in section 5 below.

The other popular version is one with intersectoral spillovers, in which each innovation produces a new intermediate product in that sector embodying the maximum $\overline{A}_{t-1}$ of all productivity parameters of the last period, across all sectors, times some factor γ that depends on the flow of innovations in the whole economy. The idea here is that if a sector has been unlucky for a long time, while the rest of the economy has progressed, the technological progress elsewhere spills over into the innovation in this sector, resulting in a larger innovation than if the innovation had occurred many years ago. The model in section 3 below is a variant of this version.

2.4 Comparative statics on growth

Equation (10) delivers several comparative-statics results, each with important policy implications on how to "manage" the growth process:

1. Growth increases with the productivity of innovations λ and with the

---

across competitive sectors is the average across sectors that did not innovate, which is approximately A_{t-1}. Making these substitutions into the above expression for per-capita GDP yields:

$$y_t/L \simeq \left((\alpha/\chi)^{\frac{1}{1-\alpha}}\mu\gamma + \alpha^{\frac{1}{1-\alpha}}(1-\mu)\right)A_{t-1} \equiv \zeta A_{t-1}$$

Since labor is paid its marginal product in the general sector, the wage rate is:

$$w_t = \partial y_t/\partial L = (1-\alpha)\, y_t/L \simeq (1-\alpha)\,\zeta A_{t-1}$$

which is also per-capita value-added in the general sector. By similar reasoning, (8) implies that per-capita value added in monopolized intermediate sectors is:

$$(1/L)\sum_{i\in M_t}\delta(\chi)\,A_{it}L/m = \delta(\chi)\left(\frac{\#M_t}{m}\right)\left(\frac{1}{\#M_t}\sum_{i\in M_t}A_{it}\right) \simeq \delta(\chi)\,\mu\gamma A_{t-1}.$$

Therefore each component of per-capita GDP is approximately proportional to A_{t-1}. Since A_t grows at approximately the constant rate g thefore per-capita GDP is approximately proportional to A_t.

supply of skilled labor L: both results point to the importance of education, and particularly higher education, as a growth-enhancing factor. Countries that invest more in higher education will achieve a higher productivity of research activities and also reduce the opportunity cost of R&D by increasing the aggregate supply of skilled labor. An increase in the size of population should also bring about an increase in growth by raising L. This "scale effect" has been challenged in the literature and will be discussed in section 5 below.

2. Growth increases with the size of innovations, as measured by γ. This result points to the existence of a wedge between private and social innovation incentives. That is, a decrease in size would reduce the cost of innovation in proportion to the expected rents; the research arbitrage equation (9) shows that these two effects cancel each other, leaving the equilibrium level of R&D independent of size. However, equation (10) shows that the social benefit from R&D, in the form of enhanced growth, is proportional not to γ but to the "incremental size" $\gamma - 1$. When γ is close to one it is not socially optimal to spend spend as much on R&D as when γ is very large, because there is little social benefit; yet a laissez-faire equilibrium would result in the same level of R&D in both cases.

3. Growth is decreasing with the degree of product market competition and/or with the degree of imitation as measured inversely by χ. Thus patent protection (or, more generally, better protection of intellectual property rights), will enhance growth by increasing χ and therefore increasing the potential rewards from innovation. However, pro-competition policies will tend to discourage innovation and growth by reducing χ and thereby forcing incumbent innovators to charge a lower limit price. Existing historical evidence supports the view that property rights protection is important for sustained long-run growth; however the prediction that competition should be unambiguously bad for innovations and growth is questioned by all recent empirical studies, starting with the work of Nickell (1996) and Blundell et al (1999). In Section 4 we shall argue that the Schumpeterian framework outlined in this section can be extended so as to reconcile theory and evidence on the effects of entry and competition on innovations, and that it also generates novel predictions regarding these effects which are borne out by empirical tests.

3 Linking growth to development: convergence clubs

With its emphasis on institutions, the Schumpeterian growth paradigm is not restricted to dealing with advanced countries that perform leading-edge R&D. It can also shed light on why some countries that were initially poor have managed to grow faster than industrialized countries, whereas others have continued to

fall further behind.

The history of cross-country income differences exhibits mixed patterns of convergence and divergence. The most striking pattern over the long run is the "great divergence" - the dramatic widening of the distribution that has taken place since the early 19th Century. Pritchett (1997) estimates that the proportional gap in living standards between the richest and poorest countries grew more than five-fold from 1870 to 1990, and according to the tables in Maddison (2001) the proportional gap between the richest group of countries and the poorest[7] grew from 3 in 1820 to 19 in 1998. But over the second half of the twentieth century this widening seems to have stopped, at least among a large group of nations. In particular, the results of Barro and Sala-i-Martin (1992), Mankiw, Romer and Weil (1992) and Evans (1996) seem to imply that most countries are converging to parallel growth paths.

However, the recent pattern of convergence is not universal. In particular, the gap between the leading countries as a whole and the very poorest countries as a whole has continued to widen. The proportional gap in per-capita income between Mayer-Foulkes's (2002) richest and poorest convergence groups grew by a factor of 2.6 between 1960 and 1995, and the proportional gap between Maddison's richest and poorest groups grew by a factor of 1.75 between 1950 and 1998. Thus as various authors[8] have observed, the history of income differences since the mid 20th Century has been one of "club-convergence"; that is, all rich and most middle-income countries seem to belong to one group, or "convergence club", with the same long-run growth rate, whereas all other countries seem to have diverse long-run growth rates, all strictly less than that of the convergence club.

The explanation we develop in this section for club convergence follows Howitt (2000), who took the cross-sectoral-spillovers variant of the closed-economy model described in section 2.3 above and allowed the spillovers to cross international as well as intersectoral borders. This international spillover, or "technology transfer", allows a backward sector in one country to catch up with the current technological frontier whenever it innovates. Because of technology transfer, the further behind the frontier a country is initially, the bigger the average size of its innovations, and therefore the higher its growth rate for a given frequency of innovations. As long as the country continues to innovate at some positive rate, no matter how small, it will eventually grow at the same rate as the leading countries. (Otherwise the gap would continue to rise and therefore the country's growth rate would continue to rise.) However, countries with poor macroeconomic conditions, legal environment, education system or credit markets will not innovate in equilibrium and therefore they will not benefit from technology transfer, but will instead stagnate.

This model reconciles Schumpeterian theory with the evidence to the effect

[7] The richest group was Western Europe in 1820 and the "Euopean Offshoots" (Australia, Canada, New Zealand and the United States) in 1998. The poorest group was Africa in both years.

[8] Baumol (1986), Durlauf and Johnson (1995), Quah (1993, 1997) and Mayer-Foulkes (2002, 2003).

that all but the poorest countries have parallel long-run growth paths. It implies that the growth rate of any one country depends not on local conditions but on global conditions that impinge on world-wide innovation rates. The same parameters which were shown in section 2.4 above to determine a closed economy's productivity-growth rate will now determine that country's relative productivity *level*. What emerges from this exercise is therefore not just a theory of club convergence but also a theory of the world's growth rate and of the cross-country distribution of productivity.

Before we develop the model we need to address the question of how our framework, in which growth depends on research and development, can be applied to the poorest countries of the world, in which, according to OECD statistics, almost no formal R&D takes place. The key to our answer is that because technological knowledge is often tacit and circumstantially specific,[9] foreign technologies cannot simply be copied and transplanted to another country no cost. Instead, technology transfer requires the receiving country to invest resources in order to master foreign technologies and adapt them to the local environment. Although these investments may not fit the conventional definition of R&D, they play the same role as R&D in an innovation-based growth model; that is, they use resources, including skilled labor with valuable alternative uses, they generate new technological possibilities where they are conducted, and they build on previous knowledge.[10] While it may be the case that implementing a foreign technology is somewhat easier than inventing an entirely new one, this is a difference in degree, not in kind. In the interest of simplicity our theory ignores that difference in degree and treats the implementation and adaptation activities undertaken by countries far behind the frontier as being analytically the same as the research and development activities undertaken by countries on or near the technological frontier. For all countries we assign to R&D the role that Nelson and Phelps (1966) assumed was played by human capital, namely that of determining the country's "absorptive capacity".[11]

3.1 A model of technology transfer

Consider one country in a world of h different countries. This country looks just like the ones described in the basic model above, except that whenever an innovation takes place in any given sector the productivity parameter attached to the new product will be an improvement over the pre-existing global leading-edge technology. That is, let $\overline{A}_{t-1}$ be the maximum productivity parameter over all countries in the sector at the end of period $t-1$; in other words the "frontier" productivity at $t-1$. Then an innovation at date t will result in a new version

[9] See Arrow (1969) and Evenson and Westphal (1995).

[10] Cohen and Levinthal (1989) and Griffith, Redding and Van Reenen (2001) have also argued that R&D by the receiving country is a necessary input to technology transfer.

[11] Grossman and Helpman (1991) and Barro and Sala-i-Martin (1997) also model technology transfer as taking place through a costly investment process, which they portray as imitation; but in these models technology transfer always leads to convergence in growth rates except in special cases studied by Grossman and Helpman where technology transfer is inactive in the long run.

of that intermediate sector whose productivity parameter is $A_t = \gamma \overline{A}_{t-1}$, which can be implemented by the innovator in this country, and which becomes the new global frontier in that sector. The frontier parameter will also be raised by the factor γ if an innovation occurs in that sector in any other country.

Therefore domestic productivity in the sector evolves according to:

$$\ln A_t = \left\{ \begin{array}{ll} \ln \overline{A}_{t-1} + \ln \gamma = \ln \overline{A}_t & \text{with probability } \mu \\ \ln A_{t-1} & \text{with probability } 1-\mu \end{array} \right\}$$

where μ is the country's innovation rate:

$$\mu = \lambda f(n)$$

and the productivity-adjusted research n is defined as:

$$n \equiv N_t / \left(\gamma \overline{A}_{t-1}\right)$$

since the targeted productivity parameter is now $\gamma \overline{A}_{t-1}$.

Meanwhile, the global frontier advances by the factor γ with every innovation anywhere in the world.[12] Therefore:

$$\ln \overline{A}_t = \left\{ \begin{array}{ll} \ln \overline{A}_{t-1} + \ln \gamma & \text{with probability } \overline{\mu} \\ \ln \overline{A}_{t-1} & \text{with probability } 1-\overline{\mu} \end{array} \right\} \tag{11}$$

where

$$\overline{\mu} = \Sigma_1^h \lambda^j f\left(n^j\right)$$

is the global innovation rate.[13] It follows from (11) that the long-run average growth rate of the frontier, measured as a difference in logs, is:[14]

$$\overline{g} = \overline{\mu} \ln \gamma \tag{12}$$

Assume there is no international trade in intermediates or general goods.[15] Then the costs and benefits of R&D are the same as in the previous model,

[12] Again we are assuming a time period small enough to ignore the possibility of simultaneous innovations in the same sector.

[13] A simpler version of the model would just have the frontier productivity grow at an exogenous rate $\overline{g}$. The model in this section has the advantage of delivering both an endogenous rate for productivity growth at the frontier and club convergence towards that frontier.

[14] The growth rate (12) expressed as a log difference is approximately the same as the rate (5) of the previous section which was expressed as a proportional increment, because the first-order Taylor-series approximation to $\ln\gamma$ at $\gamma = 1$ is $(\gamma - 1)$. We switch between these two definitions depending on which is more convenient in a given context.

[15] This is not to say that international trade is umimportant for technology transfer. On the contrary, Coe and Helpman (1995), Coe Helpman and Hoffmaister (1996), Eaton and Kortum (1996) and Savvides and Zachariadis (2004) all provide strong evidence to the effect that internation trade plays an important role in the international diffusion of technological progress. For a recent summary of this and other empirical work, see Keller (2002). Eaton and Kortum (2001) provide a simple "semi-endogenous" (see section 5 below) growth model in which endogenous innovation interacts with technology transfer and international trade in goods; in their model all countries converge to the same long-run growth rate.

except that the domestic productivity parameter A_t may differ from the global parameter $\overline{A}_t$ that research aims to improve upon. Each innovation will now change log productivity by:

$$\ln \overline{A}_{t-1} + \ln \gamma - \ln A_{t-1} = \ln \gamma + d_{t-1}$$

where

$$d_{t-1} \equiv \ln \left(\overline{A}_{t-1} / A_{t-1} \right)$$

is a measure of "distance to the frontier." As Gerschenkron (1952) argued when discussing the "advantage of backwardness," the greater the distance the larger the innovation. The average growth rate will again be the expected frequency of innovations times size:

$$g_t = \mu \left(\ln \gamma + d_{t-1} \right) \tag{13}$$

which is also larger the greater the distance to the frontier.

The distance variable d_t evolves according to:

$$d_t = \left\{ \begin{array}{cc} d_{t-1} & \text{with probability } 1 - \overline{\mu} \\ \ln \gamma + d_{t-1} & \text{with probability } \overline{\mu} - \mu \\ 0 & \text{with probability } \mu \end{array} \right\}$$

That is, with probability $1 - \overline{\mu}$ there is no innovation in the sector either globally or in this country, so both domestic productivity and frontier productivity remain unchanged; with probability $\overline{\mu} - \mu$ an innovation will occur in this sector but in some other country, in which case domestic productivity remains the same but the proportional gap grows by the factor γ; and with probability μ an innovation will occur in this sector in this country, in which case the country moves up to the frontier, reducing the gap to zero.

It follows that the expected distance $\widehat{d}_t$ evolves according to:

$$\widehat{d}_t = (1 - \mu) \, \widehat{d}_{t-1} + (\overline{\mu} - \mu) \ln \gamma.$$

If $\mu > 0$ this is a stable difference equation with a unique rest point. That is, as long as the country continues to perform R&D at a positive constant intensity n its distance to the frontier will stabilize, meaning that its productivity growth rate will converge to that of the global frontier. But if $\mu = 0$ the difference equation has no stable rest point and $\widehat{d}_t$ diverges to infinity. That is, if the country stops innovating it will have a long-run productivity growth rate of zero because innovation is a necessary condition for the country to benefit from technology transfer.

More formally, the country's long-run expected distance d^* is given by:

$$d^* = \left\{ \begin{array}{ll} (\overline{\mu}/\mu - 1) \ln \gamma & \text{if } \mu > 0 \\ \infty & \text{if } \mu = 0 \end{array} \right\} \tag{14}$$

and its long-run expected growth rate g^*, according to (12), (13) and (14) is:

$$g^* = \left\{ \begin{array}{ll} \mu \left(\ln \gamma + d^* \right) = \overline{g} & \text{if } \mu > 0 \\ 0 & \text{if } \mu = 0 \end{array} \right\}$$

Each country's innovation rate μ is determined according to the same principles as before. In particular, it will be equal $\lambda f(n)$ where n is determined by the research-arbitrage equation (9) above, provided that a positive solution to (9) exists. For example if the research-productivity function f satisfies the Inada-like condition: $f'(0) = \infty$, as in the example used above to derive the growth equation (10), then there will always exist a positive solution to (9), so all countries will converge to the frontier growth rate.

But suppose, on the contrary, that this Inada-like condition does not hold, that instead: $f'(0) < \infty$. Then the research-arbitrage condition (9) must be replaced by the more general Kuhn-Tucker conditions:

$$1 \geq \lambda f'(n)\,\delta(\chi)\,L/m \qquad \text{with } n = 0 \text{ if the inequality is strict.} \tag{15}$$

That is, for an interior solution the expected marginal cost and benefit must be equal, but the only equilibrium will be one with zero R&D if at that point the expected marginal benefit does not exceed the cost. It follows that the country will perform positive R&D if:

$$\lambda\delta(\chi)\,L/m > 1/f'(0), \tag{16}$$

but if condition (16) fails then there will be no research: $n = 0$ and hence no innovations: $\mu = 0$ and no growth: $g = 0$.

This means that countries will fall into two groups, corresponding to two convergence clubs:

1. Countries with highly productive R&D, as measured by λ, or good educational systems as measured by high λ or high L, or good property right protection as measured by a high χ, will satisfy condition (16), and hence will grow asymptotically at the frontier growth rate $\overline{g}$.

2. Countries with low R&D productivity, poor educational systems and low property right protection will fail condition (16) and will not grow at all. The gap d_t separating them from the frontier will grow forever at the rate $\overline{g}$.

3.2 World growth and distribution

Since the world growth rate $\overline{g}$ given by (12) depends on each country's innovation frequency $\mu^j = \lambda^j f\left(n^j\right)$, therefore world growth depends on the value for each country of all the factors described in section 2.4 above that determine μ^j. Thus any improvement in R&D productivity, education or property rights anywhere in the innovating world will raise the growth rate of productivity in all but the stagnating countries.

Moreover, the cross-country distribution of productivity is determined by these same variables. For according to (14) each country's long-run relative distance to the frontier depends uniquely on its own innovation frequency $\mu = \lambda f(n)$. Two countries in which the determinants of innovation analyzed in section 2.4 are the same will lie the same distance from the frontier in the long

run and hence will have the same productivity in the long run. Countries with more productive R&D, better educational systems and stronger property right protection will have higher productivity.

3.3 The role of financial development in convergence

The framework can be further developed by assuming that while the size of innovations increases with the distance to the technological frontier (due to technology transfer), the frequency of innovations depends upon the ratio between the distance to the technological frontier and the current stock of skilled workers. This enriched framework (see Howitt and Mayer-Foulkes, 2002) can explain not only why some countries converge while other countries stagnate but also why different countries may display positive yet divergent growth patterns in the long-run. Benhabib and Spiegel (2002) develop a similar account of divergence and show the importance of human capital in the process. The rest of this section presents a summary of the related model of Aghion, Mayer-Foulkes and Howitt (2004) (AMH) and discusses their empirical results showing the importance of financial development in the convergence process.

Suppose that the world is as portrayed in the previous sections, but that research aimed at making an innovation in t must be done at period $t-1$. If we assume perfectly functioning financial markets then nothing much happens to the model except that the research arbitrage condition (9) has a discount factor β on the right-hand side to reflect the fact that the expected returns to R&D occur one period later than the expenditure.[16] But when credit markets are imperfect, AMH show that an entrepreneur may face a borrowing constraint that limits her investment to a fixed multiple of her accumulated net wealth. In their model the multiple comes from the possibility that the borrower can, at a cost that is proportional to the size of her investment, decide to defraud her creditors by making arrangements to hide the proceeds of the R&D project in the event of success.[17] They also assume a two-period overlapping-generations structure in which the accumulated net wealth of an entrepreneur is her current wage income, and in which there is just one entrepreneur per sector in each country. This means that the further behind the frontier the country falls the less will any entrepreneur be able to invest in R&D relative to what is needed to maintain any given frequency of innovation. What happens in the long run to the country's growth rate depends upon the interaction between this disadvantage of backwardness, which reduces the frequency of innovations, and the above-described advantage of backwardness, which increases the size of innovations. The lower the cost of defrauding a creditor the more likely it is that the disadvantage of backwardness will be the dominant force, preventing the country from converging to the frontier growth rate even in the long run. Generally speaking, the greater the degree of financial development of a country the

[16] For simplicity we suppose that everyone has linear intertemporal preferences with a constant discount factor β.

[17] The "credit multipler" assumed here is much like that of Bernanke and Gertler (1989), as modified by Aghion, Banerjee and Piketty (1999).

more effective are the institutions and laws that make it difficult to defraud a creditor. Hence the link between financial development and the likelihood that a country will converge to the frontier growth rate.

The following simplified account of AHM shows in more detail how this link between financial development and convergence works. Suppose that entrepreneurs have no source of income other than what they can earn from innovating. Then they must borrow the entire cost of any R&D project. Because there are constant returns to the R&D technology,[18] therefore in equilibrium that cost will equal the expected benefit, discounted back to today:

$$\mu\beta\pi_t = \left(\lambda N_t / \left(\gamma \overline{A}_t\right)\right) \beta\delta\left(\chi\right) \gamma \overline{A}_t = \lambda\beta\delta\left(\chi\right) N_t$$

This is also the expected discounted benefit to a borrower from paying a cost cN_t today that would enable her to default in the event that the R&D project is successful. (There is no benefit if the project fails to produce an innovation because in that case the entrepreneur cannot pay anything to the creditor even if she has decided to be honest and therefore has not paid the cost cN_t). The entrepreneur will choose to he honest if the cost at least as great as the benefit; that is, if:

$$c \geq \lambda\beta\delta\left(\chi\right). \tag{17}$$

Otherwise she will default on any loan.

Suppose that $\beta\lambda\delta\left(\chi\right) L/m > 1/f'\left(0\right)$. This is the condition (16) above for positive growth, modified to take discounting into account. It follows that in any country where the incentive-compatibility constraint (17) holds then innovation will proceed as described in the previous section, and the country will converge to the frontier growth rate. But in any country where the cost of defrauding a creditor is less than the right-hand side of (17) no R&D will take place because creditors would rationally expect to be defrauded of any possible return from lending to an entrepreneur. Therefore convergence to the frontier growth rate will occur only in countries with a level of financial development that is high enough to put the cost of fraud at or above the limit imposed by (17).

AHM test this effect of financial development on convergence by running the following cross-country growth regression:

$$g_i - g_1 = \beta_0 + \beta_f F_i + \beta_y \cdot \left(y_i - y_1\right) + \beta_{fy} \cdot F_i \cdot \left(y_i - y_1\right) + \beta_x X_i + \varepsilon_i \tag{18}$$

where g_i denotes the average growth rate of per-capita GDP in country i over the period 1960 - 1995, F_i the country's average level of financial development, y_i the initial (1960) log of per-capita GDP, X_i a set of other regressors and ε_i a disturbance term with mean zero. Country 1 is the technology leader, which they take to be the United States.

Define $\widehat{y}_i \equiv y_i - y_1$, country i's initial relative per-capita GDP. Under the assumption that $\beta_y + \beta_{fy} F_i \neq 0$ we can rewrite (18) as:

$$g_i - g_1 = \lambda_i \cdot \left(\widehat{y}_i - \widehat{y}_i^*\right)$$

[18] See footnote 2 above.

where the steady-state value $\widehat{y}_i^*$ is defined by setting the RHS of (18) to zero:

$$\widehat{y}_i^* = -\frac{\beta_0 + \beta_f F_i + \beta_x X_i + \varepsilon_i}{\beta_y + \beta_{fy} F_i} \tag{19}$$

and λ_i is a country-specific convergence parameter:

$$\lambda_i = \beta_y + \beta_{fy} F_i \tag{20}$$

that depends on financial development.

A country can converge to the frontier growth rate if and only if the growth rate of its relative per-capita GDP depends negatively on the initial value $\widehat{y}_i$; that is if and only if the convergence parameter λ_i is negative. Thus the likelihood of convergence will increase with financial development, as implied by the above theory, if and only if:

$$\beta_{fy} < 0. \tag{21}$$

The results of running this regression using a sample of 71 countries are shown in Table 1, which indicates that the interaction coefficient β_{fy} is indeed significantly negative for a variety of different measures of financial development and a variety of different conditioning sets X. The estimation is by instrumental variables, using a country's legal origins, and its legal origins[19] interacted with the initial GDP gap $(y_i - y_1)$ as instruments for F_i and $F_i (y_i - y_1)$. The data, estimation methods and choice of conditioning sets X are all take directly from Levine, Loayza and Beck (2000) who found a strongly positive and robust effect of financial intermediation on short-run growth in a regression identical to (18) but without the crucial interaction term $F_i (y_i - y_1)$ that allows convergence to depend upon the level of financial development.

TABLE 1 HERE

AHM shown that the results of Table 1 are surprisingly robust to different estimation techniques, to discarding outliers, and to including possible interaction effects between the initial GDP gap and other right-hand-side variables.

3.4 Concluding remark

Thus we see how Schumpeterian growth theory and the quality improvement model can naturally explain club convergence patterns, the so-called twin peaks pointed out by Quah (1996). The Schumpeterian growth framework can deliver an explanation for cross-country differences in growth rates and/or in convergence patterns based upon *institutional considerations*. No one can deny that such considerations are close to what development economists have been concerned with. However, some may argue that the quality improvement paradigm,

[19] See LaPorta et al. (1998) for a detailed explanation of legal origins and its relevance as an instrument for financial development.

and new growth theories in general, remain of little help for development policy, that they merely formalize platitudes regarding the growth-enhancing nature of good property right protection, sound education systems, stable macroeconomy, without regard to specifics such as a country's current stage of development. In Section 4 and 6 below we will argue on the contrary that the Schumpeterian growth paradigm can be used to understand (i) why liberalization policies (in particular an increase in product market competition) should affect productivity growth differently in sectors or countries at different stages of technological development as measured by the distance variable d; and (ii) why the organizations or institutions that maximize growth, or that are actually chosen by societies, also vary with distance to the frontier.

4 Linking growth to IO: innovate to escape competition

One particularly unappealing feature of the basic Schumpeterian model outlined in Section 2 is the prediction that product market competition is unambiguously detrimental to growth because it reduces the monopoly rents that reward successful innovators and thereby discourages R&D investments. Not only does this prediction contradict a common wisdom that goes back to Adam Smith, but it has also been shown to be (partly) counterfactual (e.g by Geroski (1994), Nickell (1996), and Blundell et al (1999))[20].

However, as we argue in this section, a simple modification reconciles the Schumpeterian paradigm with the evidence on product market competition and innovation, and also generates new empirical predictions that can be tested with firm- and industry-level data. In this respect the paradigm can meet the challenge of seriously putting IO into growth theory. The theory developed in this section is based on Aghion-Harris-Vickers (1997) and Aghion-Harris-Howitt-Vickers (2001), but cast in the discrete-time framework introduced above.

We start by considering an isolated country in a variant of the technology-transfer model of the previous section. This variant allows technology spillovers to occur across sectors as well as across national borders. Thus there is a global technological frontier that is common to all sectors, and which is drawn on by all innovations. The model takes as given the growth rate of this global frontier, so that the frontier $\overline{A}_t$ at the end of period t obeys:

$$\overline{A}_t = \gamma \overline{A}_{t-1},$$

where $\gamma > 1$.

In each country, the general good is produced using the same kind of technology as in the previous sections, but here for simplicity we assume a continuum

[20] We refer the reader to the second part of this section where we confront theory and empirics on the relationship between competition/entry and innovation/productivity growth.

of intermediate inputs and we normalize the labor supply at $L = 1$, so that:

$$y_t = \int_0^1 A_{it}^{1-\alpha} x_{it}^{\alpha} di,$$

where, in each sector i, only one firm produces intermediate input i using general good as capital according to a one-for-one technology.

In each sector, the incumbent firm faces a competitive fringe of firms that can produce the same kind of intermediate good, although at a higher unit cost. More specifically, we assume that at the end of period t, at unit cost χ, where we assume $1 < \chi < 1/\alpha < \gamma\chi$, a competitive fringe of firms can produce one unit of intermediate input i of a quality equal to $\min(A_{it}, \overline{A}_{t-1})$, where A_{it} is the productivity level achieved in sector i after innovation has had the opportunity to occur in sector i within period t.

In each period t, there are three types of sectors, which we refer to as type-j sectors, with $j \in \{0, 1, 2\}$. A type-j sector starts up at the beginning of period t with productivity $A_{j,t-1} = \overline{A}_{t-1-j}$, that is, j steps behind the current frontier $\overline{A}_{t-1}$. The profit flow of an incumbent firm in any sector at the end of period t, will depend upon the technological position of that firm with regard to the technological frontier at the end of the period.

Between the beginning and the end of the current period t, the incumbent firm in any sector i has the possibility of innovating with positive probability. Innovations occur step-by-step: in any sector an innovation moves productivity upward by the same factor γ. Incumbent firms can affect the probability of an innovation by investing more in R&D at the beginning of the period. Namely, by investing the quadratic R&D effort $\frac{1}{2}\gamma A_{i,t-1}\mu^2$ incumbent an firm i in a type-0 or type-1 sector, innovates with probability μ.[21] However, innovation is assumed to be automatic in type-2 sectors, which in turn reflects a knowledge externality from more advanced sectors which limits the maximum distance of any sector to the technological frontier.

Now, consider the R&D incentives of incumbent firms in the different types of sectors at the beginning of period t. Firms in type-2 sectors have no incentive to invest in R&D since innovation is automatic in such sectors. Thus

$$\mu_2 = 0,$$

where μ_j is the equilibrium R&D choice in sector j.

Firms in type-1 sectors, that start one step behind the current frontier at $A_{i,t-1} = \overline{A}_{t-2}$ at the beginning of period t, end up with productivity $A_t = \overline{A}_{t-1}$ if they successfully innovate, and with productivity $A_t = \overline{A}_{t-2}$ otherwise. In either case, the competitive fringe can produce intermediate goods of the same quality but at cost χ instead of 1, which in turn, as in section 2 above, the

[21] We thus depart slightly from our formulation in the previous sections: here we take the probability of innovation, not the R&D effort, as the optimization variable. However the two formulations are equivalent: that the innovation probability $f(n) = \mu$ is a concave function of the effort n, is equivalent to saying that the effort is a convex function of the probability.

equilibrium profit is equal to:[22]

$$\pi_t = A_t \delta(\chi),$$

with

$$\delta(\chi) = (\chi - 1)(\chi/\alpha)^{\frac{1}{\alpha-1}}.$$

Thus the net rent from innovating for a type-1 firm is equal to

$$(\overline{A}_{t-1} - \overline{A}_{t-2})\delta(\chi)$$

and therefore a type-1 firm will choose its R&D effort to solve:

$$\max_{\mu}\{(\overline{A}_{t-1} - \overline{A}_{t-2})\delta(\chi)\mu - \frac{1}{2}\gamma\overline{A}_{t-2}\mu^2\},$$

which yields

$$\mu_1 = (1 - \frac{1}{\gamma})\delta(\chi).$$

In particular an increase in product market competition, measured as an reduction in the unit cost χ of the competitive fringe, will reduce the innovation incentives of a type-1 firm. This we refer to as the *Schumpeterian effect* of product market competition: competition reduces innovation incentives and therefore productivity growth by reducing the rents from innovations of type-1 firms that start below the technological frontier. This is the dominant effect, both in IO models of product differentiation and entry, and in basic endogenous growth models as the one analyzed in the previous sections. Note that type-1 firms cannot escape the fringe by innovating: whether they innovate or not, these firms face competitors that can produce the same quality as theirs at cost χ. As we shall now see, things become different in the case of type-0 firms.

Firms in type-0 sectors, that start at the current frontier, end up with productivity $\overline{A}_t$ if they innovate, and stay with their initial productivity $\overline{A}_{t-1}$ if they do not. But the competitive fringe can never get beyond producing quality $\overline{A}_{t-1}$. Thus, by innovating, a type-0 incumbent firm produces an intermediate good which is γ times better than the competing good the fringe could produce, and at unit cost 1 instead of χ for the fringe. Our assumption $\frac{1}{\alpha} < \gamma\chi$ then implies that competition by the fringe is no longer a binding constraint for an innovating incumbent, so that its equilibrium profit post-innovation, will simply be the profit of an unconstrained monopolist, namely:

$$\pi_t = \overline{A}_t \delta(1/\alpha).$$

On the other hand, a type-0 firm that does not innovate, will keep its productivity equal to $\overline{A}_{t-1}$. Since the competitive fringe can produce up to this quality level at cost χ, the equilibrium profit of a type-0 firm that does not innovate, is equal to

$$\pi_t = \overline{A}_{t-1}\delta(\chi).$$

[22] Imitation does not destroy the rents of non-innovating firms. We assume nevertheless that the firm ignores any continuation value in its R&D decision.

A type-0 firm will then choose its R&D effort to:

$$\max_{\mu}\{[\overline{A}_t\delta(1/\alpha) - \overline{A}_{t-1}\delta(\chi)]\mu - \frac{1}{2}\gamma\overline{A}_{t-1}\mu^2\},$$

so that in equilibrium

$$\mu_0 = \delta(1/\alpha) - \frac{1}{\gamma}\delta(\chi).$$

In particular an increase in product market competition, i.e a reduction in χ, will now have a fostering effect on R&D and innovation. This, we refer to as the *escape competition effect:* competition reduces pre-innovation rents of type-0 incumbent firms, but not their post-innovation rents since by innovating these firms have escaped the fringe. This in turn induces those firms to innovate in order to escape competition with the fringe.

4.1 Composition effect and the inverted-U relationship between competition and innovation

We have just seen that product market competition tends to have opposite effects on frontier and lagging sectors, fostering innovation by the former and discouraging innovation by the latter. In this section we consider the impact of competition on the steady-state aggregate innovation intensity

$$I = q_0\mu_0 + q_1\mu_1 \tag{22}$$

where q_j is the steady-state fraction of type-j sectors (recall that type-2 sectors do not perform R&D).

To get a non-trivial steady-state fraction of type-0 firms, we need that the net flows out of state 0 (which corresponds to type-0 firms that fail to innovate in the current period), be compensated by a net flow into state 0. We simply postulate such a flow into state 0, by assuming that at the end of any period t, with exogenous probability ε entry at the new frontier, that is by a type-0 firm with productivity level $\overline{A}_t$, occurs in a type-2 sector after the incumbent firm has produced. We then have the following flow equations describing the net flows into and out of states 0, 1 and 2:

$$\begin{aligned} q_2\varepsilon &= q_0(1-\mu_0); \\ q_0(1-\mu_0) &= q_1(1-\mu_1); \\ q_1(1-\mu_1) &= q_2\varepsilon; \end{aligned}$$

in which the left hand sides represents the steady-state expected flow of sectors that move into a state j and the right hand sides represent the expected outflow from the same state, for $j = 0, 1,$ and 2. This, together with the identity:

$$q_0 + q_1 + q_2 = 1,$$

implies that:

$$I = 1 - q_2(1 + 2\varepsilon),$$

where

$$q_2 = \frac{1}{1 + \frac{\varepsilon}{1-\mu_0} + \frac{\varepsilon}{1-\mu_1}}.$$

In particular, one can see that the overall effect of increased product market competition on I is ambiguous since it produces opposite effects on innovation probabilities in type-0 and type-1 sectors (i.e on μ_0 and μ_1). In fact, one can say more than that, and show that: (i) the Schumpeterian effect always dominates for γ sufficiently large; (ii) the escape competition effect always dominates for γ sufficiently close to one; (iii) for intermediate values of γ, the escape competition effect dominates when competition is initially low (with χ close to $1/\alpha$) whereas the Schumpeterian effect dominates when competition is initially high (with χ close to one). In this latter case, the relationship between competition and innovation is inverted-U shaped.

This inverted-U pattern can be explained as follows: at low initial levels of competition (i.e high initial levels of $\delta(\chi)$), type-1 firms have strong reason to innovate; it follows that many intermediate sectors in the economy will end up being type-0 firms in steady-state (this we refer to as the *composition effect* of competition on the relative equilibrium fractions of type-0 and type-1); but then the dominant effect of competition on innovation is the escape competition effect whereby more competition fosters innovation by type-0 firms. On the other hand, at high initial levels of competition, innovation incentives in type-1 sectors are so low that a sector will remain of type-1 for a long time, and therefore many sectors will end up being of type-1 in steady-state, which in turn implies that the negative Schumpeterian appropriability effect of competition on innovation should tend to dominate in that case.

4.2 Empirical predictions

The above analysis generates several interesting predictions:

1. Innovation in sectors in which firms are close to the technology frontier, react positively to an increase in product market competition;
2. Innovation reacts less positively, or negatively, in sectors in which firms are further below the technological frontier;
3. The average fraction of frontier sectors decreases, i.e the average technological gap between incumbent firms and the frontier in their respective sectors increases, when competition increases;
4. The overall effect of competition on aggregate innovation, is inverted-U shaped.[23]

These predictions have been confronted by Aghion et al (2002) with UK firm level data on competition and patenting, and we briefly summarize their findings in the next subsection.

[23] Although perhaps only the second part of the inverse U will be observable. See footnote **??** above.

4.3 Empirical evidence and relationship to literature

Most innovation-based growth models -including the quality improvement model developed in the above two sections- would predict that product market competition is detrimental to growth as it reduces the monopoly rents that reward successful innovators (we refer to this as the Schumpeterian effect of competition). However, an increasing number of empirical studies have cast doubt on this prediction. The empirical IO literature on competition and innovation starts with the pioneering work of Scherer (1965), followed by Cohen-Levin (1967), and more recently by Geroski (1994). All these papers point to a positive correlation between competition and growth. However, competition is often measured by the inverse of market concentration, an indicator which Boone (2000) and others have shown to be problematic: namely, higher competition between firms with different unit costs may actually result in a higher equilibrium market share for the low cost firm! More recently, Nickell (1996) and Blundell et al (1999) have made further steps by conducting cross-industry analyses over longer time periods and by proposing several alternative measures of competition, in particular the inverse of the Lerner index (defined as the ratio of rents over value added) or by the number of competitors for each firm in the survey. However, none of these studies would uncover the reason(s) why competition can be growth-enhancing or why the Schumpeterian effect does not seem to operate.

It is by merging the Schumpeterian growth paradigm with previous patent race models (in which each of two incumbent firms would both, compete on the product market and innovate to acquire a lead over its competitor), that Aghion-Harris-Vickers (1997), henceforth AHV, and Aghion-Harris-Howitt-Vickers (2001), henceforth AHHV, have developed new models of competition and growth with step-by-step innovations that reconcile theory and evidence on the effects of competition and growth: by introducing the possibility that innovations be made by incumbent firms that compete "neck-and-neck", these extensions of the Schumpeterian growth framework show the existence of an "escape competition"effect that counteracts the Schumpeterian effect described above. What facilitated this merger between the Schumpeterian growth approach and the patent race models, is that: (i) both featured quality-improving innovations; (ii) models with vertical innovations in turn were particularly convenient to formalize the notion of technological distance and that of "neck-and-neck" competition. A main prediction of this new vintage of endogenous growth models, is that competition should be most growth-enhancing in sectors in which incumbent firms are close to the technological frontier and/or compete "neck-and-neck" with one another, as it is in those sectors that the "escape competition" effect should be the strongest.

These models in turn have provided a new pair of glasses for deeper empirical analyses of the relationship between competition/entry and innovation/growth. The two studies we briefly mention in the remaining part of this section have not only produce interesting new findings; they also suggested a whole new way of confronting endogenous growth theories with data, one that is more directly grounded on serious microeconometric analyses based on detailed firm/industry

panels.

The paper by Aghion-Bloom-Blundell-Griffith-Howitt (2002), henceforth ABBGH, takes a new look at the effects of product market competition on innovation, by confronting the main predictions of the AHV and AHHV models to firm level data. The prediction we want to emphasize here as it is very much in tune with our theoretical discussion in the previous subsections, is that the escape competition effect should be strongest in industries in which firms are closest to the technological frontier.

ABBGH considers a UK panel of individual companies during the period 1968-1997. This panel includes all companies quoted on the London Stock Exchange over that period, and whose names begin with a letter from A to L. To compute competition measures, the study uses firm level accounting data from Datastream; product market competition is in turn measured by one minus the Lerner index (ratio of operating profits minus financial costs over sales), controlling for capital depreciation, advertising expenditures, and firm size. Furthermore, to control for the possibility that variations in the Lerner index be mostly due to variations in fixed costs, we use policy instruments such as the implementation of the Single Market Program or lagged values of the Lerner index as instrumental variables. Innovation activities, in turn, are measured both, by the number of patents weighted by citations, and by R&D spending. Patenting information comes from the US Patent Office where most firms that engage in international trade register their patents; in particular, this includes 461 companies on the London Stock Exchange with names starting by A to L, for which we already had detailed accounting data. Finally, technological frontier is measured as follows: suppose a UK firm (call it i) belongs to some industry A; then we measure technological distance by the difference between the maximum TFP in industry A across all OECD countries (we call it TFP_F , where the subscript "F" refers to the technological frontier) and the TFP of the UK firm, divided by the former:

$$m_i = \frac{TFP_F - TFP_i}{TFP_F}.$$

Figure 1 summarizes our main findings.

FIGURE 1 *HERE*

Each point on this figure corresponds to one firm in a given year. The upper curve considers only those firms in industries where the average distance to the technological frontier is less than the median distance across all industries, whereas the lower curve includes firms in all industries. We clearly see that the effect of product market competition on innovation is all the more positive that firms are closer to the technological frontier (or equivalently are more "neck-and-neck"). Another interesting finding that comes out of the Figure, is that the Schumpeterian effect is also at work, and that it dominates at high initial levels of product market competition. This in turn reflects the "composition effect" pointed out in the previous subsection: namely, as competition increases and

neck-and-neck firms therefore engage in more intense innovation to escape competition, the equilibrium fraction of neck-and-neck industries tends to decrease (equivalently, any individual firm spends less time in neck-and-neck competition with its main rivals) and therefore the average impact of the escape competition effect decreases at the expense of the counteracting Schumpeterian effect. The ABBGH paper indeed shows that the average distance to the technological distance increases with the degree of product market competition. The Schumpeterian effect was missed by previous empirical studies, mainly as a result of their being confined to linear estimations. Instead, more in line with the Poisson technology that governs the arrival of innovations both, in Schumpeterian and in patent race models, ABBGH use a semi-parametric estimation method in which the expected flow of innovations is a piecewise polynomial function of the Lerner index.

4.4 A remark on inequality and growth

Our discussion of the effects of competition on growth also sheds light on the current debate on the effects of income or wealth inequality on growth. A recent literature[24] has emphasized the idea that in an economy with credit-constraints, where the poor do not have full access to efficient investment opportunities; redistribution may enhance investment by the poor more than it reduces incentives for the rich, thereby resulting in higher aggregate productive efficiency in steady-state and higher rate of capital accumulation on the transition path to the steady-state. Our discussion of the effects of competition on innovation and growth, hints at yet another negative effect of excessive wealth concentration on growth: to the extent that innovative activities tend to be more intense in sectors in which firms or individuals compete "neck-and-neck", taxing further capital gains by firms that are already well ahead of their rivals in the same sector, may enhance the aggregate rate of innovation by shifting the overall distribution of technological gaps in the economy towards a higher fraction of neck-and-neck sectors in steady-state.

More generally, having too many sectors in which technological knowledge and/or wealth are highly concentrated, may inhibit growth as it both, discourages laggard firms or potential entrants, and reduces the leader's incentives to innovate in order to escape competition given that the competitive threat coming from laggards or potential entrants is weak; the leader may actually prefer to invest her wealth into entry deterrence activities. These considerations may in turn explain why, following a high growth period during the industrial revolution in the 19th century, growth slowed down at the turn of the 20th century in France or England at the same time wealth distribution became highly concentrated: the high concentration of wealth that resulted from the industrial revolution, turned the innovators of the mid 19th century into entrenched incumbents with the power to protect their dominant position against competition by new potential entrants.[25]

[24] For example, see Galor-Zeira (1993), Banerjee-Newman (1993), and Aghion-Bolton (1997).
[25] See Piketty et al (2003).

5 Scale effects[26]

5.1 Theory

Jones (1995) has pointed out that the simple model of the preceding sections whereby increased population leads to increased growth, by raising the size of the market for a successful entrepreneur and by raising the number of potential R&D workers, is not consistent with post-war evidence. In the United States, for example, the number of scientists and engineers engaged in R&D has grown by a factor of five since the 1950s with no significant trend increase in productivity growth. This refutes the version of the basic model in which productivity growth is a function of skilled labor applied to R&D (section 2.3 above). Likewise, the fact that productivity-adjusted R&D has grown substantially over the same period rejects the version of the model presented in section 2 above in which productivity growth is a function of productivity-adjusted research.

5.1.1 The Schumpeterian (fully endogenous) solution

Schumpeterian theory deals with this problem of the missing scale effect on productivity growth by incorporating Young's (1998) insight that as an economy grows, proliferation of product varieties reduces the effectiveness of R&D aimed at quality improvement, by causing it to be spread more thinly over a larger number of different sectors.[27] When modified this way the theory is consistent with the observed coexistence of stationary TFP growth and rising R&D input, because in a steady state the growth-enhancing effect of rising R&D input is just offset by the deleterious effect of product proliferation.

The simplest way to illustrate this modification is to suppose that the number of sectors m is proportional to the size of population L. For simplicity normalize so that $m = L$.[28] Then the growth equation (10) becomes:

$$g = \lambda^2 \delta(\chi)(\gamma - 1) \tag{23}$$

It follows directly from comparing (23) with (10) that all the comparative-statics propositions of section 2.4 above continue to hold except that now the growth rate is independent of population size.

5.1.2 The semi-endogenous solution

Jones (1999) argues that this resolution of the problem is less intuitively appealing than his alternative semi-endogenous theory, built on the idea of diminishing returns to the stock of knowledge in R&D. In this theory sustained *growth* in R&D input is necessary just to maintain a given rate of productivity growth.

[26] This section drawson Ha and Howitt (2004).

[27] Variants of this idea have been explored by van de Klundert and Smulders (1997), Peretto (1998), Dinopoulos and Thompson (1998) and Howitt (1999).

[28] Thus, in contrast to Romer (1990) where horizontal innovations drive the growth process, here product proliferation eliminates scale effects whereas long-run growth is still ultimately driven by quality-improving innovations.

Semi-endogenous growth theory has a stark long-run prediction, namely that the long-run rate of productivity growth, and hence the long-run growth rate of per-capita income, depend on the rate of population growth, which ultimately limits the growth rate of R&D labor, to the exclusion of all economic determinants.

In Jones's formulation:

$$g = \lambda f(n) A^{\phi-1} (\gamma - 1), \qquad \phi < 1$$

where the R&D input n is measured by the number R&D workers in G5 countries. Except for the assumption of diminishing returns ($\phi < 1$) this is equivalent to the original formulation (5) above. In the special case where f takes a Cobb-Douglas form we have, in continuous time:

$$g \equiv \dot{A}/A = \lambda n^{\sigma} A^{\phi-1} (\gamma - 1)$$

so that:

$$\dot{g}/g = (1 - \phi)(\gamma' g_n - g) \tag{24}$$

where $g_n = \dot{n}/n$ is the growth rate of R&D workers and $\gamma' = \sigma/(1 - \phi)$.

This semi-endogenous model is compatible with the observation of positive trend growth in R&D input, because as long as $\phi < 1$ and the time path of g_n is bounded, the differential equation (24) yields a bounded solution for productivity growth. In particular, if g_n is constant, or approaches a constant, then

$$g \to \gamma' g_n$$

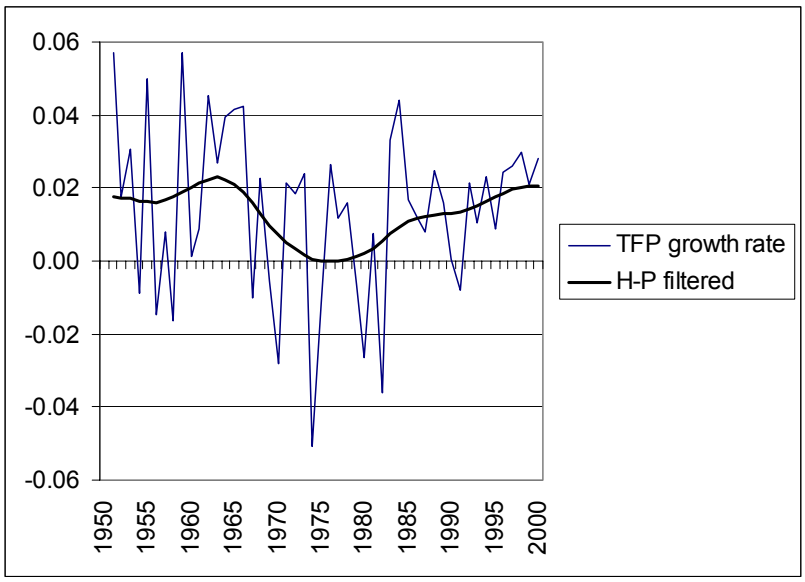
In the long run the growth rate of R&D labor cannot exceed the growth rate η of population, and in a balanced growth equilibrium it will equal η. Likewise, the growth rate of productivity-adjusted R&D expenditure will equal η along a balanced growth path. Hence the radical implication that the long-run growth rate of an economy will equal $\gamma'\eta$, independently of what fraction of society's resources are is assigned to knowledge creation. Policies to stimulate R&D will have at most transitory effects on productivity growth and, by extension, on per-capita income growth.

5.2 Evidence

These two competing approaches to reconciling R&D-based theory with the observed upward trend in R&D input offer a stark contrast. The Schumpeterian approach with product-proliferation effects retains all the characteristic comparative statics predictions of endogenous growth theory as outlined in section 2.4 above, while Jones's semi-endogenous theory denies all these predictions.

Fortunately the two competing approaches can also be tested using observed trends in productivity growth and R&D input. Specifically, the semi-endogenous model implies that the growth rate of productivity will track the growth rate

Figure 2: TFP growth rates, US, 1950-2000



of R&D input, whereas the Schumpeterian model implies that it will track the fraction of GDP spent on R&D.[29]

To derive this Schumpeterian implication note that, according to the growth equation (5), productivity growth depends on productivity-adjusted R&D per sector, n. Given the assumption $m = L$, if GDP per person grows asymptotically at the rate g then n will be proportional to the fraction of GDP spent on R&D.

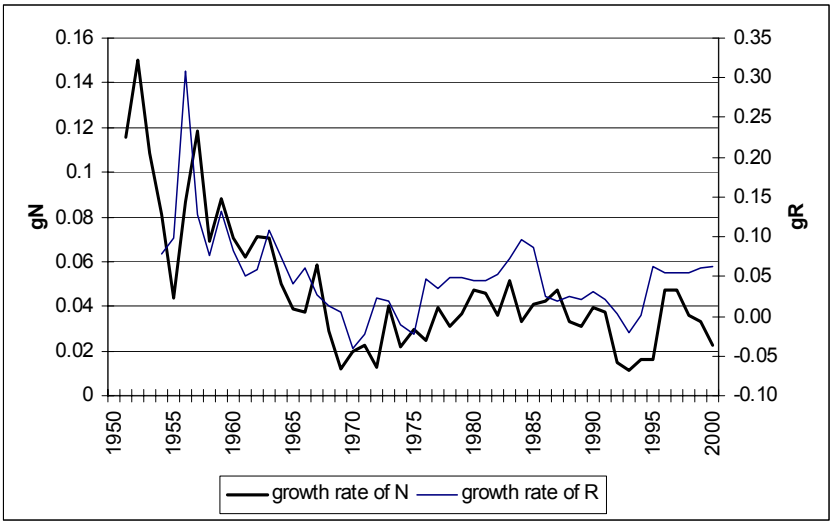
Figure 2 shows the growth rate of productivity in the United States from 1950 to 2000. There is no discernible trend. An Augmented Dickey-Fuller test rejects a unit root at the 1% significance level, confirming the stationarity of this series. Thus semi-endogenous theory implies that the growth rate of R&D input should also be trendless and stationary, whereas Schumpeterian theory implies that the R&D/GDP ratio should be trendless and stationary.

5.2.1 Results

Figure 3 shows that growth rates of the number of R&D workers in the G5 countries, N, and US R&D expenditure, R, appear to have a substantial negative trend, having fallen roughly fourfold since the early 1950s. The impression of

[29] Zachariadis (2003) shows that the fully-endogenous Schumpeterian theory without scale effects also passes a number of other tests using U.S. data. Specifically, he finds using two-digit industry level data that patenting, technological progress and productivity growth all depend upon the ratio of R&D expenditures to output, as implied by the fully endogenous theory.

Figure 3: Trend of growth rates for G5 R&D workers and US R&D expenditures



non-stationarity is supported by an Augmented Dickey-Fuller test, which fails to reject a unit root in g_N at the 5% level.

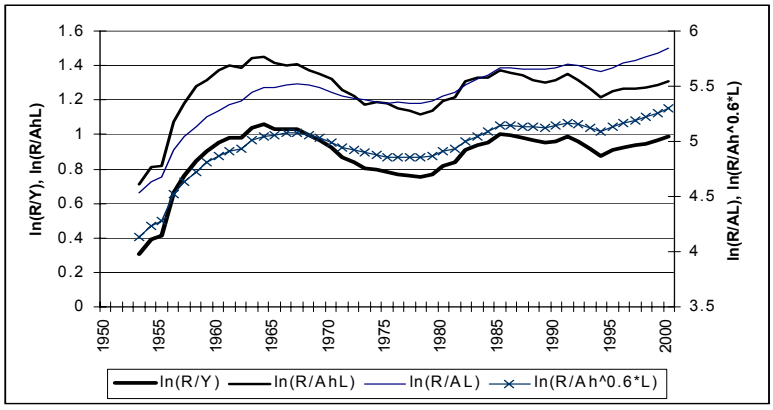
These findings are inconsistent with the implications of semi-endogenous growth theory.[30] Indeed they undermine the central proposition of semi-endogenous theory, because if productivity growth can be sustained for 50 years in the face of such a large fall in the growth rate of R&D labor then there is no reason to suppose that population growth limits productivity growth, except perhaps over a time scale of hundreds of years.

Figure 4 shows that the fraction of GDP spend on R&D in the US looks more or less stable with perhaps a small upward trend.[31] It is notable that ever since 1957, R&D as a percentage of GDP has been fluctuating between 2.1% and 2.9%, with similar movements as in productivity growth: downward trend for 1964-1975 and upward trend for 1975-2000. The stationarity of this

[30] The data on G5 R&D workers come from Jones, who had to guess at the non-US component from 1950 to 1965. However, Ha and Howitt (2004) consider a broader range of R&D measures. They also show that the formal cointegration predictions implied by semi-endogenous theory are not found in these data, even if attention is restricted to the post-1965 date, while the even tighter cointegration predictions implied by Schumpeterian theory are found. Ha and Howitt also conduct a calibration exercise and show that the semi-endogenous model fits the data of US productivity growth best when ϕ is almost equal to unity as in the fully endogenous model.

[31] There appears to be a more significant upward trend if we omit space and defense R&D, as is done by many researchers in the productivity literature on the grounds that they do not find spillovers from these components of R&D. However, this literature has not allowed for the very long lags with which we think federal R&D has its effects. Moreover, throwing out federal R&D would at times amount to throwing out about 70% of the total.

Figure 4: Trend of R&D intensity, US (log)



series is confirmed by an Augmented Dickey-Fuller test, which rejects a unit root at the 1% level. This is in conformity with the version of Schumpeterian theory presented above, adjusted to take into account the effects of product proliferation.

5.3 Concluding remarks

The scale effect whereby increased population should lead to increased productivity growth clearly refutes a simple interpretation of the model in section 2 above, in which L stands for the *number* of (skilled) individuals. However, we have shown in this section that even if we stick to this interpretation of L, a simple variant of the Schumpeterian model can be developed, which carries all the same long-run growth implications except for the scale effect. The rival semi-endogenous theory of Jones (1995), which denies endogenous growth in the very long run, is inconsistent with the observation that productivity growth can be sustained through half a century of falling growth in R&D labor. The analogous implication of amended Schumpeterian theory, namely that productivity growth can be sustained as long as society allocates a constant fraction of its resources to research, is consistent with the evidence.

Two brief remarks conclude this section. First, there is no evidence pointing to the absence of a scale effect at the world level or in small closed economies. That the stock of educated labor should affect technological convergence and productivity growth worldwide was first pointed out by Nelson and Phelps (1966). Second, if we replace L by Le^N, where e^N denotes the *quality* of the labor force as measured for example by the average number of years in schooling (so that more educated countries have more efficiency units of labor), then even

if one eliminates scale effects by taking $L = m$, there will still remain a "level effect" embodied in the e^N term, whereby a higher average number of years of education N has a positive effect on growth. In the next section we show that increasing the fraction of highly educated workers and/or increasing the average number of years in schooling, have a positive impact on the rate of productivity growth, but the extent of which depends upon the country's distance to the world technology frontier: in particular, the closer a country is to the frontier, the higher is the effect of an additional year of higher education on its rate of productivity growth.

6 Linking growth to institutional change

6.1 From Schumpeter to Gerschenkron

By linking growth to innovation and entrepreneurship, and innovation incentives in turn to characteristics of the economic environment, new growth theories made it possible to analyze the interplay between growth and the design of policies and institutions. For example, the basic model developed in Section 2 suggested that long-run growth would be best enhanced by a combination of good property right protection (to protect the rents of innovators against imitation), a good education system (to increase the efficiency of R&D activities and/or the supply of skilled manufacturing labor), and a stable macroeconomy to reduce interest rates (and thereby increase the net present value of innovative rents). Our discussion of convergence clubs in Section 3 then suggested that the same policies or institutions would also increase a country's ability to join the convergence club.

Now, new growth theories may be criticized by development economists and policy makers, precisely because of the universal nature of the policy recommendations that appear to follow from them: no matter how developed a country or sector currently is, it seems that one should prescribe the same medicines (legal reform to enforce property rights, investment climate favorable to entrepreneurship, education, macrostability,..) to maximize the growth prospects of that country or sector.

However, in his essay on *Economic Backwardness in Historical Perspective,* Gerschenkron (1962) argues that relatively backward economies could more rapidly catch up with more advanced countries by introducing "appropriate institutions" that are growth-enhancing at an early stage of development but may cease to be so at a later stage. Thus, countries like Japan or Korea managed to achieve very high growth rates between 1945 up until the 1990s with institutional arrangements involving long-term relationships between firms and banks, the predominance of large conglomerates, and strong government intervention through export promotion and subsidized loans to the enterprise sector, all of which depart from the more market-based and laissez-faire institutional model pioneered and promoted by the US.

That growth-enhancing institutions or policies might change with a coun-

try's or sector's distance to the technological frontier, should not come as a total surprise to our readers at this point: in the previous section, we saw that competition could have opposite effects on innovation incentives depending on whether firms were initially closer to or farther below the fringe in the corresponding industry (it would enhance innovations in neck-and-neck industries, and discourage it in industries where innovating firms are far below the frontier). The same type of conclusion turns out to hold true when one looks at the interplay between countries' distance to the world technology frontier and "openness". Using a cross-country panel of more than 100 countries over the 1960-2000 period, Acemoglu-Aghion-Zilibotti (2002), henceforth AAZ, regress the average growth rate over a five year period on a country's distance to the US frontier (measured by the ratio of GDP per capita in that country to per capita GDP in the US) at the beginning of the period. Then, splitting the sample of countries in two groups, corresponding respectively to a high and a low openness group according to Frankel-Romer's openness indicator, AAZ show that average growth decreases more rapidly as a country approaches the world frontier when openness is low. Thus, while a low degree of openness does not appear to be detrimental to growth in countries far below the world frontier, it becomes increasingly detrimental to growth as the country approaches the frontier. AAZ repeat the same exercise using entry costs to new firms (measured as in Djankov et al (2001)) instead of openness, and they obtain a similar conclusion, namely that high entry costs are most damaging to growth when a country is close to the world frontier, unlike in countries far below the frontier.

In this section, we shall argue that Gerschenkron's idea of "appropriate institutions" can be easily embedded into our growth framework, in a way that can help substantiate the following claims:

1. different institution or policy design affects productivity growth differently depending upon a country's or sector's distance to the technological frontier;

2. a country's distance to the technological frontier affect the type of organizations we observe in this country (e.g, bank versus market finance, vertical integration versus outsourcing,..).

The remaining part of the section is organized as follows. We first describe the growth equation which AAZ introduce to embed the notion of "appropriate institutions" into the above growth framework. We then focus on the first question about the effects of institution design on productivity growth, by concentrating on the relationship between growth and the organization of education. Finally we briefly discuss the effects of distance on equilibrium institutions in a concluding subsection.

6.2 A simple model of appropriate institutions

Consider the following variant of the multi-country growth model of Section 3. In each country, a unique general good which also serves as numéraire, is

produced competitively using a continuum of intermediate inputs according to:

$$y_t = \int_0^1 \left(A_t\left(i\right)\right)^{1-\alpha} x_t\left(i\right)^{\alpha} \; di, \tag{25}$$

where $A_t\left(i\right)$ is the productivity in sector i at time t, $x_t(i)$ is the flow of intermediate good i used in general good production again at time t, and $\alpha \in [0,1]$.

As before, ex post each intermediate good producer faces a competitive fringe of imitators that forces her to charge a limit price $p_t\left(i\right) = \chi > 1$. Consequently, equilibrium monopoly profits (gross of the fixed cost) are simply given by::

$$\pi_t\left(i\right) = \delta A_t\left(i\right)$$

where $\delta \equiv \left(\chi - 1\right)\chi^{-\frac{1}{1-\alpha}}$.

We still let

$$A_t \equiv \int_0^1 A_t\left(i\right) di$$

denote the average productivity in the country at date t, $\overline{A}_t$ the productivity at the world frontier which we assume to grow at the constant rate g from one period to the next, and $a_t = A_t/\bar{A}_t$ the (inverse) measure of the country's distance to the technological frontier at date t.

The main departure from the convergence model in Section 3, lies in the equation for productivity growth. Suppose that intermediate firms have two ways to generate productivity growth: (a) they can imitate existing world frontier technologies; (b) they can innovate upon the previous local technology. More specifically, we assume:

$$A_t\left(i\right) = \eta \bar{A}_{t-1} + \gamma A_{t-1}, \tag{26}$$

where $\eta \bar{A}_{t-1}$ and γA_{t-1} refer respectively to the imitation and innovation components of productivity growth. Imitations use the existing frontier technology at the end of period $(t-1)$, thus they multiply $\bar{A}_{t-1}$, whereas innovations build on the knowledge stock of the country, and therefore they multiply A_{t-1}.

Now dividing both sides of (26) by $\overline{A}_t$, using the fact that

$$\overline{A}_t = (1+g)\bar{A}_{t-1},$$

and integrating over all intermediate sectors i, we immediately obtain the following linear relationship between the country's distance to frontier a_t at date t and the distance to frontier a_{t-1} at date $t-1$:

$$a_t = \frac{1}{1+g}(\eta + \gamma a_{t-1}). \tag{27}$$

This equation clearly shows that the relative importance of innovation for productivity growth, increases as: (i) the country moves closer to the world technological frontier, i.e as a_{t-1} moves closer to 1, whereas imitation is more important when the country is far below the frontier, i.e when a_{t-1} is close to

zero; (ii) a new technological revolution (e.g the ITC revolution) occurs that increases the importance of innovation, i.e increases γ.

This immediately generates a theory of "appropriate institutions" and growth: suppose that imitation and innovation activities do not require the same institutions. Typically, imitation activities (i.e η in the above equation (27)) will be enhanced by long-term investments within (large) existing firms, which in turn may benefit from long-term bank finance and/or subsidized credit as in Japan or Korea since 1945. On the other hand, innovation activities (i.e γ) require initiative, risk-taking, and also the selection of good projects and talents and the weeding out of projects that turn out not to be profitable. This in turn calls for more market-based and flexible institutions, in particular for a higher reliance on market finance and speculative monitoring, higher competition and trade liberalization to weed out the bad projects, more flexible labor markets for firms to select the most talented or best matched employees, non-integrated firms to increase initiative and entrepreneurship downstream, etc. It then follows from equation (27) that the growth-maximizing institutions will evolve as a country moves towards the world technological frontier. Far below the frontier, a country will grow faster if it adopts what AAZ refers to as *investment-based* institutions or policies, whereas closer to the frontier growth will be maximized if the country switches to *innovation-based* institutions or policies.

A natural question is of course whether institutions actually change when they should from a growth- (or welfare-) maximizing point of view, in other words how do equilibrium institutions at all stages of development compare with the growth-maximizing institutions? This question is addressed in details in AAZ, and we will come back to it briefly in the last subsection.

6.3 Appropriate education systems

In his seminal paper on economic development, Lucas (1988) emphasized the *accumulation* of human capital as a main engine of growth; thus, according to the analysis in that paper, cross-country differences in growth rates across countries would be primarily attributable to differences in *rates of accumulation* of human capital. An alternative approach, pioneered by Nelson-Phelps (1966), revived by the Schumpeterian growth literature[32], would instead emphasize the combined effect of the *stock* of human capital and of the innovation process in generating long-run growth and fostering convergence. In this alternative approach, differences in growth rates across countries would be mainly attributable to differences in *stocks* of human capital, as those condition countries' ability to innovate or to adapt to new technologies and thereby catch up with the world technological frontier. Thus, in the basic model of Section 2, the equilibrium R&D investment and therefore the steady-state growth rate were shown to be increasing in the aggregate supply of (skilled) labor L and in the productivity of research λ, both of which refer more to the *stock* and *efficiency* of human capital than to its rate of accumulation.

[32] For example, see Acemoglu (1996, 2002), Aghion-Howitt-Violante (2002) and Aghion (2002).

Now, whichever approach one takes, and the evidence so far supports the two approaches as being somewhat complementary, once again one may worry about growth models delivering too general a message, namely that more education is always growth enhancing. In this subsection we will try to go one step further and argue that the AAZ specification (summarized by the above equation (26), can be used to analyze the effects, not only of the total *amount* of education, but more importantly of the *organization* of education, on growth in countries at different stages of development..

This subsection, which is based on Vandenbussche-Aghion-Meghir (2003), henceforth VAM, focuses on one particular aspect of the organization of education systems, namely the mix between primary, secondary, and higher education. We consider a variant of the AAZ model outlined in the previous subsection, in which innovation requires highly educated labor, whereas imitation can be performed by both, highly educated and lower-skill workers. A main prediction emerging from this a model, is that the closer a country gets to the world technology frontier, the more growth-enhancing it becomes to invest in higher education. In the latter part of the subsection we confront this prediction with preliminary cross-country evidence.

6.3.1 Distance to frontier and the growth impact of higher education

There is again a unique general good, produced competitively using a continuum of intermediate inputs according to:

$$y = \int_0^1 A(i)^{1-\alpha} x(i)^{\alpha} di, \tag{28}$$

where $A(i)$ is the productivity in sector i, $x(i)$ is the flow of intermediate good i used in general good production, $\alpha \in [0,1]$.

In each intermediate sector i, one intermediate producer can produce the intermediate good with leading-edge productivity $A_t(i)$, using general good as capital according to a one-for-one technology. As before, ex post each intermediate good producer faces a competitive fringe of imitators that forces her to charge a limit price $p(i) = \chi > 1$. Consequently, we have:

$$p(i) = \chi = \frac{\partial y}{\partial x},$$

so that equilibrium monopoly profits in each sector i are given by::

$$\pi(i) = (p(i) - 1)x(i) = \delta\pi(i) = \delta A(i)L$$

where $\delta = (\chi - 1)(\frac{\chi}{\alpha})^{\frac{-1}{1-\alpha}}$.

As in the previous subsection, intermediate firms can increase productivity, either by imitating frontier technologies or by innovating upon existing technologies in the country. Imitation can be performed by both types of workers,

whereas innovation requires high education. More specifically, we focus on the following class of productivity growth functions:

$$A_t(i) - A_{t-1}(i) = u_{m,i,t}^{\sigma} s_{m,i,t}^{1-\sigma} \bar{A}_{t-1} + \gamma u_{n,i,t}^{\phi} s_{n,i,t}^{1-\phi} A_{t-1}, \tag{29}$$

where $u_{m,i,t}$ (resp. $s_{m,i,t}$) is the amount of unskilled (resp. skilled) labor used in imitation in sector i at time t, $u_{n,i,t}$ (resp. $s_{n,i,t}$) is the amount of unskilled (resp. skilled) units of labor used by sector i in innovation at time t, σ (resp. ϕ) is the elasticity of unskilled labor in imitation (resp. innovation), and $\gamma > 0$ measures the relative efficiency of innovation compared to imitation in generating productivity growth.

We shall assume:

(A1) *The elasticity of skilled labor is higher in innovation than in imitation, and conversely for the elasticity of unskilled labor, that is:* $\phi < \sigma$.

Let S (resp. $U = 1 - S$) denote the fraction of the labor force with higher (resp. primary or secondary) education. Let $w_{u,t}\bar{A}_{t-1}$ (resp. $w_{s,t}\bar{A}_{t-1}$) denote the current price of unskilled (resp. skilled) labor.

The total labor cost of productivity improvement by intermediate firm i at time t, is equal to:

$$W_{i,t} = [w_{u,t}(u_{m,i,t} + u_{n,i,t}) + w_{s,t}(s_{m,i,t} + s_{n,i,t})]\overline{A}_{t-1}.$$

Letting $a_t = A_t/\bar{A}_t$ measure the country's distance to the technological frontier, and letting the frontier technology $\bar{A}_t$ grow at constant rate g, the intermediate producer will solve:

$$\max_{u_{m,i,t}, s_{m,i,t}, u_{n,i,t}, s_{n,i,t}} \{\delta[u_{m,i,t}^{\sigma} s_{m,i,t}^{1-\sigma}(1 - a_{t-1}) + \gamma u_{n,i,t}^{\phi} s_{n,i,t}^{1-\phi} a_{t-1}]\bar{A}_{t-1} - W_{i,t}\}. \tag{30}$$

Using the fact that all intermediate firms face the same maximization problem, and that there is a unit mass of intermediate firms, we necessarily have:

$$u_{j,i,t} \equiv u_{j,t}; s_{j,i,t} \equiv s_{j,t} \text{ for all } i \text{ and for } j = m, n; \tag{31}$$

and

$$S = s_{m,t} + s_{n,t}; U = 1 - S = u_{m,t} + u_{n,t}. \tag{32}$$

Taking first order conditions for the maximization problem (30), then making use of (31) and (32), and then computing the equilibrium rate of productivity growth

$$g_t = \int_0^1 \frac{A_t(i) - A_{t-1}}{A_{t-1}} di,$$

one can establish (see VAM (2003)):

Lemma 1 *Let* $\psi = \frac{\sigma(1-\phi)}{(1-\sigma)\phi}$. *If parameter values are such that the solution to (30) is interior, then we have:*

$$\frac{\partial g_t}{\partial a} = \phi(1-\phi)h'(a)h(a)^{1-\phi}[h(a)U - S],$$

where

$$h(a) = (\frac{(1-\sigma)\psi^{\sigma}(1-a)}{(1-\phi)\gamma a})^{\frac{1}{\sigma-\phi}} \geq \frac{S}{U}.$$

This, together with the fact that $h(a)$ is obviously decreasing in a given our assumption (A1), immediately implies:

Proposition 2 *A marginal increase in the fraction of labor with higher education, enhances productivity growth all the more the closer the country is from the world technology frontier, that is:*

$$\frac{\partial^2 g_t}{\partial a \partial S} > 0.$$

The intuition follows directly from the Rybczynski theorem in international trade. Stated in the context of a two sector-two input economy, this theorem says that an increase in the supply of input in the sector that uses that input more intensively, should increase "output" in that sector more than proportionally. To transpose this result to the context of our model, consider the effect of an increase in the supply of skilled labor, keeping the supply of unskilled labor fixed and for given a. Given that skilled workers contribute relatively more to productivity growth and profits if employed in innovation rather than in imitation (our Assumption (A1)), the demand for additional skilled labor will tend to be higher in innovation. But then the marginal productivity of unskilled labor should also increase more in innovation than in imitation, hence a net flow of unskilled workers should also move from imitation into innovation. This in turn will enhance further the marginal productivity of skilled labor in innovation, thereby inducing an ever greater fraction of skilled labor to move to innovation. Now the closer the country is to the technology frontier (i.e the higher a), the stronger this Rybszynski effect as a higher a increases the efficiency of both, skilled and unskilled labor, in innovation relative to imitation. A second, reinforcing, reason is that an increase in the fraction of skilled labor reduces the amount of unskilled labor available in the economy, hence reducing the marginal productivity of skilled labor in imitation, all the more the closer the country is from the frontier.

We can now confront this prediction with cross-country evidence on higher education, distance to frontier, and productivity growth.

6.3.2 Empirical evidence

The prediction that higher education has stronger growth-enhancing effects close to the technological frontier can be tested using cross-regional or cross-country data. Thus VAM consider a panel dataset of 19 OECD countries over the period 1960-2000. Output and investment data are drawn from Penn World Tables 6.1 (2002) and human capital data from Barro-Lee (2000). The Barro-Lee data indicate the fraction of a country's population that has reached a certain level of schooling at intervals of five years, so VAM use the fraction that has received

some higher education together with their measure of TFP (itself constructed assuming a constant labor share of .7 across countries) to perform the following regression:

$$g_{j,t} = \alpha_{0,j} + \alpha_1 dist_{j,t-1} + \alpha_2 \Lambda_{j,t-1} + \alpha_3 (dist_{j,t-1} * \Lambda_{j,t-1}) + u_{j,t},$$

where $g_{j,t}$ is country j's growth rate over a five year period, $dist_{j,t-1}$ is country j's closeness to the technological frontier at $t-1$ (i.e. 5 years before), $\Lambda_{j,t-1}$ is the fraction of the working age population with some higher education in the previous period and $\alpha_{0,j}$ is a country dummy controlling for country fixed effects. The closeness variable is instrumented with its lagged value at $t-2$, and the fraction variable is instrumented using expenditure on tertiary education per capita lagged by two periods, and the interaction term is instrumented using the interaction between the two instruments for closeness and for the fraction variables. Finally, the standard errors we report allow for serial correlation and heteroskedasticity.

The results from this regression are shown in Table 1 below. In particular, we find a positive and significant interaction between our education measure and closeness to the frontier, as predicted by the theory in the previous subsection. This result demonstrates that it is more important to expand years of higher education close to the technological frontier.

7 Conclusion

In this chapter we argued that the endogenous growth model with quality-improving innovations provides a framework for analyzing the determinants of long-run growth and convergence that is versatile, simple and empirically useful. Versatile, as the same framework can be used to analyze how growth interacts with development and cross-country convergence and divergence, how it interacts with industrial organization and in particular market structure, and how it interacts with organizations and institutional change. Simple, since all these aspects can be analyzed using the same elementary model. Empirically useful, as the framework generates a whole range of new microeconomic and macroeconomic predictions while it addresses empirical criticisms raised by other endogenous growth models in the literature.

Far from closing the field, the chapter suggests many avenues for future research. For example, on growth and convergence, more research remains to be done to identify the main determinants of cross-country convergence and divergence.[33] Also important, is to analyze the role of international intellectual property right protections and foreign direct investment in preventing or favoring convergence. On growth and industrial organization, we have restricted

[33] In Aghion, Howitt and Mayer-Foulkes (2004) we emphasize the role of credit constraints in R&D as a distinguishing factor between the countries that converge in growth rates and in levels towards the frontier, those that converge only in growth rates, and those that follow a divergent path towards a lower rate of long-run growth. Whether credit constraints, or other factors such as health, education, and property rights protection, are key to this three-fold classification, remains an open question

attention to product market competition among existing firms. But what can we say about entry and its impact on incumbents' innovation activities?[34] On institutions, we have just touched upon the question of how technical change interacts with organizational change. Do countries or firms/sectors actually get stuck in institutional traps of the kind described in Section 6? What enables such traps to disappear over time? How do political economy considerations interact with this process? There is also the whole issue of wage inequality and its interplay with technical change, on which the Schumpeterian approach developed in this chapter can also shed light.[35]

If we just had to select three aspects or questions, so far largely open, and which could also be explored using our approach, we would suggest the following. First, on the role of basic science in generating (very) long-term growth. Do fundamental innovations (or the so called "general purpose technologies") require the same incentive system and the same rewards as industrial innovations? How can one design incentive systems in universities so that university research would best complement private research? A second aspect is the interplay between growth and volatility. Is R&D and innovation procyclical or countercyclical, and is macroeconomic volatility always detrimental to innovation and growth? Answering this question in turn opens up a whole new research topic on the macropolicy of growth[36] A third aspect is the extent to which our growth paradigm can be applied to less developed economies. In particular, can we use the new growth approach developed in this chapter to revisit the important issue of poverty reduction?[37] On all these questions, we believe that over time compelling answers will emerge from a fruitful dialogue between applied theorists, in particular those working on endogenous growth models of the kind developed in this chapter, and microeconometricians who use firm-level panel data to analyze the interplay between competition and innovation or between productivity growth and organizations.

Finally, in this chapter we have argued that modelling growth as resulting from quality-improving innovations, provides a natural framework to address a whole array of issues from competition to development, each time with theoretical predictions that can be empirically tested and also lead to more precise policy prescriptions. However, one might think of more direct ways of testing the quality-ladder model against the variety model analyzed in the other chapters. For example, in current work with Pol Antras and Susanne Prantl, we are using a panel data set of UK firms over the past fifteen years, to assess whether variety had any impact on innovation and growth. Using input-output tables, our preliminary results suggest that exit of input firms has but a positive effect on the productivity growth of final producers.

Abstract

We analyze recent contributions to growth theory based on the model of expanding variety of Romer [Romer, P. (1990). "Endogenous technological change". Journal of Political Economy 98, 71–102]. In the first part, we present different versions of the benchmark linear model with imperfect competition. These include the "lab-equipment" model, "labor-for-intermediates" and "directed technical change". We review applications of the expanding variety framework to the analysis of international technology diffusion, trade, cross-country productivity differences, financial development and fluctuations. In many such applications, a key role is played by complementarities in the process of innovation.

1. Introduction

Endogenous growth theory formalizes the role of technical progress in explaining modern economic growth. Although this is a relatively recent development, many of its ideas were already stressed by authors such as Kuznets, Griliches, Schmookler, Rosenberg and Schumpeter. During the 1950s and 1960s, mainstream economics was dominated by the one-sector neoclassical growth model of Solow (1956) and Swan (1956), whose main focus was on capital accumulation. The model postulated the existence of an aggregate production function featuring constant returns to scale and returns to each input falling asymptotically to zero; given that some inputs cannot be accumulated, the model could not generate sustained growth unless technology was assumed to improve exogenously. This simple treatment of technology as exogenous was considered as unsatisfactory for two main reasons: first, by placing the source of sustained growth outside the model, the theory could not explain the determinants of long-run economic performance and second, empirical evidence pointed out that technical progress often depends on deliberate economic decisions.

The first attempts to endogenize the rate of technical change addressed the first, but not the second, problem. Assuming technical progress to be an unintentional by-product of the introduction of new capital goods through a process named "learning-by-doing", Arrow (1962) was able to generate sustained growth at a rate that depended on investment decisions. Attempts at explicitly modeling investment in innovation faced another difficulty. A replication argument suggests that, for a given state of technology, production functions should exhibit constant returns to scale. If technical progress is considered as an additional input, however, the technology features increasing returns to scale and inputs cannot be paid their marginal product. Models of learning-by-doing avoided the problem by assuming that increasing returns were external to firms, thereby preserving perfect competition. However, this approach is not viable once investment in technology is recognized as intentional. The solution was to follow the view of Schumpeter (1942), that new technologies provide market power and that investment in innovation is motivated by the prospect of future profits. In this spirit, Shell (1973) studied the case of a single monopolist investing in technical change and Nordhaus (1969a) wrote a growth model with patents, monopoly power and many firms. In neither case did the equilibrium feature sustained growth.[1]

A tractable model of imperfect competition under general equilibrium was not available until the analysis of monopolistic competition in consumption goods by Dixit and Stiglitz (1977), later extended to differentiated inputs in production by Ethier (1982). These models also showed how increasing returns could arise from an expansion in the number of varieties of producer and consumer goods, an idea that is at the core of the models studied in this chapter. The first dynamic models of economic growth with monopolistic competition and innovation motivated by profits were built by Judd (1985)

[1] See Levhari and Sheshinski (1969) on necessary and sufficient conditions for the existence of steady-state growth in the presence of increasing returns to scale.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 4
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

and Grossman and Helpman (1989). Yet, these authors were interested in aspects other than endogenous growth and none of their models featured long-run growth. Romer (1987), who formalized an old idea of Young (1928), was the first to show that models of monopolistic competition could generate long-run growth through the increased specialization of labor across an increasing range of activities. The final step was taken in Romer (1990), which assumed that inventing new goods is a deliberate costly activity and that monopoly profits, granted to innovators by patents, motivate discoveries. Since then, the basic model of endogenous growth with an expanding variety of products has been extended in many direction.

The distinctive feature of the models discussed in this chapter is "horizontal innovation": a discovery consists of the technical knowledge required to manufacture a new good that does not displace existing ones. Therefore, innovation takes the form of an expansion in the variety of available products. The underlying assumption is that the availability of more goods, either for final consumption or as intermediate inputs, raises the material well-being of people. This can occur through various channels. Consumers may value variety per se. For example, having a TV set and a Hi-Fi yields more utility than having two units of any one of them. Productivity in manufacturing may increase with the availability of a larger set of intermediate tools, such as hammers, trucks, computers and so on. Similarly, specialization of labor across an increasing variety of activities, as in the celebrated Adam Smith example of the pin factory, can make aggregate production more efficient. The main alternative approach is to model innovation as quality improvements on a given array of products ("vertical innovation"), so that technical progress makes existing products obsolete. This process of "creative destruction" was emphasized by Schumpeter and has been formalized in Aghion and Howitt (1992), Grossman and Helpman (1991a, 1991b) and Segerstrom, Anant and Dinopoulos (1990). The two approaches naturally complement each other. The main advantage of models with horizontal innovation lies in their analytical tractability, making them powerful tools for addressing a wide range of questions. However, because of their simplistic view on the interaction between innovators, these models are less suited to studying the effects of competition between " leaders" and "follower" on the growth process.

Section 1 of this chapter describes a simplified version of Romer (1990) and some extensions used in the literature. The model exhibits increasing returns to scale and steady-state endogenous growth in output per capita and the stock of knowledge. The key feature of the theory is the emphasis on investments in technical knowledge as the determinant of long-run economic growth. Ideas and technological improvements differ from other physical assets, because they entail important public good elements. Inventing new technology is typically costly, while reproducing ideas is relatively inexpensive. Therefore, technical knowledge is described as a non-rival good. Nevertheless, firms are willing to invest in innovation because there exists a system of intellectual property rights (patents) guaranteeing innovators monopoly power over the production and sales of particular goods.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 5
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

Growth models with an expanding variety of products are a natural dynamic counterpart to trade models based on increasing returns and product differentiation. As such, they offer a simple framework for studying the effects of market integration on growth and other issues in dynamic trade theory. This is the subject of Section 2, which shows how trade integration can produce both static gains, by providing access to foreign varieties, and dynamic gains, by raising the rate at which new goods are introduced. Product-cycle trade and imitation are also considered.

In many instances, technical progress may be non-neutral towards different factors or sectors. This possibility is considered in Section 3, where biased technical change is incorporated in the basic growth model. By introducing several factors and sectors, the economic incentives to develop technologies complementing a specific factor, such as skilled workers, can be studied. These incentives critically depend on the definition of property rights over the production of new ideas. The high variability in the effectiveness of patent laws across countries has important bearings on the form of technical progress. In particular, governments in less developed countries may have an incentive not to enforce intellectual property rights in order to speed up the process of technology adoption. However, the undesired side effect of free-riding is that innovators in industrialized countries lose incentives to create improvements that are most useful in developing countries, but of limited application in industrialized markets.

Section 4 introduces complementarity in innovation. While innovation has no effect on the profitability of existing intermediate firms in the benchmark model, in reality new technologies can substitute or complement existing technologies. Innovation may cause technological obsolescence of previous technologies, as emphasized by Schumpeterian models. In other cases, new technologies complement rather than substitute the old ones. For instance, the market for a particular technology tends to be small at the time of its introduction, but grows as new compatible applications are developed. This complementarity in innovation can lead to multiple equilibria and poverty traps.

Complementarities in the growth process may also arise from financial markets, as suggested in Section 5. The progressive endogenous enrichment of asset markets, associated with the development of new intermediate industries, may improve the diversification opportunities available to investors. This, in turn, makes savers more prepared to invest in high-productivity risky industries, thereby fostering further industrial and financial development. As a result, countries at early stages of development go through periods of slow and highly volatile growth, eventually followed by a take-off with financial deepening and steady growth.

Finally, Section 6 shows how models with technological complementarities can generate rich long-run dynamics, including endogenous fluctuations between periods of high and low growth. Cycles in innovation and growth can either be due to expectational indeterminacy, or the deterministic dynamics of two-sector models with an endogenous market structure.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 6

2. Growth with expanding variety

In this section, we present the benchmark model of endogenous growth with expanding variety, and some extensions that will be developed in the following sections.

2.1. The benchmark model

The benchmark model is a simplified version of Romer (1990), where, for simplicity, we abstract from investments in physical capital. The economy is populated by infinitely lived agents who derive utility from consumption and supply inelastic labor. The population is constant, and equal to L. Agents' preferences are represented by an isoelastic utility function:

$$U = \int_0^\infty \mathrm{e}^{-\rho t} \frac{C_t^{1-\theta} - 1}{1-\theta} \,\mathrm{d}t. \tag{1}$$

The representative household sets a consumption plan to maximize utility, subject to an intertemporal budget constraint and a No-Ponzi game condition. The consumption plan satisfies a standard Euler equation:

$$\dot{C}_t = \frac{r_t - \rho}{\theta} \cdot C_t. \tag{2}$$

There is no physical capital, and savings are used to finance innovative investments.

The production side of the economy consists of two sectors of activity: a competitive sector producing a homogeneous final good, and a non-competitive sector producing differentiated intermediate goods. The final-good sector employs labor and a set of intermediate goods as inputs. The technology for producing final goods is represented by the following production function:

$$Y_t = L_{y,t}^{1-\alpha} \int_0^{A_t} x_{j,t}^{\alpha} \,\mathrm{d}j, \tag{3}$$

where x_j is the quantity of the intermediate good j, A_t is the measure of intermediate goods available at t, L_y is labor and $\alpha \in (0, 1)$. This specification follows Spence (1976), Dixit and Stiglitz (1977) and Ethier (1982). It describes different inputs as imperfect substitutes, which symmetrically enter the production function, implying that no intermediate good is intrinsically better or worse than any other, irrespective of the time of introduction. The marginal product of each input is decreasing, and independent of the measure of intermediate goods, A_t.

The intermediate good sector consists of monopolistically competitive firms, each producing a differentiated variety j. Technology is symmetric across varieties: the production of one unit of intermediate good requires one unit of final good, assumed to be the numeraire.[2] In addition, each intermediate producer is subject to a sunk cost to

[2] In Romer (1990), the variable input is physical capital, and the economy has two state variables, i.e., physical capital and knowledge.

design a new intermediate input variety. New designs are produced instantaneously and with no uncertainty. The innovating firm can patent the design, and acquire a perpetual monopoly power over the production of the corresponding input.

In the absence of intellectual property rights, free-riding would prevent any innovative activity. If firms could costlessly copy the design, competition would drive ex-post rents to zero. Then, no firms would have an incentive, ex-ante, to pay a sunk cost to design a new input.

The research activity only uses labor. An important assumption is that innovation generates an intertemporal externality. In particular, the design of a (unit measure of) new intermediate good requires a labor input equal to $1/(\delta A_t)$. The assumption that labor productivity increases with the stock of knowledge, A_t, can be rationalized by the idea of researchers benefiting from accessing the stock of applications for patents, thereby obtaining inspiration for new designs.

The law of motion of technical knowledge can be written as:

$$\dot{A}_t = \delta A_t L_{x,t}, \tag{4}$$

where δ is a parameter and L_x denotes the aggregate employment in research. The rate of technological change is a linear function of total employment in research.[3] Finally, feasibility requires that $L \geqslant L_{x,t} + L_{y,t}$.

First, we characterize the equilibrium in the final good sector. Let w denote the wage, and p_j be the price of the j'th variety of intermediate input. The price of the final product is the numeraire. The representative firm in the competitive final sector takes prices as parametric and chooses production and technology so as to maximizes profit, given by:

$$\pi_t^Y = L_{y,t}^{1-\alpha} \int_0^{A_t} {x_{j,t}}^{\alpha} \,\mathrm{d}j - w_t L_{y,t} - \int_0^{A_t} p_{j,t} x_{j,t} \,\mathrm{d}j. \tag{5}$$

The first-order conditions yield the following factor demands:

$$p_{j,t} = \alpha L_{y,t}^{1-\alpha} {x_{j,t}}^{\alpha-1} \quad \forall j \in [0, A_t] \tag{6}$$

and

$$w_{y,t} = (1-\alpha) L_{y,t}^{-\alpha} \int_0^{A_t} {x_{j,t}}^{\alpha} \,\mathrm{d}j. \tag{7}$$

[3] Jones (1995) generalizes this technology and lets

$$\dot{A}_t = \delta A_t^{\gamma_a} L_{x,t}^{(1-\gamma_L)},$$

where $\gamma_A \leqslant 1$ is a positive externality through the stock of knowledge and γ_L is a negative externality that can be interpreted as coming from the duplication of research effort. Assuming $\gamma_A < 1$ leads to qualitative differences in the prediction of the model. In particular, the specification where $\gamma_A = 1$ and $\gamma_L = 0$, which is the model discussed here, generates scale effects. See further discussion later in this chapter and, especially, in Chapter ? of this Handbook.

Next, consider the problem of intermediate producers. A firm owning a patent sets its production level so as to maximize the profit, subject to the demand function (6). The profit of the firm producing the jth variety is $\pi_{j,t} = p_{j,t}x_{j,t} - x_{j,t}$. The optimal quantity and price set by the monopolist are

$$x_{j,t} = x_t = \alpha^{2/(1-\alpha)}L_{y,t} \quad \text{and} \quad p_{j,t} = p = 1/\alpha, \tag{8}$$

respectively. Hence, the maximum profit for an intermediate producer is

$$\pi_{j,t} = \pi_t = (p-1)x_t = \frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)}L_{y,t}. \tag{9}$$

Substitution of x_t into (7) yields the equilibrium wage as:

$$w_t = (1-\alpha)\alpha^{2\alpha/(1-\alpha)}A_t. \tag{10}$$

Next, we guess-and-verify the existence of a balanced growth (BG) equilibrium, such that consumption, production and technical knowledge grow at the same constant rate, γ, and the two sectors employ constant proportions of the workforce.[4] In BG, both the production and the profits of intermediate firms, as given by Equations (8) and (9), are constant over time and across industries. Thus, $x_t = x$ and $\pi_t = \pi$.

Free entry implies that the present discounted value (PDV) of profits from innovation cannot exceed the entry cost. By the Euler equation, (2), the interest rate is also constant in BG. Hence, the PDV of profits equals π/r. The entry cost is given by the wage paid to researchers, i.e., $w_t/(\delta A_t)$. Therefore, the free entry condition can be written as:

$$\frac{\pi}{r} \leqslant \frac{w_t}{\delta A_t}. \tag{11}$$

We can then use (9) and (10), and substitute the expressions of π and w_t into (11):

$$\frac{(\frac{1-\alpha}{\alpha})\alpha^{2/(1-\alpha)}L_y}{r} \leqslant \frac{(1-\alpha)\alpha^{2\alpha/(1-\alpha)}}{\delta}. \tag{12}$$

The right-hand side expression is the marginal cost of innovation, independent of A_t, due to the cancellation of two opposite effects. On the one hand, labor productivity and, hence, the equilibrium wage grow linearly with A_t. On the other hand, the productivity of researchers increases with A_t, due to the intertemporal knowledge spillover. Thus, the unit cost of innovation is constant over time. Note that, without the externality, the cost of innovation would grow over time, and technical progress and growth would come to a halt, like in the neoclassical model.

For innovation to be positive, (12) must hold with equality. We can use (i) the resource constraint, implying that $L_y = L - L_x$, and (ii) the fact that, from (4) and BG, $L_x = \gamma/\delta$, to express (12) as a relationship between the interest rate and the growth rate:

$$r = \alpha(\delta L - \gamma). \tag{13}$$

[4] The equilibrium that we characterized can be proved to be unique. Moreover, the version of Romer's model described here features no transitional dynamics, as in AK models [Rebelo (1991)].

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 9
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

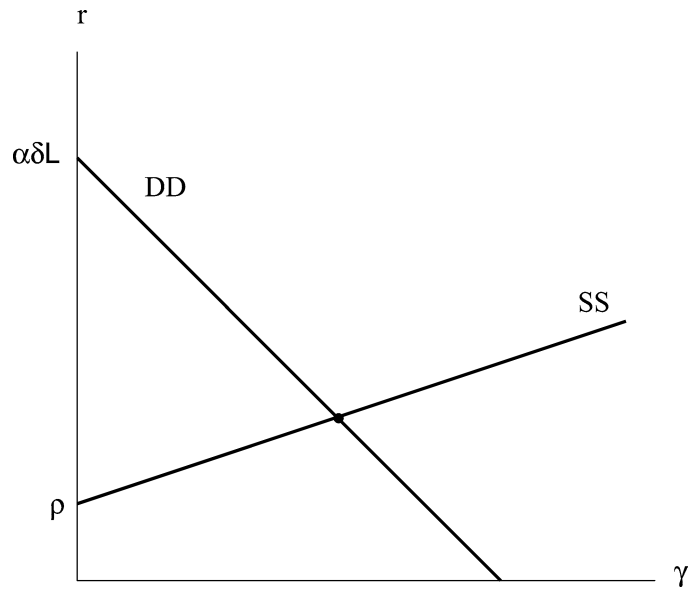

Figure 1.

Equation (13) describes the equilibrium condition on the production side of the economy: the higher is the interest rate that firms must pay to finance innovation expenditure, the lower is employment in research and growth.

Finally, the consumption Euler equation, (2), given BG, yields:

$$r = \rho + \theta\gamma, \tag{14}$$

which is the usual positive relation between interest rate and growth. Figure 1 plots the linear equations (13) and (14), which characterize the equilibrium. The two equations correspond, respectively, to the DD (demand for funds) and SS (supply of savings) linear schedules.

An interior solution exists if and only if $\alpha\delta L > \rho$. When this condition fails to be satisfied, all workers are employed in the production of consumption goods. When it is positive, the equilibrium growth rate is

$$\gamma = \frac{\delta\alpha L - \rho}{\alpha + \theta}, \tag{15}$$

showing that the growth rate is increasing in the productivity of the research sector (δ), the size of the labor force (L) and the intertemporal elasticity of substitution of consumption ($1/\theta$), while it is decreasing in the elasticity of final output to labor, ($1 - \alpha$), and the discount rate.

The trade-off between final production (consumption), on the one hand, and innovation and growth, on the other hand, can be shown by substituting the equilibrium

expression of x into the aggregate production function, (3). This yields:

$$Y_t = \alpha^{2\alpha/(1-\alpha)} L_y A_t = \alpha^{2\alpha/(1-\alpha)} (L - \gamma/\delta) A_t. \tag{16}$$

The decentralized equilibrium is inefficient for two reasons:[5]

1. Intermediate firms exert monopoly power, and charge a price in excess of the marginal cost of production. This leads to an underproduction of each variety of intermediate goods.
2. the accumulation of ideas produces externalities not internalized in the laissez-faire economy. Innovating firms compare the private cost of innovation, $w_t/(\delta A_t)$, with the present discounted value of profits, π/r. However, they ignore the spillover on the future productivity of innovation.

Contrary to Schumpeterian models, innovation does not cause "creative destruction", i.e., no rent is reduced by the entry of new firms. As a result, growth is always suboptimally low in the laissez-faire equilibrium. Policies aimed at increasing research activities (e.g., through subsidies to R&D or intermediate production) are both growth- and welfare-enhancing. This result is not robust, however. Benassy (1998) shows that in a model where the return to specialization is allowed to vary and does not depend on firms' market power (α), research and growth in the laissez-faire equilibrium may be suboptimally too high.

2.2. Two variations of the benchmark model: "lab-equipment" and "labor-for intermediates"

We now consider two alternative specifications of the model that have been used in the literature, and that will be discussed in the following sections. The first specification is the so-called "lab-equipment" model, where the research activity uses final output instead of labor as a productive input.[6] More formally, Equation (4) is replaced by the condition $\dot{A}_t = Y_x/\mu$, where Y_x denotes the units of final output devoted to research (hence, consumption is $C = Y - Ax - Y_x$) and μ the output cost per unit of innovation. In the lab-equipment model, there is no research spillover of the type discussed in the benchmark model. Labor is entirely allocated to final production ($L_y = L$), and the free-entry condition (12) is replaced by

$$\frac{\frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)} L}{r} \leqslant \mu. \tag{17}$$

[5] There is an additional reason why, in general, models with a Dixit–Stiglitz technology can generate inefficient allocations in laissez-faire, namely that the range of intermediate goods produced is endogenous. The standard assumption of complete markets is violated in Dixit–Stiglitz models, because there is no market price for the goods not produced. This issue is discussed in Matsuyama (1995, 1997). A dynamic example of such a failure is provided by the model of Acemoglu and Zilibotti (1997), which is discussed in detail in Section 6.

[6] The "lab-equipment" model was first introduced by Rivera-Batiz and Romer (1991a); see also Barro and Sala-i-Martin (1995).

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 11
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

Hence, using the Euler condition, (14), we obtain the following equilibrium growth rate:

$$\gamma = \frac{(1-\alpha)\alpha^{(1+\alpha)/(1-\alpha)}L/\mu - \rho}{\theta}.$$

Sustained growth is attained by allocating a constant share of production to finance the research activity.

The second specification assumes that labor is not used in final production, but is used (instead of final output) as the unique input in the intermediate goods production.[7] More formally, the final production technology is

$$Y_t = Z^{1-\alpha}\int_0^{A_t} x_{j,t}^{\alpha}\,\mathrm{d}j, \tag{18}$$

where Z is a fixed factor (e.g., land) that is typically normalized to unity and ignored. In this model, $1/A_t$ units of labor are required to produce one unit of any intermediate input, with constant marginal costs. Therefore, in this version of the model, innovation generates a spillover on the productivity of both research and intermediate production.[8] We refer to this version as the "labor-for-intermediates" model.

It immediately follows that, in equilibrium, the production of each intermediate firm equals $x = L - L_x$. The price of intermediates is once more a mark-up over the marginal cost, $p_t = w_t/(\alpha A_t)$. In a BG equilibrium, wages and technology grow at the same rate, hence their ratio is constant. Let $\omega \equiv (w_t/A_t)$. The maximum profit is, then:

$$\pi = \left(\frac{1-\alpha}{\alpha}\right)\omega x = \frac{1-\alpha}{\alpha}\omega(L - L_x).$$

The free entry condition can be expressed as:

$$\frac{1-\alpha}{r\alpha}(L - L_x) \leqslant \frac{1}{\delta},$$

hence,

$$\gamma = \left(\frac{1-\alpha}{\alpha}L\delta - \rho\right)\Big/\left(\frac{1-\alpha}{\alpha} + \theta\right).$$

Clearly, both the "lab-equipment" and "labor-for-intermediates" model yield solutions qualitatively similar to that of the benchmark model.

[7] We follow the specification used by Young (1993). A related approach, treating the variety of inputs as consumption goods produced with labor, is examined in Grossman and Helpman (1991a, 1991b).

[8] The spillover on the productivity of intermediate production is not necessary to have endogenous growth. Without it, an equilibrium can be found in which production of each intermediate falls as A grows: $\gamma_A = -\gamma_x$. In this case, employment in production, Ax, is constant and the growth rate of Y is $(1-\alpha)\gamma_A$.

aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

2.3. Limited patent protection

In this section, we discuss the effects of limited patent protection. For simplicity, we focus on the lab-equipment version discussed in the previous section. The expectation of monopoly profits provides the basic incentive motivating investment in innovation; at the same time, monopoly rights introduce a distortion in the economy that raises prices above marginal costs and causes the underprovision of goods. Since the growth rate of knowledge in the typical decentralized equilibrium is below the social optimum, the presence of monopoly power poses a trade-off between dynamic and static efficiency, leading to the question, first studied by Nordhaus (1969a, 1969b), of whether there exists an optimal level of protection of monopoly rights. In the basic model, we assumed the monopoly power of innovators to last forever. Now, we study how the main results change when agents cannot be perfectly excluded from using advances discovered by others. A tractable way of doing this is to assume monopoly power to be eroded at a constant rate, so that in every instant, a fraction m of the monopolized goods becomes competitive.[9] Then, for a given range of varieties in the economy, A_t, the number of "imitated" intermediates that have become competitive, A_t^*, follows the law of motion:

$$\dot{A}_t^* = m\big(A_t - A_t^*\big). \tag{19}$$

Stronger patent protection can be considered as a reduction in the imitation rate m. Note that the model now has two state variables, A_t and A_t^*, and will exhibit transitional dynamics. In general, from any starting point, the ratio A_t^*/A_t will converge to the steady-state level:[10]

$$\frac{A^*}{A} = \frac{m}{\gamma + m}, \tag{20}$$

where $\gamma \equiv \dot{A}/A$.

Once a product is imitated, the monopoly power of the original producer is lost and its prices is driven down to the marginal cost by competition. Thus, at each point in time, intermediates still produced by monopolists are sold as before at the markup price $1/\alpha$, while for the others, the competitive price is one. Substituting prices into demand functions yields the quantity of each intermediate sold in equilibrium:

$$\begin{aligned} x_j &= \alpha^{1/(1-\alpha)} L \equiv x^* \quad \text{for } j \in \big(0, A_t^*\big), \\ x_j &= \alpha^{2/(1-\alpha)} L \equiv x \quad \text{for } j \in \big(A_t^*, A_t\big). \end{aligned} \tag{21}$$

Note that $x^* > x$, because the monopolized goods have a higher price.

[9] A growth model with limited patent life is developed by Judd (1985). Here, we follow Barro and Sala-i-Martin (1995). An alternative way of introducing limited patent protection is to assume monopolies to have a deterministic lifetime T. In this case, the PDV of an innovation is $(1-\mathrm{e}^{-rT})\pi/r$ (assuming balanced growth).

[10] This can be seen imposing $\dot{A}^*/A^* = \gamma$ in (19).

Free entry requires the PDV of profits generated by an innovation, V, to equal its cost μ. Along the balanced growth path, where the interest rate is constant, arbitrage in asset markets requires the instantaneous return to innovation, π/μ, to equal the real interest rate adjusted for imitation risk: $r + m$.[11] Since prices and quantities of the monopolized goods are identical to those in the basic model, π is not affected by imitation. Imitation only affects the duration of the profit flow, which is reflected in the effective interest rate. Therefore, limiting patent lives introduces a new inefficiency: although the benefit from a discovery is permanent for the economy, the reward for the innovator is now only temporary. Using the Euler equation for consumption growth, $\gamma = (r - \rho)/\theta$, and the adjusted interest rate in (17), we get the growth rate of the economy:

$$\gamma = \frac{1}{\theta}\left[(1-\alpha)\alpha^{(1+\alpha)(1-\alpha)}\frac{L}{\mu} - m - \rho\right].$$

As expected, the growth rate is decreasing in the imitation rate, as the limited duration of the monopoly effectively reduces the private value of an innovation. If we were concerned about long-run growth only, it would then be clear that patents should always be fully and eternally protected. However, for a given level of technology, A_t, output is higher the shorter is the patent duration (higher m), as can be seen by substituting equilibrium quantities (21) and the ratio of imitated goods (20) in the production function (3):

$$Y_t = \alpha^{2\alpha/(1-\alpha)} A_t L\left[1 + \left(\frac{m}{\gamma + m}\right)\left(\alpha^{-\alpha/(1-\alpha)} - 1\right)\right].$$

Therefore, a reduction in the patent life entails a trade-off between an immediate consumption gain and future losses in terms of lower growth, and its quantitative analysis requires the calculation of welfare along the transition. Kwan and Lai (2003) perform such an analysis, both numerically and by linearizing the BG equilibrium in the neighborhood of the steady-state, and show the existence of an optimum patent life. They also provide a simple calibration, using US data on long-run growth, markups and plausible values for ρ and θ, to suggest that over-protection of patents is unlikely to happen, whereas the welfare cost of under-protection can be substantial.

Alternatively, the optimal patent length can be analytically derived in models with a simpler structure. For example, Grossman and Lai (2004) construct a modified version of the model described above, where they assume quasi-linear functions. They show the

[11] A simple way of seeing this is through the following argument. In a time interval $\mathrm{d}t$, the firm provides a profit stream $\pi \cdot \mathrm{d}t$, a capital gain of $\dot{V} \cdot \mathrm{d}t$ if not imitated and a capital loss V if imitated (as the value of the patent would drop to zero). In the limit $\mathrm{d}t \to 0$, the probability of being imitated in this time interval is $m \cdot \mathrm{d}t$ and the probability of not being imitated equals $(1 - m \cdot \mathrm{d}t)$. Therefore, the expected return for the firm is $\pi \cdot \mathrm{d}t + (1 - m \cdot \mathrm{d}t)\dot{V} \cdot \mathrm{d}t - mV \cdot \mathrm{d}t$. Selling the firm and investing the proceeds in the capital market would yield an interest payment of $rV \cdot \mathrm{d}t$. Arbitrage implies that the returns from these two forms of investment should be equal and in a steady state $\dot{V} = 0$, implying $\pi/V = r + m$.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 14
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

optimal patent length to be an increasing function of the useful life of a product, of consumers' patience and the ratio of consumers' and producers' surplus under monopoly to consumers' surplus under competition. In addition, they derive the optimal patent length for noncooperative trading countries and find that advanced economies with a higher innovative potential will, in general, grant longer patents. A similar point is made in Lai and Qiu (2003).

3. Trade, growth and imitation

Growth models with an expanding variety of products are a natural dynamic counterpart to the widely-used trade models based on increasing returns and product differentiation developed in the 1980s [e.g., Helpman and Krugman (1985)]. As such, they offer a simple framework for studying the effects of market integration on growth and other issues in dynamic trade theory. Quality-ladder models have also been proposed in this literature, but they are a less natural counterpart to the static new trade theory, as they do not focus on the number of varieties available in an economy and their growth rate. As we shall see, economic integration can provide both static gains, through the access to a wider range of goods, and dynamic gains, through an increase in the rate at which new varieties are introduced. However, the results may vary when integration is limited to commodity markets with no international diffusion of knowledge [Rivera-Batiz and Romer (1991a)] and when countries differ in their initial stock of knowledge [Devereux and Lapham (1994)].

Finally, the analysis in this section is extended to product-cycle trade: the introduction of new products in advanced countries and their subsequent imitation by less developed countries. An important result will be to show that, contrary to the closed economy case, imitation by less developed countries may spur innovation and growth [Helpman (1993)].

3.1. Scale effects, economic integration and trade

In this section, we use the benchmark model to discuss the effects of trade and integration. The model features scale effects. Take two identical countries with identical labor endowment, $L = L^*$. In isolation, both countries would grow at the same rate, as given by (15). But if they merge, the growth rate of the integrated country increases to:

$$\gamma^I = \frac{\delta\alpha(L + L^*) - \rho}{\alpha + \theta} = \frac{2\alpha\delta L - \rho}{\alpha + \theta}.$$

Therefore, the model predicts that economic integration boosts growth.

Integration, even if beneficial, may be difficult to achieve. However, in many instances, trade operates as a substitute for economic integration. Rivera-Batiz and Romer

(1991a) analyze under which condition trade would attain the same benefits as economic integration. To this aim, they consider two experiments:[12]

1. The economies can trade at no cost in goods and assets, but knowledge spillovers remain localized within national borders;
2. In addition, knowledge spillovers work across borders after trade.

In both cases, to simplify the analysis, the two economies are assumed to produce, before trade, disjoint subsets of intermediate goods. This assumptions avoids complications arising from trade turning monopolies into duopolies in those industries which exist in both countries. Clearly, after trade, there would be no incentive for overlap in innovation, and the importance of inputs that were historically produced in both countries would decline to zero over time.

We start from the case analyzed by Rivera-Batiz and Romer (1991a), where the two countries are perfectly identical before trade. Namely, $L = L^*$ and $A_0 = A_0^*$, where the star denotes the *foreign* economy, and time zero denotes the moment when trade starts. Since, in a BG equilibrium, $\gamma = \delta L_x$, trade can only affect growth via the split of the workforce between production and research. Such a split, however, is not affected by trade, for in the symmetric equilibrium, trade increases by the same proportion the productivity of workers in production and the profitability of research. Since both the cost and private benefit of innovation increase by the same factor, investments in innovation remain unchanged.

More formally, the after trade wage is

$$w_{\text{trade}} = (1-\alpha)L_y^{-\alpha}x^{\alpha}\big(A + A^*\big), \tag{22}$$

which is twice as large as in the pre-trade equilibrium since at the moment of trade liberalization, $A = A^*$. Higher labor costs are a disincentive to research. But trade also increases the market for intermediate goods. Each monopolist can now sell its product in two markets. Since the demand elasticity is the same in both markets, the monopoly price equals $1/\alpha$ in both markets. Thus, the after trade profit is

$$\pi_{\text{trade}} = (p-1)(x+x^*) = 2\frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)}L_y.$$

The free-entry condition becomes, for both countries:

$$2\frac{\frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)}L_y}{r} \leqslant 2\frac{(1-\alpha)\alpha^{2\alpha/(1-\alpha)}}{\delta}, \tag{23}$$

which, after simplifying, is identical to (12). Therefore, the split of the workforce between production and research remains unchanged, and trade has no permanent effects on growth. Opening up to free trade, however, induces a once-and-for-all gain: both output and consumption increase in both countries, similarly to an unexpected increase

[12] The original article considers two versions of the model, one using the benchmark set-up and the other using the "lab-equipment" version. For the sake of brevity, we restrict the attention to the first. Romer (1994) extends the analysis to the case when a tariff on imports is imposed.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 16
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

in the stock of knowledge, since final producers in both countries can use a larger set of intermediate goods.

This result is not robust to asymmetric initial conditions. Devereux and Lapham (1994) show that if, initially, the two countries have different productivity levels, trade leads to specialization and a rise in the world growth rate.[13] Consider the economies described above, but assume that $A_0 < A_0^*$. Recall that free-entry implies:

$$V \leqslant \frac{w}{\delta A} \quad \text{and} \quad V^* \leqslant \frac{w^*}{\delta A^*},$$

where V, V^* denote the PDV of profits for an intermediate firm located at home and abroad, respectively. First, trade in intermediate goods and free capital markets equalize the rate of return to both financial assets (r) and labor (w).[14] Second, monopoly profits are independent of firms' locations, thereby implying that the value of firms must be the same all over the world: $V = V^* = V^w$. Therefore, at the time of trade liberalization, we must have:

$$\frac{w_{\text{trade}}}{\delta A} > \frac{w_{\text{trade}}}{\delta A^*} \geqslant V^w,$$

implying that no innovation is carried out in equilibrium in the (home) country, starting from a lower productivity. Moreover, the productivity gap in R&D widens over time: indeed, trade forever eliminates the incentives to innovate in the initially poorer country.

In the richer (foreign) country, however, trade boosts innovation.[15] The value of foreign firms must satisfy the following Bellman equation:

$$rV^* = \dot{V}^* + \frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)}\big(L_y^* + L\big),$$

where we note that $L_y = L$. The free-entry condition implies that:

$$V^* = \frac{(1-\alpha)\alpha^{2\alpha/(1-\alpha)}}{\delta}\frac{A^* + A}{A^*}.$$

Since knowledge only accumulates in the foreign country, the value of intermediate firms must decline over time, and in the long-run tend to its pre-trade value, i.e., $V^* = (1-\alpha)\alpha^{2\alpha/(1-\alpha)}/\delta$. Therefore, in the long run, the free-entry condition is

$$\frac{\frac{1-\alpha}{\alpha}\alpha^{2/(1-\alpha)}(L + L_y^*)}{r} \leqslant \frac{(1-\alpha)\alpha^{2\alpha/(1-\alpha)}}{\delta}. \tag{24}$$

[13] See also Rivera-Batiz and Romer (1991b) on the effects of trade restrictions with asymmetric countries.

[14] Recall Equation (22). The equalization of wages descends from a particular feature of the equilibrium, i.e., that the marginal product of labor is independent of the level of employment in production (since x is linear in L_y). This feature is not robust. If the production technology had land as an input, for instance, wages would not be equalized across countries; see Devereux and Lapham (1994) for an analysis of the more general case.

[15] Our discussion focuses on a world where no economy becomes fully specialized in research, since this seems to be the empirically plausible case.

Comparing (24) with (12) shows that trade reduces employment in production and, consequently, increases the long-run research activity in the foreign country, which implies that trade increases growth. In terms of Fig. 1, trade creates an outward shift in the DD schedule, leading to a higher interest rate and faster growth in equilibrium.

The result can be interpreted as trade leading to specialization. The home country specializes in final production, while the foreign country diversifies between manufacturing and innovation.[16] This is efficient, since there are country-wide economies of scale in innovation. Although trade leads to zero innovation in the home country, markets are integrated: final good producers, in both countries, can use the same varieties of intermediates and all consumers in the world can invest in the innovative firms of the foreign economy. Therefore, the location of innovation and firms has no impact on the relative welfare of the two countries.

Consider now the case when trade induces cross-country flows of ideas, i.e., if the knowledge spillover is determined, after trade, by the world stock of ideas contained in the union of A and A^*. When free trade is allowed, the accumulation of knowledge in each country is given by

$$\dot{A} = \delta L_x\big(A + A^*\big) \quad \text{and} \quad \dot{A}^* = \delta L_x^*\big(A + A^*\big).$$

Even if trade did not affect the allocation of the workforce between production and research, the rate of growth of technology would increase. But there is an additional effect; the larger knowledge spillover increases labor productivity in research, inducing an increase of employment in research. Formally, the total effect is equivalent to an increase in parameter δ. In terms of Figure 1, trade in goods plus flow of ideas imply an upward shift of the DD locus for both countries. Hence, trade attains the same effect as economic integration (increasing δ is equivalent to increasing L). This result is robust to asymmetric initial conditions.

3.2. Innovation, imitation and product cycles

The model just presented may be appropriate for describing trade integration between similar countries, but it misses important features of North–South trade. In a seminal article, Vernon (1966) argued that new products are first introduced in rich countries (the North), where R&D capabilities are high and the proximity to large and rich markets facilitates innovation. After some time, when a product reaches a stage of maturity and manufacturing methods become standardized, the good can easily be imitated and then, the bulk of production moves to less developed countries (the South), to take advantage of low wages. The expanding variety model provides a natural framework for studying the introduction of new goods and their subsequent imitation (product cycle trade).[17]

[16] Home-country patent holders will still produce intermediates, but as compared to the world's stock of intermediates, they will be of measure zero.

[17] Quality ladder models of innovation have been used to study product-cycles by, among others, Grossman and Helpman (1991a, 1991b), Segerstrom et al. (1990) and Dinopoulos and Segerstrom (2003).

We have already discussed imitation within the context of a closed economy. Here, we extend the analysis to the case where a richer North innovates, while a poorer South only engages in imitation. The analysis yields new results that modify some of the previous conclusions on the effect of imitation on innovation. The key questions are, first, how the transfer of production to the South through imitation affects the incentives to innovate and, second, how it affects the income distribution between North and South.

Following Helpman (1993), consider a two-region model of innovation, imitation and trade. Assume that R&D, producing new goods, is performed in the North only and that costless imitation takes place in the South at a constant rate m.[18] The imitation rate can be interpreted as an inverse measure of protection of Intellectual Property Rights (IPRs). Once a good is copied in the South, it is produced by competitive firms. Therefore, at every point in time, there is a range A_t^N of goods produced by monopolists in the North and a range A_t^S of goods that have been copied and are produced in the South by competitive firms. Given that the rate of introduction of new good is $\gamma = \dot{A}_t/A_t$, where $A_t = A_t^N + A_t^S$, and that monopolized goods are copied at the instantaneous rate m, $\dot{A}_t^S = mA_t^N$, it follows that a steady-state where the ratio A_t^N/A_t^S is constant must satisfy:

$$\frac{A^N}{A} = \frac{\gamma}{\gamma + m} \quad \text{and} \quad \frac{A^S}{A} = \frac{m}{\gamma + m}. \tag{25}$$

We use the "labor-for-intermediates" version of the growth model, so that the price of a single variety depends on the prevailing wage rate in the country where it is manufactured. This is an important feature of product cycle models, allowing the North to benefit from low production costs in the South for imitated goods. Therefore, we define the aggregate production function as in (18):

$$Y_t = \int_0^{A_t} {x_i}^{\alpha}\,\mathrm{d}i, \tag{26}$$

where A_t is the (growing) range of available products x_i and $\varepsilon = 1/(1-\alpha)$ is the elasticity of substitution between any two varieties. Intermediates are manufactured with $1/A_t$ units of labor per unit of output in both regions. Northern firms charge a monopoly price, as long as their products have not been imitated, equal to a constant markup $1/\alpha$ over the production cost, given by the wage rate. On the contrary, Southern firms produce imitated goods that have become competitive and sell them at a price equal to the marginal cost. To summarize:

$$p_t^N = \frac{w_t^N}{\alpha A_t} \quad \text{and} \quad p_t^S = \frac{w_t^S}{A_t}, \tag{27}$$

where p_t^N and p_t^S are the prices of any variety of intermediates produced in the North and South, respectively.

[18] The rate of imitation is made endogenous in Grossman and Helpman (1991b).

As in the benchmark model, innovation requires labor: the introduction of new products per unit of time $\dot{A}_t$ equals $\delta A_t L_x$, where L_x is the (Northern) labor input employed in R&D, δ is a productivity parameter and A_t captures an externality from past innovations. This implies that the growth rate of the economy is a linear function of the number of workers employed in R&D, $\gamma = L_x\delta$. As usual, profits generated by the monopoly over the sale of the new good are used to cover the cost of innovation. Since the profits per product are a fraction $(1-\alpha)$ of total revenue $p^N x$ and the labor market clears, $A_t^N x/A_t + \gamma/\delta = L^N$, profits can be written as:

$$\pi^N = \frac{1-\alpha}{\alpha}\frac{w_t^N}{A_t^N}\left(L^N - \frac{\gamma}{\delta}\right). \tag{28}$$

Arbitrage in asset markets implies that $(r+m)V^N = \pi^N + \dot{V}^N$, where V^N is the PDV of a new good and the effective interest rate is adjusted by the imitation risk. Along a BG path, $\dot{V}^N = 0$ and free entry ensures that the value of an innovation equals its cost, $w_t^N/\delta A_t$. Combining these considerations with (25) and (28) yields:

$$\frac{1-\alpha}{\alpha}\big(\delta L^N - \gamma\big)\frac{\gamma+m}{\gamma} = r+m. \tag{29}$$

Together with the Euler equation for consumption growth, (29) provides an implicit solution for the long-run growth rate of innovation. Note that the left-hand side is the profit rate (i.e., instantaneous profits over the value of the innovation) and the right-hand side represents the effective cost of capital, inclusive of the imitation risk.

To see the effect of a tightening of IPRs (a reduction of m), consider how an infinitesimal change in m affects the two sides of (29). Taking a log linear approximation, the impact of m on the profit rate is $1/(\gamma+m)$, whereas the effect on the cost of capital is $1/(r+m)$. In the case of log preferences, studied by Helpman (1993), $r > \gamma$. Hence, a reduction of m has a larger impact on the profit rate than on the effective cost of capital, thereby reducing the profitability of innovation and growth. What is the effect on the fraction of goods produced in the North? Rewriting (29) with the help of (25) as:

$$\frac{A^N}{A} = \frac{1-\alpha}{\alpha}\big(\delta L^N - \gamma\big)\frac{1}{r+m}, \tag{30}$$

it becomes apparent that a reduction of m increases the share of goods manufactured in the North, both through its direct effect and by reducing γ and r.

To understand these results, note that stronger IPRs have two opposite effects. First, a lower imitation rate prolongs the expected duration of the monopoly on a new product developed in the North, thereby increasing the returns to innovation. Second, since firms produce for a longer time in the North, it rises the demand for Northern labor, w^N, and hence, the cost of innovation. For the specification with log utility, the latter effect dominates and innovation declines. More generally, the link between the rate of imitation and innovation can go either way [as in Grossman and Helpman (1991a)]. However, the important result here is that tighter IPRs does not necessarily stimulate innovation in the long run.

The effect of IPRs on the North–South wage ratio can be found using (27), together with the relative demand for intermediates:[19]

$$\frac{w^N}{w^S} = \alpha\left[\frac{A^N}{A^S}\frac{L_S}{L_N - \gamma/\delta}\right]^{1/\varepsilon}. \tag{31}$$

Given that a decline in the imitation rate m raises $(A^N/A^S)/(L_N - \gamma/\delta)$ (see Equation (30)), a tightening of IPRs raises the relative wage of the North. Helpman (1993) computes welfare changes in the North and in the South (including transitional dynamics) after a change in the imitation rate m, and concludes that the South is unambiguously hurt by a decline in imitation. Moreover, if the imitation rate is not too high, the North can also be worse-off.

More recent papers on product cycles, incorporating the notion that stronger IPRs make relocation of production to the South a more attractive option, have come to different conclusions. For example, by assuming that Northern multinationals can produce in the South and that Southern firms can only imitate after production has been transferred to their country, Lai (1998) shows that stronger IPRs increase the rate of product innovation and the relative wage of the South. Similarly, Yang and Maskus (2001) find that if Northern firms can license their technology to Southern producers, being subject to an imitation risk, stronger IPRs reduce the cost of licensing, free resources for R&D and foster growth, with ambiguous effects on relative wages. Finally, the literature on appropriate technology [e.g., Diwan and Rodrik (1991), Acemoglu and Zilibotti (2001), Gancia (2003)] has shown that, when the North and the South have different technological needs, the South has an incentive to protect IPRs in order to attract innovations more suited to their technological needs. Some of these results are discussed in the next sections.

4. Directed technical change

So far, technical progress has been modeled as an increase in total factor productivity (A) that is neutral towards different factors and sectors. For many applications, however, this assumption is not realistic. For example, there is evidence that technical progress has been skill-biased during the last century and that this bias accelerated during the 1980s. Similarly, the fact that the output shares of labor and capital have been roughly constant in the US while the capital–labor ratio has been steadily increasing

[19] Relative demand for intermediates is:

$$\frac{p^N}{p^S} = \left(\frac{x^N}{x^S}\right)^{\alpha-1}.$$

Using $x^N = AL_y^N/A^N$, $x^S = AL_y^S/A^S$ and the pricing formula (27) yields the expression in the text.

suggests that technical change has mainly been labor-augmenting.[20] Further, industry studies show R&D intensity to vary substantially across sectors. In order to build a theory for the direction of technical change, a first step is to introduce more sectors into the model. Then, studying the economic incentives to develop technologies complementing a specific factor or sector can help understand what determines the shape of technology.

An important contribution of this new theory will be to shed light on the determinants of wage inequality [Acemoglu (1998, 2003a)]. Another application studies under which circumstances technologies developed by profit-motivated firms are appropriate for the economic conditions of the countries where they are used. The analysis will demonstrate that, since IPRs are weakly protected in developing countries, new technologies tend to be designed for the markets and needs of advanced countries. As a result, these technologies yield a low level of productivity when adopted by developing countries [Acemoglu and Zilibotti (2001)]. Trade can reinforce this problem and create interesting general equilibrium effects.

Although most of the results discussed in this section can be derived using models of vertical innovation, the expanding variety approach has proved to be particularly suited for addressing these issues because of its analytical tractability and simple dynamics. For instance, creative destruction, a fundamental feature of quality-ladder models, is not a crucial element for the problems at hand, and abstracting from it substantially simplifies the analysis.

4.1. Factor-biased innovation and wage inequality

Directed technical change was formalized by Acemoglu (1998), and then integrated by Acemoglu and Zilibotti (2001) into a model of growth with expanding variety, to explain the degree of skill-complementarity of technology.[21] In this section, we discuss the expanding variety version [following the synthesis of Acemoglu (2002)] by extending the "lab-equipment" model to two sectors employing skilled and unskilled labor, respectively. Consider the following aggregate production function:

$$Y = \left[Y_L^{(\varepsilon-1)/\varepsilon} + Y_H^{(\varepsilon-1)/\varepsilon}\right]^{\varepsilon/(\varepsilon-1)}, \tag{32}$$

where Y_L and Y_H are goods produced with unskilled labor, L, and skilled labor, H, respectively. Y represents aggregate output, used for both consumption and investment, as a combination of the two goods produced in the economy, with an elasticity of substitution equal to ε. Maximizing Y under a resource constraint gives constant elasticity demand functions, implying a negative relationship between relative prices and relative

[20] Unless the production function is Cobb–Douglas, in which case the direction of technical progress is irrelevant. Empirical estimates suggest that the elasticity of substitution between labor and capital is likely to be less than one. See Hamermesh (1993) for a survey of early estimates and Krusell et al. (2000) and Antras (2004) for more recent contributions.

[21] Important antecedents are Kennedy (1964), Samuelson (1965) and Atkinson and Stiglitz (1969).

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 22
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

quantities:

$$\frac{P_H}{P_L} = \left[\frac{Y_L}{Y_H}\right]^{1/\varepsilon}, \tag{33}$$

where P_L and P_H are the prices of Y_L and Y_H, respectively. Aggregate output is chosen as the numeraire, hence:

$$\left(P_L^{1-\varepsilon} + P_H^{1-\varepsilon}\right)^{1/(1-\varepsilon)} = 1. \tag{34}$$

The distinctive feature of this model is that the two goods are now produced using different technologies:

$$\begin{aligned} Y_L &= L^{1-\alpha} \int_0^{A_L} {x_{L,j}}^{\alpha}\, \mathrm{d}j, \\ Y_H &= H^{1-\alpha} \int_0^{A_H} {x_{H,j}}^{\alpha}\, \mathrm{d}j, \end{aligned} \tag{35}$$

where $x_{L,j}$, $j \in [0, A_L]$, are intermediate goods complementing unskilled labor, whereas $x_{H,j}$, $j \in [0, A_H]$ complement skilled labor. This assumption captures the fact that different factors usually operate with different technologies and that a new technology may benefit one factor more than others.[22] For example, it has been argued that computers boosted the productivity of skilled more than that of unskilled labor, whereas the opposite occurred after the introduction of the assembly line. As before, technical progress takes the form of an increase in the number of intermediate goods, $[A_L, A_H]$, but now an innovator must decide which technology to expand. The profitability of the two sectors pins down, endogenously, the direction of technical change. In a steady-state equilibrium, there is a constant ratio of the number of intermediates used by each factor, A_H/A_L, and this can be interpreted as the extent of the "endogenous skill-bias" of the technology.

The analysis follows the same steps as in model with a single factor. Final good producers take the price of their output (P_L, P_H), the price of intermediates $(p_{L,j}, p_{H,j})$ and wages (w_L, w_H) as given. Consider a variety j used in the production of Y_L. Profit maximization gives the following isoelastic demand:

$$x_{L,j} = \left[\frac{\alpha P_L}{p_{L,j}}\right]^{1/(1-\alpha)} L, \tag{36}$$

and an equivalent expression for $x_{H,j}$.

The intermediate good sector is monopolistic, with each producer owning the patent for a single variety. The cost of producing one unit of any intermediate good is one

[22] The analysis can be generalized to specifications where, in the spirit of Heckscher–Ohlin models, each sector uses all productive factors, but factor intensities differ across sectors. The model can also be generalized to more than two factors and sectors.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 23
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

unit of the numeraire. The symmetric structure of demand and technology implies that all monopolists set the same price, $p_{Lj} = p_L$. In particular, given the isoelastic demand, they set $p_L = 1/\alpha$ and sell the quantity $x_{L,j} = (\alpha^2 P_L)^{1/(1-\alpha)} L$. The profit flow accruing to intermediate producers can therefore be expressed as

$$\pi_L = (1-\alpha)\alpha^{(1+\alpha)/(1-\alpha)} (P_L)^{1/(1-\alpha)} L. \tag{37}$$

Similar conclusions are reached for varieties used in the production of Y_H, leading to

$$\pi_H = (1-\alpha)\alpha^{(1+\alpha)/(1-\alpha)} (P_H)^{1/(1-\alpha)} H. \tag{38}$$

From (37)–(38), it immediately follows that the relative profitability in the two sectors is given by

$$\frac{\pi_H}{\pi_L} = \left(\frac{P_H}{P_L}\right)^{1/(1-\alpha)} \frac{H}{L}, \tag{39}$$

which, since profits are used to finance innovation, is also the relative profitability of R&D directed to the two sectors. The first term in (39) represents the "price effect": there is a greater incentive to invent technologies producing more expensive goods.[23] The second term is the "market size" effect: the incentive to develop a new technology is proportional to the number of workers that will be using it.[24]

Next, using the price of intermediates in (36) and (35) gives final output in each sector:

$$\begin{aligned} Y_L &= \alpha^{2\alpha/(1-\alpha)} P_L^{\alpha/(1-\alpha)} A_L L, \\ Y_H &= \alpha^{2\alpha/(1-\alpha)} P_H^{\alpha/(1-\alpha)} A_H H. \end{aligned} \tag{40}$$

Note the similarity with (16). As in the benchmark model, output – in each sector – is a linear function of technology and labor. But sectoral output now also depends on sectoral prices, P_L and P_H, since a higher price of output increases the value of productivity of intermediates, but not their costs, and therefore encourages firms to use more of them, thereby raising labor productivity. Note that this is not the case in the one-sector model since there, the price of output is proportional to the price of intermediates.

We can now solve for prices and wages as functions of the state of technology and endowments. Using (40) into (33) and noting that the wage bill is a constant fraction of sectoral output, yields:

$$\frac{P_H}{P_L} = \left[\frac{A_H}{A_L}\frac{H}{L}\right]^{-(1-\alpha)/\sigma}, \tag{41}$$

$$\frac{w_H}{w_L} = \left[\frac{A_H}{A_L}\right]^{1-1/\sigma} \left[\frac{H}{L}\right]^{-1/\sigma}, \tag{42}$$

[23] The price effect, restated in terms of factor prices, was emphasized by Hicks (1932) and Habakkuk (1962).

[24] Market size, although in the context of industry- and firm-level innovation, was emphasized as a determinant of technical progress by Griliches and Schmookler (1963), Schmookler (1966) and Schumpeter (1950).

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 24
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

where $\sigma \equiv 1 + (1-\alpha)(\varepsilon - 1)$ is, by definition, the elasticity of substitution between H and L.[25] Note that the skill premium, w_H/w_L, is decreasing in the relative supply of skilled labor (H/L) and increasing in the skill-bias (A_H/A_L).

The final step is to find the equilibrium for technology. We assume, as in the lab-equipment model of Section 2.2, that the development of a new intermediate good to require a fixed cost of μ units of the numeraire. Free entry and an arbitrage condition require the value V_z of an innovation directed to factor $Z \in \{L, H\}$ to equal its cost. Since the value of an innovation is the PDV of the infinite stream of profits it generates, an equilibrium with a positive rate of innovation in both types of intermediates such that the ratio A_H/A_L remains constant, i.e., a BG path where P_H/P_L, w_H/w_L and π_H/π_L are also constant, requires profit equalization in the two sectors, $\pi_H = \pi_L = \pi$. Imposing this restriction yields the equilibrium skill-bias of technology,

$$\frac{A_H}{A_L} = \left[\frac{H}{L}\right]^{\sigma-1}. \tag{43}$$

Equation (43) shows that, as long as workers of different skill levels are gross substitutes ($\sigma > 1$), an increase in the supply of one factor will induce more innovation directed to that specific factor. This is the case because, with $\sigma > 1$, the market size effect dominates the price effect, and technology is biased towards the abundant factor. The opposite is true if $\sigma < 1$. As usual, the growth rate of the economy can be found from the free-entry condition $\pi_Z/r = \mu$, $Z \in \{L, H\}$. Using (34), (41) and (43) to substitute for prices and the interest rate from the Euler equation, yields:

$$\gamma = \frac{1}{\theta}\left[\frac{(1-\alpha)\alpha^{(1+\alpha)/(1-\alpha)}}{\mu}\left(L^{\sigma-1} + H^{\sigma-1}\right)^{1/(\sigma-1)} - \rho\right].$$

If we only had one factor (e.g., $H = 0$), the growth rate would reduce to that of the benchmark model.

Directed technical change has interesting implications on factor prices. Using (43), the skill-premium becomes:

$$\frac{w_H}{w_L} = \left[\frac{H}{L}\right]^{\sigma-2}. \tag{44}$$

Equation (44) shows that the slope of the labor demand curve, i.e., the relationship between relative wages and relative labor supply, can be either positive or negative and is the result of two opposite forces. On the one hand, a large supply of one factor depresses the price of its product while, on the other hand, it induces a technology bias in its favor, thereby raising its productivity. A high substitutability between H and L implies a weak price effect of an increase in relative supply, which makes a positive relationship more likely. In particular, if $\sigma > 2$, the market size effect is sufficiently strong to not

[25] This is the short-run elasticity of substitution between L and H, for a given technology A_L and A_H.

only dominate the price effect on technical change (see Equation (43)), but also the substitution effect between skilled and unskilled workers at a given technology.

This result can help rationalize several facts. First, it suggests that technical change has been skill biased during the past 60 years, because of the steady growth in the supply of skilled labor. Second, the case $\sigma > 2$ offers an explanation for the fall and rise in the US skill premium during the 1970s and 1980s. In the 1970s, there was a large increase in the supply of skilled labor (H/L). Assuming this shock to be unexpected, the model predicts an initial fall in the skill premium (recall that A_H/A_L is a state variable that does not immediately adjust), followed by its rise due to the induced skill biased technical change, a pattern broadly consistent with the evidence.

In Acemoglu (2003b), this set-up is used to study the direction of technical progress when the two factors of production are capital and labor. Beyond the change of notation, the resulting model has an important qualitative difference, as capital can be accumulated. The main finding is that, when both capital and labor augmenting innovations are allowed, a balanced growth path still exists and features labor-augmenting technical progress only. The intuition is that, while there are two ways of increasing the production of capital-intensive goods (capital-augmenting technical change and accumulation), there is only one way of increasing the production of labor-intensive goods (labor-augmenting technical progress). Therefore, in the presence of capital accumulation, technical progress must be more labor-augmenting than capital-augmenting. Further, Acemoglu shows that, if capital and labor are gross complements (i.e., the elasticity of substitution between the two is less than one), which seems to be the empirically relevant case [see, for example, Antras (2004)], the economy converges to the balanced growth path.

Finally, the theory of directed technical change can be used to study which industries attract more innovation and why R&D intensity differs across sectors. In this exercise, following a modified version of Klenow (1996), we abstract from factor endowments as determinants of technology, by assuming there to be a single primary input, which we call labor. Instead, other characteristics can make one sector more profitable than others. Major explanations put forward in the literature on innovation are industry differences in technological opportunities, market size and appropriability of rents, all factors that can easily be embedded in the basic model with two sectors. In particular, to capture the market size hypothesis, we introduce a parameter η defining the relative importance of industry i in aggregate consumption:

$$Y = \left[\eta Y_i^{(\varepsilon-1)/\varepsilon} + (1-\eta) Y_j^{(\varepsilon-1)/\varepsilon}\right]^{\varepsilon/(\varepsilon-1)}.$$

Differences in technological opportunities can be incorporated by allowing the cost of an innovation, μ_i, to vary across sectors. Finally, we assume that an inventor in industry i can only extract a fraction λ_i of the profits generated by his innovation. The previous analysis carries over almost unchanged, with the main difference that we now need to solve for the allocation of labor across industries. This can be done requiring all

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 26
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

industries to pay the same wage, i.e., setting (42) equal to one:

$$\frac{L_i}{L_j} = \left(\frac{A_i}{A_j}\right)^{\sigma-1}.$$

Solving the new arbitrage condition stating that innovation for the two industries should be equally profitable in BG, $\lambda_i \pi_i/\mu_i = \lambda_j \pi_j/\mu_j$, yields the relative industry-bias of technology:

$$\frac{A_i}{A_j} = \left(\frac{\lambda_i}{\lambda_j}\frac{\mu_j}{\mu_i}\right)^{1/(2-\sigma)} \left(\frac{\eta}{1-\eta}\right)^{\varepsilon/(2-\sigma)}.$$

As expected, industries with a larger market size, better technological opportunities and higher appropriability attract more innovations.[26] Empirical estimates surveyed by Cohen and Levin (1989) suggest that about one half of the industry differences in research intensity can be attributed to the available measures of these three factors.

4.2. Appropriate technology and development

Directed technical change has interesting implications for the analysis of some development issues. Acemoglu and Zilibotti (2001) show that technologies resulting from directed technical change are optimal for the economic conditions of the markets where they are sold. They analyze the implications of this finding in a two-country world where technological innovation takes place in the North, and the South does not enforce (or imperfectly enforce) IPRs. In this environment, innovators in the North can only extract rents from selling technologies (embodied in new varieties of intermediate goods) in the Northern market, since new technologies can be copied and locally produced in the South. Thus, innovation does not respond to the factor endowment of the South: the equilibrium skill-bias of technical change (see Equation (43) in the previous section) is determined by the factor endowment of the North only. In this sense, technological development tends to be "inappropriate" for the South: there is too much investment in inventing new technologies augmenting the productivity of skilled workers, and too little in inventing new technologies augmenting the productivity of unskilled workers. Such excessive skill-bias prevents the South from fully profiting from technological improvements. The theory can explain North–South productivity differences, even when the technology is identical and there are no significant barriers to technology adoption.[27]

[26] This is true as long as $\sigma < 2$. This restriction is required to have balanced growth. If violated, e.g., if goods are highly substitutable, it would be profitable to direct innovation to one sector only.

[27] Evidence on cross-country TFP differences is provided by, among others, Klenow and Rodriguez-Clare (1997), Hall and Jones (1999), Caselli, Esquivel and Lefort (1996) and Prescott (1998). The view that technological differences arise from barriers to technology adoption is expressed by, among others, Parente and Prescott (1994) and Prescott (1998).

We start by studying the set of advanced countries, called North. A continuum of measure one of final goods is produced by competitive firms. Final goods, indexed by $i \in [0,1]$, are aggregated to give a composite output, $Y = \exp(\int_0^1 \log y_i \, \mathrm{d}i)$, which is the numeraire. There are two differences with respect to the model of the previous section: first, there is a continuum of sectors, not just two, and second, the elasticity of substitution between sectors is unity.[28] Each good i can be produced with both skilled and unskilled labor using two sets of intermediate goods: intermediates $[0, A_L]$ used by unskilled workers only and intermediates $[0, A_H]$ used by skilled workers only. Therefore, despite the continuum of sectors, there are only two types of technologies, as in the basic model of directed technical change. The production function takes the following form:

$$y_i = \big[(1-i)l_i\big]^{1-\alpha} \int_0^{A_L} x_{L,v,i}^{\alpha} \, \mathrm{d}v + [ih_i]^{1-\alpha} \int_0^{A_H} x_{H,v,i}^{\alpha} \, \mathrm{d}v, \tag{45}$$

where l_i and h_i are the quantities of unskilled and skilled labor employed in sector i, respectively, and $x_{z,v,i}$ is the quantity of intermediate good of type v used in sector i together with the labor of skill level $z = L, H$. Note that sectors differ in labor-augmenting productivity parameters, $(1-i)$ for the unskilled technology and i for the skilled technology, so that unskilled labor has a comparative advantage in sectors with a low index. Producers of good i take the price of their product, P_i, the price of intermediates ($p_{L,v}$, $p_{H,v}$) and wages (w_L, w_H) as given. Profit maximization gives the following demands for intermediates:

$$x_{L,v,i} = (1-i)l_i[\alpha P_i / p_{L,v}]^{1/(1-\alpha)} \quad \text{and} \quad x_{H,v,i} = ih_i[\alpha P_i / p_{H,v}]^{1/(1-\alpha)}. \tag{46}$$

The intermediate good sector is monopolistic. Each producer holds the patent for a single type of intermediate good v, and sells its output to firms in the final good sectors. The cost of producing one unit of any intermediate is conveniently normalized to α^2 units of the numeraire. Profit maximization by monopolists implies that prices are a constant markup over marginal costs, $p = \alpha$. Using the price of intermediates together with (46) and (45) gives the final output of sector i as a linear function of the number of intermediate goods and labor:

$$y_i = P_i^{\alpha/(1-\alpha)}\big[A_L(1-i)l_i + A_H i h_i\big]. \tag{47}$$

From (47), it is easily seen that all sectors whose index i is below a threshold level J will use the unskilled technology only and the remaining sectors will employ the skilled technology only. This happens because of the comparative advantage of unskilled workers in low index sectors and the linearity of the production function (there is no incentive to combine the two technologies and, for a given i, one always dominates the other).

[28] The composite output Y can be interpreted as a symmetric Cobb–Douglas over the measure of final goods $i \in [0,1]$.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 28
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

The total profits earned by monopolists are:

$$\pi_{L,v} = (1-\alpha)\alpha \int_0^1 P_i^{1/(1-\alpha)}(1-i)l_i \,\mathrm{d}i \quad \text{and}$$
$$\pi_{H,v} = (1-\alpha)\alpha \int_0^1 P_i^{1/(1-\alpha)} i h_i \,\mathrm{d}i. \tag{48}$$

Note that, by symmetry, $\pi_{L,v} = \pi_{L,j}$ and $\pi_{H,v} = \pi_{H,j}$. Given the Cobb–Douglas specification in (45), the wage bill in each sector is a fraction $(1-\alpha)$ of sectoral output. Therefore, Equation (47) can be used to find wages:[29]

$$w_L = (1-\alpha)P_i^{1/(1-\alpha)}A_L(1-i) \quad \text{and} \quad w_H = (1-\alpha)P_i^{1/(1-\alpha)}A_H i. \tag{49}$$

Defining $P_L \equiv P_0$, $P_H \equiv P_1$ and dividing equations in (49) by their counterparts in sectors 0 and 1, respectively, it is possible to derive the following pattern of prices: for $i \leqslant J$, $P_i = P_L(1-i)^{-(1-\alpha)}$ and for $i \geqslant J$, $P_i = P_H i^{-(1-\alpha)}$. Intuitively, the price of a good produced with skilled (unskilled) labor is decreasing in the sectoral productivity of skilled (unskilled) workers. Next, note that to maximize Y, expenditures across goods must be equalized, i.e., $P_i y_i = P_H y_1 = P_L y_0$ (as for a symmetric Cobb–Douglas). This observation, plus the given pattern of prices and full employment, imply that labor is evenly distributed among sectors: $l_i = L/J$, $h_i = H/(1-J)$, as prices and sectoral productivity compensate each other. Finally, in sector $i = J$, it must be the case that both technologies are equally profitable or $P_L(1-J)^{-(1-\alpha)} = P_H J^{-(1-\alpha)}$; this condition, using $P_H y_1 = P_L y_0$ and (47), yields:

$$\frac{J}{1-J} = \left(\frac{P_H}{P_L}\right)^{1/(1-\alpha)} = \left(\frac{A_H}{A_L}\frac{H}{L}\right)^{-1/2}. \tag{50}$$

The higher the relative endowment of skill (H/L) and the skill-bias of technology (A_H/A_L), the larger the fraction of sectors using the skill-intensive technology $(1-J)$. Finally, integrating $P_i y_i$ over [0, 1], using (47), (50) and the fact that the consumption aggregate is the numeraire (i.e., $\exp[\int_0^1 \ln P_i \,\mathrm{d}i] = 1$) gives a simple representation for aggregate output:

$$Y = \exp(-1)\left[(A_L L)^{1/2} + (A_H H)^{1/2}\right]^2, \tag{51}$$

which is a CES function of technology and endowments, with an elasticity of substitution between factors equal to two.

So far, the analysis defines an equilibrium for a given technology. Next, we need to study innovation and characterize the equilibrium skill-bias of technology, (A_H/A_L). As before, technical progress takes the form of an increase in A_L and A_H and is the

[29] In Acemoglu and Zilibotti (2001), there is an additional parameter ($Z > 1$), which is here omitted for simplicity, which augments the productivity of skilled workers, ensuring that the skill premium is positive in equilibrium.

result of directed R&D investment. The cost of an innovation (of any type) is equal to μ units of the numeraire, and R&D is profitable as long as the PDV of the infinite flow of profits that a producer of a new intermediate expects to earn covers the fixed cost of innovation. Finally, free entry ensures that there are no additional profits. Using the price pattern, instantaneous profits can be simplified as:

$$\pi_H = \alpha(1-\alpha)P_H^{1/(1-\alpha)}H. \tag{52}$$

A parallel expression gives π_L. Balanced growth requires $\pi_L = \pi_H$; in this case, A_H and A_L grow at the same rate, the ratio A_H/A_L is constant as are J, P_L and P_H. Imposing $\pi_L = \pi_H$ in (52) and using (50) yields:

$$\frac{A_H}{A_L} = \frac{1-J}{J} = \frac{H}{L}. \tag{53}$$

Note that the equilibrium skill-bias is identical to that of (43) in the special case when $\sigma = 2$. Further, (53) shows that the higher is the skill endowment of a country, the larger is the range of sectors using the skilled technology. This is a complete characterization of the equilibrium for fully integrated economies developing and selling technologies in their markets with full protection of IPRs and can be interpreted as a description of the collection of rich countries, here called the North.

Consider now Southern economies, where skilled labor is assumed to be relatively more scarce: $H^S/L^S < H^N/L^N$. Assume that intellectual property rights are not enforced in the South and that there is no North–South trade. It follows that intermediate producers located in the North cannot sell their goods or copyrights to firms located in the South, so that the relevant market for technologies is the Northern market only. Nonetheless, Southern producers can copy Northern innovations at a small but positive cost. As a consequence, no two firms in the South find it profitable to copy the same innovation and all intermediates introduced in the North are immediately copied (provided that the imitation cost is sufficiently small) and sold to Southern producers by a local monopolist. Under these assumptions, firms in the South take the technologies developed originating in the North as given and do not invest in innovation.[30] This means that both the North and the South use the same technologies, but $A_H/A_L = H^N/L^N$, i.e., the skill-bias is determined by the factor endowment of the North, since this is the only market for new technologies. Except for this, the other equilibrium conditions also apply to the South after substituting the new endowments, H^S and L^S.

We are now ready to answer the following questions: are technologies appropriate for the skill endowment of the countries where they are developed? What happens to aggregate productivity if they are used in a different economic environment?

[30] Imitation can be explicitly modelled as an activity similar to innovation, but less costly. Assuming the cost of an innovation of type z to decrease with the distance from the relevant technology frontier A_Z^N, as in Barro and Sala-i-Martin (1997), would yield very similar results.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 30
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

Simple differentiation on (51) establishes that Y is maximized for $A_H/A_L = H/L$. This is exactly condition (53), showing that the equilibrium skill-bias is optimally chosen for the Northern skill composition. On the contrary, since factor abundance in the South does not affect the direction of technical change, new technologies developed in the North are inappropriate for the needs of the South. As a consequence, output per capita, $Y/(L + H)$ is greater in the North than in the South. The reason for these productivity differences is a technology–skill mismatch. To understand why, note that, from Equation (50), $J^S > J^N$. Rewriting (53) as $A_H J^N = A_L(1 - J^N)$ and inspecting Equation (47) reveals that unskilled workers are employed in the North up to sector J^N, where they become as productive as skilled workers. This basic efficiency condition is violated in the South, where $A_H J^S > A_L(1 - J^S)$. Because of its smaller skill endowment, the South is using low-skill workers in some sectors where high-skill workers would be more productive.

This result can help understand the existence of substantial differences in TFP across countries, even when the technology is common. In particular, Acemoglu and Zilibotti (2001) compare the predictive power of their model in explaining cross-country output differences with that of a comparable neoclassical model, where all countries have access to the same technologies and output is Cobb–Douglas in labor, human and physical capital. Their computations suggest that the proposed mechanism can account for one-third to one half of the total factor productivity gap between the United States and developing countries. Predictions on the pattern of North–South, cross-industry, productivity differences are also tested. Since the South uses the same technology $[A_L, A_H]$ as the rest of the world, but it has a higher relative price for skill-intensive goods, it follows that the value of productivity in LDCs relative to that of the North should be higher in skill-intensive sectors. The empirical analysis supports this prediction.

The view that countries adopt different technologies out of a world "menu", and that the choice of the appropriate technology depends on factor endowments, particularly on the average skill of the labor force, finds support in the analysis of Caselli and Coleman (2000). However, these authors also find that many poor countries choose technologies inside the world technology frontier, thereby suggesting that barriers to technology adoption may also be important to explain the low total factor productivity of these countries.

4.3. Trade, inequality and appropriate technology

We have seen that directed technical change can help understand inequality, both within and between countries. Several authors have stressed that international trade is another important determinant of income distribution. For example, Wood (1994) argues that the higher competition with imports from LDCs may be responsible for the deterioration in relative wages of low-skill workers in the US in the past decades. Further, there is a widespread concern that globalization may be accompanied by a widening of income differences between rich and poor countries. Although the analysis of these issues goes beyond the scope of this paper, we want to argue that R&D-driven endoge-

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 31
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

nous growth models can fruitfully be used to understand some of the links between trade and inequality. In particular, we now show that trade with LDCs can have a profound impact on income distribution, beyond what is suggested by static trade theory, through its effect on the direction of technical change. By changing the relative prices and the location of production, international trade can change the incentives for developing innovations targeted at specific factors or sectors, systematically benefiting certain groups or countries more than others. A key assumption in deriving these results is that, as in the previous paragraph, LDCs do not provide an adequate protection of IPRs.

First, consider the effect of trade in the benchmark model of directed technical change. The analysis follows Acemoglu (2002, 2003a). Recall that the profitability of an innovation depends on its market size and the price of the goods it produces, as in Equation (39). What happens to technology if we allow free trade in Y_L and Y_H between a skill-abundant North and a skill-scarce South? The market size for innovations does not change, because inventors continue to sell their machines in the North only. But trade, at first, will increases the relative price of skill-intensive goods in the North. To see this, note that trade generates a single world market with a relative price depending on the world supply of goods. Since skills are scarcer in the world economy than in the North alone, trade will increase the relative price of skill-intensive goods in the North (the opposite will happen in the South). In particular, world prices are now given by Equation (41) using world endowments:

$$\frac{P_H}{P_L} = \left(\frac{A_H}{A_L}\frac{H^W}{L^W}\right)^{-(1-\alpha)/\sigma}. \tag{54}$$

This change in prices, for a given technology, makes skill-complement innovations more profitable and accelerates the creation of skill-complementary machines. Since, along the BG path, both types of innovations must be equally profitable and hence $\pi_H = \pi_L$, Equation (39) shows that this process continues until the relative price of goods has returned to the pre-trade level in the North. Substituting Equation (54) into (39) and imposing $\pi_H = \pi_L$, yields the new equilibrium skill bias of technology:

$$\frac{A_H}{A_L} = \frac{L^W}{H^W}\left[\frac{H^N}{L^N}\right]^{\sigma}. \tag{55}$$

Given that $H^N/L^N > H^W/L^W$, the new technology is more skill-biased and skilled workers in the North earn higher wages. The effect on the skill premium can be seen by substituting (55) into (42):

$$\frac{w_H}{w_L} = \left[\frac{H^N}{L^N}\frac{L^W}{H^W}\right]\left[\frac{H^N}{L^N}\right]^{\sigma-2}. \tag{56}$$

The effect of a move from autarky to free trade can be approximated by the elasticity of the skill premium to a change in L^W/H^W computed at $L^W/H^W = L^N/H^N$ (that is, starting from the pre-trade equilibrium). Equation (56) shows this elasticity to be unity.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 32
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

Thus, if, for example, L^W/H^W were 4% higher than L^N/H^N, the model would predict trade to raise the skill premium by the same 4%.[31]

Without technical change, instead, the reaction of the skill premium to a change in the perceived scarcity of factors due to trade depends on the degree of substitutability of skilled and unskilled workers. From Equation (42), the elasticity of the skill premium to a change in L/H would be $1/\sigma$, less than in the case of endogenous technology as long as $\sigma > 1$, i.e., when skilled and unskilled workers are gross substitutes. Therefore, with directed technical change and $\sigma > 1$, trade increases the skill premium in the North by more than would otherwise be the case: for example, if the elasticity of substitution is 2, the endogenous reaction of technical progress doubles the impact of trade on wage inequality.

Note that another direct channel through which trade can affect factor prices in models of endogenous technical change is by affecting the reward to innovation. If trade increases the reward to innovation (for example, through the scale effect) and the R&D sector is skill-intensive relative to the rest of the economy, trade will naturally spur wage inequality. This mechanism is studied by Dinopoulos and Segerstrom (1999) in a quality-ladder growth model with no scale effects.[32]

What are the implications of trade opening for cross-country income differences? We have seen that trade induces a higher skill bias in technology; given the result of Acemoglu and Zilibotti (2001) that the excessive skill-complementarity of Northern technologies is a cause of low productivity in Souther countries, it may seem natural to conclude that trade would then increase productivity differences. However, this conclusion would be premature. In the absence of any barriers, trade equalizes the price of goods; given that the production functions adopted so far rule out complete specialization, this immediately implies that factor prices and sectoral productivity are also equalized. This does not mean that trade equalizes income levels; because of their different skill-composition, the North and the South will still have differences in income per capita, but nothing general can be said.[33]

The fact that trade generates productivity convergence crucially depends on factor prices being equalized by trade. Since factor price equalization is a poor approximation of reality, it is worth exploring the implications of models with endogenous technologies when this property does not hold. A simple way of doing this is to add Ricardian productivity differences, so that trade opening leads to complete specialization. In this

[31] Borjas, Freeman and Katz (1997) show that 4% is a plausible estimate of the increase in the unskilled labor content of US trade with LDCs between 1980 and 1995. Therefore, this simple exercise may give a sense of how much of the roughly 20% increase in the US skill premium in the same period can be attributed to trade.

[32] Recently, other papers have suggested that trade between identical countries may as well increase skill premia through its effect on technology. See, for example, Epifani and Gancia (2002), Neary (2003) and Thoenig and Verdier (2003).

[33] A general result is that the endogenous response of technology makes trade less beneficial for LDCs than would otherwise be the case. This occurs because, after trade opening, the skill premium rises as a result of the induced skill-biased technical change. Given that the North is more skilled-labor abundant, it proportionally benefits more from a higher skill premium.

case, the endogenous response of technology to weak IPRs in LDCs becomes a force promoting productivity divergence.[34] Further, trade with countries providing weak protection for IPRs may have an adverse effect on the growth rate of the world economy. These results, shown by Gancia (2003), can be obtained by modifying Acemoglu and Zilibotti (2001) as follows. First, we allow the elasticity of substitution between final goods to be larger than one: $Y = [\int_0^1 y_i{}^{(\varepsilon-1)/\varepsilon}\,\mathrm{d}i]^{\varepsilon/(\varepsilon-1)}$, with $\varepsilon > 1$. Then, we assume that each good y_i can be produced by competitive firms both in the North and the South, using sector-specific intermediates and labor:

$$y_i = \left[(1-i)l_i^S\right]^{1-\alpha}\int_0^{A_i}\left(x_{i,v}^S\right)^{\alpha}\mathrm{d}v + \left[il_i^N\right]^{1-\alpha}\int_0^{A_i}\left(x_{i,v}^N\right)^{\alpha}\mathrm{d}v. \tag{57}$$

There are three important differences with respect to (45). First, $(1-i)$ and i now capture Ricardian productivity differences between the North and South, implying that the North is relatively more productive in high index sectors. Second, intermediate goods are sector specific, not factor specific (there is now a continuum $[0, 1]$ of technologies, not only two). Third, there is only one type of labor. Given that the endogenous component of technology (A_i) is still assumed to be common across countries, the sectoral North–South productivity ratio only depends on the Ricardian elements. The new implication is that countries specialize completely under free trade, as each good is only manufactured in the location where it can be produced at a lower cost.

The equilibrium can be represented by the intersection of two curves, as in Dornbusch et al. (1977). For any relative wage, the first curve gives the range $[0, J]$ of goods efficiently produced in the South: $\frac{J}{1-J} = \frac{w^N}{w^S}$. The second curve combines trade balance and a BG research arbitrage condition, requiring profits to be equalized across sectors and countries. To find this, the model assumes that the owner of a patent can only extract a fraction $\lambda < 1$ of the profits generated by its innovation in the South, so that λ can be interpreted as an index of the strength of international IPRs protection. The trade balance plus the research arbitrage condition turn out to be [see Gancia (2003)]:

$$\frac{w^N}{w^S} = \lambda^{-\widetilde{\sigma}}\left[\frac{L^S}{L^N}\frac{\int_J^1 (i)^{\widetilde{\sigma}/(1-\widetilde{\sigma})}\,\mathrm{d}i}{\int_0^J (1-i)^{\widetilde{\sigma}/(1-\widetilde{\sigma})}\,\mathrm{d}i}\right]^{1-\widetilde{\sigma}}, \tag{58}$$

with $\widetilde{\sigma} \equiv (1-\alpha)(\varepsilon-1) \in (0, 1)$.[35] As long as $\widetilde{\sigma} > 0$ (i.e., $\varepsilon > 1$), the wage gap is decreasing in the degree of protection of IPRs in the South, λ. The reason is that weaker protection of IPRs shifts innovations out of Southern sectors and increases the relative productivity of the North. From the condition $\frac{J}{1-J} = \frac{w^N}{w^S}$, it is easily seen that a weaker

[34] The idea that trade may magnify cross-country inequality was put forward by several economists. Some examples are Stiglitz (1970), Young (1991), Krugman and Venables (1995), Matsuyama (1996), Rodriguez-Clare (1996) and Ventura (1997).

[35] $\widetilde{\sigma} < 1$ guarantees balanced growth across sectors. $\widetilde{\sigma} > 0$, i.e., an elasticity of substitution between goods greater than one, rules out immiserizing growth.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 34
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

protection of IPRs in the South, by raising w^N/w^S, is accompanied by a reduction in sectors $[1-J]$ located in the North, because higher wages make the North less competitive. A second result emerges by calculating the growth rate of the world economy. In particular, Gancia (2003) shows the growth rate of the world economy to fall with λ and approach zero if λ is sufficiently low. The reason is that a lower λ shifts innovation towards Northern sectors and, at the same time, induces the relocation of more sectors to the South, where production costs become lower. This, in turn, implies that a wider range of goods becomes subject to weak IPRs and hence, to a low innovation incentive.

5. Complementarity in innovation

In the models described so far, innovation has no effect on the profitability of existing intermediate firms. This is a knife-edge property which descends from the specification of the final production technology, (3). In general, however, new technologies can substitute or complement existing technologies.

Innovation often causes technological obsolescence of previous technologies. Substitution is emphasized, in an extreme fashion, by Schumpeterian models such as Aghion and Howitt (1992). In such models, innovation provides "better of the same", i.e., more efficient versions of the pre-existing inputs. Growth is led by a process of creative destruction, whereby innovations do not only generate but also destroy rents over time. This has interesting implications for dynamics: the expectation of future innovations discourages current innovation, since today's innovators expect a short life of their rents due to rapid obsolescence. More generally, substitution causes a decline in the value of intermediate firms over time, at a speed depending on the rate of innovation in the economy.

There are instances, however, where new technologies complement rather than substitute old technologies. The market for a particular technology is often small at the moment of its first introduction. This limits the cash-flow of innovating firms, which initially pose little threat to more established technologies. However, the development of new compatible applications expands the market for successful new technologies over time, thereby increasing the profits earned by their producers. Rosenberg (1976) discusses a number of historical examples, where such complementarities were important. A classical example is the steam engine. This had been invented in the early part of the XVIIIth Century, but its diffusion remained very sporadic before a number of complementary innovations (e.g., Watt's separate condenser) made it competitive with the waterwheels, which remained widespread until late in the XIXth Century.

Complementarity in innovation raises interesting issues concerning the enforcement and design of intellectual property rights. For instance, what division of the surplus between basic and secondary innovation maximizes social welfare? This issue is addressed by Scotchmer and Green (1995) who construct a model where innovations are sequentially introduced, and the profits of major innovators can be undermined by subsequent derivative innovations. In this case, the threat of derivative innovations can reduce the

incentive for firms to invest in major improvements in the first place. However, too strong a defense of the property right of basic innovators may reduce the incentive to invest in socially valuable derivative innovations. Scotchmer and Green (1995) show that the optimal policy in fact consists of a combination of finite breath and length of patents. Scotchmer (1996) instead argues that it may be optimal to deny patentability to derivative innovations, instead allowing derivative innovations to be developed under licensing agreements with the owner of the basic technology. More recently, Bessen and Maskin (2002) show that when there is sufficient complementarity between innovations (as in the case of the software industry), weak patent laws may be conducive to more innovation than strong patent laws. The reason is that while the incumbent's current profit is increased by strong patent laws, its prospect of developing future profitable innovation is reduced when patent laws inhibit complementary innovations.

While this literature focuses on the partial equilibrium analysis of single industries, complementarity in innovation also has implications on broader development questions. Multiple equilibria originating from coordination failures [of the type emphasized, in different contexts, by Murphy, Shleifer and Vishny (1989), and Cooper and John (1988)] can arise when there is complementarity in innovation. Countries can get locked-in into an equilibrium with no technology adoption, and temporary big-push policies targeting incentives to adopt new technologies may turn out to be useful.[36] One such example is Ciccone and Matsuyama (1996). In their model, multiple equilibria and poverty traps may arise from the two-way causality between the market size of each intermediate good and their variety: when the availability of intermediates is limited, final good producers are forced to use a labor intensive technology which, in turn, reduces the incentive to introduce new intermediates.

Young (1993) constructs a model where innovation expands the variety of both intermediate and final goods. New intermediate inputs are not used by mature final industries, and their market is initially thin. The expansion of the market for technologies over time creates complementarity in innovation. The details of this model are discussed in the remainder of this section. To this aim, we augment the benchmark model of Section 2 with the endogenous expansion in the variety of final goods.[37] Over time, innovative investments make new intermediate inputs available to final producers, as in Romer's model. However, as a by-product (spillover), they also generate an equivalent expansion of the set of final goods that can be produced. There are no property rights defined on the production of new final goods, and these are produced by competitive firms extraneous to the innovation process.

[36] Interestingly, in models with complementarity in innovation, market economies may be stuck in no-growth traps that are inefficient in the sense that the optimal intertemporal allocation would require positive investment and growth. See, for example, Ciccone and Matsuyama (1999).

[37] Models featuring an expanding variety of final products include Judd (1985), Grossman and Helpman (1989, Chapter 3) and, more recently, Xie (1998) and Funke and Strulik (2000). Here, we follow Young (1993) which, in turn, is close to Judd's paper.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 36
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

A_t will now denote the measure of both final goods and intermediate goods available in the economy at t. Final products are imperfect substitutes in consumption, and the instantaneous utility function is:[38]

$$V_t = \int_0^{A_t} \ln(C_{s,t})\,\mathrm{d}s,$$

with total utility being

$$U = \int_0^{\infty} \mathrm{e}^{-\rho t} V_t\,\mathrm{d}t.$$

This specification implies that consumers' needs grow as new goods become available. Suppose, for instance, that a measure ε of new goods is introduced between time t and $t + j$. At time t, consumers are satisfied with not consuming the varieties yet to be invented. However, at time $t + j$, the same consumers' utility would fall to minus infinity if they did not consume the new goods.

The productive technology for the s'th final good is given by

$$Q_s = \left(\int_0^{\min[s\Theta, A]} x_{j,s}^{\alpha}\,\mathrm{d}j\right)^{1/\alpha}, \tag{59}$$

where $\Theta \geqslant 1$ is a parameter. Note that labor is not used in the final goods production. First, to build the intuition in the simplest case, we maintain that all final goods are produced with the same technology employing all available varieties of intermediate inputs. More formally, we characterize the equilibrium in the limit case where $\Theta \to \infty$, so that $\min[s\Theta, A] = A$. This assumption will be relaxed later.

We use the "labor-for-intermediates" model introduced in Section 2.2, where labor is used for research and intermediate production and the productivity of labor in intermediate production equals A_t. We choose the nominal wage as the numeraire.[39] Hence, the profit of an intermediate producer can be expressed as:

$$\pi = \frac{1-\alpha}{\alpha}\frac{x}{A} = \frac{1-\alpha}{\alpha}\frac{L - L_x}{A}. \tag{60}$$

Note that profits fall over time at the rate at which knowledge grows. In a BG equilibrium, the interest rate is constant and A grows at the constant rate γ. Free entry implies:

$$\int_t^{\infty} \mathrm{e}^{-r\tau}\pi_\tau\,\mathrm{d}\tau = \frac{1-\alpha}{\alpha}\frac{L - \gamma/\delta}{A_t(r+\gamma)} \leqslant \frac{1}{\delta A_t},$$

[38] This is the benchmark specification in Young (1993), where it is then extended to general CES preferences across goods. The logarithmic specification is analytically convenient because of the property that consumers spend an equal income share on all existing goods.

[39] Note that we cannot simply set the price of the final good as the numeraire, as there is an increasing variety of final goods.

where we have used the fact that $\gamma = \delta L_x$. Simplifying terms yields

$$\frac{1-\alpha}{\alpha}\frac{\delta L - \gamma}{r+\gamma} \leqslant 1 \tag{61}$$

The intertemporal optimality condition for consumption also differs from the benchmark model. In particular, if E denotes the total expenditure in final goods, the Euler condition is:[40]

$$\frac{\dot{E}}{E} = r - \rho + \frac{\dot{N}_t}{N_t}.$$

In a BG equilibrium, the total expenditure on consumption goods is constant. Hence,

$$r = \rho - \gamma. \tag{62}$$

This expression can be substituted into (61) to give a unique solution for γ. As long as growth is positive, we have

$$\gamma = \delta L - \frac{\alpha\rho}{1-\alpha},$$

which is almost identical to (15), except for the constant term $\alpha/(1-\alpha)$ being replaced by $1/\alpha$. In the limit case considered so far ($\Theta \to \infty$), the model is isomorphic to Romer (1990).

Next, we move to the general case where $\Theta \geqslant 1$ is finite. This implies that final producers cannot use the entire range of intermediate goods. In particular, an intermediate good indexed by s cannot be used by "mature" final industries having an index j, such that $j < s/\Theta$. This assumption captures the idea that a technology mismatch develops over time between mature final good industries and new technologies.[41]

An important implication of this assumption is that, when introduced, a new technology (intermediate input) is only required by a limited number of final industries. Thus, the monopolist producing a new variety has a small cash-flow. This is especially true when the parameter Θ is small: as $\Theta \to 1$, there is no demand for a new intermediate good at the time of its first appearance. However, the market for technologies expands over time, as new final goods using "modern" technologies appear. This dynamic market size effect generates complementarity in the innovation process. An innovator is eager to see rapid technical progress, as this expands the number of users of the new technology.

Countering this effect, there is a process of "expenditure diversion" that reduces, *ceteris paribus*, the demand for each intermediate good. Over time, technical progress expands the number of intermediate inputs over which final producers spread their

[40] See Young (1993, p. 783) for the derivation of this Euler equation.

[41] In principle, it would seem natural to assume that new final goods do not use very old intermediate goods. Young (1993, p. 780) argues that allowing for this possibility would not change the main results, but would make the analysis more involved.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 38
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

demand. As noted above, the total expenditure on final goods is constant in a BG equilibrium. Since final good firms make zero profits at all times, and intermediates are the only inputs, the total expenditure on the intermediate goods must also be constant. Therefore, an increase in A dilutes the expenditure over a larger mass of intermediate goods, and reduces the profit of each existing intermediate firm. This effect generates substitution rather than complementarity in innovation.

The dynamic market size effect may dominate for young intermediate firms. But as a technology becomes more mature, the expenditure dilution effect takes over. Thus, firms can go through a life-cycle: their profit flow increases over time at an earlier stage and decreases at a later stage.

We denote by $\pi(A_\tau, A_t)$ the profit realized at time τ by an intermediate producer who entered the market in period $t < \tau$. Solving the profit maximization problem for the intermediate monopolist, subject to the demand from final industries, leads to the following expression:

$$\pi(A_\tau, A_t) = \frac{1-\alpha}{\alpha A_\tau}(L - L_x)\left(1 + \frac{\gamma(\tau - t) - 1}{\Theta}\right). \tag{63}$$

It is easily verified that as $\Theta \to \infty$, the solution becomes identical to (60), where nominal profits fall at the same rate as A_t.

Free-entry implies:

$$\int_t^\infty \mathrm{e}^{-r(\tau-t)}\pi(A_\tau, A_t)\,\mathrm{d}\tau \leqslant \frac{1}{\delta A_t}. \tag{64}$$

Solving the integral on the left-hand side, using the Euler condition, $r + \gamma = \rho$, and simplifying terms yields the following equilibrium condition:

$$f_{\mathrm{FE}}(\gamma) = \frac{1-\alpha}{\alpha\rho^2\Theta}(\delta L - \gamma)\big(\gamma + \rho(\Theta - 1)\big) \leqslant 1, \tag{65}$$

where all terms but γ are parameters. For sufficiently large values of Θ, i.e., when the market for new technology is large, $f'_{\mathrm{FE}}(\gamma) < 0$ and the equilibrium is unique. However, if $\Theta < 1 + \delta L/\rho$, $f_{\mathrm{FE}}(\gamma)$ is non-monotonic, and multiple equilibria are possible.

Figure 2 describes the three possible cases. As long as $\rho > \gamma$, which is a necessary and sufficient condition for the interest rate to be positive, $f_{\mathrm{FE}}(\gamma)$ is increasing in Θ. For a range of small Θ's, there is no equilibrium with positive innovation (lower curve). The only equilibrium is a point such as X', featuring zero growth.

For an intermediate range of Θ, we have $f_{\mathrm{FE}}(\gamma) = 1$ in correspondence of two values of γ (intermediate curve). This implies that (for generic economies), there exist three equilibria, where equilibria such as point X feature zero innovation and growth. Firms contemplating entry expect no expansion of the market size for new technologies. Furthermore, such market size is too small to warrant profitable deviations, and the expectation of no innovation is fulfilled in equilibrium. Equilibria such as point Y are

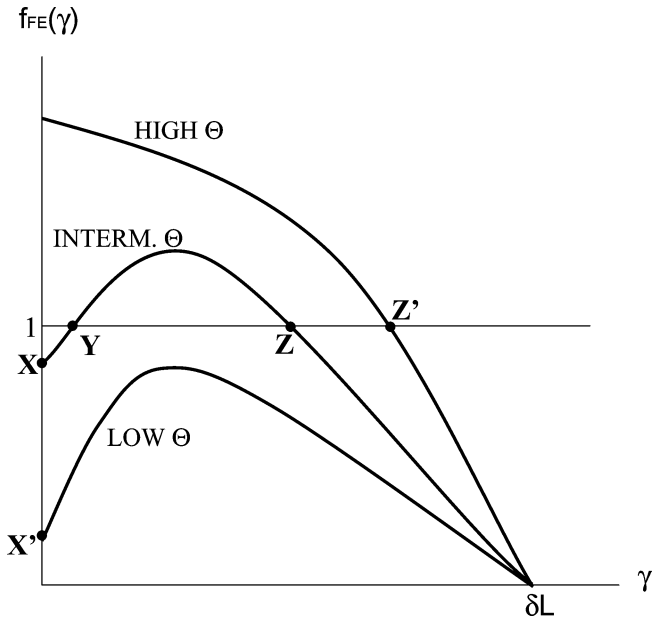

Figure 2.

characterized by local complementarity in innovation: the expectation of higher future innovation and growth increases the value of new firms, stimulating current entry and innovation. In steady-state (BG), this implies a positive slope of the locus $f_{\mathrm{FE}}(\gamma)$.[42] Eventually, for sufficiently high growth rates, the diversion effect dominates. Thus, in an equilibrium like Z, the value of innovating firms depends negatively on the speed of innovation.[43]

Finally, for a range of large Θ's, substitution dominates throughout (upper curve). The initial market for new technologies is sufficiently large to make the expenditure diversion effect dominate the market size effect, even at low growth rates. The equilibrium is unique, and the solution is isomorphic to that of the benchmark model of expanding variety.

[42] As mentioned above, firms go through a life-cycle here. When a new technology is introduced, the profit flow of an innovating firm is small. As time goes by, the expenditure diversion effect becomes relatively more important. The value of a firm upon entry is the PDV of its profit stream. Local complementarity occurs if, for a particular γ, profits increase at a sufficiently steep rate in the earlier part of the firm's life-cycle.

[43] If the expectational stability of the equilibria in the sense of Evans and Honkapohja (2001) is tested, equilibria such as point Y are not found to be E-stable, while equilibria such as X and Z are stable. See the discussion in Section 7.2.

6. Financial development

A natural way in which the expansion of the variety of industries can generate complementarities in the growth process is through its effects on financial markets. Acemoglu and Zilibotti (1997) construct a model where the introduction of new securities, associated with the development of new intermediate industries, improves the diversification opportunities available to investors. Investors react by supplying more funds, which fosters further industrial and financial development, generating a feedback.[44] The model offers a theory of development. At early stages of development, a limited number of intermediate industries are active (due to technological nonconvexities), which limits the degree of risk-spreading that the economy can achieve. To avoid highly risky investments, agents choose inferior but safer technologies. The inability to diversify idiosyncratic risks introduces a large amount of uncertainty in the growth process. In equilibrium, development proceeds in stages. First, there is a period of "primitive accumulation" with a highly variable output, followed by take-off and financial deepening and finally, steady growth. Multiple equilibria and poverty traps are possible in a generalized version of the model.

The theory can explain why the growth process is both slow and highly volatile at early stages of development, and stabilizes as an economy grows richer. Evidence of this pattern can be found in the accounts of pre-industrial growth given by a number of historians, such as Braudel (1979), North and Thomas (1973) and DeVries (1990). For instance, in cities such as Florence, Genoa and Amsterdam, prolonged periods of prosperity and growth have come to an end after episodes of financial crises. Interestingly, these large set-backs were not followed (as a neoclassical growth model would instead predict) by a fast recovery but, rather, by long periods of stagnation. Similar phenomena are observed in the contemporary world. Acemoglu and Zilibotti (1997) document robust evidence of increases in GDP per capita being associated with large decreases in the volatility of the growth process. It has also been documented that higher volatility in GDP is associated with lower growth [Ramey and Ramey (1995)].

We here describe a simplified version of the model. Time is discrete. The economy is populated by overlapping generations of two-period lived households. The population is constant, and each cohort has a unit mass ($L = 1$). There is uncertainty in the economy, which we represent by a continuum of equally likely states $s \in [0, 1]$. Agents are assumed to consume only in the second period of their lives.[45] Their preferences are parameterized by the following (expected) utility function, inducing unit relative risk

[44] This paper is part of a recent literature on the two-way relationship between financial development and growth. This includes Bencivenga and Smith (1991), Greenwood and Jovanovic (1990) and Zilibotti (1994). In none of these other papers does financial development take the form of an expansion in the "variety" of assets.

[45] This is for simplicity. Acemoglu and Zilibotti (1997) assume that agents consume in both periods. It is also possible to study the case of a general CRRA utility function.

aversion:

$$E_t U(c_{t+1}) = \int_0^1 \log\bigl(c_{t+1}^s\bigr)\mathrm{d}s. \tag{66}$$

The production side of the economy consists of a unique final good sector, and a continuum of intermediate industries. The final good sector uses intermediate inputs and labor to produce final output. Output in state s is given by the following production function:

$$Y_{s,t} = (x_{s,t-1} + x_{\Phi,s,t-1})^{\alpha} L^{1-\alpha}. \tag{67}$$

The term in brackets is "capital", and it is either produced by a continuum of intermediate industries, each producing some state-contingent amount of output (x_s), or a separate sector using a "safe technology" (x_Φ). The measure of the industries with a state-contingent production, A_t, is determined in equilibrium, and A_t can expand over time, like in Romer's model, but it can also fall. Moreover, $A_t \in [0, 1]$, i.e., the set of inputs is bounded.

In their youth, agents work in the final sector and earn a competitive wage, $w_{s,t} = (1-\alpha)Y_{s,t}$. At the end of this period, they take portfolio decisions: they can place their savings in a set of risky securities ($\{F_i\}_{i\in[0,A_t]}$), consisting of state-contingent claims to the output of the intermediate industries or, in a safe asset (ϕ), consisting of claims to the output of the safe technology. After the investment decisions, the uncertainty unravels, the security yields its return and the amount of capital brought forward to the next period is determined. The capital is then sold to final sector firms and fully depreciates after use. Old agents consume their capital income and die.

Intermediate industries use final output for production. An intermediate industry $i \in [0, A_t]$ is assumed to produce a positive output only if state $s = i$ occurs. In all other states of nature, the firm is not productive. Moreover, the ith industry is only productive if it uses a minimum amount of final output, M_i, where

$$M_i = \max\left\{0, \frac{D}{(1-x)}(i-x)\right\},$$

with $x \in (0, 1)$. This implies that some intermediate industries require a certain minimum size, M_i, before being productive. In particular, industries $i \leqslant x$ have no minimum size requirement, and for the rest of the industries, the minimum size requirement increases linearly with the index i.

To summarize, the intermediate technology is described by the following production function:

$$x_{i,s} = \begin{cases} RF_i & \text{if } i = s \text{ and } F_i \geqslant M_i, \\ 0 & \text{otherwise.} \end{cases}$$

Since there are no start-up costs, all markets are competitive. Thus, firms retain no profits, and the product is entirely distributed to the holders of the securities. The jth security entitles its owner to a claim to R units of capital in state j (as long as the minimum size constraint is satisfied, which is always the case in equilibrium), and otherwise

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 42
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

to nothing. Savings invested in the "safe technology" give the return

$$x_{\Phi,s} = r\phi, \quad \forall s \in [0, 1],$$

where $r < R$. Thus, one unit of the safe asset is a claim to r units of capital in all states of nature.

Since the risky securities yield symmetric returns, and there is safety in numbers, it is optimal for risk-averse agents to hold a portfolio containing all available securities in equal amounts. More formally, the optimal portfolio decision features $F_i = F$, for all $i \in [0, A_t]$. We refer to this portfolio consisting of an equal amount of all traded risky securities as a *balanced portfolio*.

If $A_t = 1$, a balanced portfolio of risky securities bears no risk, and first-order dominates the safe investment. However, due to the presence of technological non-convexities (minimum size requirements), not all industries are in general activated. When $A_t < 1$, the inferior technology is safer, and there is a trade-off between risk and productivity. In this case, the optimal investment decision of the representative saver can be written as:

$$\max_{\phi_t, F_t} A_t \log\left[\rho_{G,t+1}(RF_t + r\phi_t)\right] + (1 - A_t)\log\left[\rho_{B,t+1}(r\phi_t)\right], \tag{68}$$

subject to

$$\phi_t + A_t F_t \leqslant w_t. \tag{69}$$

$\rho_{\tilde{s},t+1}$ denotes the rate of return of capital, which is taken as parametric by agents, and does not affect the solution of the program.[46] Agents also take A_t, i.e., the set of securities offered, as parametric.

Simple maximization yields:

$$\phi_t^* = \frac{(1 - A_t)R}{R - rA_t} w_t, \tag{70}$$

$$F_{i,t}^* = \begin{cases} F(A_t) \equiv \frac{R-r}{R-rA_t} w_t, & \forall i \leqslant A_t, \\ 0 & \forall i > A_t. \end{cases} \tag{71}$$

Figure 3 expresses the demand for each risky asset, $F(A_t)$ (FF schedule), as a function of the measure of intermediate industries which are active. The FF schedule is

[46] In equilibrium:

$$\rho_{G,t+1} = \alpha(RF_t + r\phi_t)^{\alpha-1}$$

and

$$\rho_{B,t+1} = \alpha(r\phi_t)^{\alpha-1}.$$

$\rho_{G,t+1}$ applies in the "good state", i.e., when the realized state is $i \leqslant A_t$, while $\rho_{B,t+1}$ is the marginal product of capital in the "bad" state, when the realized state is $i > A_t$ and no risky investment pays off.

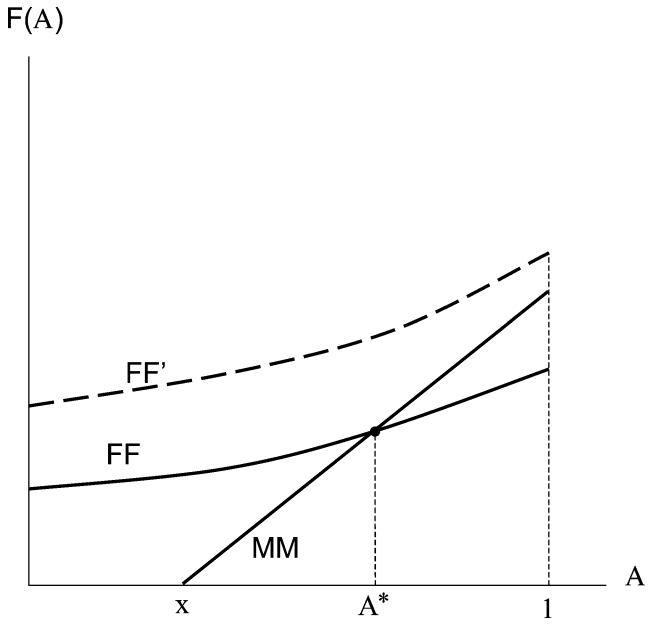

Figure 3.

upward sloping, implying that there is complementarity in the demand for risky assets: the demand for *each asset* grows with the variety of intermediate industries.

Complementarity arises because the more active are intermediate industries, the better is risk-diversification. Thus, as A_t increases, savers shift their investments away of the safe asset into high-productivity risky projects (the "stock market"). Such complementarity hinges on risk aversion being sufficiently high.[47] In general, similar to Young (1993), an increase in A creates two effects. On the one hand, investments in the stock market become safer because of better diversification opportunities, which induces complementarity. On the other hand, investments are spread over a larger number of assets, inducing substitution. With sufficiently high risk aversion, including the unit CRRA specification upon which we focus, the first effect dominates.

The equilibrium measure of active industries, A_t^*, is determined (as long as $A^* < 1$) by the following condition:

$$F\left(A_t^*\right) = M_{A_t^*}.$$

[47] Suppose agents were risk averse, but only moderately so. Suppose, in particular, that they were so little risk-averse that they would decide not to hold any safe asset in their portfolio. Then, an expansion in the set of risky securities would induce agents to spread their savings (whose total amount is predetermined) over a larger number of assets. In this case, assets would be substitutes rather than complements.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 44
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

In Figure 3, the equilibrium is given by the intersection of schedules FF and MM, where the latter represents the distribution of minimum size requirements across industries. Intuitively, A_t^* is the largest number of industries for which the technological non-convexity can be overcome, subject to the demand of securities being given by (71).[48]

Growth increases wage income and the stock of savings over time. In equilibrium, this induces an expansion of the intermediate industries, A_t^*. This can once more be seen in Figure 3: growth creates an upward shift of the FF schedule, causing the equilibrium to move to the left. Therefore, growth triggers financial development. In particular, when the stock of savings becomes sufficiently large, the financial market is sufficiently thick to allow all industries to be active. In the case described by the dashed curve, FF′, the economy is sufficiently rich to afford $A_t^* = 1$. The inferior safe technology is then abandoned. Financial development, speeds up growth by channelling investments towards the more productive technology.

The stochastic equilibrium dynamics of GDP can be explicitly derived:

$$Y_{t+1} = \begin{cases} F_B(Y_t) = \left((1-\alpha)\dfrac{r(1-A_t^*)}{R - rA_t^*} RY_t\right)^{\alpha} & \text{prob. } 1 - A_t^*, \\ F_G(Y_t) = \left((1-\alpha)RY_t\right)^{\alpha} & \text{prob. } A_t^*, \end{cases} \tag{72}$$

where $A_t^* = A(Y_{t-1}) \leqslant 1$ is the equilibrium measure of intermediate industries, such that $A' \geqslant 0$.[49] The first line corresponds to the case of a "bad realization" at time t, such that $s \in (A_t^*, 1]$. In this case, none of the active intermediate industries turned out to pay-off at time t, and capital at time $t+1$ is only given by the return of the safe technology. The second line corresponds to the case of a "good realization" at t, such that $s \in [0, A_t^*]$. In this case, the risky investment paid off at time t, and capital and output are relatively large at time $t+1$. Note that the probability of a good realization increases with the level of development, since $A'(Y_{t-1}) \geqslant 0$ (with strict inequality as long as $A^* < 1$).

Figure 4 describes the dynamics. The two schedules represent output at time $t+1$ as a function of output at time t conditional on good news ($F_G(Y_t)$) and bad news ($F_B(Y_t)$), respectively. At low levels of capital ($Y \leqslant Y_L$), the marginal product of capital is very high, which guarantees that growth is positive, even conditional on bad news. In the intermediate range where $Y \in [Y_L, Y_M]$, growth only occurs if news is good, since $F_B(Y_t) < Y_t < F_G(Y_t)$. The threshold Y_L is not a steady-state; however, it is a point around which the economy will spend some time. When the initial output is below Y_L, the economy necessarily grows towards it. When it is above Y_L, output falls back whenever bad news occurs. So, in this region, the economy is still exposed to undiversified risks, and experiences fluctuations and set-backs. Finally, for $Y \geqslant Y_M$, there are

[48] Acemoglu and Zilibotti (1997) show the laissez-faire portfolio investment to be inefficient. Efficiency would require more funds to be directed to industries with large non-convexities, i.e., agents not holding a balanced portfolio. The inefficiency is robust to the introduction of a rich set of financial institutions.

[49] Acemoglu and Zilibotti (1997) derive a closed-form solution for A_t^* that we do not report here.

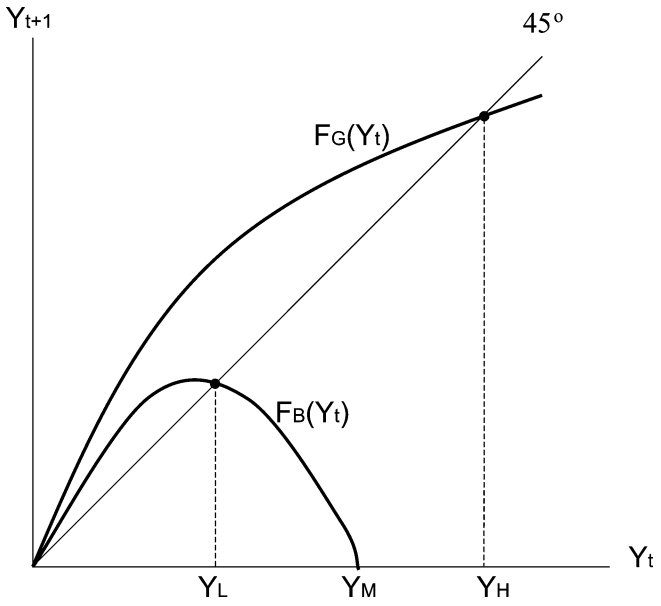

Figure 4.

enough savings in the economy to overcome all technological non-convexities. When the economy enters this region, all idiosyncratic risks are removed, and the economy deterministically converges to Y_H.[50]

Note that it may appear as if, in the initial stage, countries striving to take off do not grow at a sustained rate during long periods. The demand for insurance takes the form of investments in low-productivity technologies, and poor economies tend to have low total factor productivity and slow growth.

In the case described by Figure 4, the economies "almost surely" converge to a unique steady-state. Different specifications of the model can, however, lead to less optimistic predictions. With higher risk aversion, for instance, traps can emerge, as in the example described in Figure 5. An economy starting with a GDP in the region $[0, Y_{MM})$ would never attain the high steady-state Y_H, and would instead perpetually wander in the trapping region $[0, Y_{LL}]$. Conversely, an economy starting above Y_M would certainly converge to the high steady-state, Y_H. Finally, the long-run fate of an economy starting in the region $[Y_{MM}, Y_M]$ would be determined by luck: an initial set of positive

[50] That the economy converges "almost surely" to a steady-state where all risk is diversified away only occurs under parameter restrictions ensuring that $Y^{SS} > Y^1$. Although the model presented here is neoclassical and features zero growth in the long run, it is possible to augment it with spillover of the learning-by-doing type, as in Romer (1986), and make it generate self-sustained growth.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 46
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

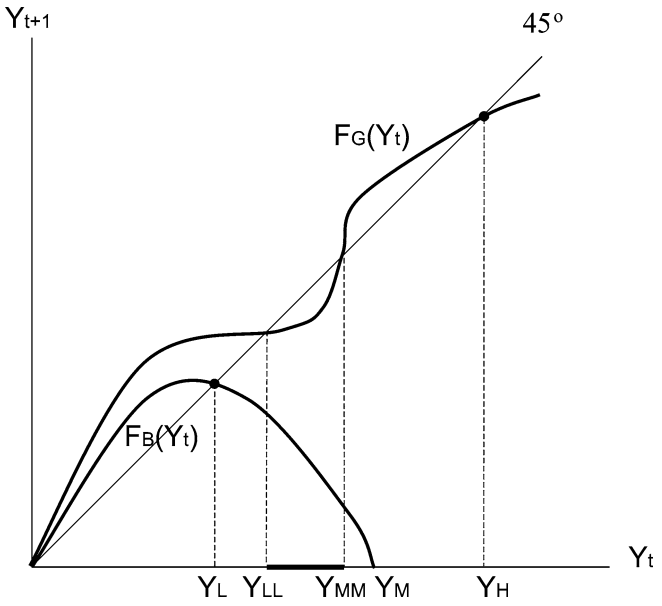

Figure 5.

draws would bring this economy into the basin of attraction of the good equilibrium. A single set-back, however, would forever jeopardize its future development.[51]

The model can be extended in a number of directions. A two-country extension shows that international capital flows may lead to divergence, rather than convergence between economies. This result is due to the interplay between two forces: first, decreasing returns to capital would tend to direct foreign investments towards poorer countries, as in standard neoclassical models. Second, the desire to achieve better diversification pushes investments towards thicker markets. The latter force tends to prevail at some earlier stages of the development process. So, poor countries suffer an outflow of capital, which spills over to lower income and wages for the next generation, thereby slowing down the growth process. The analysis of capital flows, financial integration and financial crises in the context of similar models is further developed in recent papers by Martin and Rey (2000, 2001 and 2002). A different extension of the model is pursued by Cetorelli (2002) who shows that the theory can account for phenomena such as "club convergence", economic miracles, growth disasters and reversals of fortune.

[51] Consider, for instance, the limit case where agents are infinitely risk-averse. In this case, agents refuse to invest in the stock-market as long as this entails some uncertainty, i.e., as long as there are not enough savings in the economy to open all industries. Thus, an economy starting above Y_M converges to Y_H, while an economy starting below Y_M converges to Y_L, and is stuck in a poverty trap.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 47
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

Recent empirical studies analyze implications of the theory about the patterns of risk-sharing and diversification. Kalemli-Ozcan et al. (2001, 2003) document that regions with access to better insurance through capital markets can afford a higher degree of specialization. Using cross-country data at different levels of disaggregation, Imbs and Wacziarg (2003) find robust evidence of sectoral diversification increasing in GDP. However, their findings also suggest that, at a relatively late stage of the development process, the pattern reverts and countries once more start to specialize. This tendency for advanced countries to become more specialized as they grow can be explained by factors emphasized by the "new economic geography" literature [Krugman (1991)], from which the theory described in this section abstracts, such as agglomeration externalities and falling transportation costs.

7. Endogenous fluctuations

In the models reviewed so far, the economies converge in the long run to balanced-growth equilibria characterized by linear dynamics. Growth models with expanding variety and technological complementarities can, however, generate richer long-run dynamics, including limit cycles. In this section, we review two such models.

In the former, based on Matsuyama (1999), cycles in innovation and growth arise from the deterministic dynamics of two-sector models with an endogenous market structure. The theory can explain some empirical observations about low-frequency cycles, and their interplay with the growth process. In particular, it predicts that waves of rapid growth mainly driven by "factor accumulation" are followed by spells of innovation-driven growth. Interestingly, these latter periods are characterized by lower investments and slower growth. This is consistent with the findings of Young (1995) that the growth performance of East-Asian countries was mainly due to physical and human capital accumulation, while there was little total factor productivity (TFP) growth. According to Matsuyama's theory, the observation of low TFP growth should not lead to the pessimistic conclusions that growth is destined to die-off. Rather, rapid factor accumulation could set the stage for a new phase of growth characterized by more innovative activity. The predictions of this theory bear similarities to those of models with General Purpose Technologies (GPT), e.g., Helpman (1998) and Aghion and Howitt (1998, Chapter 8). For instance, they predict that a period of rapid transformation and intense innovation (e.g., the 1970's) can be associated with productivity slowdowns. However, GPT-based theories rely on the exogenous arrival of new "fundamental" innovations generating downstream complementarities. In contrast, cycles in Matsuyama (1999) are entirely endogenous.[52]

[52] Cyclical equilibria can also emerge in Schumpeterian models, due to the dynamic relationship between innovative investments and creative distruction. An example is the seminal contribution of Aghion and Howitt (1992). More recently, Francois and Lloyd-Ellis (2003) construct a Schumpeterian model where entrepreneurs

In the latter model, based on Evans et al. (1998), cycles in innovation and growth are instead driven by expectational indeterminacy. The mechanism in this paper is different, as cycles hinge on multiple equilibria and sunspots. Some main predictions are also different: contrary to Matsuyama (1999), the equilibrium features a positive comovement of investments and innovation. The main contribution of the paper is to show that cycles can be learned by unsophisticated agents holding adaptive expectations. Thus, the predictive power of the theory does not rest on the assumption that agents' expectations are rational and that agents can compute complicated dynamic equilibria.

7.1. Deterministic cycles

Matsuyama (1999) presents a model of expanding variety where an economy can perpetually oscillate in equilibrium between periods of innovation and periods of no innovation. Cycles arise from the deterministic periodic oscillations of two state variables (physical capital and knowledge). Unlike the model that will be discussed in the next section, the equilibrium is determinate and there are no multiple steady-states.

More specifically, the source of the oscillatory dynamics is the market structure of the intermediate goods market. Monopoly power is assumed to be eroded after one period. The loss of monopoly power is due to the activity of a competitive fringe which can copy the technology with a one-period lag. In every period, new industries are monopolized, while mature industries are competitive. The profits of innovators depend on the market structure of the intermediate sector. The larger is the share of competitive industries in the intermediate sector, the lower is the profit of innovative firms, since competitive industries sell larger quantities and charge lower prices. In periods of high innovation, a large share of industries are monopolized, which increases the profitability of innovation, thereby generating a feedback. In these times, investment in physical capital is low due to the crowding out from the research activity. Conversely, times of low innovation are times of high competition, since old monopolies lose power and there are few new firms. Thus, the rents accruing to innovative firms are small. In these periods, savings are invested in physical capital, and while innovation is low, the high accumulation of physical capital creates the conditions for future innovation to be profitable.

Time is discrete. The production of final goods is as in (3), where we set $L_y = L = 1$. Intermediate goods are produced using physical capital, with one unit of capital producing one unit of intermediate product, x. Innovation also requires capital, with a requirement of μ units of capital per innovation. Monopoly power is assumed to last one period only. Therefore, in period t, all intermediate inputs with an index $z \in [0, A_{t-1}]$

can decide to time the implementation of innovations [similarly to Shleifer (1986)]. In this model, agents time the implementation so as to profit from buoyant demand and maximize the duration of their leadership. This mechanism leads to a clustering of innovations and endogenous cycles. While this model can explain some features of fluctuations at business cycle frequencies, Matsuyama's model is better suited for the analysis of long waves.

are competitively priced, whereas all those with an index $z \in [A_{t-1}, A_t]$ are monopolistically priced. The prices of competitive and non-competitive varieties are $p_t^c = r_t$ and $p_t^m = r_t/\alpha$, respectively, where the superscript $h \in \{c, m\}$ denotes the market structure. The relative demand for two varieties x_t^c and x_t^m must be

$$\frac{x_t^c}{x_t^m} = \left(\frac{p_t^c}{p_t^m}\right)^{-1/(1-\alpha)} = \alpha^{-1/(1-\alpha)}. \tag{73}$$

The one-period monopoly profit is $\pi_t = p_t^m x_t^m - r_t x_t^m = x_t^m r_t(1-\alpha)/\alpha$. Since patents expire after one period, π_t is also the value of a monopolistic firm at the beginning of period t. Therefore, free-entry implies:

$$\frac{1-\alpha}{\alpha} x_t^m \leqslant \mu, \tag{74}$$

with equality holding when innovation is positive.

Capital is assumed to fully depreciate after each period. The stock of capital can be allocated to research or intermediate production, subject to the following resource constraint:

$$K_{t-1} = A_{t-1} x_t^c + (A_t - A_{t-1})\big(x_t^m + \mu\big),$$

implying

$$A_t - A_{t-1} = A_{t-1} \max\left\{0, \frac{(1-\alpha)K_{t-1}}{\mu A_{t-1}} - \alpha^{-\alpha/(1-\alpha)}\right\}, \tag{75}$$

where we have used (73) and (74) to eliminate x_t^c and x_t^m. As shown by (75), there exists a threshold to the capital-knowledge ratio that triggers positive innovation. In particular, innovation occurs if $K_{t-1}/A_{t-1} \geqslant \alpha^{-\alpha/(1-\alpha)}(1-\alpha)^{-1}\mu \equiv k_L$. If $K_{t-1}/A_{t-1} < k_L$, then, all capital is allocated to intermediate production, all intermediate industries are competitive and final production is given by the standard neoclassical Cobb–Douglas technology:

$$Y_t = A_{t-1}^{1-\alpha} K_{t-1}^{\alpha}. \tag{76}$$

In this case, an economy is said to be in a "Solow regime", with decreasing returns to capital. Since there is no investment in innovation, A is constant and the dynamics has a neoclassical character. In contrast, if $K_{t-1}/A_{t-1} \geqslant k_L$, then a positive share of the capital stock is allocated to innovation and final production equals:

$$Y_t = A_{t-1}\left[\alpha^{-1/(1-\alpha)}\frac{\alpha}{1-\alpha}\mu\right]^{\alpha} + (A_t - A_{t-1})\left[\frac{\alpha}{1-\alpha}\mu\right]^{\alpha}.$$

Using (75) and simplifying terms, this equation can be written as

$$Y_t = DK_{t-1}, \tag{77}$$

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 50
aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

where $D \equiv (k_L)^{-(1-\alpha)}$. In this case, the returns to capital are constant, like in endogenous growth models, and the economy is said to be in a "Romer regime".[53]

For tractability, we assume a constant savings rate, implying that $K_t = sY_t$.[54] Define $k_t = k_L^{-1} \cdot K_t/A_t$ as the (adjusted) capital-to-knowledge ratio. Then, standard algebra using (75), (76) and (77) establishes the following equilibrium law of motion:

$$k_t = f(k_{t-1}) = \begin{cases} sDk_{t-1}^{\alpha} & \text{if } k_{t-1} < 1, \\ \dfrac{sDk_{t-1}}{1 + \alpha^{-\alpha/(1-\alpha)}(k_{t-1} - 1)} & \text{if } k_{t-1} \geqslant 1. \end{cases} \tag{78}$$

The mapping $k_t = f(k_{t-1})$ has two fixed points. The first is $k = 0$, the second can either be $k = (sD)^{1/(1-\alpha)} \equiv \hat{k}_1$, if $sD \leqslant 1$, or $k = 1 + \alpha^{\alpha/(1-\alpha)}(sD - 1) \equiv \hat{k}_2$, if $sD \geqslant 1$. In the former case, the fixed point lies in the range of the " Solow regime", while in the latter, it lies in the range of the "Romer regime".[55]

Three cases are possible:

1. If $sD \leqslant 1$, the economy converges monotonically to $k = \hat{k}_1$. In this case, the economy never leaves the Solow regime, and there are no innovative investments. The neoclassical dynamics converge to a stagnating level of GDP per capita.
2. If $sD > \max\{1, \alpha^{-\alpha/(1-\alpha)} - 1\}$, then capital first monotonically accumulates in the Solow regime, with no innovation. The economy overcomes the development threshold, $k = 1$ in finite time, and the process of innovation starts thereafter. Eventually, the economy converges to the BG equilibrium $\hat{k}_2$ in an oscillatory fashion. In the BG, capital and knowledge are accumulated at the same positive rate, and income per capita grows over time.
3. If $sD \in (1, \alpha^{-\alpha/(1-\alpha)} - 1]$, the economy does not converge asymptotically to any BG equilibrium, and perpetually oscillates in the long run between the Solow- and the Romer-regime. This case is described by Figure 6. On the one hand, there is no steady-state in the Solow-regime, which rules out that the economy can be trapped in a stable equilibrium with no innovation. On the other hand, the steady-state $\hat{k}_2$ is locally unstable and cannot be an attractor of the dynamics in itself. Instead, there exists a period-2 cycle, such that one of the periodic points lies in the Solow regime (k_S), while the other lies in the Romer regime (k_R).[56] The period-2

[53] Zilibotti (1995) finds similar dichotomic equilibrium dynamics in a one-sector model with learning-by-doing spillovers. Economies may converge to a stationary steady-state with "Solow dynamics" or embark on a virtuous path of "Romer dynamics" with self-sustained growth. Cycles cannot arise in equilibrium, while multiple self-fulfilling prophecies exist.

[54] Matsuyama (2001) relaxes this restriction and characterizes equilibrium by a second-order difference equation. Some of the main results, like the existence of a period-2 cycle, survive this generalization.

[55] It is easily verified that $f'(0) > 1$, $f'(\hat{k}_1) = \alpha \in (0, 1)$, and $f'(\hat{k}_2) = -(\alpha^{-\alpha/(1-\alpha)} - 1)/(sD)$, where $f'(\hat{k}_2) \in (-1, 0)$ if $sD > \alpha^{-\alpha/(1-\alpha)} - 1$ and $f'(\hat{k}_2) < -1$ if $sD \in (1, \alpha^{-\alpha/(1-\alpha)} - 1)$. These properties are used to establish the results discussed below.

[56] A period-2 cycle exists if, given a mapping $x_{t+1} = f(x_t)$, $f(f(\cdot))$ has fixed points other than the fixed point of $f(\cdot)$. A sufficient condition is that (i) $f(\cdot)$ is continuous, (ii) there exists a closed, finite interval, I, such that $f(I) \subset I$ and (iii) $f(\cdot)$ has an unstable fixed point. (i) and (iii) are clearly satisfied; (iii) is established in the next footnote for the interval I_{abs}.

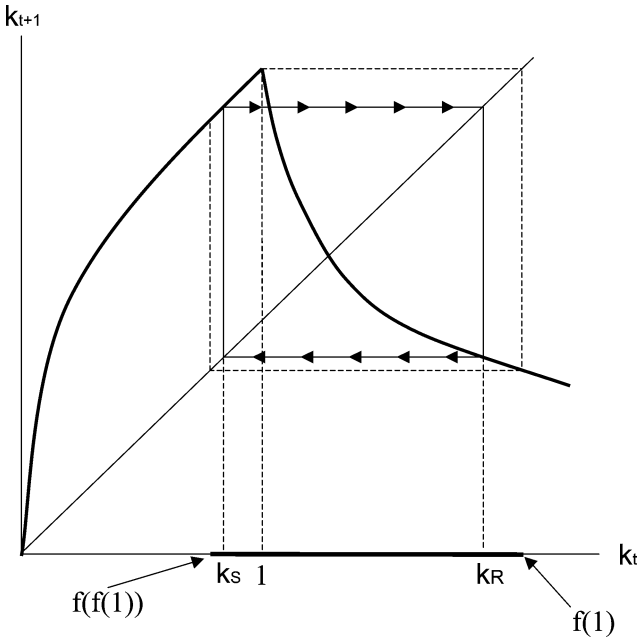

Figure 6.

cycle is not necessarily stable, and if it is unstable, the economy can converge to cycles of higher periodicity or feature chaos. A general property of the dynamics is that the economy necessarily enters the region $I_{\text{abs}} = [f(f(1)), f(1)]$ (shaded in Figure 6), and never escapes from it.[57]

In the case described by Figure 6, the model predicts that a poor economy would first grow through capital accumulation, and eventually enter the absorbing region I_{abs}. Then, there is an alternance of periods of innovation and periods of no innovation. GDP per capita grows on average, but at a non-steady rate, and there are cycles in the innovative activity. Interestingly, output and capital grow more quickly in periods of no innovation (Solow regime) than in periods of high innovation (Romer regime). Another implication is that if an economy grows quickly, but has a low TFP growth, this does not imply that growth will die-off. Rather, fast capital accumulation can create the conditions for future waves of innovation, and vice versa.

[57] To prove this result, two properties of the mapping need to be shown [see Azariadis (1993)]. First, $f(\cdot)$ must be unimodal, i.e., (i) $f(\cdot)$ must be continuous; (ii) $f(\cdot)$ must be increasing in some left-hand neighborhood of 1 and decreasing in some right-hand neighborhood of 1. Second, it must be the case that $f(f(1)) < 1$. That f is unimodal is immediate by inspection. After some algebra, it can also be proved that $f(f(1)) < 1$.

7.2. Learning and sunspots

Evans et al. (1998) propose the following generalization of the technology (3) for final production:

$$Y = L^{1-\alpha}\left[\int_0^A x_j^{\zeta}\,\mathrm{d}j\right]^{\phi}, \tag{79}$$

where $\zeta\phi = \alpha$. This specification encompasses the technology (3), in the case of $\phi = 1$, and allows intermediate inputs to be complements or substitutes. They focus on the case of complementarity ($\phi > 1$), and show that in this case, the equilibrium can feature multiple steady states, expectational indeterminacy and sunspots. They emphasize the possibility of equilibria where the economy can switch stochastically between periods of high and low growth.

Time is discrete, and intermediate firms rent physical capital from consumers to produce intermediate goods. One unit of capital is required per unit of intermediate good produced. Capital is assumed not to depreciate. The resource constraint of this economy is:

$$Y_t = C_t + K_t \cdot \chi\left(\frac{K_{t+1} - K_t}{K_t}\right),$$

where $\chi(.)$ is a function such that $\chi' > 0$, $\chi'' \geqslant 0$. If there are no costs of adjustment, then, $\chi(x) = x$. If $\chi'' > 0$, there are convex costs of adjustments.

By proceeding as in Section 2, we can characterize the equilibrium of the intermediate industry.[58] The profit of intermediate producers, in particular, turns out to be:

$$\pi = \Omega A^{\xi}(r\ p_K)^{\alpha/(\alpha-1)}, \tag{80}$$

where $\xi \equiv (\phi - 1)/(1 - \alpha)$ and $\Omega \equiv (1 - \zeta)\zeta^{(1+\alpha)/(1-\alpha)}\phi^{1/(1-\alpha)}L$ are two positive constant. We denote by p_K the relative price of capital, expressed in terms of the consumption good numeraire. If there are no adjustment costs, then, $p_K = 1$ while, in general, $p_K = \chi'(.)$. Note that profits increase with A, as long as $\phi > 1$.

Two technical assumptions ensure that the model has BG properties. First, the design of a new good requires A_t^{ξ} units of output. Second, innovative investments incurred at t only give the first profit in period $t + 1$. Free entry then implies:

$$\sum_{s=0}^{\infty} \frac{\pi_{t+s}}{(1+r)^{s+1}} \leqslant p_{K,t} A_t^{\xi}. \tag{81}$$

In a BG equilibrium, consumption and capital grow at the common rate, γ. When $\phi > 1$, this rate exceeds the growth rate of technical knowledge, $\gamma_A \equiv A_{t+1}/A_t$. In particular,

[58] Note that firms rent, and do not own, their capital stock. Adjustment costs are borne at the aggregate level, not at the level of each decision unit. Therefore, it continues to be legitimate to write the profit maximization problem for intermediate producers as a sequence of static maximization problems.

aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

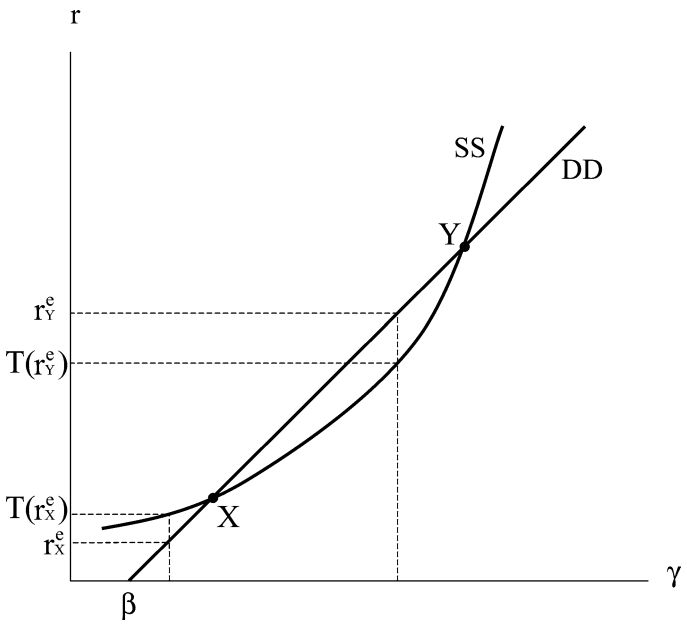

Figure 7.

it can be shown that $\gamma = \gamma_A^{1+\xi}$. Substituting (80) into (81), and solving, yields:

$$\gamma = \left(1 + r - \Omega(p_K)^{-1/(1-\alpha)} r^{-\alpha/(1-\alpha)}\right)^{(\phi-\alpha)/(\phi-1)}, \tag{82}$$

which is the analogue of Equation (13) in the benchmark model.

The model is closed by the (discrete time) Euler equation for consumption:

$$\gamma = \left[\beta(1+r)\right]^{1/\sigma}, \tag{83}$$

where β is the discount factor. Equations (82) and (83) fully characterize the equilibrium.

Figure 7 provides a geometric representation for the case of logarithmic preferences and zero adjustment cost ($p_K = 1$). The SS curve is linear, with the slope β^{-1}. The DD curve is also positively sloped. In the case represented, the two curves cross twice, thereby implying that there are two BG equilibria featuring positive innovation and growth (points X and Y).

Standard stability analysis is inappropriate for dynamic models with perfect foresight. It is possible, however, to analyze the expectational stability (E-stability) of the BG equilibria. E-stability is tested as follows. Set an arbitrary initial level for the expected interest rate r^e, and let agents choose their optimal savings plan according to (83). This implies a notional growth rate of consumption and capital, as determined by the SS curve. Next, firms take action. At the notional growth rate, there is a unique interest

rate consistent with the no-arbitrage condition implied by (82), as shown by the DD curve. The composition of these two operations define a mapping from an expected to a realized interest rate:

$$r_t = T\left(r_t^e\right). \tag{84}$$

A perfect foresight BG equilibrium is a fixed point to the mapping, $r = T(r)$. After consumers have observed the realized interest rate, they update their expectations about next period's interest rate using adaptive learning, i.e.:

$$r_{t+1}^e = r_t^e + \psi_t\left(r_t - r_t^e\right), \tag{85}$$

where $\xi_t = \psi/t$. The sequence $\{\psi_t\}$ determines how sensitive the expectations are to past errors, and it is known as the gain sequence. Substituting (84) into (85) defines a dynamic system, whose stability can be analyzed by linearization techniques. In general, expectational stability occurs whenever $T'(r) < 1$, where r is the steady-state interest rate.[59]

An inspection of Figure 7 shows the equilibrium X to be E-stable, while the equilibrium Y is not. Let r_X^e and r_Y^e denote two expected interest rates which are below the equilibria X and Y, respectively. Then, in the case of the equilibrium X, $T(r_X^e) > r_X^e$, and the adaptive adjustment moves the economy towards the equilibrium, inducing convergence. In contrast, in the case of the equilibrium Y, $T(r_Y^e) < r_Y^e$, and the adaptive adjustment moves the economy away from the equilibrium, thereby inducing divergence.

In the case analyzed so far, only one BG is E-stable, and E-stability can be used as a selection criteria. It is possible, however, that multiple E-stable BG equilibria exist in the general model with convex adjustment costs.

Figure 8 describes a case with four steady-states, two of them being E-stable. Equilibria such as X and Z are E-stable (note that $T(r_X^e) > r_X^e$ and $T(r_Z^e) > r_Z^e$). Moreover, in the neighborhood of these equilibria, there exist stationary sunspot equilibria. In one such equilibrium, the economy switches stochastically between two points in the neighborhood of X and Z, respectively, with switching probabilities given by a time-invariant transition probability matrix. The fact that both X and Z are E-stable is sufficient for any stationary sunspot equilibrium in their neighborhood to be E-stable in itself.[60]

We conclude that a modified version of the model of growth with expanding variety can generate endogenous fluctuations. The key assumptions are complementarity between capital goods and convex adjustment costs to capital. The former assumption guarantees the existence of multiple BG equilibria, around which sunspot equilibria can be constructed. The latter assumption guarantees that the sunspot equilibrium is expectationally stable, i.e., it can be learned through adaptive expectations.

[59] See Evans and Honkapohja (2001) for a state-of-art analysis of expectational indeterminacy.

[60] For general discussion of sunspot equilibria, see Azariadis and Guesnerie (1986), Grandmont (1986) and Azariadis (1993).

aid: 1003 pii: S1574-0684(05)01003-8 docsubty: REV

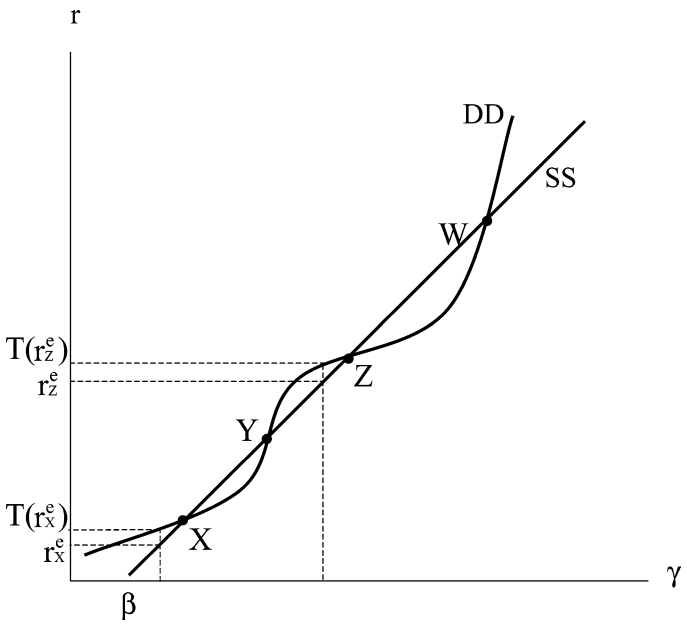

Figure 8.

The model assumes increasing returns to physical and knowledge capital. The reduced form representation of the final good technology is:

$$Y = A^{\phi-\alpha} K_F^{\alpha},$$

where $K_F = Ax$ denotes aggregate capital used in intermediate production. Empirical estimates suggest that $\alpha \leqslant 0.4$, which implies that the lower bound to the output elasticity of knowledge to generate multiplicity is $\phi - \alpha = 0.6$. Evans et al. (1998) provide a numerical example of an E-stable sunspot equilibrium, assuming $\phi = 4$. Recent estimations from Porter and Stern (2000) using patent numbers report $\phi - \alpha$ to be around 0.1, however. Therefore, the model seems to require somehow extreme parameters to generate endogenous fluctuations.

Augmenting the model with other accumulated assets, such as human capital, may help obtain the results under realistic parameter configurations. This is complicated by the presence of scale effects in the expanding variety model. However, in a recent paper, Dalgaard and Kreiner (2001) formulate a version of the model with human capital accumulation and without scale effects. In their model, both human capital (embodied knowledge) and technical change (disembodied knowledge) are used to produce final goods. The scale effect is avoided by congestion effects in the accumulation of human capital. An interesting feature of this model is that, unlike other recent models without scale effects, positive long-run growth in income per capita does not hinge on positive population growth.

aghion v.2005/07/15 Prn:25/07/2005; 9:04 F:aghion1003.tex; VTEX/Ramune p. 56

8. Conclusions

In this chapter, we have surveyed recent contributions to growth theory inspired by Romer's (1990) expanding variety model. Key features of the theory are increasing returns through the introduction of new products that do not displace existing ones and the existence of monopoly rents providing an incentive for firms to undertake costly innovative investments. This model has had a tremendous impact on the literature, and we could only provide a partial review of its applications. Then, we decided to focus on a few major themes: trade and biased technical change, with their effects on growth and inequality, financial development, complementarity in the process of innovation and endogenous fluctuations.

While only being a limited selection, these applications give a sense of the success of the model in providing a tractable framework for analyzing a wide array of issues in economic growth. In fact, we have shown how the model can incorporate a number of general equilibrium effects that are fundamental in the analysis of trade, wage inequality, cross-country productivity differences and other topics. Further, while the original model has linear AK-dynamics, we have surveyed recent generalizations featuring richer dynamics, which can potentially be applied to the study of financial development and innovations waves. Given its longevity, flexibility and simplicity, we are convinced that the growth model with horizontal innovation will continue to be useful in future research.

From Stagnation to Growth: Unified Growth Theory*

Oded Galor†

August 11, 2004

Abstract

This chapter examines the process of development from an epoch of Malthusian stagnation to a state of sustained economic growth. The analysis focuses on recently advanced unified growth theories that capture the intricate evolution of income per capita, technology, and population over the course of human history. Deciphering the underlying forces that triggered the transition from stagnation to growth and the associated phenomenon of the great divergence in income per capita across countries has been widely viewed as one of the most significant challenges facing researchers in the field of growth and development. The inconsistency of non-unified growth models with the main characteristics of the process of development across most of human history induced growth theorists to advance an alternative theory that captures in a single unified framework the epoch of Malthusian stagnation, the modern era of sustained economic growth, and the recent transition between these distinct regimes. Unified growth theory reveals the underlying micro foundations that are consistent with the growth process over the entire history of the human species, enhancing the confidence in the viability of the theory, its predictions and policy implications for the growth process of less developed economies.

Keywords: Growth, Technological Progress, Demographic Transition, Income Distribution, Human Capital, Evolution, Natural Selection, Malthusian Stagnation, Class Structure.

Stephen W. Hawking - A Brief History of Time.

1 Introduction

This chapter examines the recent advance of a *unified growth theory* that is designed to capture the process of development over the entire course of human history.

The inconsistency of exogenous and endogenous neoclassical growth models with some of the most fundamental features of process of development, has led recently to a search for a unified theory that would unveil the underlying micro-foundations of the growth process in its entirety, capturing the epoch of Malthusian stagnation that characterized most of human history, the contemporary era of modern economic growth, and the underlying driving forces that triggered the recent transition between these regimes and the associated phenomenon of the Great Divergence in income per capita across countries.

The evolution of economies over the major portion of human history was marked by Malthusian Stagnation. Technological progress and population growth were miniscule by modern standards and the average growth rate of income per capita in various regions of the world was even slower due to the offsetting effect of population growth on the expansion of resources per capita. In the past two centuries, in contrast, the pace of technological progress increased significantly in association with the process of industrialization. Various regions of the world economy departed from the Malthusian trap and experienced initially a considerable rise in the growth rates of income per capita and population. Unlike episodes of technological progress in the pre-Industrial Revolution era that failed to generate sustained economic growth, the increasing role of human capital in the production process in the second phase of the Industrial Revolution ultimately prompted a demographic transition, liberating the gains in productivity from the counterbalancing effects of population growth. The decline in population growth and the associated enhancement in technological progress and human capital formation paved the way for the emergence of the modern state of sustained economic growth.

The fundamental factors that generated the remarkable escape from the Malthusian trap have been shrouded in mystery until recently and their significance for the understanding of the contemporary growth process have been under-explored.

- What accounts for the epoch of stagnation that characterized most of human history?
- What is the origin of the sudden spurt in growth rates of output per capita and population?
- Why had episodes of technological progress in the pre-industrialization era failed to generate sustained economic growth?
- What was the source of the dramatic reversal in the positive relationship between income per capita and population that existed throughout most of human history?
- What triggered the demographic transition?
- Would the transition to a state of sustained economic growth have been feasible without the demographic transition?
- What are the underlying behavioral and technological structures that can simultaneously account for these distinct phases of development and what are their implications for the contemporary growth process of developed and underdeveloped countries?

The perplexing phenomenon of the Great Divergence in income per capita across regions of the world in the past two centuries presents an additional mystery about the growth process.

- What accounts for the sudden take-off from stagnation to growth in some countries in the world and the persistent stagnation in others?
- Why has the positive link between income per capita and population growth reversed its course in some economies but not in others?
- Why have the differences in per capita incomes across countries increased so markedly in the last two centuries?
- Has the transition to a state of sustained economic growth in advanced economies adversely affected the process of development in less-developed economies?

Deciphering the fundamental determinants of the transition from stagnation to growth and the great divergence has been widely viewed as one of the most significant research challenges facing researchers in the field of growth and development.

The transitions from a Malthusian epoch to a state of sustained economic growth and the related phenomenon of the Great Divergence, as depicted in Figure 2.1, have significantly shaped the contemporary world economy.[1] Nevertheless, the distinct qualitative aspects of the growth process during most of human history were virtually ignored in the shaping of neoclassical growth models, resulting in a growth theory that is only consistent with a small fragment of human history.

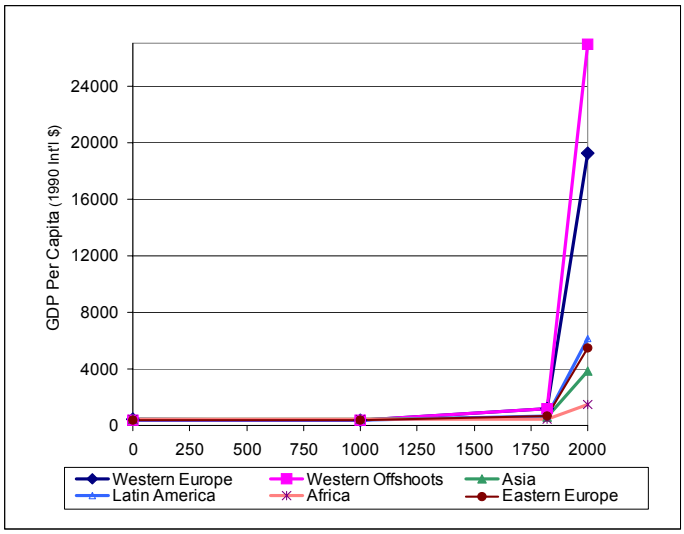

Figure 2.1. The Evolution of Regional Income per Capita over the Years 1 - 2001

Sources: Maddison (2003)[2]

[1]The ratio of GDP per capita between the richest region and the poorest region in the world was only 1.1:1 in the year 1000, a 2:1 in the year 1500 and 3:1 in the year 1820. In the course of the 'Great Divergence' the ratio of GDP per capita between the richest region (Western offshoots) and the poorest region (Africa) has widened considerably from a modest 3:1 ratio in 1820, to a 5:1 ratio in 1870, a 9:1 ratio in 1913, a 15:1 in 1950, and a huge 18:1 ratio in 2001.

[2]According to Maddison's classification, "Western Offshoots" consists of United States, Canada, Australia and New Zealand.

The preoccupation of growth theory with the empirical regularities that have characterized the growth process of developed economies in the past century and of less developed economies in the last few decades, has become harder to justify from a scientific viewpoint in light of the existence of vast evidence about qualitatively different empirical regularities that characterized the growth process over most of human existence. Is there a scientific justification for the use of selective observations, only about the contemporary growth process, in formulating theory about the current growth process? Could we be confident about the predictions of a theory that is not based on micro foundations that are consistent with the main elements of the entire growth process? As argued by Copernicus, *"it is as thuoght an artist were to gather the hands, feet, head and other members for his images from diverse models, each part perfectly drawn, buut not related to a single body, and since they in no way match each other, the result would be monster rather than man"*.[3] The evolution of theories in older scientific disciplines suggests that theories that are founded on the basis of a subset of the existing observations and their driving forces, may be attractive in the short run, but non-robust and ultimately non-durable in the long run.[4] The attempts to develop unified theories in physics have been based on the conviction that all physical phenomena should ultimately be explainable by some underlying unity.[5] Similarly, the entire process of development and its basic causes ought to be captured by a unified growth theory.

In recent years, it has been increasingly recognized that the understanding of the contemporary growth process would be fragile and incomplete unless growth theory could be based on proper micro-foundations that reflect the qualitative aspects of the growth process and their central driving forces. Moreover, it has become apparent that a comprehensive understanding of the hurdles faced by less developed economies in reaching a state of sustained economic growth would be futile unless the factors that prompted the transition of the currently developed economies into a state of sustained economic growth could be identified and their implications would be modified to account for the differences in the growth structure of less developed economies in an interdependent world.

The transition from stagnation to growth and the associated phenomenon of the great divergence have been the subject of an intensive research in the growth literature in recent years.[6] The inconsistency of exogenous and endogenous neoclassical growth models with the process of development along most of human history, induced growth theorists to search for an alternative theory that could capture in a single unified framework the contemporary era of sustained economic growth, the epoch of Malthusian stagnation that had characterized most of human history, and the driving forces that brought about the recent transition between these distinct regimes.

Imposing the constraint that a single theory should account for the entire intricate process of development and its prime causes in the last thousands of years is a discipline that would enhance the viability of growth theory. A unified theory of economic growth reveals the fundamental micro-foundations that are consistent with the process of economic development over the entire course of human history, rather that with the last century only, boosting the confidence in growth theory, its predictions and policy implications. Moreover, it improves the understanding of the underlying factors

[3] Quoted in Kuhn (1957).

[4] For instance, Classical Thermodynamics that lacked micro-foundations was ultimately superseded by the micro-based Statistical Mechanics.

[5] *Unified Field Theory*, for instance, proposes to unify by a set of general laws the four distinct forces that are known to control all the observed interactions in matter: electromagnetism, gravitation, the weak force, and the strong force. The term unified field theory was coined by Einstein, whose research on relativity had led him to the hypothesis that it should be possible to find a unifying theory for the electromagnetic and gravitational forces.

[6] The transition from Malthusian stagnation to sustained economic growth was explored by Galor and Weil (1999, 2000), Lucas (2002), Galor and Moav (2002), Hansen and Prescott (2002), Jones (2001), Stokey (2002), as well as others, and the association of Great Divergence with the transition was analyzed by Galor and Mountford (2003).

that led to the transition from stagnation to growth of the currently developed countries, shedding light on the growth process of the less developed economies.

2 Historical Evidence

This section examines the historical evidence about the evolution of the relationship between income per capita, population growth, technological change and human capital formation along three distinct regimes that have characterized the process of economic development: The Malthusian Epoch, The Post-Malthusian Regime, and the Sustained Growth Regime.

During the Malthusian Epoch that characterized most of human history, technological progress and population growth were insignificant by modern standards. The level of income per capita had a positive effect on population and the average growth rate of income per capita in the long-run, as depicted in Figure 2.2, was negligible due to the slow pace of technological progress as well as the counterbalancing effect of population growth on the expansion of resources per capita. During the Post Malthusian Regime, the pace of technological progress markedly increased in association with the process of industrialization, triggering a take-off from the Malthusian trap. The growth rate of income per capita increased significantly, as depicted in Figures 2.1 and 2.2, but the positive Malthusian effect of income per capita on population growth was still maintained, generating a sizeable increase in population growth that offset some of the potential gains in income per capita. The acceleration in the rate of technological progress in the second phase of the Industrial Revolution, and its interaction with human capital formation ultimately prompted the demographic transition. The rise in aggregate income was not counterbalanced by population growth, enabling technological progress to bring about sustained increase in income per capita.

2.1 The Malthusian Epoch

For thousand of years, humans were subjected to persistent struggle for existence. Survival, argued Malthus (1798), necessitated a *"perpetual struggle for room and food."* Resources generated by technological progress and land expansion were channeled primarily towards an increase in the size of the population, with a minor long-run effect on income per capita. Thus, as reflected in the viewpoint of a prominent observer of the period, *"the most decisive mark of the prosperity of any country is the increase in the number of its inhabitants"* (Smith 1776).

The evolution of population and output per capita across most of human history was consistent with the Malthusian paradigm. The positive effect of the standard of living on population growth along with diminishing labor productivity kept income per capita in the proximity of a subsistence level.[7] Periods marked by the absence of changes in the level of technology or in the availability of land, were characterized by a stable population size as well as a constant income per capita, whereas periods characterized by improvements in the technological environment or in the availability of land generated temporary gains in income per capita, leading ultimately to a larger but not richer population. Technologically superior countries had eventually denser populations but their standard of living did not reflect the degree of their technological advancement.

[7]This subsistence level of consumption may be well above the minimal physiological requirements that are necessary in order to sustain an active human being.

2.1.1 Income per capita

During the Malthusian epoch the average growth rate of output per capita was negligible and the standard of living did not differ greatly across countries. As depicted in Figure 2.2 the average level of income per capita during the first millennium fluctuated around $450 per year, and the average growth rate of output per capita in the world was nearly zero.[8] This state of Malthusian stagnation persisted until the end of the 18th century. The average level of income per capita in the world economy remained below $670 per year in the years 1000-1820 and the average growth rate of the world income per capita was miniscule, creeping at a rate of about 0.05% per year (Maddison 2001).

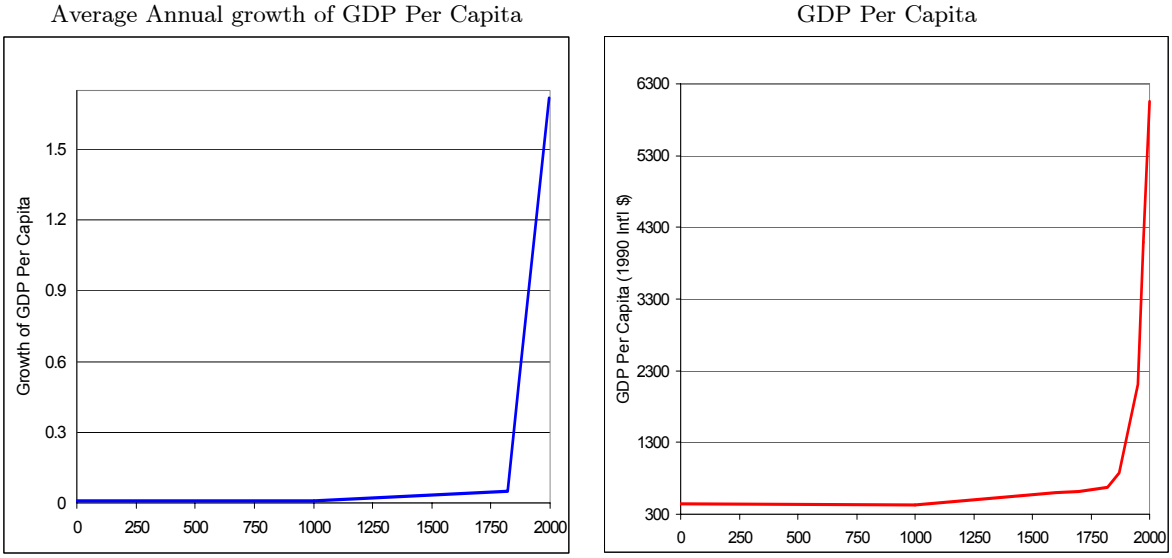

Figure 2.2. The Evolution of the World Income Per Capita over the Years 1-2001
Source: Maddison (2001, 2003)

This pattern of stagnation was observed across all regions of the world. As depicted in Figure 2.1, the average level of income per capita in Western and Eastern Europe, the Western Offshoots, Asia, Africa, and Latin America was in the range of $400-450 per year in the first millennium and the average growth rates in each of these regions was nearly zero. This state of stagnation persisted until the end of the 18th century across all regions and the average level of income per capita in the years 1000-1820 ranged from $418 per year in Africa, $581 in Asia, $692 in Latin America, and $683 in Eastern Europe, to $1202 in the Western Offshoots, and $1204 in Western Europe. Furthermore, the average growth rate of output per capita over this period ranged from 0% in the impoverish region of Africa to a sluggish rate of 0.14% in the prosperous region of Western Europe.

Despite the stability in the evolution of the world income per capita in the Malthusian epoch, from a perspective of a millennium, wages and income per capita had fluctuated significantly within regions deviating from their sluggish long-run trend over decades and sometimes over few centuries. In particular, as depicted in Figure 2.3, real GDP per capita in England fluctuated drastically over most of the past millennium. It declined during the 13th century, and increased sharply during the 14th and the 15th century in response to the catastrophic population decline in the aftermath of the Black Death. This two-century rise in per capita real income stimulated population growth and brought about a decline in income per capita in the 16th century back to its level in the first half of the 14th century.

[8]Maddison's estimates of income per capita are evaluated in terms of 1990 international dollars.

Real income per capita increased once again in the 17th century and remained stable during the 18th century, prior to its rise during the take-off from the Malthusian epoch in the 19th century.

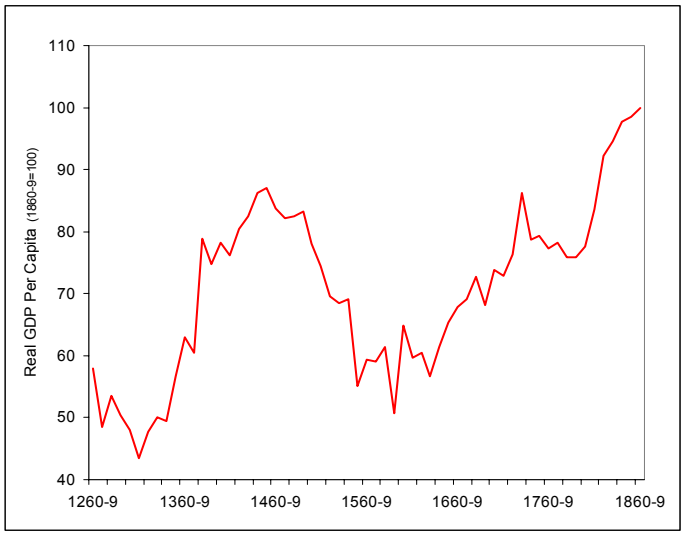

Figure 2.3. Fluctuations in Real GDP Per Capita: England, 1260-1870

2.1.2 Income and Population Growth

Population Growth and Income level

Population growth over this Malthusian era followed the Malthusian pattern as well. As depicted in Figures 2.4 and 2.5, the slow pace of resource expansion in the first millennium was reflected in a modest increase in the population of the world from 231 million people in the year 1 to 268 million in the year 1000; a miniscule average growth rate of 0.02% per year.[9] The more rapid (but still very slow) expansion of resources in the period 1000-1500, permitted the world population to increase by 63% over this period, from 268 million in the year 1000 to 438 million in the year 1500; a slow 0.1% average growth rate per year. Resource expansion over the period 1500-1820 had a more significant impact on the world population, that grew 138% from 438 million in the year 1500 to 1041 million in the year 1820; an average pace of 0.27% per year.[10] This positive effect of income per capita on the size of the population was maintained in the last two centuries as well, as world population reached a remarkable level of nearly 6 billion people.

[9]Since output per capita grew at an average rate of 0% per year over the period 0-1000, the pace of resource expansion was approximately equal to the pace of population growth, namely, 0.02% per year.

[10]Since output per capita in the world grew at an average rate of 0.05% per year in the time period 1000-1500 as well as in the period 1500-1820, the pace of resource expansion was approximately equal to the sum of the pace of population growth and the growth of output per capita. Namely, 0.15% per year in the period, 1000-1500 and 0.32% per year in the period 1500-1820.

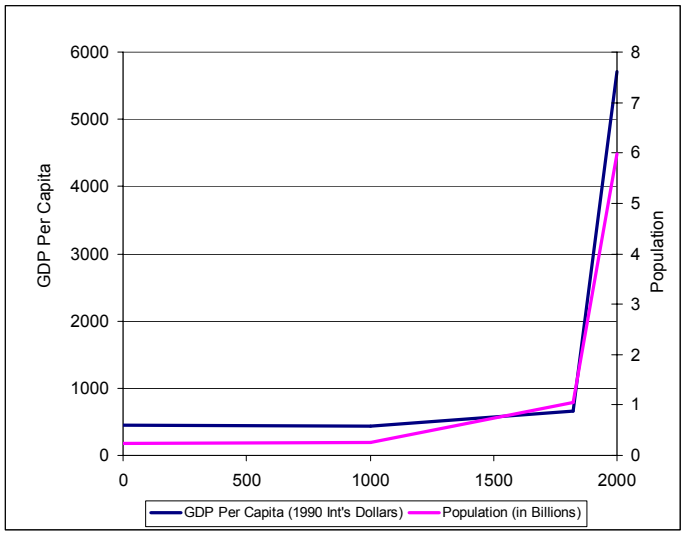

Figure 2.4. The Evolution of World Population and Income Per Capita over the Years 1 - 2000
Source: Maddison (2001)

Moreover, the gradual increase in income per capita during the Malthusian epoch was associated with a monotonic increase in the average rate of growth of world population, as depicted in Figure 2.5.[11]

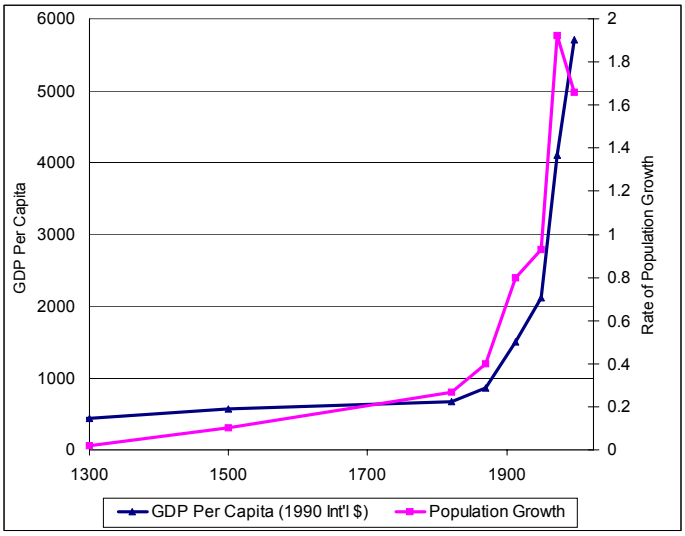

Figure 2.5. Population Growth and Income Per Capita in the World Economy
Source: Maddison (2001)

Fluctuations in Income and Population

Fluctuations in population and wages exhibited the Malthusian pattern as well. Episodes of technological progress, land expansion, favorable climatic conditions, or major epidemics (that resulted in a decline of the adult population), brought about a temporary increase in real wages and income per

[11]Lee (1997) reports positive income elasticity of fertility and negative income elasticity of mortality from studies examining a wide range of pre-industrial countries. Similarly, Wrigley and Schofield (1981) find a strong positive correlation between real wages and marriage rates in England over the period 1551-1801. Clark (2003) finds that in England, at the beginning of the 17th century, the number of surviving offspring is higher among households with higher level of income and literacy rates, suggesting that the positive effect of income on fertility is present cross-sectionally, as well.

capita. In particular, as depicted in Figure 2.6, the catastrophic decline in the population of England during the Black Death (1348-1349), from about 6 millions to about 3.5 millions people, increased significantly the land-labor ratio, tripling real wages in the subsequent 150 years. Ultimately, however, most of this increase in real resources per capita was channelled towards increased fertility rates, increasing the size of the population, and bringing the real wage rate in the 1560s back to the proximity of its pre-plague level.[12]

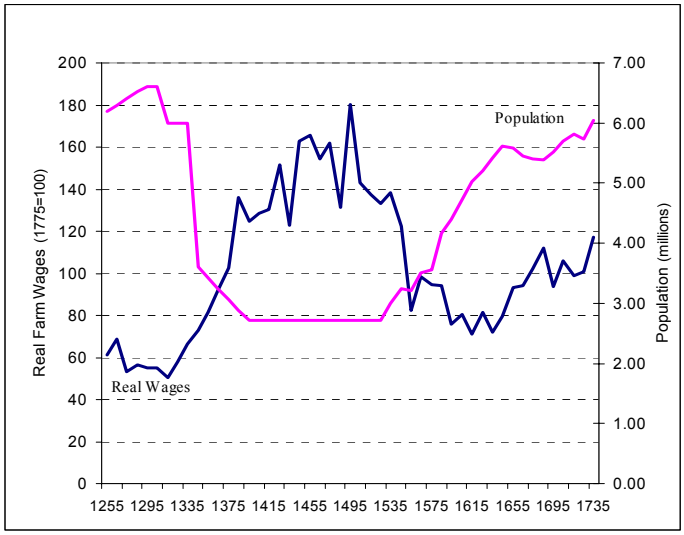

Figure 2.6. Population and Real Wages: England, 1250-1750
Source: Clark (2001, 2002)

Population Density

Variations in population density across countries during the Malthusian epoch reflected primarily cross country differences in technologies and land productivity. Due to the positive adjustment of population to an increase in income per capita, differences in technologies or in land productivity across countries resulted in variations in population density rather than in the standard of living.[13] For instance, China's technological advancement in the period 1500-1820 permitted its share of world population to increase from 23.5% to 36.6%, while its income per capita in the beginning and the end of this time interval remained constant at roughly $600 per year.[14]

This pattern of increased population density persisted until the demographic transition, namely, as long as the positive relationship between income per capita and population growth was maintained. In the period 1600-1870, United Kingdom's technological advancement relative to the rest of the world more than doubled its share of world population from 1.1% to 2.5%. Similarly, in the period 1820-1870, the land abundant, technologically advanced, economy of the US. experienced a 220% increased in its share of world population from 1% to 3.2%.[15]

[12]Reliable population data is not available for the period 1405-1525 and figure 2.6 is depicted under the assumption maintained by Clark (2001) that population was rather stable over this period.

[13]Consistent with the Malthusian paradigm, China's sophisticated agricultural technologies, for example, allowed high per-acre yields, but failed to raise the standard of living above subsistence. Similarly, the introduction of the potato in Ireland in the middle of the 17th century generated a large increase in population over two centuries without a significant improvements in the standard of living. Furthermore, the destruction of potatoes by fungus in the middle of the 19th century, generated a massive decline in population due to the Great Famine and mass migration [Mokyr 1985].

[14]The Chinese population more than tripled over this period, increasing from 103 million in the year 1500 to 381 million in the year 1820.

[15]The population of the United Kingdom nearly quadrupled over the period 1700-1870, increasing from 8.6 million in

Mortality and Fertility

The Malthusian demographic regime was characterized by fluctuations in fertility rates, reflecting variability in income per capita as well as changes in mortality rates. Periods of rising income per capita permitted a raise the number of surviving offspring, inducing an increase in fertility rates along with a reduction in mortality rates, due to improved nourishment, and health infrastructure. Periods of rising mortality rates (e.g., the black death) induced an increase in fertility rates so as to maintain the number of surviving offspring that can be supported by existing resources.

The relationship between fertility and mortality during the Malthusian epoch was complex. Demographic patterns in England during the 14th and 15th centuries, as depicted in Figure 2.6, suggest that an (exogenous) increase in mortality rates was associated with a significant rise in fertility rates. However, the period 1540-1820 in England, vividly demonstrates a negative relationship between mortality rates and fertility rates. As depicted in Figure 2.7, an increase in mortality rates over the period 1560-1650 was associated with a decline in fertility rates, whereas a decline in mortality rates in the time period 1680-1820 was associated with increasing fertility rates.

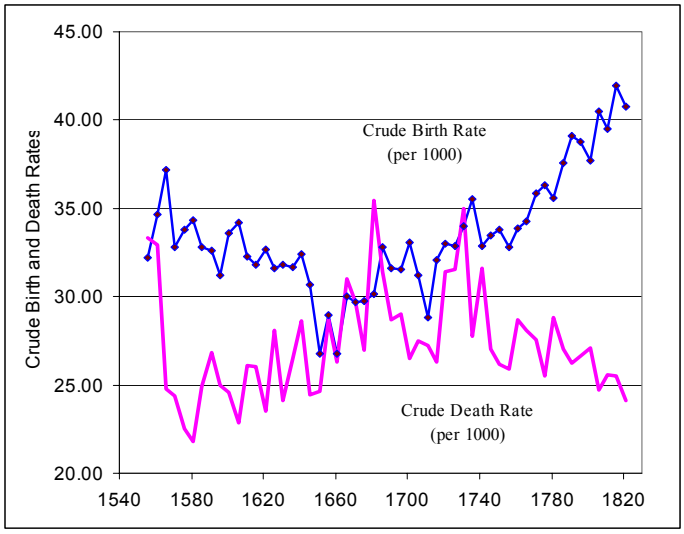

Figure 2.7. Fertility and Mortality: England 1540-1870
Source: Wrigley and Schofield (1981)

Life Expectancy

Life expectancy at birth fluctuated in the Malthusian epoch, ranging from 24 in Egypt in the time period 33 - 258 AD, to 42 in England at the end 16th century. In the initial process of European urbanization, the percentage of urban population increased six-fold from about 3% in 1520 to nearly 18% in 1750 (de Vries (1984) and Bairoch (1988)). This rapid increase in population density, without significant changes in health infrastructure, generated a rise in mortality rates and a decline in life expectancy. As depicted in Figures 2.7 and 2.8, over the period 1580-1740 mortality rates increased by 50% from 0.022 to 0.032, and life expectancy at birth fell from 42 to 28 (Wrigley and Schofield, 1981). A decline in mortality along with a rise in life expectancy began in the 1740s. Life expectancy at birth rose from 28 to 41 in England and from 25 to 40 in France over the period 1740-1830 (Livi-Bacci 1997).

the year 1700 to 31.4 million in the year 1870. Similarly, the population of the United states increased 40-fold, from 1.0 million in the year 1700 to 40.2 million in the year 1870, due to a significant labor migration, as well as high fertility rates.

2.2 The Post-Malthusian Regime

The pace of technological progress markedly increased along with the process of industrialization, instigating a take-off from the Malthusian epoch.[16] The growth rate of output per capita increased significantly, as depicted in Figures 2.1-2.3, but the positive Malthusian effect of income per capita on population growth was still maintained, generating a sizeable increase in population growth, as depicted in Figure 2.4 and 2.5, offsetting some of the gains in income.

The take-off of developed regions from the Malthusian regime was associated with the Industrial Revolution and occurred in the beginning of the 19th century, whereas the take-off of less developed regions occurred towards the beginning of the 20th century and was delayed in some countries well into the 20th century. The Post-Malthusian Regime ended with the decline in population growth in Western Europe and the Western Offshoots towards the end of the 19th century and in less developed regions in the second half of the 20th century.

2.2.1 Income Per Capita

During the Post-Malthusian Regime the average growth rate of output per capita increased significantly and the standard of living started to differ considerably across countries. As depicted in Figure 2.2, the average growth rate of output per capita in the world increased from 0.05% per year in the time period 1500-1820 to 0.53% per year in 1820-1870, and 1.3% per year in 1870-1913. The timing of the take-off and its magnitude differed across regions. As depicted in Figure 2.9, the take-off from the Malthusian Epoch and the transition to the Post-Malthusian Regime occurred in Western Europe, the Western Offshoots, and Eastern Europe at the beginning of the 19th century, whereas in Latin America, Asia (excluding China) and Africa it took place at the end of the 19th century.

[16] Ironically, it was only shortly before the time that Malthus wrote, that some regions in the world began to emerge from the trap that he described.

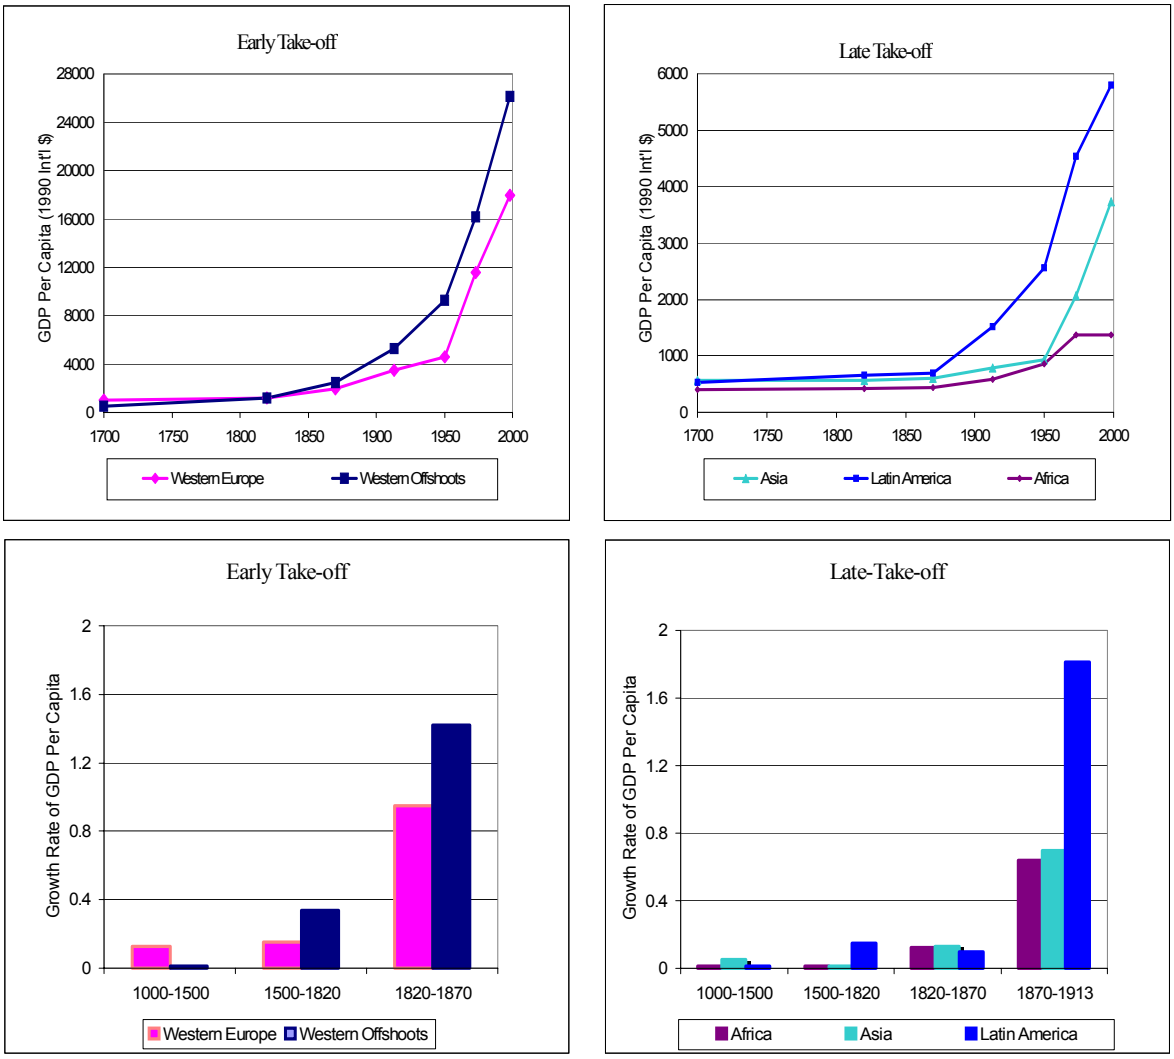

Figure 2.9. The Differential Timing of the Take-off Across Regions.
Source: Maddison (2001)

Among the regions that took off at the beginning of the 19th century, the growth rate of income per capita in Western Europe increased from 0.15% per year in the years 1500-1820 to 0.95% per year in the time period 1820-1870, and the growth rates of income per capita of the Western Offshoots increased over this period from 0.34% per year to 1.42% per year. In contrast, the take-off in Eastern Europe was more modest, and its growth rate increased from 0.1% per year in the period 1500-1820 to 0.63% per year in the time interval 1820-1870. Among the regions that took-off towards the end of the 19th century, the average growth rate of income per capita in Latin America jumped from a sluggish rate of 0.11% per year in the years 1820-1870 to a considerable 1.81% per year in the time period 1870-1913, whereas Africa's growth rates increased more modestly from 0.12% per year in the years 1820-1870 to 0.64% per year in time interval 1870-1913 and 1.02% per year in the period 1913-1950. Asia's (excluding Japan, China and India) take-off was modest as well, increasing from 0.13% per year in the years 1820-1870 to 0.64% per year in the 1870-1913 period.[17]

[17]Japan's average growth rate increased from 0.19% per year in the period 1820-1870, to 1.48% per year in the period

The level of income per capita in the various regions of the world, as depicted in Figure 2.1, ranged in the year 1870 from $444 in Africa, $543 in Asia, $698 in Latin America, and $871 in Eastern Europe, to $1974 in Western Europe and $2431 in the Western Offshoots. Thus, the differential timing of the take-off from the Malthusian epoch, increased the gap between the richest regions of Western Europe and the Western Offshoots to the impoverished region of Africa from about 3:1 in 1820 to approximately 5:1 in 1870.

The acceleration in technological progress and the accumulation of physical capital and to a lesser extent human capital, generated a gradual rise in real wages in the urban sector and (partly due to labor mobility) in the rural sector as well. As depicted in Figure 2.10, the take-off from the Malthusian epoch in the aftermath of the Industrial Revolution was associated in England with a modest rise in real wages in the first decades of the 19th century and a very significant rise in real wages after 1870.[18] A very significant rise in real wages was experienced by France, as well, after 1860.

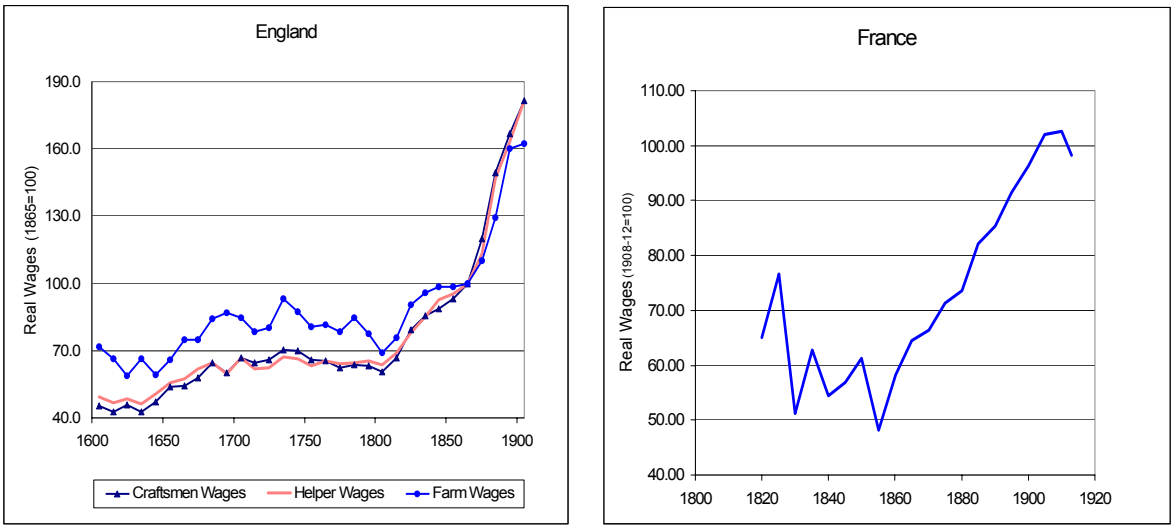

Figure 2.10. Real Wages in England and France During the take-off from the Malthusian Epoch

2.2.2 Income and Population Growth

The rapid increase in income per capita in the Post-Malthusian Regime was channeled partly towards an increase in the size of the population. During this Regime, the Malthusian mechanism linking higher income to higher population growth continued to function, but the effect of higher population on diluting resources per capita, and thus lowering income per capita, was counteracted by the acceleration in technological progress and capital accumulation, allowing income per capita to rise despite the offsetting effects of population growth.

The Western European take-off along with that of the Western Offshoots brought about a sharp increase in population growth in these regions and consequently a modest rise in population growth in the world as a whole. The subsequent take-off of less developed regions and the associated increase in their population growth brought about a significant rise in the population growth in the world. The

1870-1913. India's growth rate increased from 0% per year to 0.54% per year over this period , whereas China's take-off was delayed till the 1950s.

[18] Stokey (2001)'s quantitative study attributes about half of the rise in real wage over the period 1780-1850 to the forces of international trade. Moreover, technological change in manufacturing was 3 times as important as technological change in the energy sector in contributing to output growth.

rate of population growth in the world increased from an average rate of 0.27% per year in the period 1500-1820 to 0.4% per year in the years 1820-1870, and to 0.8% per year in the time interval 1870-1913. Furthermore, despite the decline in population growth in Western Europe and the Western Offshoots towards the end of the 19th century and the beginning of the 20th century, the delayed take-off of less developed regions and the significant increase in their income per capita prior to their demographic transitions generated a further increase in the rate of population growth in the world to 0.93% per year in the years 1913-1950 and a sharp rise to a high rate 1.92% per year in the period 1950-1973. Ultimately, the onset of the demographic transition in less developed economies in the second half of the 20th century, gradually reduced population growth rates to 1.66% per year in the 1973-1998 period (Maddison 2001).

Growth in Income Per Capita and Population Growth

As depicted in Figure 2.11, the take-off in the growth rate of income per capita in all regions of the world was associated with a take-off in population growth. In particular, the average growth rates of income per capita in Western Europe over the time period 1820-1870 rose to an annual rate of 0.95% (from 0.15% in the earlier period) along with a significant increase in population growth to an annual rate of about 0.7% (from 0.26% in the earlier period). Similarly, the average growth rates of income per capita in the Western Offshoots over the years 1820-1870 rose to an annual rate of 1.42% (from 0.34% in the earlier period) along with a significant increase in population growth to an annual rate of about 2.87% (from 0.43% in the earlier period).

A similar pattern is observed in Asia, and as depicted in Figure 2.11 in Africa and Latin America as well. The average growth rates of income per capita in Latin America over the years 1870-1913 rose to an annual rate of 1.81% (from 0.1% in the period 1820-1870) and subsequently by 1.43% in time interval 1913-1950 and 2.52% in the time period 1950-1973 along with a significant increase in population growth to an annual rate of 1.64% in the period 1870-1913, 1.97% in the years 1913-1950, and 2.73% in the period 1950-1973, prior to the decline in the context of the demographic transition. Similarly, the average growth rates of income per capita in Africa over the 1870-1913 period rose to an annual rate of 0.64%, (from 0.12% in the period 1820-1870) and subsequently by 1.02% in the years 1913-1950 and 2.07% in the period 1950-1973 along with a monotonic increase in population growth from a modest average annual rate of 0.4% in the years 1820-1870, to a 0.75% in the years 1870-1913, 1.65% in the years 1913-1950, 2.33% in the time interval 1950-1973, and a rapid average annual rate of 2.73% in the 1973-1998 period .

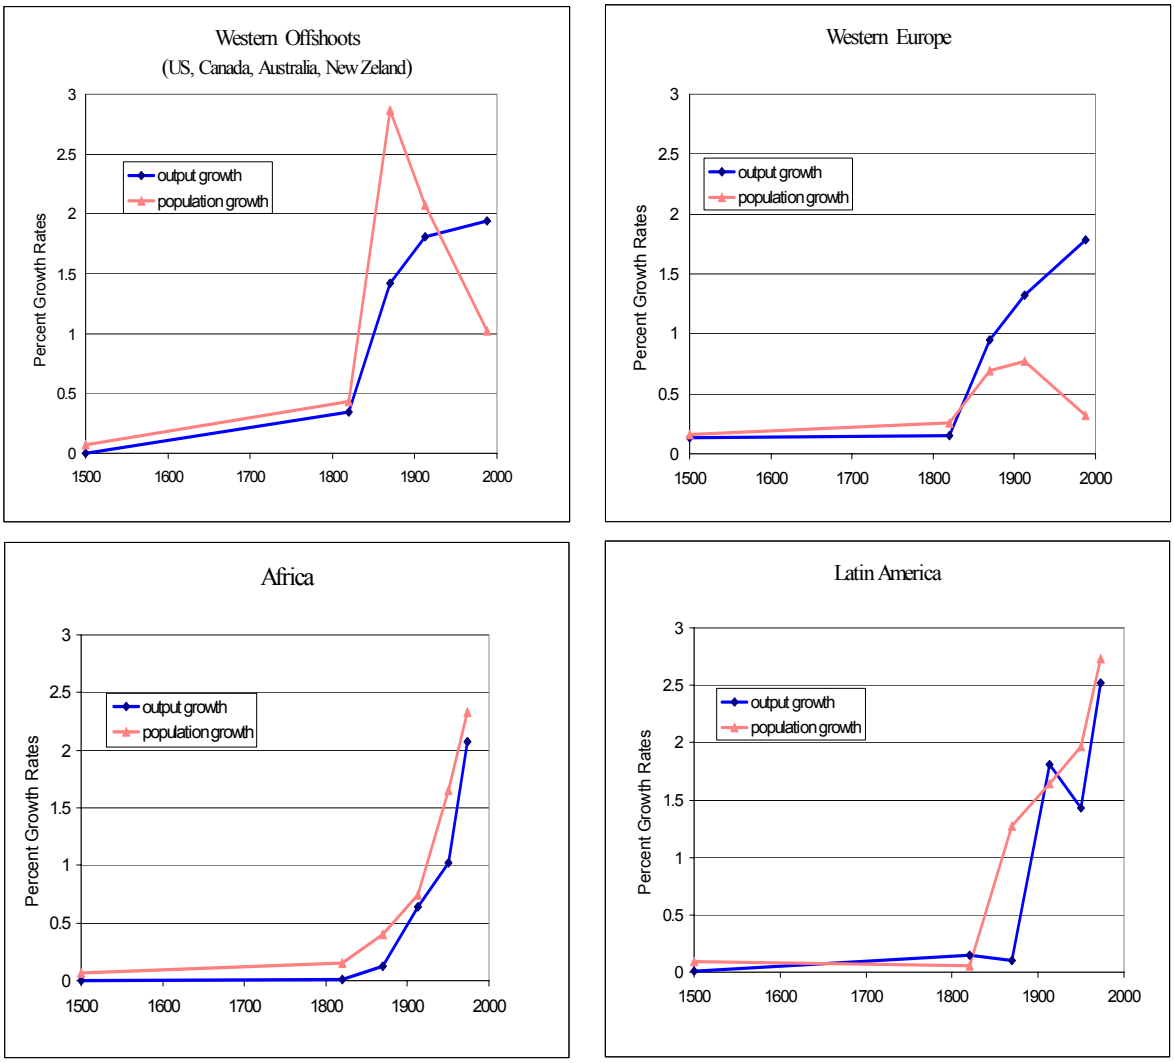

Figure 2.11. Regional Growth of GDP Per Capita and Population: 1500-2000
Source: Maddison (2001)

Ultimately, however, most regions experienced a demographic transition and thereby a transition to a state of sustained economic growth that enabled economies to convert a larger share of the fruits of factor accumulation and technological progress into the growth of output per capita.

Technological leaders and land-abundant regions during the Post-Malthusian era improved their relative position in the world in terms of their level of income per capita as well as their population size. The increase in population density of technological leaders persisted as long as the positive relationship between income per capita and population growth was maintained. Western Europe's technological advancement relative to the rest of the world increased its share of world population by 16% from 12.8% in 1820 to 14.8% in 1870, where the regional technological leader, the United Kingdom, increased its share of world population by 25% (from 2% to 2.5%) over this fifty year period. Moreover, land abundance and technological advancement in the Western Offshoots (US, Australia, New Zealand and Canada) increased their share of world population by 227% over a fifty year period, from 1.1% in 1820 to 3.6% in 1870.

The rate of population growth relative to the growth rate of aggregate income declined gradually over the period. For instance, the growth rate of total output in Europe was 0.3% per year between 1500

and 1700, and 0.6% per year between 1700 and 1820. In both periods, two thirds of the increase in total output was matched by increased population growth, and the growth of income per capita was only 0.1% per year in the earlier period and 0.2% in the later one. In the United Kingdom, where growth was the fastest, the same rough division between total output growth and population growth can be observed: total output grew at an annual rate of 1.1% in the 120 years after 1700, while population grew at an annual rate of 0.7%. Population and income per capita continued to grow after 1820, but increasingly the growth of total output was expressed as growth of income per capita. Population growth was 40% as large as total output growth over the time period 1820-1870, dropping further after the demographic transition to about 20% of output growth over the 1929-1990 period.

Fertility and Mortality

The relaxation in the households' budget constraints in the Post-Malthusian Regime permitted an increase in fertility rates along with an increase in literacy rates and years of schooling. Despite the decline in mortality rates, fertility rates (as well as population growth) increased in most of Western Europe until the second half of the 19th century (Coale and Treadway (1986)).[19] In particular, as depicted in Figure 2.12, in spite of a century of a decline in mortality rates, the crude birth rates in England increased over the 18th century and the beginning of the 19th century. Thus, the *Net Reproduction Rate (*i.e., the number of daughters per woman who reach the reproduction age) increased for about the replacement level of 1 surviving daughters per women in 1740 to about 1.5 surviving daughters per woman in the eve of the demographic transition in 1870.

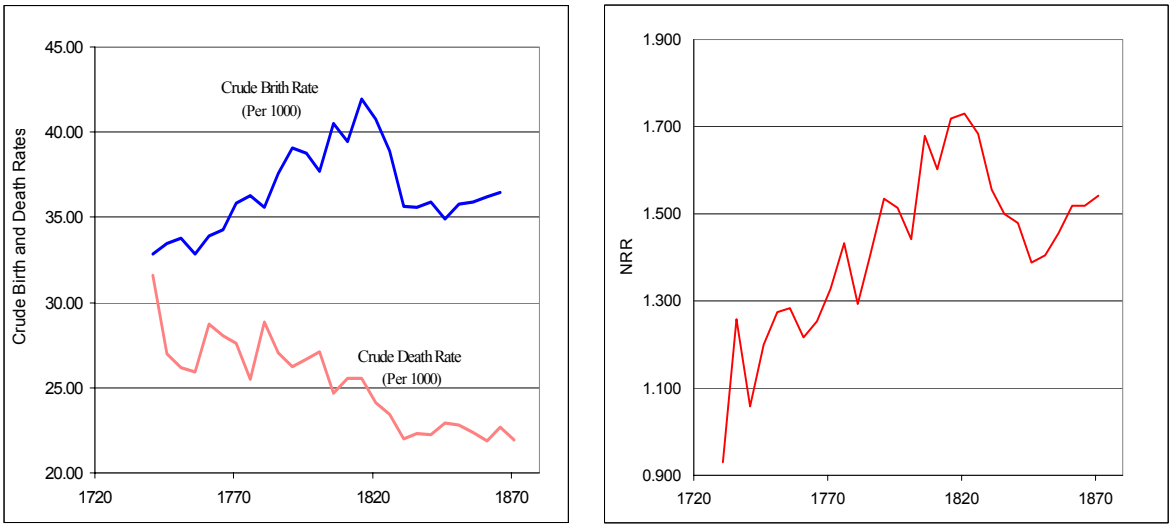

Figure 2.12. Fertility, Mortality and Net Reproduction Rate: England, 1730-1871
Source: Wrigley and Schofield (1981)

It appears that the significant rise in income per capita in the Post-Malthusian Regime increased the desirable number of surviving offspring and thus, despite the decline in mortality rates, fertility increased significantly so as to enable households to reach this higher desirable level of surviving offspring.

Fertility Rates and Marriage Age

Fertility was controlled during this period, despite the absence of modern contraceptive methods,

[19] See Dyson and Murphy (1985) as well.

partly via adjustment in marriage rates.[20] As depicted in Figure 2.13, increased fertility was achieved by earlier female's age of marriages and a decline in fertility by a delay in the marriage age. The same pattern is observed in the relationship between *Crude Birth Rates* and Female's age of marriages, or alternatively *Crude Marriage Rates* (per 1000).

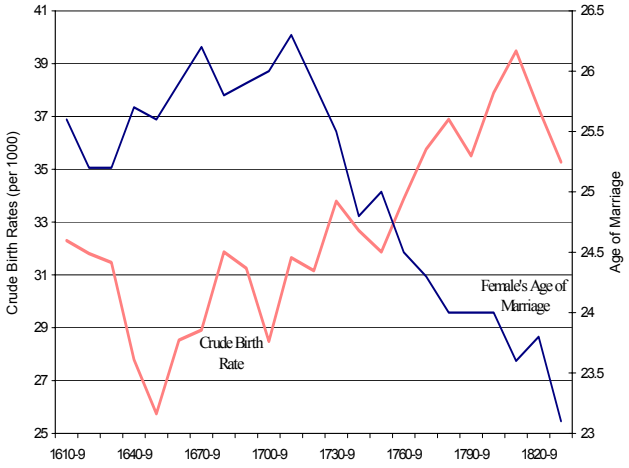

Figure 2.13. Fertility Rates and Female's Age of Marriage
Source: Wrigley and Schofield (1983)

2.2.3 Industrialization and Urbanization

The take-off of developed and less developed regions from the Malthusian epoch was associated with the acceleration in the process of industrialization as well as with a significant rise in urbanization.

Industrialization

The take-off in the developed regions was accompanied by a rapid process of industrialization. As depicted in Figure 2.14, Per-Capita Level of Industrialization (measuring per capita volume of industrial production) increased significantly in the United Kingdom since 1750, rising 50% over the 1750-1800 period, quadrupling in the years 1800-1860, and nearly doubling in the time period 1860-1913. Similarly per-capita level of industrialization accelerated in the United States, doubling in the 1750-1800 as well as 1800-1860 periods , and increasing six-fold in the years 1860-1913. A similar pattern was experienced by Germany, France, Sweden, Switzerland, Belgium, and Canada as of 1800, and industrialization nearly doubled in the 1800-1860 period, further accelerating in the time interval 1860-1913.

The take-off of less developed economies in the 20th century was associated with increased industrialization as well. However, as depicted in Figure 2.14, during the 19th century these economies experienced a decline in *per capita industrialization* (i.e., per capita volume of industrial production), reflecting the adverse effect of the sizable increase in population on the level of industrial production per capita (even in the absence of an absolute decline in industrial production) as well as the forces of globalization and colonialism, that induced less developed economies to specialize in the production of raw materials.[21]

[20] This mechanism is reflected in the assertion of William Cobbett (1763 - 1835) – a leader of the campaign against the changes brought by the Industrial Revolution – *"... men, who are able and willing to work, cannot support their families, and ought... to be compelled to lead a life of celibacy, for fear of having children to be starved."*

[21] The sources of the decline in the industrialization of less developed economies is explored by Galor and Mountford (2003). The effect of colonialism on the patterns of production and thus trade is examined by Acemoglu, Johnson and

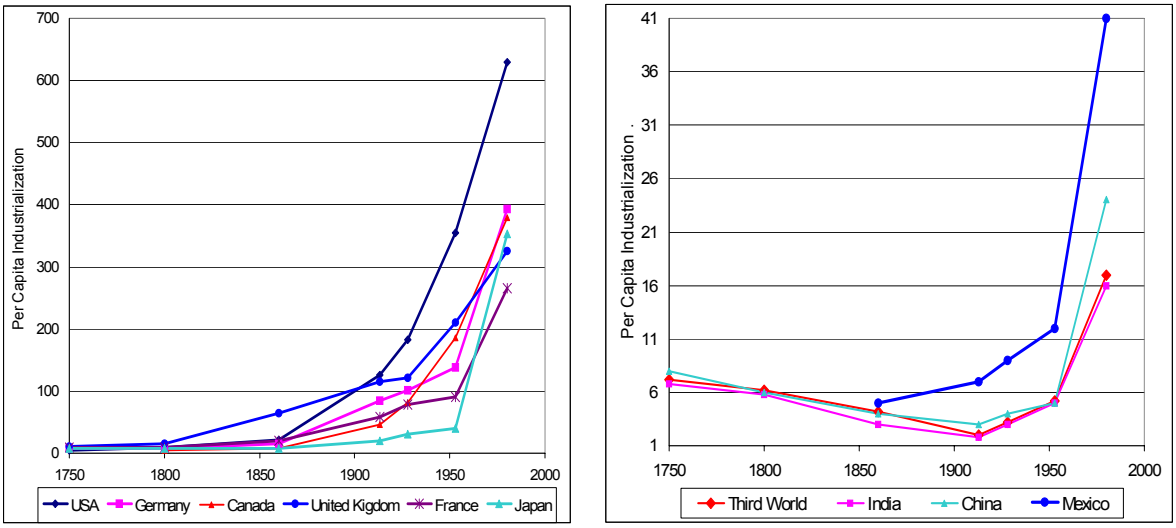

Figure 2.14. Per Capita Levels of Industrialization: (UK in 1900=100)

Source: Bairoch (1982)[22]

Urbanization

The take-off from Malthusian stagnation and the acceleration in the process of industrialization increased significantly the process of urbanization. As depicted in Figure 2.15, the percentage of the population that lived in European cities with a population larger than 10,000 people nearly tripled over the years 1750-1870, from 17% to 54%. Similarly, the percentage of the population in England that lived in cities with population larger than 5,000 quadrupled over the 1750-1910 period, from 18% to 75% (Bairoch 1988)).

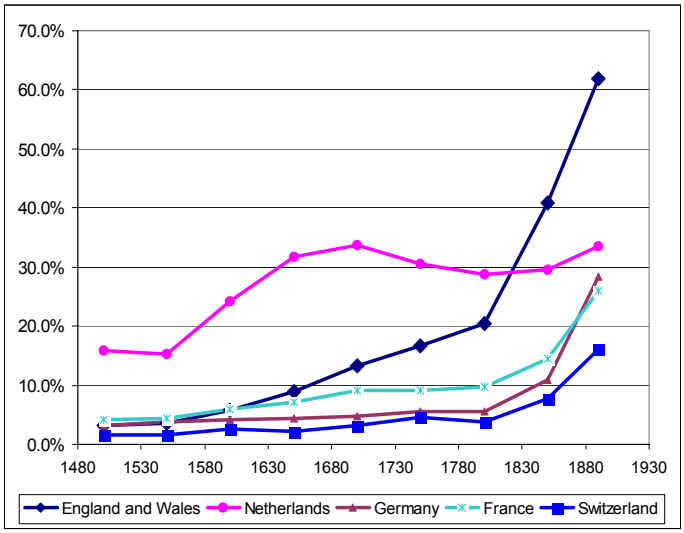

Figure 2.15. Percentage of the Population in Cities with Population larger than 10,000

Robinson (2001) and Bertocchi and Canova (2002).

[22]Notes: Countries are defined according to their 1913 boundaries. Germany from 1953 is defined as East and West Germany. India after 1928 includes Pakistan.

This rapid processes of industrialization and urbanization was accompanied by a rapid decline in the share of agricultural production in total output, as depicted in Figure 2.16. For instance, this share declined in England from 40% in 1790 to 7% in 1910.

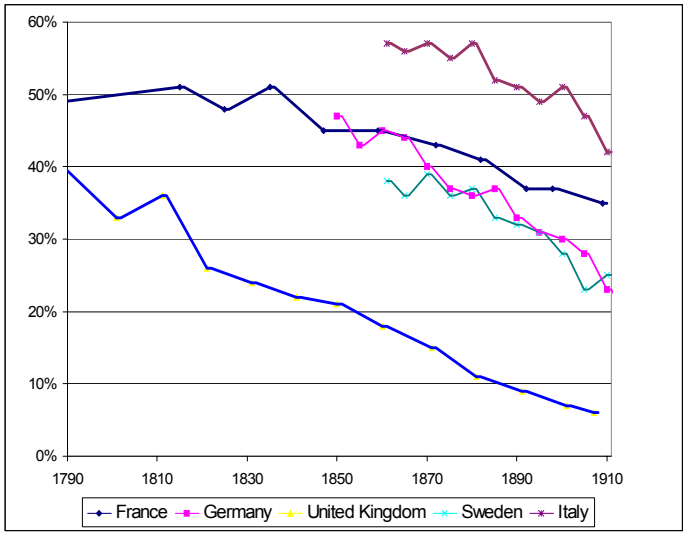

Figure 2.16. The Decline in the Percentage of Agricultural Production in Total Output: Europe: 1790-1910
Source: Mitchell (1981)

2.2.4 Early Stages of Human Capital Formation

The acceleration in technological progress during the Post-Malthusian Regime and the associated increase in income per capita stimulated the accumulation of human capital in the form of literacy rates, schooling, and health. The increase in the investment in human capital was induced by the gradual relaxation in the households budget constraints (as reflected by the rise in real wages and income per capita), as well as by qualitative changes in the economic environment that increased the demand for human capital and induced households to invest in the education of their offspring.

In the first phase of the Industrial Revolution, human capital had a limited role in the production process. Education was motivated by a variety of reasons, such as religion, enlightenment, social control, moral conformity, sociopolitical stability, social and national cohesion, and military efficiency. The extensiveness of public education was therefore not necessarily correlated with industrial development and it differed across countries due to political, cultural, social, historical and institutional factors. In the second phase of the Industrial Revolution, however, the demand for education increased, reflecting the increasing skill requirements in the process of industrialization.[23]

During the post-Malthusian regime, the average number of years of schooling in England and Wales rose from 2.3 for the cohort born between 1801 and 1805 to 5.2 for the cohort born in the year 1852-1856 (Matthews et al., 1982). Furthermore, human capital as reflected by the level of health of the labor force increased over this period. In particular, between 1740 and 1840 life expectancy at birth rose from 33 to 40 in England (Figure 2.8), and from 25 to 40 in France.

The process of industrialization was ultimately characterized by a gradual increase in the relative importance of human capital in less developed economies as well. As documented by Barro and

[23]Evidence suggests that in Western Europe, the economic interests of capitalists were a significant driving force behind the implementation of educational reforms, reflecting the interest of capitalists in human capital formation and thus in the provision of public education [Galor and Moav (2004)].

Lee (2000) educational attainment increased significantly across all less developed regions in the Post-Malthusian Regime (that ended with the decline in population growth in the 1970s in Latin America and Asia, and was still in motion in Africa at the end of the 20th century). In particular, the average years of schooling increased from 3.5 in 1960 to 4.4 in 1975, in Latin America, from 1.6 in 1960 to 3.4 in 2000 in Sub-Saharan Africa, and from 1.4 in 1960 to 1.9 in 1975 in South Asia.

2.3 The Sustained Growth Regime

The acceleration in technological progress and industrialization in the Post-Malthusian Regime and its interaction with the accumulation of human capital brought about a demographic transition, paving the way to a transition to an era of sustained economic growth. In the post demographic-transition period, the rise in aggregate income due to technological progress and factor accumulation has no longer been counterbalanced by population growth, permitting sustained growth in income per capita in regions that have experienced sustained technological progress and factor accumulation.

The transition of the developed regions of Western Europe and the Western Offshoots to the state of sustained economic growth occurred towards the end of the 19th century, whereas the transition of the less developed regions of Asia and Latin America occurred towards the end of the 20th century. Africa, in contrast, is still struggling to make this transition.

2.3.1 Growth of Income Per Capita

During the Sustained Growth Regime the average growth rate of output per capita increased significantly in association with the decline in population growth. As depicted in Figure 2.11, the decline in population growth in Western Europe as well as the Western Offshoots was followed by a significant increase in income per capita and in many of the less advanced economies a significant increase in income per capita was followed by a demographic transition.

Income per capita in the last century has advanced at a stable rate of about 2% per year in Western Europe and the Western Offshoots, as depicted in Figure 2.17.

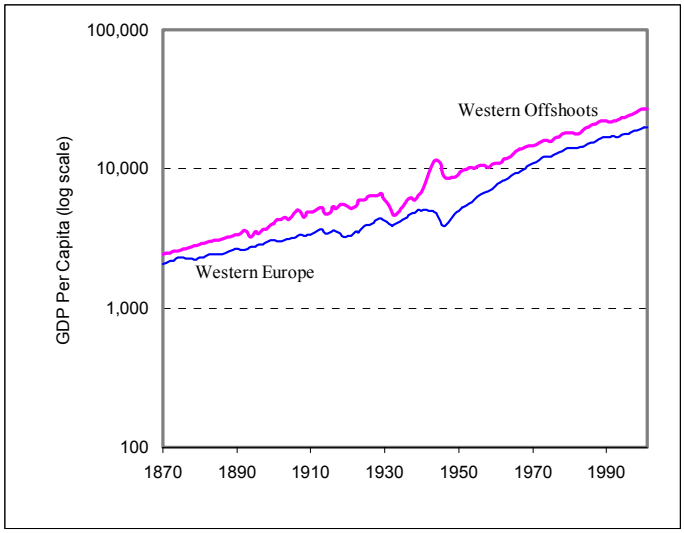

Figure 2.17. Sustained Economic Growth: Western Europe and the Western Offshoots, 1870-2001
Source: Maddison (2003)

In contrast, less developed regions experienced a sustained growth rate of output per capita only in the last decades. As depicted in Figure 2.18, the growth rate of output per capita in Asia has been stable in the last 50 years, the growth rate in Latin America has been declining over this period, and the growth of Africa vanished in the last few decades.[24]

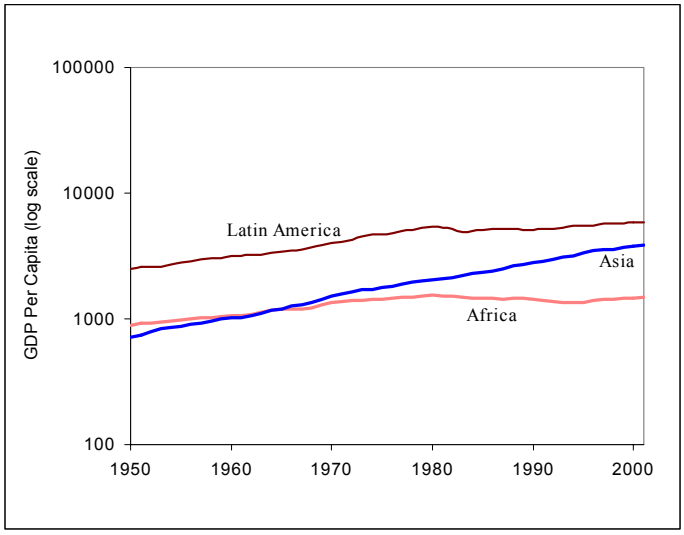

Figure 2.18. Income Per Capita in Africa, Asia and Latin America, 1950-2001
Source: Maddison (2003)

The transition to a state of sustained economic growth in developed as well as less developed regions was accompanied by a rapid process of industrialization. As depicted in Figure 2.14, the *Per Capita Level of Industrialization* (measuring per capita volume of industrial production) doubled in the time period 1860-1913 and tripled in the course of the 20th century. Similarly the per capita level of industrialization in the United States, increased six-fold over the years 1860-1913, and tripled along the 20th century. A similar pattern was experienced by Germany, France, Sweden, Switzerland, Belgium, and Canada where industrialization increased significantly in the time interval 1860-1913 as well as over the rest of the 20th century. Moreover, less developed economies that made the transition to a state of sustained economic growth in recent decades have experienced a significant increase in industrialization.

The transition to a state of sustained economic growth was characterized by a gradual increase in the importance of the accumulation of human capital relative to physical capital as well as with a sharp decline in fertility rates. In the first phase of the Industrial Revolution (1760-1830), capital accumulation as a fraction of GDP increased significantly whereas literacy rates remained largely unchanged. Skills and literacy requirements were minimal, the state devoted virtually no resources to raise the level of literacy of the masses, and workers developed skills primarily through on-the-job training (Green 1990, and Mokyr 1990, 1993). Consequently, literacy rates did not increase during the period 1750-1830 (Sanderson 1995)). As argued by Landes (1969, p. 340) "although certain workers - supervisory and office personal in particular - must be able to read and do the elementary arithmetical operations in order to perform their duties, large share of the work of industry can be performed by illiterates as indeed it was especially in the early days of the Industrial Revolution."

In the second phase of the Industrial Revolution, however, capital accumulation subsided, the education of the labor force markedly increased and skills became necessary for production. The investment ratio which increased from 6% in 1760 to 11.7% in the year 1831, remained at around 11%

[24]Extensive evidence about the growth process in the last four decades is surveyed by Barro and Sala-i-Martin (2003).

on average in the years 1856-1913 (Crafts 1985 and Matthews et al. 1982). In contrast, the average years of schooling of the male labor force which did not change significantly until the 1830s, tripled by the beginning of the 20th century (Matthews et al. 1982, p 573). The significant rise in the level of income per capita in England as of 1865, as depicted in Figure 2.19, was associated with an increase in the standard of living (Voth (2004), and an increase in school enrollment of 10-year olds from 40% in 1870 to 100% in 1900. Moreover, Total fertility Rates in England sharply declined over this period from about 5 in 1875, to nearly 2 in 1925.

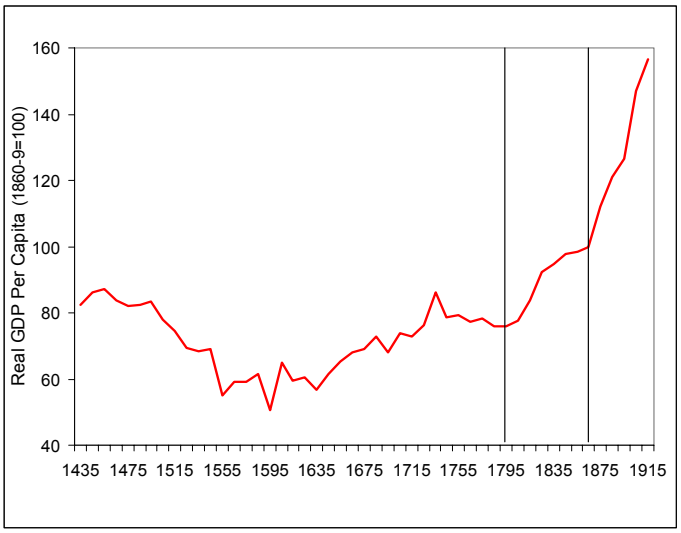

Figure 2.19. The Sharp Rise in Real GDP Per Capita in the transition to Sustained Economic Growth: England 1870-1915
Source: Clark (2001) and Feinstein (1972)

The transition to a state of sustained economic growth in the US, as well, was characterized by a gradual increase in the importance of the accumulation of human capital relative to physical capital. Over the time period 1890-1999 the contribution of human capital accumulation to the growth process in the US nearly doubled whereas the contribution of physical capital declined significantly. Goldin and Katz (2001) show that the rate of growth of educational productivity was 0.29% per year over the 1890-1915 period, accounting for about 11% of the annual growth rate of output per capita over this period.[25] In the period 1915-1999, the rate of growth of educational productivity was 0.53% per year accounting for about 20% of the annual growth rate of output per capita over this period. Abramovitz and David (2000) report that the fraction of the growth rate of output per capita that is directly attributed to physical capital accumulation declined from an average of 56% in the years 1800-1890 to 31% in the period 1890-1927 and 21% in the time interval 1929-1966.

2.3.2 The Demographic Transition

The demographic transitions swept the world in the course of the last century. The unprecedented increase in population growth during the Post-Malthusian regime was ultimately reversed and the demographic transition brought about a significant reduction in fertility rates and population growth in various regions of the world, enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of income per capita. The demographic transition enhanced the growth process via three channels: (a) Reduction of the dilution of the stock of capital

[25] They measure educational productivity by the contribution of education the educational wage differentials.

and land. (b) Enhancement of the investment in the human capital of the population. (c) Alteration of the age distribution of the population which temporarily increased the size of the labor force relative to the population as a whole.

The Decline in Population Growth

The evolution of population growth in the world economy, as depicted in Figure 2.5, has been non-monotonic. The growth of world population was sluggish during the Malthusian epoch, creeping at an average annual rate of about 0.1% over the years 0-1820. The Western European take-off along with that of the Western Offshoots brought about a sharp increase in population growth in these regions and consequently in the world as a whole. The annual average rate of population growth in the world increased gradually reaching 0.8% in the years 1870-1913. The delayed take-off of less developed regions and the significant increase in their income per capita generated a further gradual increase in the rate of population growth in the world, despite the decline in population growth in Western Europe and the Western Offshoots, reaching a high level of 1.92% per year in the period 1950-1973, . Ultimately, however, the onset of the demographic transition in less developed economies in the second half of the 20th century, reduced population growth to an average rate of about 1.63% per year in the 1973-1998 period.

The timing of the demographic transition differed significantly across regions. As depicted in Figure 2.20, the reduction in population growth occurred in Western Europe, the Western Offshoots, and Eastern Europe towards the end of the 19th century and in the beginning of the 20th century, whereas Latin America and Asia experienced a decline in the rate of population growth only in the last decades of the 20th century. Africa's population growth, in contrast, has been rising steadily, although this pattern is likely to reverse in the near future due to the decline in total fertility rate in this region since the 1980s.

The Western Offshoots experienced the earliest decline in population growth, from an average annual rate of 2.87% in the period 1820-1870 to an annual average rate of 2.07% in the time interval 1870-1913 and 1.25% in the years 1913-1950.[26] In Western Europe population growth declined from a significantly lower average level of 0.77% per year in the period 1870-1913 to an average rate of 0.42%

[26]Migration played a significant role in the rate of population growth of these land-abundant countries.

per year in the 1913-1950 period. A similar reduction occurred in Eastern Europe as well.[27]

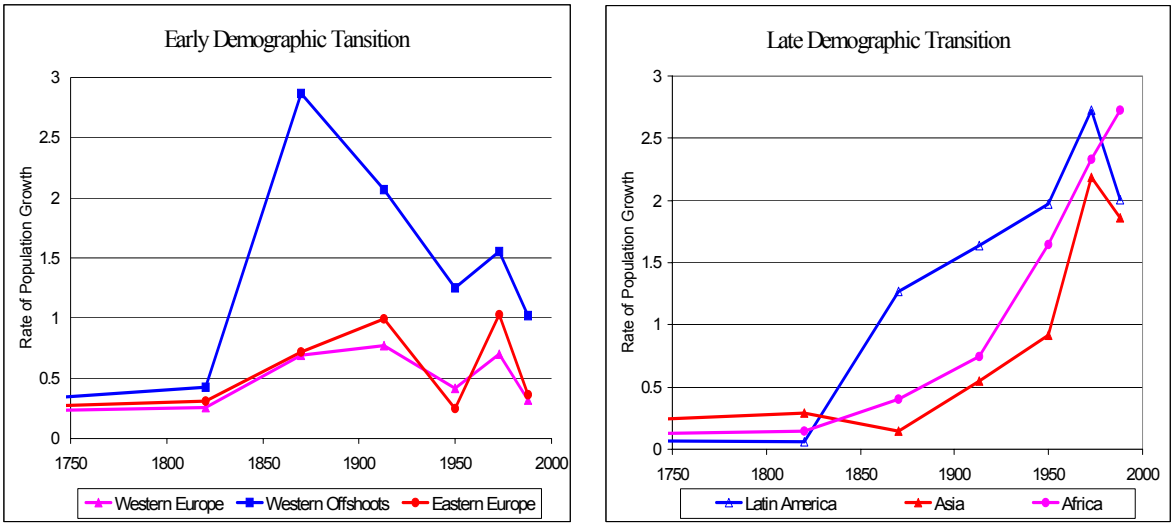

Figure 2.20. The Differential Timing of the Demographic Transition Across Regions
Source: Maddison (2001)

In contrast, in Latin America and Asia the reduction in population growth started to take place in the 1970s, whereas the average population growth in Africa has been rising, despite a modest decline in fertility rates.[28] Latin America experienced a decline in population growth from an average annual rate of 2.73% in the years 1950-1973 to an annual average rate of 2.01% in the period 1973-1998 Similarly, Asia (excluding Japan) experienced a decline in population growth from an average annual rate of 2.21% in the time period 1950-1973 to an average annual rate of 1.86% in the 1973-1998 period. Africa's increased resources in the Post-Malthusian Regime, however, has been channeled primarily towards population growth.

Africa's population growth rate has increased monotonically from a modest average annual rate of 0.4% over the years 1820-1870, to a 0.75% in the time interval 1870-1913, 1.65% in the period 1913-1950, 2.33% in 1950-1973, and a rapid average annual rate of 2.73% in the 1973-1998 period . Consequently, the share of the African population in the world increased by 41% in the 60 year period, 1913-1973 (from 7% in 1913 to 9.9% in 1973), and an additional 30% in the last 25 years, from 9.9% in 1973 to 12.9% in 1998. The decline in fertility in less developed regions, however, has been more significant, indicating a sharp forthcoming decline in population growth in the next decades.

Fertility Decline

The decline in population growth stem from a decline in fertility rates. As depicted in Figure 2.21, *Total Fertility Rate* over the period 1960-1999 plummeted from 6 to 2.7 in Latin America and declined sharply from 6.14 to 3.14 in Asia.[29] Furthermore, *Total Fertility Rate* in Western Europe and the Western Offshoots declined over this period below the replacement level: from 2.8 in 1960 to 1.5 in 1999 in Western Europe and from 3.84 in 1960 to 1.83 in 1999 in the Western Offshoots. (World

[27] A sharper reduction in population growth occurred in the United Kingdom, from 0.87% per year in the period 1870-1913 to 0.27% per year in the period 1913-1950.

[28] As depicted in Figure 2.18, the decline in Total Fertility Rate in these countries started earlier. The delay in the decline in population growth could be attributed to an increase in life expectancy as well as an increase in the relative size of cohorts of women in a reproduction age.

[29] For a comprehensive discussion of the virtues and drawbacks of the various measures of fertility: *TFR*, *NNR*, and *CBR*, see Weil (2004).

Development Indicators, 2001). Even in Africa the *Total Fertility Rate* declined moderately from 6.55 in 1960 to 5.0 in 1999.

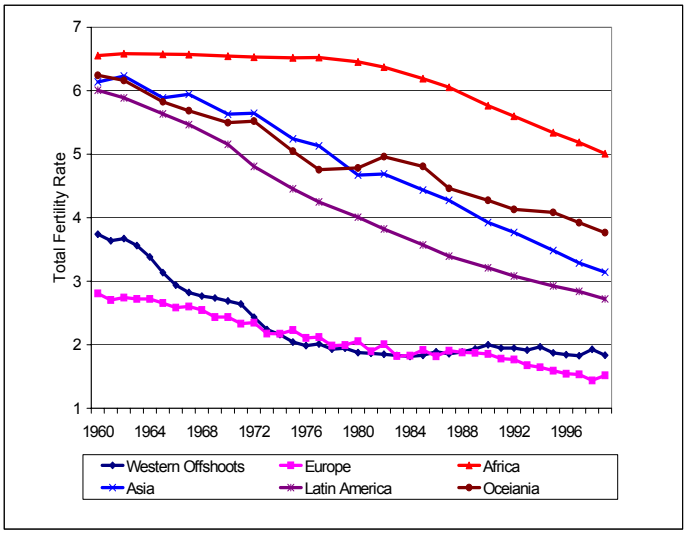

Figure 2.21. The Evolution of Total Fertility Rate Across Regions, 1960-1999
Source: World Development Indicators (2001).

The demographic transition in Western Europe occurred towards the turn of the 19th century. A sharp reduction in fertility took place simultaneously in several countries in the 1870s, and resulted in a decline of about 1/3 in fertility rates in various states within a 50 year period.[30]

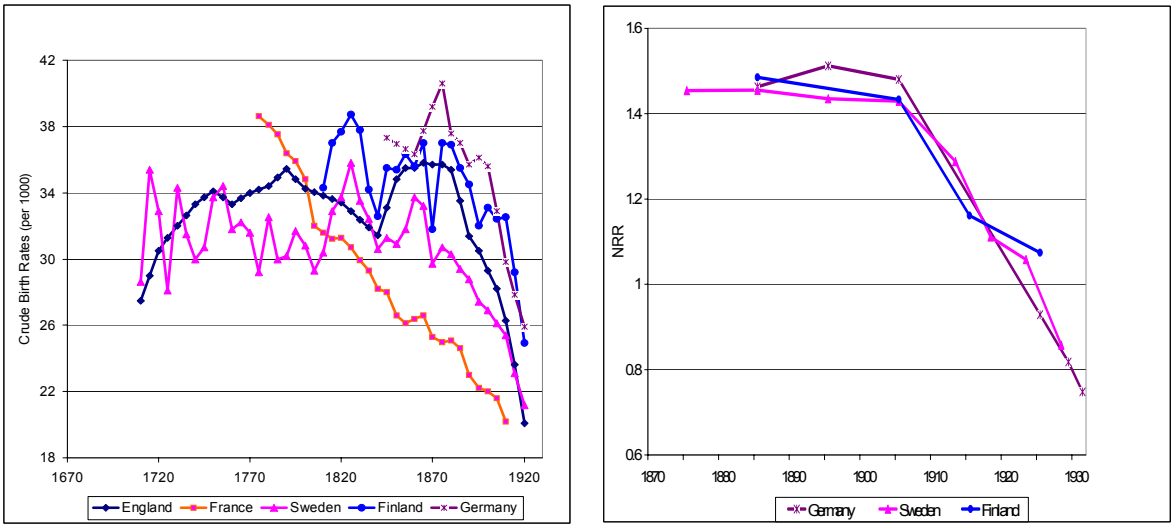

Figure 2.22. The Demographic Transition in Western Europe:
Crude Birth Rates and *Net Reproduction Rates*
Source: Andorka (1978) and Kuzynski (1969)

As depicted in Figure 2.22, *Crude Birth Rates* in England declined by 44%, from 36 (per 1000) in 1875, to 20 (per 1000) in 1920. Similarly, live births per 1000 women aged 15-44 fell from 153.6 in

[30]Coale and Treadway (1986) find that a 10% decline in fertility rates was completed in 59% of all European countries in the time period 1890-1920. In particular, a 10% decline was completed in Belgium in 1881, Switzerland in 1887, Germany in 1888, England and Wales in 1892, Scotland in 1894, Netherlands in 1897, Denmark in 1898, Sweden in 1902, Norway in 1903, Austria in 1907, Hungary in 1910, Finland in 1912, Greece and Italy in 1913, Portugal in 1916, Spain 1920, and Ireland in 1922.

1871-80 to 109.0 in 1901-10 (Wrigley, 1969). In Germany, *Crude Birth Rates* declined 37%, from 41 (per 1000) in 1875 to 26 (per 1000) in 1920. Sweden's *Crude Birth Rates* declined 32%, from 31 (per 1000) in 1875 to 21 (per 1000) in 1920, and in Finland they declined 32%, from 37 in 1875 to 25 (per 1000) in 1920. Finally, although the timing of demographic transition in France represents an anomaly, starting in the second half of the 18th century, France experienced an additional significant reduction in fertility in the time period 1865-1910, where *Crude Birth Rates* declined by 26%, from 27 (per 1000) in 1965 to 20 (per 1000) in 1910.

The decline in the crude birth rates in the course of the demographic transition was accompanied by a significant decline in the *Net Reproduction Rate (*i.e., the number of daughters per woman who reach the reproduction age), as depicted in Figure 2.22. Namely, the decline in fertility during the demographic transition outpaced the decline in mortality rates, and brought about a decline in the number of children who survived to their reproduction age.

Similar patterns are observed in the evolution of *Total Fertility Rates* in Western Europe, as depicted in Figure 2.23. *Total Fertility Rates* (TFR) peaked in the 1870s and then decline sharply and simultaneously across Western European States. In England, TFR declined by 51%, from 4.94 children in 1875, to 2.4 in 1920. In Germany, TFR declined 57%, from 5.29 in 1885 to 2.26 in 1920. Sweden's TFR declined 61%, from 4.51 in 1876 to 1.77 in 1931, in Finland they declined 52%, from 4.96 in 1876 to 2.4 in 1931 and in France where a major decline occurred in the years 1750-1850, additional decline took place in the same time period from 3.45 in 1980 to 1.65 in 1920.

Mortality Decline

The mortality decline which preceded the decline in fertility rates in most countries in the world, with the notable exceptions of France and the United States, has been, unjustifiably, viewed by demographers as the prime force behind the demographic transition. The evidence provided in section 3.3.1, suggests that this viewpoint is inconsistent with historical evidence.

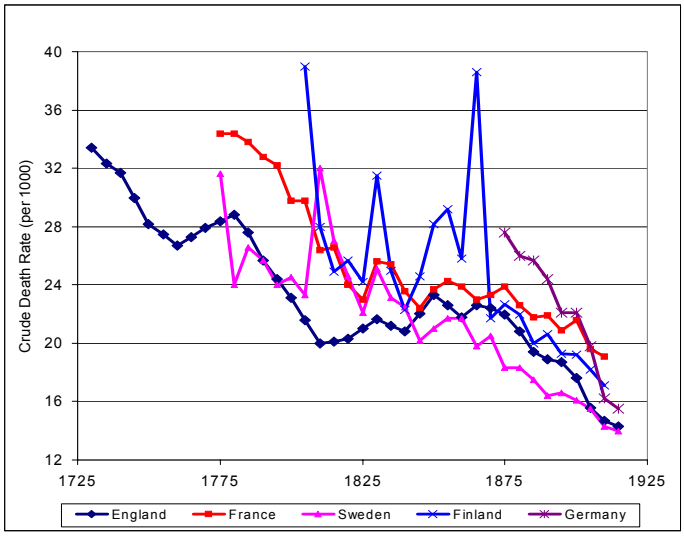

Figure 2.24. The Mortality Decline in Western Europe, 1730-1920
Source: Andorka (1978)

The decline in mortality rates preceded the decline in fertility rates in Western European countries in the 1730-1920 period, as depicted in Figures 2.22 and 2.24. The decline in mortality rates began in England 140 years prior to the decline in fertility and in Sweden and Finland nearly 100 years prior to the decline in fertility.

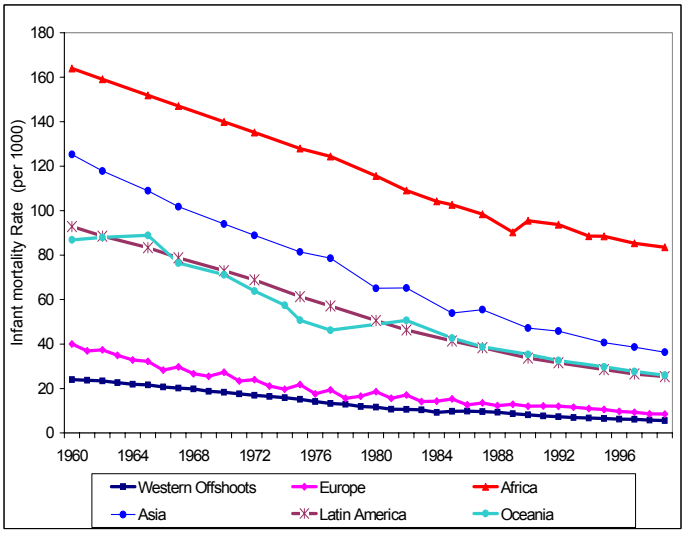

Figure 2.25. The Decline in Infant Mortality Rates Across Regions, 1960-1999
Source: World Development Indicators (2001).

A similar sequence of events emerges from the pattern of mortality and fertility decline in less developed regions. As depicted in Figures 2.21 and 2.25, a sharp decline in infant mortality rates as of 1960 preceded the decline in fertility rates in Africa that took place in 1980. Moreover, the existing evidence shows a simultaneous reduction in mortality and fertility in the 1960-2000 period in all other regions.[31]

[31]Extrapolation about mortality rates prior to 1960 suggests that a similar pattern appears in Asia and Latin America.

Life Expectancy

The decline in mortality rates in developed countries since the 18th century, as depicted in Figure 2.24, corresponded to a gradual increase in life expectancy generating a further inducement for investment in human capital. As depicted in Figure 2.26, life expectancy at birth in England increased at a stable pace from 32 years in the 1720s to about 41 years in the 1870s. This pace of the rise in life expectancy increased towards the end of the 19th century and life expectancy reached the levels of 50 years in the year 1906, 60 years in the year 1930 and 77 years in the year 1996.

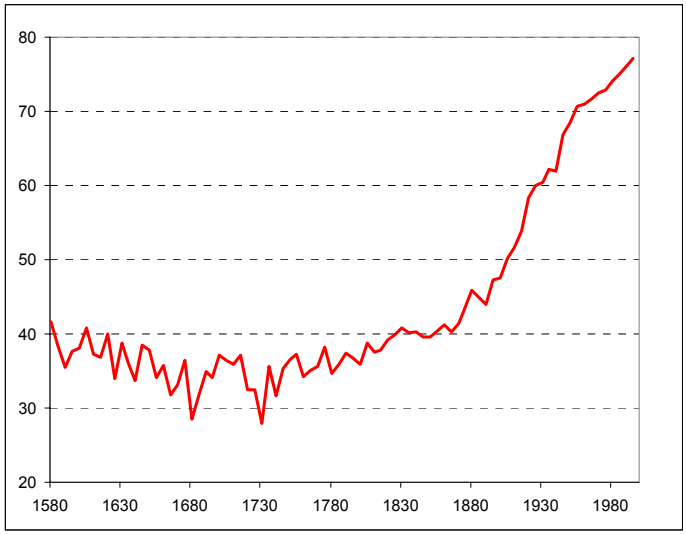

Figure 2.26. The Evolution of Life Expectancy: England 1726-1996
Source: Wrigley and Schofield (1981) for 1726-1871 and Human Mortality Database (2003) for 1876-1996

Similarly, the significant decline in mortality rates across the developed regions in the last two centuries and across less developed regions in the past century, corresponded to an increase in life expectancy. As depicted in Figure 2.27, life expectancy increased significantly in developed regions in the 19th century, whereas the rise in life expectancy in less developed regions occurred throughout the 20th century, stimulating further human capital formation.

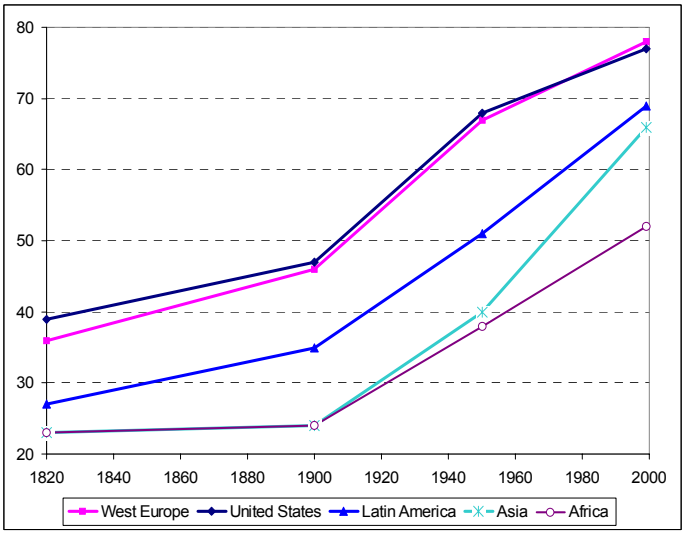

Figure 2.27. The Evolution of Life Expectancy Across Regions, 1820-1999
Source: Maddison (2001).

In particular, life expectancy nearly tripled in the course of the 20th century in Asia, rising from a level of 24 years in 1960 to 66 years in 1999, reflecting the rise in income per capita as well as the diffusion of medical technology. Similarly, life expectancy in Africa doubled from 24 years in 1900 to 52 years in 1999. The more rapid advancement in income per capita in Latin America generated an earlier rise in life expectancy, and life expectancy increased modestly during the 19th century and more significantly in the course of the 20th century, from 35 years in 1900 to 69 years in 1999.

2.3.3 Industrial Development and Human Capital Formation

The process of industrialization was characterized by a gradual increase in the relative importance of human capital for the production process. The acceleration in the rate of technological progress increased gradually the demand for human capital, inducing individuals to invest in education, and stimulating further technological advancement. Moreover, in developed as well as less developed regions the onset of the process of human capital accumulation preceded the onset of the demographic transition, suggesting that the rise in the demand for human capital in the process of industrialization and the subsequent accumulation of human capital played a significant role in the demographic transition and the transition to a state of sustained economic growth.

Developed Economies[32]

As observed by Abramowitz (1993 p. 224), "In the nineteenth century, technological progress was heavily biased in a physical capital-using direction...the bias shifted in an intangible (human and knowledge) capital-using direction and produced the substantial contribution of education and other intangible capital accumulation to this century productivity growth." Furthermore, as argued by Goldin (2001), "The modern concept of the wealth of nations emerged by the early twentieth century. It was that capital embodied in the people — human capital — mattered."

In the first phase of the Industrial Revolution, the extent of public education was not correlated with industrial development and it differed across countries due to political, cultural, social, historical and institutional factors. Human capital had a limited role in the production process and education served religious, social, and national goals. In contrast, in the second phase of the Industrial Revolution the demand for skilled labor in the growing industrial sector markedly increased, human capital formation was designed primarily to satisfy the increasing skill requirements in the process of industrialization, and industrialists became involved in shaping the education system.

Notably, the reversal of the Malthusian relation between income and population growth during the demographic transition, corresponded to an increase in the level of resources invested in each child. For example, the literacy rate among men, which was stable at around 65% in the first phase of the Industrial Revolution, increased significantly during the second phase, reaching nearly 100% at the end of the 19th century (Clark 2003), and the proportion of children aged 5 to 14 in primary schools increased significantly in the second half of the 19th century, from 11% in 1855 to 74% in 1900. A similar pattern is observed in other European societies (Flora et al. 1983). In particular, as depicted in Figure 2.28, the proportion of children aged 5 to 14 in primary schools in France increased significantly in the second half of the 19th century, from 30% in 1832 to 86% in 1901.

[32]This section is closely based on the research of Galor and Moav (2004b).

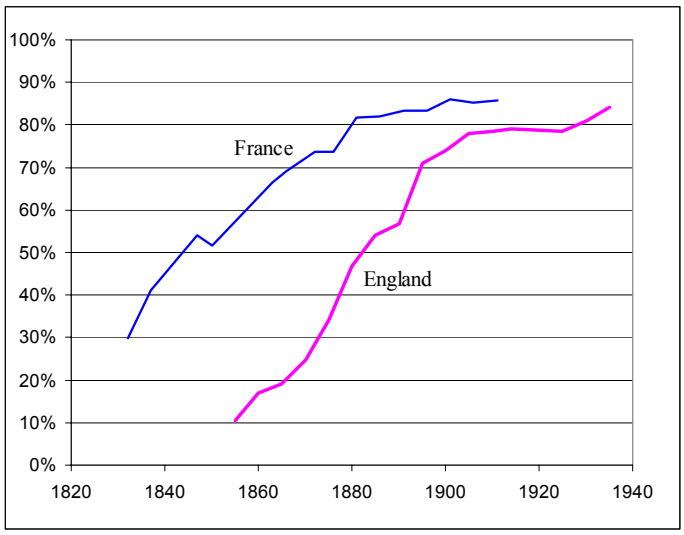

Figure 2.28. The Fraction of Children Age 5-14 in Public Primary Schools, 1820-1940
Source: Flora et al. (1983)

Evidence about the evolution of the return to human capital over this period are scarce and controversial. They do not indicate that the skill premium increased markedly in Europe over the course of the 19th century (Clark 2003). One can argue that the lack of clear evidence about the increase in the return to human capital over this period is an indication for the absence of a significant increase in the demand for human capital. This partial equilibrium argument, however is flawed. The return to human capital is an equilibrium price that is affected both by the demand and the supply of human capital. Technological progress in the second phase of the Industrial Revolution brought about an increase in the demand for human capital, and indeed, in the absence of a supply response, one would have expected an increase in the return to human capital. However, the significant increase in schooling that took place in the 19th century, and in particular the introduction of public education that lowered the cost of education, generated a significant increase in the supply of educated workers. Some of this supply response was a direct reaction of the increase in the demand for human capital, and thus may only operate to partially offset the increase in the return to human capital. However, the removal of the adverse effect of credit constraints on the acquisition of human capital (as reflected by the introduction of public education) generated an additional force that increased the supply of educated labor and operated towards a reduction in the return to human capital.[33]

A. The Industrial Base for Education Reforms in the 19th Century

Education reforms in developed countries in the 18th and the 19th century provide a profound insight about the significance of industrial development in the formation of human capital (and thus in the onset of the demographic transition) in the second half of the 19th century. In particular, the variation in the timing of the establishment of a national system of public education between England and Continental Europe is instrumental in isolating the role of industrial forces in human capital formation from other forces such as social control, moral conformity, enlightenment, sociopolitical stability, social and national cohesion, and military efficiency.

[33]This argument is supported indirectly by contemporary evidence about a higher rate of returns to human capital in less developed economies than in developed economies (Psacharopoulos and Patrinos 2002). The greater prevalence of credit markets imperfections and other barriers for the acquisition of skills in less developed economies generated only a partial supply response to industrial demand for human capital, contributing to this differential in the skill premium.

England In the first phase of the Industrial Revolution (1760-1830), capital accumulation increased significantly without a corresponding increase in the supply of skilled labor. The investment ratio increased from 6% in 1760 to 11.7% in the year 1831 (Crafts 1985, p. 73). In contrast, literacy rates remained largely unchanged and the state devoted virtually no resources to raising the level of literacy of the masses. During the first stages of the Industrial Revolution, literacy was largely a cultural skill or a hierarchical symbol and had limited demand in the production process.[34] For instance, in 1841 only 4.9% of male workers and only 2.2% of female workers were in occupations in which literacy was strictly required (Mitch 1992, pp. 14-15). During this period, an illiterate labor force could operate the existing technology, and economic growth was not impeded by educational retardation.[35] Workers developed skills primarily through on-the-job training, and child labor was highly valuable.

The development of a national public system of education in England lagged behind the continental countries by nearly half a century and the literacy rate hardly increased in the period 1750-1830 (Sanderson 1995, pp. 2-10).[36] As argued by Green (1990, pp. 293-294), "Britain's early industrialization had occurred without direct state intervention and developed successfully, at least in its early stages, within a laissez-faire framework. Firstly, state intervention was thought unnecessary for developing technical skills, where the initial requirements were slight and adequately met by traditional means. Secondly, the very success of Britain's early industrial expansion encouraged a complacency about the importance of scientific skills and theoretical knowledge which became a liability in a later period when empirical knowledge, inventiveness and thumb methods were no longer adequate." Furthermore, as argued by Landes (1969, p. 340) "although certain workers - supervisory and office personnel in particular - must be able to read and do the elementary arithmetical operations in order to perform their duties, large share of the work of industry can be performed by illiterates as indeed it was especially in the early days of the industrial revolution."

England initiated a sequence of reforms in its education system since the 1830s and literacy rates gradually increased. The process was initially motivated by a non-industrial reasons such as religion, social control, moral conformity, enlightenment, and military efficiency, as was the case in other European countries (e.g., Germany, France, Holland, Switzerland) that had supported public education much earlier.[37] However, in light of the modest demand for skills and literacy by the capitalists, the level of governmental support was rather small.[38]

In the second phase of the Industrial Revolution, the demand for skilled labor in the growing industrial sector markedly increased and the proportion of children aged 5 to 14 in primary schools increased from 11% in 1855 to 25% in 1870 (Flora et al. 1983). Job advertisements, for instance, suggest that literacy became an increasingly desired characteristic for employment as of the 1850s (Mitch 1993, p. 292). In light of the industrial competition from other countries, capitalists started to recognize the importance of technical education for the provision of skilled workers. As noted by Sanderson 1995, pp. 10-13), "reading ...enabled the efficient functioning of an urban industrial society laced with letter writing, drawing up wills, apprenticeship indentures, passing bills of exchange, and notice and

[34]See Mokyr (1993, 2001).

[35]Some have argued that the low skill requirements even declined over this period. For instance, Sanderson (1995, p. 89) suggests that "One thus finds the interesting situation of an emerging economy creating a whole range of new occupations which require even less literacy and education than the old ones."

[36]For instance, in his parliamentary speech in defense of his 1837 education bill, the Whig politician, Henry Brougham, reflected upon this gap: "It cannot be doubted that some legislative effort must at length be made to remove from this country the opprobrium of having done less for education of the people than any of the more civilized nations on earth" (Green (1990, pp.10-11)).

[37]The proximity of the education acts in the UK to major wars suggests that the provision of public education was partly a compensation for the services of soldiers.

[38]Even in 1869 the government funded only one-third of school expenditure (Green, 1990, pp. 6-7).

advertisement reading." Moreover, manufacturers argued that: "universal education is required in order to select, from the mass of the workers, those who respond well to schooling and would make a good foreman on the shop floor" (Simon 1987, p. 104).

As it became apparent that skills were necessary for the creation of an industrial society, replacing previous ideas that the acquisition of literacy would make the working classes receptive to radical and subversive ideas, capitalists lobbied for the provision of public education for the masses.[39] The pure laissez-faire policy failed in developing a proper educational system and capitalists demanded government intervention in the provision of education. As James Kitson, a Leeds iron-master and an advocate of technical education explained to the Select Committee on Scientific Instruction (1867-1868): "...the question is so extensive that individual manufacturers are not able to grapple with it, and if they went to immense trouble to establish schools they would be doing it in order that others may reap the benefit" (Green, 1990, p. 295).[40]

An additional turning point in the attitude of capitalists towards public education was the Paris Exhibition of 1867, where the limitations of English scientific and technical education became clearly evident. Unlike the 1851 exhibition in which England won most of the prizes, the English performance in Paris was rather poor; of the 90 classes of manufacturers, Britain dominated only in 10. Lyon Playfair, who was one of the jurors, reported that: "a singular accordance of opinion prevailed that our country has shown little inventiveness and made little progress in the peaceful arts of industry since 1862." This lack of progress "upon which there was most unanimity conviction is that France, Prussia, Austria, Belgium and Switzerland possess good systems of industrial education and that England possesses none" (Green 1990, p. 296).[41]

In 1868, the government established the Parliamentary Select Committee on Scientific Education. This was the origin of nearly 20 years of various parliamentary investigations into the relationship between science, industry, and education, that were designed to address the capitalists' outcry about the necessity of universal public education. A sequence of reports by the committee in 1868, the Royal Commission on Scientific Instruction and the Advancement of Science during the period 1872-75, and by the Royal Commission on Technical Education in 1882, underlined the inadequate training for supervisors, managers and proprietors, as well as workers. They argued that most managers and proprietors did not understand the manufacturing process and thus, failed to promote efficiency, investigate innovative techniques or value the skills of their workers (Green 1990, pp. 297-298). In particular, W. E. Forster, the Vice President of the committee of the Council of Education told The House of Commons: "Upon the speedy provision of elementary education depends our industrial prosperity...if we leave our work-folk any longer unskilled...they will become overmatched in the competition of the world" (Hurt 1971, pp. 223-224). The reports made various recommendations which highlighted the need to redefine elementary schools, to revise the curriculum throughout the entire school system, particularly with respect to industry and manufacture, and to improve teacher training.

In addition, in 1868, secondary schools were investigated by the Schools Inquiry Commission, which found a very unsatisfactory level for the vast majority of schools that employed untrained teachers and used antiquated methods. Their main proposal was to organize a state inspection of secondary

[39]There was a growing consensus among workers and capitalists about the virtues of reform. The labor union movement was increasingly calling for a national system of non-sectarian education. The National Education League (founded in 1869 by radical Liberals and Dissenters) demanded a free, compulsory, non-sectarian national system of education (Green, 1990, p. 302).

[40]Indeed, the Factory Act of 1802 required owners of textile mills to provide elementary instruction for their apprentices, but the law was poorly enforced (Cameron (1989, p. 216-217)).

[41]Moreover, the Nussey brothers, who had written a report on woolen textiles at the Exhibition, returned to Leeds to start a movement for a Yorkshire College of Science.

schools and to provide efficient education geared towards the specific needs of its consumers. In particular, the Royal Commission on Technical Education of 1882 confirmed that England was being overtaken by the industrial superiority of Prussia, France and the United States and recommended the introduction of technical and scientific education into secondary schools.

It appears that the government gradually yielded to the pressure by capitalists as well as labor unions, as reflected by its increased contributions to elementary as well as higher education. In the 1870 Education Act, the government assumed responsibility for ensuring universal elementary education, although it did not provide either free or compulsory education at the elementary level. The Act created a national provision without an integrated system, where voluntary schools existed beside state schools. In 1880, prior to the significant extension of the franchise of 1884 that made the working class the majority in most industrial countries, education was made compulsory throughout England. The 1889 Technical Instruction Act allowed the new local councils to set up technical instruction committees, and the 1890 Local Taxation Act provided public funds that could be spent on technical education (Green, 1990, p. 299).

School enrollment of 10-year olds increased from 40% in 1870 to 100% in 1900, the literacy rate among men, which was stable at around 65% in the first phase of the Industrial Revolution, increased significantly during the second phase reaching nearly 100% at the end of the 19th century (Clark 2002), and the proportion of children aged 5 to 14 in primary schools increased significantly in the second half of the 19th century, from 11% in 1855 to 74% in 1900 (Flora et al. 1983). Finally, the 1902 Balfour Act marked the consolidation of a national education system and created state secondary schools (Ringer 1979 and Green 1990, p. 6) and science and engineering and their application to technology gained prominence (Mokyr 1990, 2002).

Continental Europe The early development of public education occurred in the western countries of continental Europe (e.g., Prussia, France, Sweden, and the Netherlands) well before the Industrial Revolution. The provision of public education at this early stage was motivated by several goals such as social and national cohesion, military efficiency, enlightenment, moral conformity, sociopolitical stability as well as religious reasons. However, as was the case in England, massive educational reforms occurred in the second half of the 19th century due to the rising demand for skills in the process of industrialization. As noted by Green (1990, pp. 293-294) "In continental Europe industrialization occurred under the tutelage of the state and began its accelerated development later when techniques were already becoming more scientific; technical and scientific education had been vigorously promoted from the center as an essential adjunct of economic growth and one that was recognized to be indispensable for countries which wished to close Britain's industrial lead."

In France, indeed, the initial development of the education system occurred well before the Industrial Revolution, but the process was intensified and transformed to satisfy industrial needs in the second phase of the Industrial Revolution. The early development of elementary and secondary education in the 17th and 18th centuries was dominated by the Church and religious orders. Some state intervention in technical and vocational training was designed to reinforce development in commerce, manufacturing and military efficiency. After the French Revolution, the state established universal primary schools. Nevertheless, enrolment rates remained rather low. The state concentrated on the development of secondary and higher education with the objective of producing an effective elite to operate the military and governmental apparatus. Secondary education remained highly selective, offering general and technical instruction largely to the middle class (Green 1990, pp. 135-137 and 141-142)). Legislative proposals during the National Convention quoted by Cubberley (1920, pp. 514-517) are revealing about the

underlying motives for education in this period: "...Children of all classes were to receive education, physical, moral and intellectual, best adapted to develop in them republican manners, patriotism, and the love of labor...They are to be taken into the fields and workshops where they may see agricultural and mechanical operations going on..."

The process of industrialization in France and the associated increase in the demand for skilled labor, as well as the breakdown of the traditional apprenticeship system, significantly affected the attitude towards education. State grants for primary schools were gradually increased in the 1830s and legislation made an attempt to provide primary education in all regions, extend the higher education, and provide teacher training and school inspections. The number of communities without schools fell by 50% from 1837 to 1850 and as the influence of industrialists on the structure of education intensified, education became more stratified according to occupational patterns (Anderson 1975 p. 15, 31). According to Green 1990, p.157): "[This] legislation...reflected the economic development of the period and thus the increasing need for skilled labor." The eagerness of capitalists for rapid education reforms was reflected by the organization of industrial societies that financed schools specializing in chemistry, design, mechanical weaving, spinning, and commerce (Anderson 1975, p 86, 204).

As was the case in England, industrial competition led industrialists to lobby for the provision of public education. The Great Exhibition of 1851 and the London Exhibition of 1862 created the impression that the technological gap between France and other European nations was narrowing and that French manufacturers ought to invest in the education of their labor force to maintain their technological superiority. Subsequently, the reports on industrial education by commissions established in the years 1862 to 1865 reflected the plea of industrialists for the provision of industrial education on a large scale and for the implementation of scientific knowledge in the industry. "The goal of modern education...can no longer be to form men of letters, idle admirers of the past, but men of science, builders of the present, initiators of the future."[42] (Anderson 1975, p. 194).

Education reforms in France were extensive in the second phase of the Industrial Revolution, and by 1881 a universal, free, compulsory and secular primary school system had been established and technical and scientific education further emphasized. Illiteracy rates among conscripts tested at the age of 20 declined gradually from 38% in 1851-55 to 17% in 1876-80 (Anderson 1975, p. 158)), and the proportion of children aged 5 to 14 in primary schools increased from 51.5% in 1850 to 86% in 1901 (Flora et al. 1983)). Hence, the process of industrialization, and the increase in the demand for skilled labor in the production process, led industrialists to support the provision of universal education, contributing to the extensiveness of education as well as to its focus on industrial needs.

In Prussia, as well, the initial steps towards compulsory education took place at the beginning of the 18th century well before the Industrial Revolution. Education was viewed at this stage primarily as a method to unify the state. In the second part of the 18th century, education was made compulsory for all children aged 5 to 13. Nevertheless, these regulations were not strictly enforced due to the lack of funding associated with the difficulty of taxing landlords for this purpose, and due to the loss of income from child labor. At the beginning of the 19th century, motivated by the need for national cohesion, military efficiency, and trained bureaucrats, the education system was further reformed, establishing provincial and district school boards, making education a secular activity and compulsory for a three-year period, and reconstituting the Gymnasium as a state institution that provided nine years of education for the elite (Cubberly 1920 and Green 1990).

The process of industrialization in Prussia and the associated increase in the demand for skilled labor led to significant pressure for educational reforms and thereby to the implementation of universal

[42] L'Enseignement professionnel, ii (1864), p. 332, quoted in Anderson (1975).

elementary schooling. Taxes were imposed to finance the school system and teacher training and certification were established. Secondary schools started to serve industrial needs as well, and the Realschulen, which emphasized the teaching of mathematics and science, was gradually adopted, and vocational and trade schools were founded. Total enrolment in secondary school increased sixfold from 1870 to 1911 (Flora et al. 1983). "School courses...had the function of converting the occupational requirements of public administration, commerce and industry into educational qualifications..." (Muller 1987, pp. 23-24). Furthermore, the Industrial Revolution significantly affected the nature of education in German universities. German industrialists who perceived advanced technology as the competitive edge that could boost German industry, lobbied for reforms in the operation of universities, and offered to pay to reshape their activities so as to favor their interest in technological training and industrial applications of basic research (McClelland 1980, p. 300-301).

The structure of education in the Netherlands also reflected the interest of capitalists in the skill formation of the masses. In particular, as early as the 1830s, industrial schools were established and funded by private organizations, representing industrialists and entrepreneurs. Ultimately, in the latter part of the 19th century, the state, urged by industrialists and entrepreneurs, started to support these schools (Wolthuis, 1999, pp. 92-93, 119, 139-140, 168, 171-172).

United States The process of industrialization in the US also increased the importance of human capital in the production process. Evidence provided by Abramowitz and David (2000) and Goldin and Katz (2001) suggests that over the period 1890-1999, the contribution of human capital accumulation to the growth process of the United States nearly doubled.[43] As argued by Goldin (2001), the rise of the industrial, business and commerce sectors in the late 19th and early 20th centuries increased the demand for managers, clerical workers, and educated sales personnel who were trained in accounting, typing, shorthand, algebra, and commerce. Furthermore, in the late 1910s, technologically advanced industries demanded blue-collar craft workers who were trained in geometry, algebra, chemistry, mechanical drawing, etc. The structure of education was transformed in response to industrial development and the increasing importance of human capital in the production process, and American high schools adapted to the needs of the modern workplace of the early 20th century. Total enrolment in public secondary schools increased 70-fold from 1870 to 1950. (Kurian, 1994).[44]

B. Human Capital, Factor Prices and Inequality

In the first phase of the Industrial Revolution, prior to the implementation of significant education reforms, physical capital accumulation was the prime engine of economic growth. In the absence of significant human capital formation, the concentration of capital among the capitalist class widened

[43]It should be noted that literacy rates in the US were rather high prior to this increase in the demand for skilled labor. Literacy rates among the white population were already 89% in 1870, 92% in 1890, and 95% in 1910 (Engerman and Sokoloff (2000)). Education in earlier periods was motivated by social control, moral conformity, and social and national cohesion, as well as required skills for trade and commerce. In particular, Field (1976) and Bowles and Gintis (1975) argue that educational reforms are designed to *sustain* the existing social order, by displacing social problems into the school system.

[44]As noted by Galor and Moav (2004), due to differences in the structure of education finance in the US in comparison to European countries, capitalists in the US had only limited incentives to lobby for the provision of education and support it financially. Unlike the central role that government funding played in the provision of public education in European countries, the evolution of the education system in the US was based on local initiatives and funding. The local nature of the education initiatives in the US induced community members, in urban as well as rural areas, to play a significant role in advancing their schooling system. American capitalists, however, faced limited incentives to support the provision of education within a county in an environment where labor was mobile across counties and the benefits from educational expenditure in one county may be reaped by employers in other counties. "The impetus to expand education to the secondary level was primarily a grassroots movement led by parents, employers, and even young people themselves" (Goldin (1999)).

wealth inequality. Once education reforms were implemented, however, the significant increase in the return to labor relative to capital, as well as the significant increase in the real return to labor and the associated accumulation of assets by the workers, brought about a decline in inequality.

Evidence suggests that in the first phase of the Industrial Revolution, prior to the implementation of education reforms, capital accumulation brought about a gradual increase in wages along with an increase in the wage-rental ratio. Education reforms in the second phase of the Industrial Revolution were associated with a sharp increase in real wages along with a sharp increase in the wage-rental ratio.[45] Finally, wealth inequality widened in the first phase of the Industrial Revolution and reversed its course in the second phase, once significant education reforms were implemented.

As documented in Figure 2.29, over the time period 1823-1915, wealth inequality in the UK reached a peak around 1870 and declined thereafter, in close association with the patterns of enrolment rates and factor prices, depicted in Figures 2.28 and 2.29.[46] It appears that the decline in inequality is associated with the significant changes that occurred around 1870 in the relative returns to the main factors of production possessed by capitalists and workers. These changes in factor prices reflect the increase in enrolment rates – in particular the process of education reforms from 1830 to 1870 and its consolidation in the Education Act of 1870 – and its delayed effect on the skill level per worker.

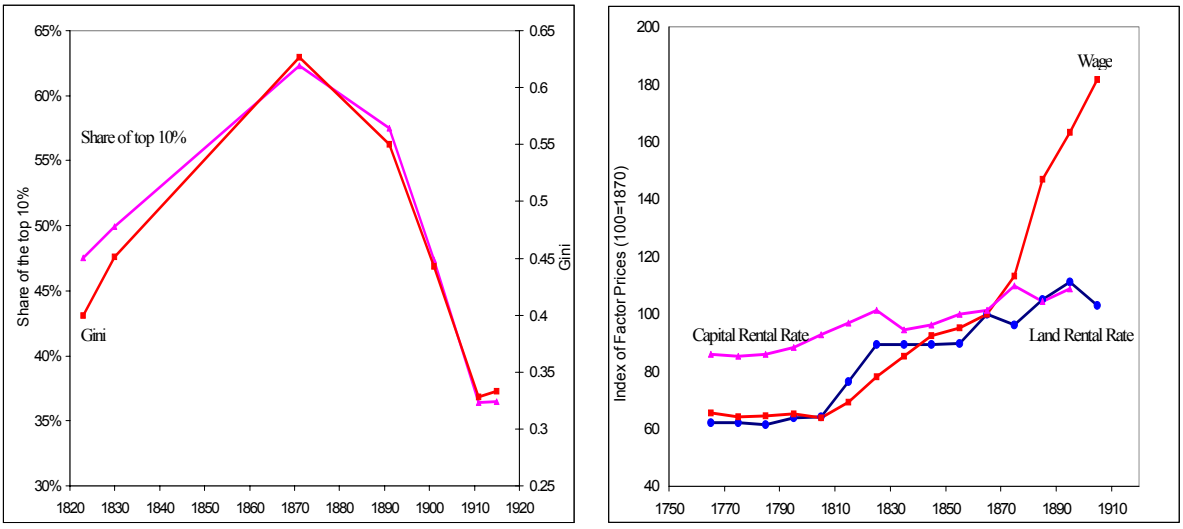

Figure 2.29. Wealth Inequality and Factor Prices: England 1820-1920
Source: Williamson (1985) for inequality and Clark (2002, 2003) for factor prices

Similar patterns of the effect of education on factor prices and therefore on inequality are observed in France as well. As argued by Morrisson and Snyder (2000), wealth inequality in France increased during the first half of the 19th century, and started to decline in the last decades of the 19th century in close association with the rise in education rates depicted in Figure 2.28, the rise in real wages depicted in Figure 2.10, and a declining trend of the return to capital over the 19th century. The decline in inequality in France appears to be associated with the significant changes in the relative returns to the main factors of production possessed by capitalists and workers in the second part of the 19th century As depicted in Figures 2.10, based on the data presented in Levy-Leboyer and Bourguignon (1990), real wages as well as the wage-rental ratio increased significantly as of 1860, reflecting the rise in the demand

[45]It should be noted that the main source of the increase in real wages was not a decline in prices. Over this period nominal wages increased significantly as well.

[46]It should be noted that the return to capital increased moderately over this period, despite the increase in the supply of capital, reflecting technological progress, population growth, and accumulation of human capital.

for skilled labor and the effect of the increase in enrolment rates on the skill level per worker.

The German experience is consistent with this pattern as well. Inequality in Germany peaked towards the end of the 19th century (Morrisson and Snyder 2000) in association with a significant increase in the real wages and in the wage-rental ratio from the 1880s (Spree 1977 and Berghahn 1994), which is in turn related to the provision of industrial education in the second half of the 19th century.

The link between the expansion of education and the reduction in inequality is present in the US as well. Wealth inequality in the US, which increased gradually from colonial times until the second half of the 19th century, reversed its course at the turn of the century and maintained its declining pattern during the first half of the 20th century (Lindert and Williamson 1976). As argued by Goldin (2001), the emergence of the "new economy" in the early 20th century increased the demand for educated workers. The creation of publicly funded mass modern secondary schools from 1910 to 1940 provided general and practical education, contributed to workers productivity and opened the gates for college education. This expansion facilitated social and geographic mobility and generated a large decrease in inequality in economic outcomes.

C. Independence of Political Reforms in the 19th Century

The 19th century was marked by significant political reforms along with the described education reforms. One could therefore challenge the significance of the industrial motive for education reform, suggesting that political reforms during the 19th century shifted the balance of power towards the working class and enabled workers to implement education reforms against the interest of the industrial elite, has no empirical support. However, political reforms that took place in the 19th century had no apparent effect on education reforms over this period, strengthening the hypothesis that indeed industrial development, and the increasing demand for human capital, were the trigger for human capital formation and the demographic transition.[47] Education reforms took place in autocratic states that did not relinquish political power throughout the 19th century, and major reforms occurred in societies in the midst of the process of democratization well before the stage at which the working class constituted the majority among the voters.

In particular, the most significant education reforms in the UK were completed before the voting majority shifted to the working class. The patterns of education and political reforms in the UK during the 19th century are depicted in Figure 2.30. The Reform Act of 1832 nearly doubled the total electorate, but nevertheless only 13% of the voting-age population were enfranchised. Artisans, the working classes, and some sections of the lower middle classes remained outside of the political system. The franchise was extended further in the Reform Acts of 1867 and 1884 and the total electorate nearly doubled in each of these episodes. However, working-class voters did not become the majority in all urban counties until 1884 (Craig 1989).

The onset of England's education reforms, and in particular, the fundamental Education Act of 1870 and its major extension in 1880 occurred prior to the political reforms of 1884 that made the working class the majority in most counties. As depicted in Figure 2.30, a trend of significant increase in primary education was established well before the extension of the franchise in the context of the 1867 and 1884 Reform Acts. In particular, the proportion of children aged 5 to 14 in primary schools increased five-fold (and surpassed 50%) over the three decades prior to the qualitative extension of the franchise in 1884 in which the working class was granted a majority in all urban counties. Furthermore, the political reforms do not appear to have any effect on the pattern of education reform. In fact, the average growth rate of education attendance from decade to decade over the period 1855 to 1920

[47] See for instance, Acemoglu and Robinson (2000), where the extension of the franchise during the 19th century is viewed as a commitment devise ensuring future income redistribution from the elite to the masses.

reaches a peak at around the Reform Act of 1884 and starts declining thereafter. It is interesting to note, however, that the abolishment of education fees in nearly all elementary schools occurs only in 1891, after the Reform Act of 1884, suggesting that the political power of the working class may have affected the distribution of education cost across the population, but consistent with the proposed thesis, the decision to educate the masses was taken independently of the political power of the working class.

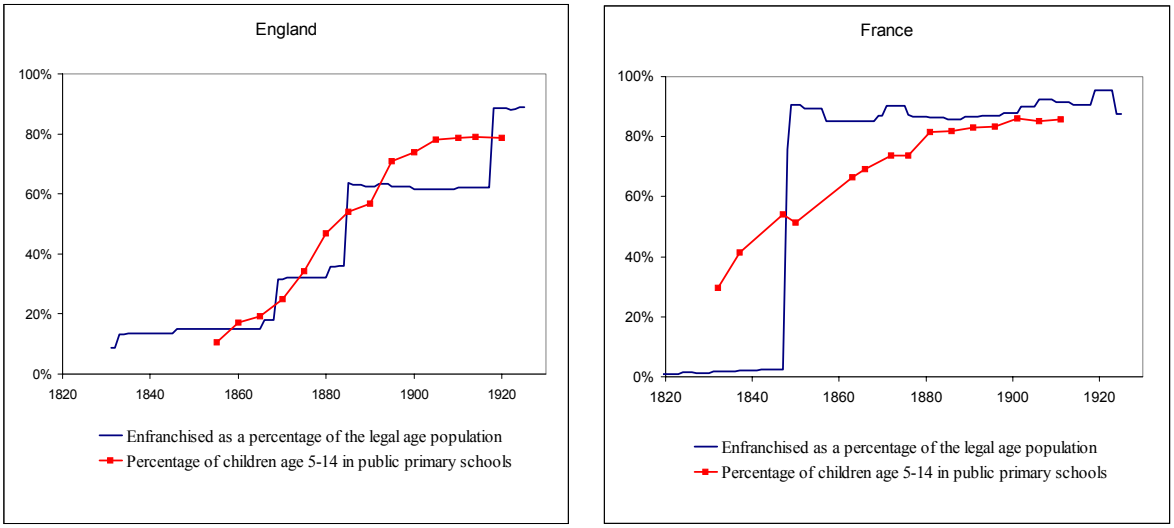

Figure 2.30. The Evolution of Voting Rights and School Enrolment
Source: Flora et al. (1983)

In France, as well, the expanding pattern of education preceded the major political reform that gave the voting majority to the working class. The patterns of education and political reforms in France during the 19th century are depicted in Figure 2.30. Prior to 1848, restrictions limited the electorate to less than 2.5% of the voting-age population. The 1848 revolution led to the introduction of nearly universal voting rights for males. Nevertheless, the proportion of children aged 5 to 14 in primary schools doubled (and exceeded 50%) over the two decades prior to the qualitative extension of the franchise in 1848 in which the working class was granted a majority among voters. Furthermore, the political reforms of 1848 do not appear to have any effect on the pattern of education expansion.

A similar pattern occurs in other European countries. Political reforms in the Netherlands did not affect the trend of education expansion and the proportion of children aged 5 to 14 in primary schools exceeded 60% well before the major political reforms of 1887 and 1897. Similarly, the trends of political and education reforms in Sweden, Italy, Norway, Prussia and Russia do not lend credence to the alternative hypothesis.

Less Developed Economies

The process of industrialization was characterized by a gradual increase in the relative importance of human capital in less developed economies as well. As depicted in Figure 2.31, educational attainment increased significantly across all less developed regions. Moreover, in line with the pattern that emerged among developed economies in the 19th century, the increase in educational attainment preceded the decline in total fertility rates. In particular, the average years of schooling in Africa increased by 44% (from 1.56 to 2.44) prior to the onset of decline in total fertility rates in 1980, as depicted in Figure 2.23, whereas the available data for Asia and Latin America demonstrates a simultaneous increase in educational attainment and a decline in fertility.

Source: Barro and Lee (2000)

2.3.4 International Trade and Industrialization

The process of industrialization in developed economies was enhanced by the expansion of international trade. During the 19th century, North-South trade, as well as North-North trade, expanded significantly due to a rapid industrialization in Northwest Europe as well as the reduction of trade barriers and transportation costs and the benefits of the gold standard. The ratio of world trade to output was about 2% in 1800, but then it rose to 10% in 1870, to 17% in 1900 and 21% in 1913 (Estavadeordal, Frantz, and Taylor 2002). While much of this trade occurred between industrial economies a significant proportion was between industrial and non-industrial economies. As shown in Table 2.1, before 1900 nearly 50% of manufactured exports were to non-European and non-North American economies. By the end of 19th century a clear pattern of specialization emerged. The UK and Northwest Europe were net importers of primary products and net exporters of manufactured goods, whereas the exports of Asia, Oceania, Latin America and Africa were overwhelmingly composed of primary products. (Findlay and O'Rourke 2001).

Table 2.1. Regional Shares of World Trade in Manufactures
Source: Yates (1959)

	1876-1880		1896-1900		1913	
	Exports	Imports	Exports	Imports	Exports	Imports
U.K. and Ireland	37.8%	9.1%	31.5%	10.4%	25.3%	8.2%
Northwest Europe	47.1%	18.1%	45.8%	20.3%	47.9%	24.4%
Other Europe	9.2%	13.3%	10.3%	12.2%	8.3%	15.4%
U.S. and Canada	4.4%	7.7%	7.4%	9.6%	10.6%	12.1%
Rest of the World	1.5%	51.8%	5.0%	47.5%	7.9%	39.9%

Atlantic trade as well as trade with Asia, in an era of colonialism, had a major effects on European growth starting in the late 16th century (Acemoglu et al. 2003). Furthermore, later expansion of international trade contributed further to the process of industrialization in the UK and Europe (O'Rourke and Williamson 1999). For the UK, the proportion of foreign trade to national income grew from about 10% in the 1780s to about 26% over the years 1837-45, and 51.5% in the time period 1909-13 (Kuznets 1967). Other European economies experienced a similar pattern as well. The proportion of foreign trade to national income on the eve of World War I was 53.7% in France, 38.3% in Germany , 33.8% in Italy, and 40.4% in Sweden (Kuznets 1967, Table 4). Furthermore, export was critical for the viability of some industries, especially the cotton industry, where 70% of the UK output was exported in the 1870's. The quantitative study of Stokey (2001) suggests that trade was instrumental for the increased share of manufacturing in total output in the UK, as well as for the significant rise in real wages. Thus while it appears that technological advances could have spawned the Industrial Revolution without an expansion of international trade, the growth in exports increased the pace of industrialization and the growth rate of output per capita.[48]

2.4 The Great Divergence

The differential timing of the take-off from stagnation to growth across countries and the corresponding variations in the timing of the demographic transition led to a great divergence in income per capita as well as population growth.

The last two centuries have witnessed dramatic changes in the distribution of income and population across the globe. Some regions have excelled in the growth of income per capita, while other regions have been dominant in population growth. Inequality in the world economy was negligible till the 19th century. The ratio of GDP per capita between the richest region and the poorest region in the world was only 1.1:1 in the year 1000, a 2:1 in the year 1500 and 3:1 in the year 1820. As depicted in Figure 2.32, there has been a 'Great Divergence' in income per capita among countries and regions in the past two centuries. In particular, the ratio of GDP per capita between the richest region (Western offshoots) and the poorest region (Africa) has widened considerably from a modest 3:1 ratio in 1820, to a 5:1 ratio in 1870, a 9:1 ratio in 1913, a 15:1 in 1950, and a huge 18:1 ratio in 2001.

[48] Pomeranz (2000), provides historical evidence for the vital role of trade in the 'take off' of the European economies. He argues that technological and development differences between Europe and Asia were minor around 1750, but the discovery of the New World enabled Europe, via Atlantic trade, to overcome 'land constraints' and to take-off technologically.

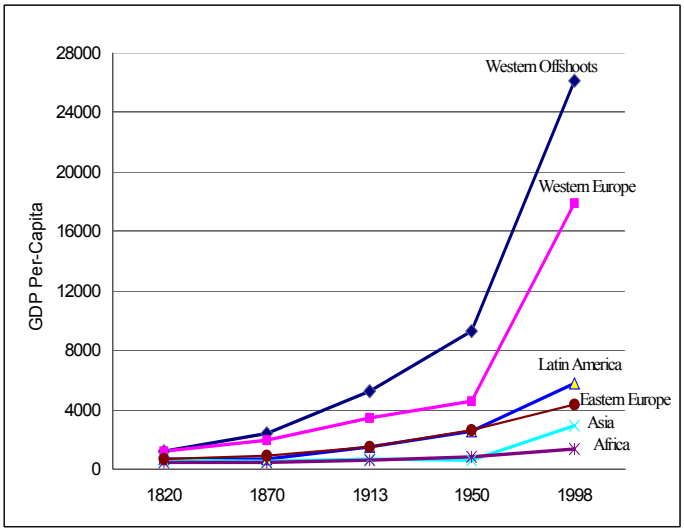

Figure 2.32. The Great Divergence
Source: Maddison (2001)

An equally momentous transformation occurred in the distribution of world population across regions, as depicted in Figure 2.33. The earlier take-off of Western European countries increased the amount of resources that could be devoted for the increase in family size, permitting a 16% increase in the share of their population in the world economy within a 50 year period (from 12.8% in 1820 to 14.8% in 1870). However, the early onset in the Western European demographic transition and the long delay in the demographic transition of less developed regions well into the 2nd half of the twentieth century led to a 55% decline in the share of Western European population in the world, from 14.8% in 1870 to 6.6% in 1998. In contrast, the prolongation of Post-Malthusian period among less developed regions in association with the delay in their demographic transition well into the second half of 20th century, channeled their increased resources towards a significant increase in their population. Africa's share of world population increased 84%, from 7% in 1913 to 12.9% in 1998, Asia's share of world population increased 11% from 51.7% in 1913 to 57.4% in 1998, and Latin American countries increased their share in world population from 2% in 1820 to 8.6% in 1998.

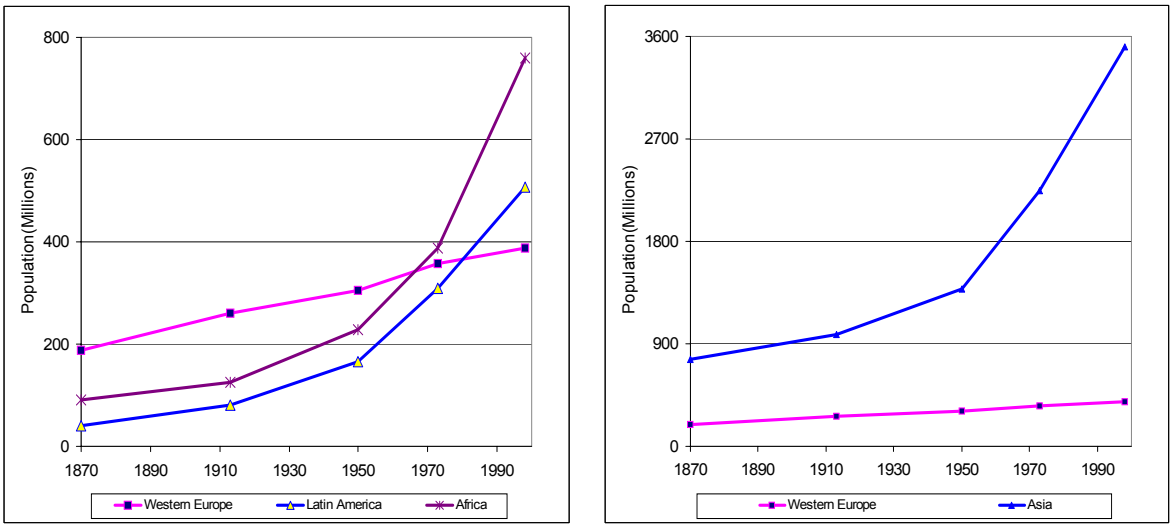

Figure 2.33. Divergence in Regional Populations

Thus, while the ratio of income per capita in Western Europe to that in Asia has tripled in the last two centuries, the ratio of Asian to European population has doubled.[49]

The divergence that has been witnessed in the last two centuries has been maintained across countries in the last decades as well (e.g., Jones 1997 and Pritchett 1997). Interestingly, however, Sala-i-Martin (2002) has shown that the phenomenon has not been maintained in recent decades across people in the world, (i.e., when national boundaries are removed).

3 The Fundamental Challenges

The discovery of a unified theory of economic growth that could account for the intricate process of development in the last thousands of years is one of the most significant research challenges facing researchers in the field of growth and development. A unified theory would unveil the underlying micro-foundations that are consistent with entire the process of economic development, enhancing the confidence in the viability of growth theory, its predictions and policy implications, while improving the understanding of the driving forces that led to the recent transition from stagnation to growth and the Great Divergence. Moreover, a comprehensive understanding of the hurdles faced by less developed economies in reaching a state of sustained economic growth would be futile unless the forces that initiated the transition of the currently developed economies into a state of sustained economic growth would be identified and modified to account for the differences in the structure of less developed economies in an interdependent world.

The evidence presented in section 2 suggests that the preoccupation of growth theory with the empirical regularities that have characterized the growth process of developed economies in the past century and of less developed economies in the last few decades, has become harder to justify from a scientific viewpoint. Could we justify the use of selective observations about the recent course of the growth process and its principal causes in the formulating exogenous and endogenous neoclassical growth models? Could we be confident about the predictions of a theory that is not based on micro-foundations that match the major characteristics of the entire growth process? The evolution of theories in older scientific disciplines suggests that theories that are founded on the basis of a subset of the existing observations are fragile and non-durable.

3.1 Mysteries of the Growth Process

The underlying determinants of the stunning recent escape from the Malthusian trap have been shaded in mystery and their significance for the understanding of the contemporary growth process has been explored only very recently. What are the major economic forces that led to the epoch of Malthusian stagnation that had characterized most of human history? What is the origin of the sudden spurt in growth rates of output per capita and population that occurred in the course of the take-off from stagnation to growth? Why had episodes of technological progress in the pre-industrialization era failed to generate sustained economic growth? What was the source of the dramatic reversal in the positive relationship between income per capita and population that existed throughout most human history? What are the main forces that prompted the demographic transition? Would the transition to a state of sustained economic growth be feasible without the demographic transition? Are there

[49] Over the period 1820-1998, the ratio between income per capita in Western Europe and Asia (excluding Japan) grew 2.9 times, whereas the ratio between the Asian population (excluding Japan) and the Western European population grew 1.7 times [Maddison, 2001].

underlying unified behavioral and technological structures that can account for these distinct phases of development simultaneously and what are their implications for the contemporary growth process?

The mind-boggling phenomenon of the Great Divergence in income per capita across regions of the world in the past two centuries, that accompanied the take-off from an epoch of stagnation to a state of sustained economic growth, presents additional unresolved mysteries about the growth process. What accounts for the sudden take-off from stagnation to growth in some countries in the world and the persistent stagnation in others? Why has the positive link between income per capita and population growth reversed its course in some economies but not in others? Why have the differences in income per capita across countries increased so markedly in the last two centuries? Has the pace of transition to sustained economic growth in advanced economies adversely affected the process of development in less-developed economies?

The transitions from a Malthusian epoch to a state of sustained economic growth and the emergence of the Great Divergence have shaped the current structure of the world economy. Nevertheless, neoclassical growth models abstracted from these the significant aspects of the growth process. In recent years, however, it has been increasingly recognized that the understanding of the contemporary growth process would be fragile and incomplete unless growth theory would be based on proper micro-foundations that reflect the growth process in its entirety.

3.2 The Incompatibility of Non-Unified Growth Theories

Existing (non-unified) growth models are unable to capture the growth process throughout human history. Malthusian models capture the growth process during the Malthusian epoch but are incompatible with the transition to the Modern Growth Regime. Neoclassical growth models (with endogenous or exogenous technological change), in contrast, are compatiable with the growth process of the *developed* economies during the Modern Growth Regime, but fail to capture the evolution of economies during the Malthusian epoch, the origin of the take-off from the Malthusian epoch into the Post-Malthusian Regime, and the sources of the demographic transition and the emergence of the modern growth regime. Moreover, the failure of non-unified growth models in identifying the underlying factors that led to the transition from stagnation to growth limits their applicability for the contemporary growth process of the less developed economies and thereby for the current evolution of the world income distribution.

3.2.1 Malthusian and Post-Malthusian Theories

The Malthusian Theory

The Malthusian theory, as was outlined initially by Malthus (1798), captures the main attributes of the epoch of Malthusian stagnation that had characterized most of human existence, but is utterly inconsistent with the prime characteristics of the modern growth regime.[50]

The theory suggests that the stagnation in the evolution of income per capita over this epoch reflected the counterbalancing effect of population growth on the expansion of resources, in an environment characterized by diminishing returns to labor. The expansion of resources, according to Malthus, would lead to an increase in population growth, reflecting the natural result of "passion between the sexes".[51] In contrast, when population size would grow beyond the capacity of the available resources,

[50]The Malthusian theory was formalized recently. Kremer (1993) models a reduced-form interaction between population and technology along a Malthusian equilibrium, and Lucas (2002) presents a Malthusian model in which households optimize over fertility and consumption, labor is subjected to diminishing returns due to the presence of a fixed quantity of land, and the Malthusian level of income per capita is determined endogenously.

[51]As argued by Malthus (1798), *"The passion between the sexes has appeared in every age to be so nearly the same, that it may always be considered, in algebraic language as a given quantity."*

it would be reduced by the "preventive check" (i.e., intentional reduction of fertility) as well as by the "positive check" (i.e., the tool of nature due to malnutrition, disease, and famine).

According to the theory, periods marked by the absence of changes in the level of technology or in the availability of land, were characterized by a stable population size as well as a constant income per capita. In contrast, episodes of technological progress, land expansion, and favorable climatic conditions, brought about temporary gains in income per capita, triggering an increase in the size of the population which led ultimately to a decline in income per capita to its long-run level. The theory proposes therefore that variations in population density across countries during the Malthusian epoch reflected primarily cross-country differences in technologies and land productivity. Due to the positive adjustment of population to an increase in income per capita, differences in technologies or in land productivity across countries resulted in variations in population density rather than in the standard of living.

The Malthusian theory generates predictions that are largely consistent with the characteristics of economies during the Malthusian epoch, as described in Section 2.1: (a) Technological progress or resource expansion would lead to a larger population, without altering the level of income in the long run. (b) Income per capita would fluctuate during the Malthusian epoch around a constant level. (c) Technologically superior countries would have eventually denser populations but their standard of living in the long run would not reflect the degree of their technological advancement. These predictions, however, are irremediably inconsistent with the relationship between income per capita and population that has existed in the post-demographic transition era as well as with the state of sustained economic growth that had characterized the Modern Growth Regime.

Unified theories of economic growth, in contrast, incorporate the main ingredients of the Malthusian economy into a broader context focusing on the interaction in this epoch between technology and the size of the population and the distribution of its characteristics, that generate the main ingredients of the Malthusian epoch but lead to an inevitable take-off to the Post Malthusian Regime.

The Post-Malthusian Theory

The Post-Malthusian theories capture the acceleration of the growth rate of income per capita and population growth that occurred in the Post-Malthusian Regime in association with the process of industrialization. They do not capture, however, the stagnation during the Malthusian epoch and the economic forces that gradually emerged in this era and brought about the take-off from the Malthusian trap. Moreover, these theories do not account for the factors that ultimately originated the demographic transition and the transition to a state of sustained economic growth.[52]

These theories suggest that the acceleration in technological progress and the associated rise in income per capita was only channeled partly towards an increase in the size of the population. Although, the Malthusian mechanism linking higher income to higher population growth continued to function, the effect of higher population on diluting resources per capita, and thus lowering income per capita, was counteracted by the acceleration in technological progress and capital accumulation, allowing income

[52]Models that are not based on Malthusian elements are unable to capture the long epoch of Malthusian stagnation in which output per capita fluctuates around a subsistence level. For instance, an interesting research by Goodfriend and McDermott (1995) demonstrates that exogenous population growth increases population density and hence generates a greater scope for the division of labor inducing the development of markets and economic growth. Their model, therefore generates a take-off from non-Malthusian stagnation to Post-Malthusian Regime in which population and output are positively related. The model lacks Malthusian elements and counter-factually it implies therefore that since the emergence of a market economy over 5000 years ago growth has been strictly positive. Moreover, it does not generate the forces that would bring about the demographic transition and ultimately sustained economic growth. In the long-run the economy remains in the Post-Malthuisan regime in which the growth of population and output are positively related. Other non-Malthusian models that abstracts from population growth and generate an acceleration of output growth along the process of industrialization include Acemoglu and Zilibotti (1997).

per capita to rise despite the offsetting effects of population growth.

Kremer (1993), in an attempt to defend the role of the scale effect in endogenous growth models, examines a reduced-form of the coevolution of population and technology in a Malthusian and Post Malthusian environment, providing evidence for the presence of a scale effect in the pre-demographic transition era. [53] Kremer's Post-Malthusian theory does not identify the factors that brought about the take-off from the Malthusian trap, as well as the driving forces behind the demographic transition and the transition to a state of sustained economic growth.

Unified theories capture the main characteristics of the Post-Malthusian Regime, and generate, in contrast, the endogenous driving forces that brought about the take-off from the Malthusian epoch into this regime and ultimately enabled the economy to experience a demographic transition and to reside in a state of sustained economic growth.

3.2.2 Theories of Modern Economic Growth

Exogenous growth models (e.g. Solow 1956) that have focused primarily on the role of factor accumulation in the growth process, as well as endogenous growth models (e.g., Romer 1990, Grossman and Helpman 1991, and Aghion and Howitt 1992) that have devoted their attention to the role of endogenous technological progress in the process of development, were designed to capture the main characteristics of the Modern Growth Regime. These models, however, are inconsistent with the pattern of development that had characterized economies over most of human existence. They do not account for Malthusian epoch the economic factors that brought about the take-off from the Malthusian regime into the Post-Malthusian Regime, and the forces that brought about the demographic transition and ultimately the state of sustained economic growth.[54]

Modern non-unified growth theory has not developed the research methodology that would enable researchers to shed light on the principal factors that would enable less developed economies that are in a state of Malthusian stagnation, or in a post-Malthusian regime to take-off to a state of sustained economic growth. Moreover, most endogenous and exogenous growth models are inconsistent with the changes in the demographic regime along the process of development.[55] With few exceptions non-unified growth models do not generate the hump-shaped relationship between income per capita and population growth in the process of development. Most growth models with endogenous population have been oriented toward the modern regime, capturing the recent negative relationship between population growth and income per capita, but failing to capture the positive effect of income per capita on population growth that had characterized most human existence and the economic factors that triggered the demographic transition.[56]

[53] Komlos and Artzrouni (1990) simulates an escape from a Malthusian trap based on the Malthusian and Boserupian interaction between population and technology.

[54] Non-unified growth models are inconsistent with the process of development in the Malthusian epoch. Moreover, as long as the neoclassical production structure of non-decreasing returns to scale is maintained, they could not be modified to account for the Malthusian epoch by the incorporation of endogenous population growth. Suppose that the optimal growth model would be augmented to account for endogenous population. Suppose further that the parameters of the model would be chosen so as to assure that the level of income per capita would reflect the level that existed during the Malthusian epoch and population growth will be near replacement level as was the case during this era. This equilibrium would not possess the prime characteristic of a Malthusian equilibrium. Namely, technological progress would raise income per capita permanently since adjustments in population growth would not offset this rise of income (as long as the return to labor is characterized by non-diminishing returns to scale).

[55] In fact, most endogenous growth models that focus exclusively on the modern growth regime are inconsistent with the demographic structure within this regime, predicting a positive effect of population growth on (the growth rate of) income per capita. A notable exception is Dalgaard and Kreiner (2001).

[56] Earlier papers that captures aspects of the cross-section relationship between income per capita and fertility includes Ben Zion and Razin (1975), Barro and Becker, (1989) and Becker, Murphy and Tamura (1990), and recent ones include Deopke and De la Croix (2003) and Moav (2005).

3.3 Theories of the Demographic Transition and Their Empirical Validity

The theories of the demographic transition attempt to capture the determinants of the significant reduction in fertility rates and population growth that characterized the world in the past century, following the unprecedented increase in population growth during the Post-Malthusian regime, enabling economies to convert a increasing share of the benefits of factor accumulation and technological progress into growth of output per capita.

There are several factors that could have theoretically triggered a demographic transition. The simultaneity of the demographic transition across Western European countries suggests that a common cause may have originated the various transitions. Was it an outcome of a simultaneous decline in mortality rates across Western European countries? Was it associated with a nearly simultaneous rise in income across Western European countries? An outcome of the rise in the relative wages of women in the second phase of the Industrial Revolution? Or was it a consequence of the universal rise in the demand for education and the associated decline in child labor in the second phase of the Industrial Revolution? Historical evidence suggests that demographers' explanation of the demographic transition - the decline in mortality - is highly implausible. Moreover, Becker's emphasis on the role of rising income in the demographic transition is inconsistent with the evidence. Empirical evidence suggests that the rise in the demand for human capital is the most significant force behind the demographic transition and it is therefore a critical building block in existing unified theories.

3.3.1 The Decline in Infant and Child Mortality

The decline in infant and child mortality rates that preceded the decline in fertility rates in most countries in the world, with the notable exceptions of France and the US, has been demographers' favorite explanation for the onset of the decline in fertility in the course of the demographic transition.[57] Nevertheless, it appears that this simplistic viewpoint is based on weak theoretical reasonings and is inconsistent with historical evidence.

Existing theories suggest that parents generate utility from the number (and possibly the quality) of their surviving offspring. A decline in mortality rates, therefore, would be expected to lead to a corresponding reduction in total fertility rates, but not necessarily to a reduction in the number of children reaching adulthood. While it is highly plausible that mortality rates were among the factors that affected the level of total fertility rates along human history, historical evidence does not lend credence to the argument that the decline in mortality rates accounts for the *reversal* of the positive historical trend between income and fertility. A careful examination of the various factors that affect fertility rates (i.e., mortality rate, income level, the return to investment in child quality, and the gender wage gap) reveals that this argument is inconsistent with the evidence.

The decline in mortality rates does not appear to be the trigger for the decline in fertility in Western Europe. As demonstrated in Figures 2.23 and 2.24, the mortality decline in Western Europe started nearly a century prior to the decline in fertility and it was associated initially with increasing fertility rates in some countries and non-decreasing fertility rates in other countries

In particular, as demonstrated in Figure 3.1, the decline in mortality started in England in the 1730s and was accompanied by a steady increase in fertility rates until 1820. The significant rise in income per capita in the Post-Malthusian Regime increased the desirable number of surviving offspring and thus, despite the decline in mortality rates, fertility increased significantly so as to reach this higher

[57] The effect of the decline in mortality rates on the prolongation of productive life and thus on the return to human capital is discussed in section 3.3.3.

desirable level of surviving offspring.[58] As depicted in Figure 3.1, the decline in fertility during the demographic transition occurred in a period in which this pattern of increased income per capita (and its potential positive effect on fertility) was intensified, while the pattern of declining mortality (and its adverse effect on fertility) maintained the trend that existed in the 140 years that preceded the demographic transition, suggesting that in the absence of the intervention of a third factor fertility would have risen further.[59] Thus, the reversal in the fertility patterns in England as well as other Western European countries in the 1870s suggests that it is very likely that the demographic transition was prompted by a different universal force.[60]

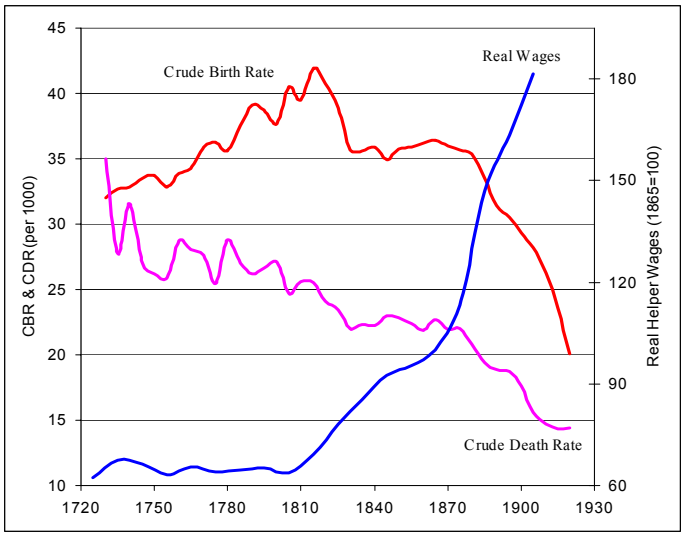

Figure 3.1. Fertility, Mortality and Real Wages, England 1730-1920
Source: Wrigley and Schofield (1981), Clark (2002), and Andorka (1978)

Furthermore, most relevant from an economic point of view is the cause of the reduction in net fertility (i.e. the number of children reaching adulthood). The decline in the number of surviving offspring that was observed during the demographic transition (e.g., Figure 2.22) is unlikely to follow from mortality decline. Mortality decline would lead to a reduction in the number of surviving offspring if the following set implausible of conditions would be met:[61] (i) there exists a significant precautionary demand for children, i.e., individuals are significantly risk averse with respect to their expected number of surviving offspring and they hold a buffer stock of children in a high mortality environment (highly improbable from an evolutionary perspective), (ii) risk aversion with respect to consumption is smaller than risk aversion with respect to fertility (evolutionary theory would suggest the opposite), (iii) sequential fertility (i.e., replacement of non-surviving children) is modest,[62] and (iv) parental resources

[58]The argument is valid even if fertility rates would have remained unchanged over this period.

[59]One could argue that the decline in mortality was not internalized into the decision of household who had difficulties separating temporary decline from a permanent one. This argument is highly implausible given the fact that mortality declined monotonically for nearly 140 years prior to the demographic transition. It is inconceivable that six generations of household did not update information about mortality rates in their immediate surrounding, while keeping the collective memories about mortality rates two centuries earlier.

[60]The mortality channel is inconsistent with additional evidence: the decline in fertility started in France and the US prior to the decline in mortality rates

[61]In particular, the theoretical analysis of Kalemli-Ozcan (2002) generates a reduction in net fertility in reaction to a decline in mortality assuming (implicitly) that all these implausible conditions are satisfied. Eckstein et al. (1999) argue in their structural quantitative analysis of the demographic transition in Sweden, that mortality decline played a role in the demographic transition. Their underlying theoretical structure, however, requires conditions (iii) and (iv) as well as specific interactions between mortality, wages, and the return to human capital.

[62]Doepke (2005) shows that regardless of the degree of risk aversion, the feasibility of sequential fertility is sufficient to preclude the decline in net fertility in reaction to a decline in mortality.

saved from the reduction in the number of children that do not survive to adulthood do not lead to a rise in fertility.[63]

A quantitative analysis by Doepke (2005) supports the viewpoint that a decline in infant mortality rates was not the trigger for the decline in net fertility during the demographic transition. Utilizing the mortality and fertility data from England in the time period 1861–1951, he shows that the decline in child mortality in this time period should have resulted in an rise in net fertility rates, in contrast to the evidence, suggesting that other factors generated the demographic transition. Similar conclusions about the insignificance of the mortality decline in the decline in fertility during the demographic transition is reached in the quantitative analysis of Fernandez-Vilaverde (2003).

3.3.2 The Rise in the Level of Income Per Capita

The rise in income per capita prior to the demographic transition has led some researchers to argue that the demographic transition was triggered by the rise in income per capita and its asymmetric effects on the income of households on the one hand and the opportunity cost of raising children on the other hand.

Becker (1981) advanced the argument that the decline in fertility in the course of the demographic transition is a by-product of the rise in income per capita that preceded the demographic transition. He argues that the rise in income induced a fertility decline because the positive income effect on fertility that was generated by the rise in wages was dominated by the negative substitution effect that was brought about by the rising opportunity cost of children. Similarly, Becker and Lewis (1973) argue that the income elasticity with respect to child quality is greater than that with respect to child quantity, and hence a rise in income led to a decline in fertility along with a rise in the investment in each child.

This theory, however, is counter-factual. It suggests that the timing of the demographic transition across countries in similar stages of development would reflect differences in income per capita. However, remarkably, as depicted in Figure 2.22, the decline in fertility occurred in the same decade across Western European countries that differed significantly in their income per capita. In 1870, on the eve of the demographic transition, England was the richest country in the world, with a GDP per capita of \$3191.[64] In contrast, Germany that experienced the decline in fertility in the same years as England, had in 1870 a GDP per capita of only \$1821 (i.e., 57% of that of England). Sweden's GDP per capita of \$1664 in 1870 was 48% of that of England, and Finland's GDP per capita of \$1140 in 1870 was only 36% of that of England, but their demographic transitions occurred in the same decade as well.

The simultaneity of the demographic transition across Western European countries that differed significantly in their income per capita suggests that the high level of income that was reached by Western Europeans countries in the Post-Malthusian regime had a very limited role in the demographic transition.[65] Furthermore, a quantitative analysis of the demographic transition in England, conducted by Fernandez-Vilaverde (2003), demonstrates that Becker's theory is counter-factual. In contrast to Becker's theory, the calibration suggests that a rise in income would have resulted in an increase in fertility rates, rather than in the observed decline in fertility.

Interestingly, and consistent with subsequent theories that underlined the critical role of technological progress in the demographic transition, despite the large differences in the *levels* of income

[63] An additional force that operates against the decline in the number of surviving offspring is the physiological constraint on the feasible number of birth per woman. If this constraint is binding for some households in a high mortality regime, a reduction in mortality would operate towards an increase the number of surviving offspring.

[64] Source: Maddison (2001). GDP per capita is measured in 1990 international dollars.

[65] Furthermore, cross-section evidence within countries suggest that the elasticity of the number of surviving offspring with respect to wage income was positive prior to the demographic transition (e.g., Clark (2003)), in contrast to Becker's argument that would require a hump-shaped relationship.

per capita across European countries that experiences the demographic transition in the same time period, the *growth rates* of income per capita of these European countries were rather similar during their demographic transition, ranging from 1.9% per year over the period 1870-1913 in the UK, 2.12% in Norway, 2.17% in Sweden, and 2.87% in Germany.

3.3.3 The Rise in the Demand for Human Capital

The gradual rise in the demand for human capital in the second phase of the Industrial Revolution as well as in the process of industrialization of less developed economies, as documented in section 2.3.3, and its close association with the timing of the demographic transitions, has led researchers to argue that the increasing role of human capital in the production process (rather than the rise in income) induced households to increase their investment in the human capital of their offspring, ultimately leading to the onset of the demographic transition.

Galor and Weil (1999, 2000), argue that the acceleration in the rate of technological progress increased gradually the demand for human capital in the second phase of the Industrial Revolution, inducing parents to invest in the human capital of their offspring. The increase in the rate of technological progress and the associated increase in the demand for human capital brought about two effects on population growth. On the one hand, improved technology eased households' budget constraints and provided more resources for quality as well as quantity of children. On the other hand, it induced a reallocation of these increased resources toward child quality. In the early stages of the transition from the Malthusian regime, the effect of technological progress on parental income dominated, and the population growth rate as well as the average quality increased. Ultimately, further increases in the rate of technological progress that were stimulated by human capital accumulation induced a reduction in fertility rates, generating a demographic transition in which the rate of population growth declined along with an increase in the average level of education. Thus, consistent with historical evidence, the theory suggests that prior to the demographic transition, population growth increased along with investment in human capital, whereas the demographic transition brought about a decline in population growth along with a further increase in human capital formation.[66]

Moreover, Galor and Weil's theory suggests that a universal rise in the demand for human capital in Western Europe (as documented in section 2.3.3) followed by a rapid growth rates of output per-capita generated the observed simultaneous onset of the demographic transition across Western European countries that differed significantly in their levels of income per capita. The simultaneous increase in educational attainment across Western European countries in the second phase of the Industrial Revolution appears as a plausible common cause that brought about the demographic transition. The rise in the demand for human capital in the second phase of the Industrial Revolution in some Western European countries (as documented in section 2.3.3) and the expectations for an imminent increase in the demand for human capital in the other Western European countries led to a significant increase in the investment in children's education and therefore to a decline in fertility.

In particular, as depicted in Figure 3.2, the demographic transition in England was associated with a significant increase in the investment in child quality as reflected by years of schooling. Quantitative evidence provided by Doepke (2004) suggests that indeed, educational policy played an important role in the demographic transition in England.

[66] Quantitative evidence provided by Greenwood and Seshadri (2002) is supportive of the role of the rise in the demand for skilled labor in the demographic transition in the US. They demonstrate that technological progress in an industrial, skilled-intensive, sector that is larger than that in an unskilled-intensive, agricultural sector matches the data on the US demographic transition.

Reinforcing Mechanisms

The Decline in Child Labor

The effect of the rise in the demand for human capital on the reduction in the desirable number of surviving offspring was magnified via its adverse effect on child labor. It gradually increased the wage differential between parental labor and child labor inducing parents to reduce the number of their children and to further invest in their quality (Hazan and Berdugo 2002).[67] Moreover, the rise in the importance of human capital in the production process induced industrialists to support education reforms (Galor and Moav 2004) and thus laws that abolish child labor (Doepke and Zilibotti 2003), inducing a reduction in child labor and thus in fertility. Doepke (2004) provides quantitative evidence that suggests that indeed, child labor law, and to a lesser extent educational policy, played an important role in the demographic transition.

The Rise in Life Expectancy

The impact of the increase in the demand for human capital on the decline in the desirable number of surviving offspring may have been reinforced by the rise in life expectancy.

The decline in mortality rates in developed countries since the 18th century, as depicted in Figure 2.24, and the recent decline in mortality rates in less developed countries, as depicted in Figure 2.25, corresponded to a gradual increase in life expectancy. As depicted in Figure 2.26, life expectancy in England increased at a stable pace from 32 years in the 1720s to about 41 years in the 1870. This pace of the rise in life expectancy increased and life expectancy reached 50 years in 1900, 69 years in 1950 and 77 years in 1999. Similarly, life expectancy increased in Western Europe during the 19th century from 36 in 1820 to 46 in 1900, 67 in 1950 and 78 in 1999. In less developed economies life expectancy increased markedly in the 20th century, as depicted in Figure 2.27.

[67] Hazan and Berdugo (2002)'s hypothesis is consistent with existing historical evidence. For instance, Horrell and Humphries (1995) suggest, based on data from the United Kingdom, that the earnings of children age 10-14 as a percentage of father's earning declined from the period 1817-1839 to the period 1840-1872 by nearly 50% if the father was employed in a factory. Interestingly, the effect is significantly more pronounced if the father was employed in skilled occupations (i.e., high wage agriculture) rather than low skilled occupations (i.e., mining), reflecting the rise in the relative demand for skilled workers and its effect on the decline in the relative wages of children.

Despite the gradual rise in life expectancy prior to the demographic transition investment in human capital was rather insignificant as long as a technological demand for human capital had not emerged. In particular, the increase in life expectancy in England occurred 150 years prior to the demographic transition and may have resulted in a gradual increase in literacy rates, but not at a sufficient level to induce a reduction in fertility. Similarly, the rise in life expectancy in less developed regions in the first half of the 20th century has not generated a significant increase in education and a demographic transition.

In light of the technologically based rise in the demand for human capital in the second phase of the Industrial Revolution, as documented in section 2.3.3, the rise in the expected length of productive life has increased the potential rate of return to investments in children's human capital, and thus re-enforced and complemented the inducement for investment in education and the associated reduction in fertility rates.[68]

Changes in Marriage Institutions.

The effect of the rise in the demand for human capital on the desirable quality of children, and thus on the decline in fertility was reinforced by changes in marriage institutions. Gould, Moav and Simhon (2003) suggest that the rise in the demand for human capital increased the demand for quality women who have a comparative advantage in raising quality children, increasing the cost of marriage. Polygamy therefore became less affordable, inducing the transition from polygamy to monogamy, and reinforcing the decline in fertility. Edlund and Lagerlof (2002) suggest that love marriage, as opposed to arranged marriage, redirected the payment for the bride from the parent to the couple, promoting investment and human capital accumulation and thus reinforcing the decline in fertility.

Natural Selection and the Evolution of Preference for Offspring's Quality

The impact of the increase in the demand for human capital on the decline in the desirable number of surviving offspring may have been magnified by cultural or genetic evolution in the attitude of individuals toward child quality. An evolutionary change in the attitude of individuals towards human capital could have generated a swift response to the increase in demand for human capital, generating a decline in fertility along with an increase in human capital formation.

Human beings, like other species, confront the basic trade-off between offspring's quality and quantity in their implicit Darwinian survival strategies. Preference for child quantity as well as for child quality reflects the well-known variety in the quantity-quality survival strategies (or in the K and r strategies) that exists in nature (e.g., MacArthur and Wilson 1967) and the allocation of resources between offspring quantity and quality is subjected to evolutionary changes (Lack 1954).

Galor and Moav (2002) propose that during the epoch of Malthusian stagnation that characterized most of human existence, individuals with a higher valuation for offspring quality gained an evolutionary advantage and their representation in the population gradually increased. The agricultural revolution facilitated the division of labor and fostered trade relationships across individuals and communities,

[68]This mechanism was outlined by Galor and Weil (1999) and was examined in different settings by Erlich and Lui (1991), and Hazan and Zoabi (2004). It should be noted, however, that as argued by Moav (2005), the rise in the potential return to investment in child quality due to the prolongation of the productive life is not as straightforward as it may appear. It requires that the prolongation of life would affect the return to quality more than the return to quantity. For example, if parents derive utility from the aggregate wage income of their children, prolongation of life would increase the return to quantity and quality symmetrically. Hence, additional mechanism that would increase the relative complementarity between life expectancy and human capital would be needed to assure the rise in the return to human capital. For instance, Hazan and Zoabi (2004) assume that an increase in life expectancy, and thus the health of students, enhances the production process of human capital and thus increases the relative return to child quality. Alternatively, Moav (2005) argues that an increase in life expectancy, while having no effect on parental choice between quality and quantity, induce the offspring to increase their own human capital bringing about lower fertility rates in the next generation due to the comparative advantage of educated parents in educating their children.

enhancing the complexity of human interaction and raising the return to human capital. Moreover, the evolution of the human brain in the transition to Homo sapiens and the complementarity between brain capacity and the reward for human capital has increased the evolutionary optimal investment in the quality of offspring. The distribution of valuation for quality lagged behind the evolutionary optimal level and individuals with traits of higher valuation for their offspring's quality generated higher income and, in the Malthusian epoch when income was positively associated with aggregate resources allocated to child rearing, a larger number of offspring. Thus, the trait of higher valuation for quality gained the evolutionary advantage, and the Malthusian pressure gradually increased the representation in the population of individuals whose preferences were biased towards child quality.

This evolutionary process was reinforced by its interaction with economic forces. As the fraction of individuals with high valuation for quality increased, technological progress intensified, raising the rate of return to human capital. The increase in the rate of return to human capital along with the increase in the bias towards quality in the population reinforced the substitution towards child quality, setting the stage for a more rapid decline in fertility along with a significant increase in investment in human capital.

This mechanism is consistent with the gradual rise in literacy rates prior to the Industrial Revolution, as depicted in Figure 5.1. It suggests that the increase in the investment in human capital prior to the Industrial Revolution was a reflection of changes in the composition of preference for quality in the population that stimulated investment in human capital, prior to the increase in the demand for human capital in the second phase of the Industrial Revolution.

3.3.4 The Decline in the Gender Gap

The rise in women's relative wages in the last two centuries and its potential impact on the rise in female labor force participation and the associated decline in fertility rates have been the center of another theory of the demographic transition that generates the observed hump-shaped relationship between income per capita and population growth, as depicted in Figure 2.15.

The rise in women's relative wages along with declining fertility rates has been observed in a large number of developed and less developed economies. In particular, as depicted in Figure 3.3, this pattern is observed in the US during the period 1800-1940.

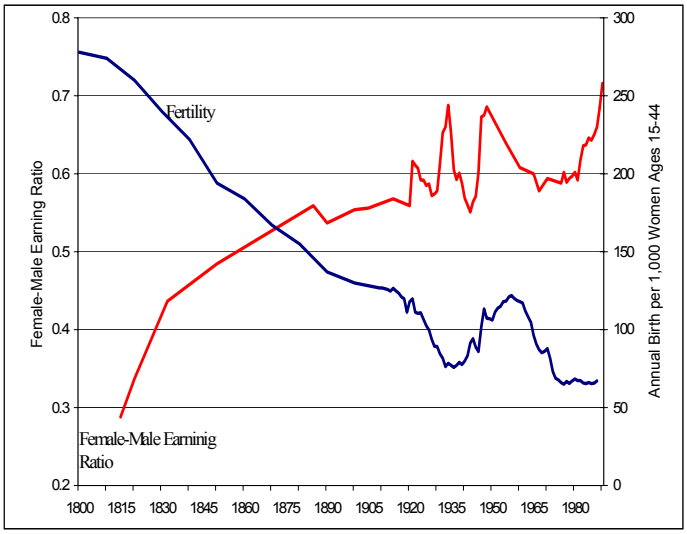

Figure 3.3. Female Relative Wages and Fertility Rates
United States 1800-1990
Source: U.S. Bureau of the Census, (1975), Goldin (1990), and Hernandez (2000)

Galor and Weil (1996) argue that technological progress and capital accumulation increased the relative wages of women in the process of industrialization. They maintain that technological progress along with physical capital accumulation complemented mental-intensive tasks rather than physical-intensive tasks and thus, in light of the comparative advantage of women in mental-intensive tasks, the demand for women's labor input gradually increased in the industrial sector, increasing the absolute wages of men and women but decreasing the gender wage gap. As long as the rise in women wages was insufficient to induce a significant increase in women's labor force participation, fertility increased due to the rise in men's wages.[69] Ultimately, however, the rise in women's relative wages was sufficient to induce a significant increase in labor force participation, generating a demographic transition.[70] Unlike the single-parent model in which an increase in income generates conflicting income and substitution effect that cancel one another if preferences are homothetic, in the two-parent household model, if most of the burden of child rearing is placed on women, a rise in women's relative wages increases the opportunity cost of raising children more than the household income, generating a pressure towards a reduction in fertility.

Moreover, the process of development in the Post-Malthusian Regime was associated with a gradual decline in the human capital gap between male and female. As depicted in Figure 3.4, literacy rates among women which were in 1840 only 76% of those among men, grew faster in the 19th century

[69]The U-shaped pattern of female labor force participation in the process of industrialization follows from the coexistence of an industrial sector and a non-modern production sector that is not fully rival with child rearing. Women's marginal product in non-modern sector was not affected by capital accumulation in the industrial sector, while women's potential wages in the modern sector increased. In the early process of industrialization, therefore, capital accumulation increased labor productivity in the industrial sector, family income increased via men's wages, while female wages, based on the production of market goods in the home sector did not change. Fertility increased due to the income effect and female labor force participation fell. Once capital accumulation and technological progress increases female relative wages sufficiently, capital accumulation raised women's relative wages, inducing a rise in female labor force participation in the industrial sector and reducing fertility.

[70]Cavalcanti and Tavares (2003) demonstrate theoretically and empirically that the decline in the gender wage gap and the increase in labor force participation increase government expenditure on public goods reducing the cost of child rearing, further enhancing the decline in fertility.

reaching men's level in 1900.

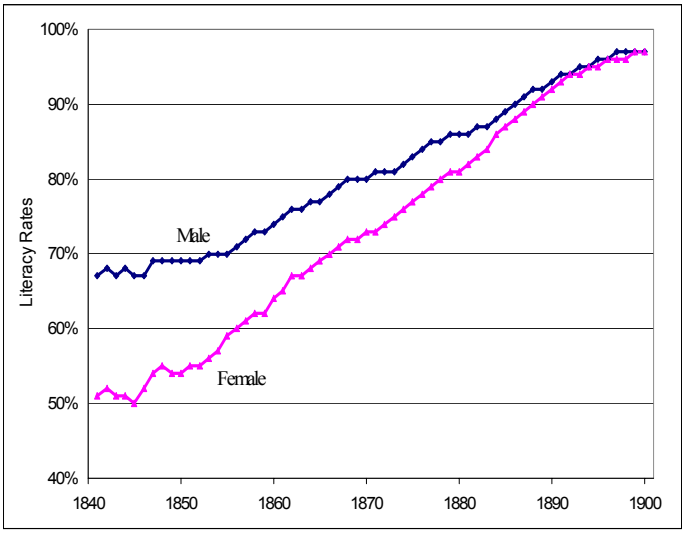

Figure 3.4. The Decline in the Human Capital Gap between Male and Female: England 1840-1900
Source: Cipolla(1969)

Lagerlof (2003b) argues that the process of development permitted a gradual improvement in the level of female education, raising the opportunity cost of children and initiating a fertility decline.

3.3.5 Other Theories

The Old-Age Security Hypothesis

The old-age security hypothesis has been proposed as an additional mechanism for the onset of the demographic transition. suggests that in the absence of capital markets that permit intertemporal lending and borrowing, children are assets that permit parents to smooth consumption over their life-time.[71] The process of development and the establishment of capital markets reduce this motivation for rearing children, contributing to the demographic transition.

Although old-age support is a plausible element that may affect the level of fertility, it appears as a minor force. The importance of the decline in the role of children as assets in the onset of the demographic transition is questionable. The rise in fertility rates prior to the demographic transition, in a period of improvements in the credit markets, raises doubts about the significance of the mechanism. Furthermore, cross-section evidence does not indicate that wealthier individuals that presumably had a better access to credit markets had a small number of surviving offspring. On the contrary, fertility rates in the pre-demographic transition era are positively related to skills, income and wealth (e.g., Lee 1997 and Clark 2003).[72]

Exogenous Shocks - Luck

Becker, Murphy and Tamura (1990) advance a theory that emphasizes the role of a major exogenous shock in triggering the demographic transition, underlying the role of luck in the determination of the relative timing of the demographic transition across nations as well as the wealth of nations.[73]. They

[71] See Neher (1971) and Caldwell (1976) for earlier studies and Boldrin and Jones (2002) for a recent quantitative analysis.

[72] Moreover, examples of species in nature in which offspring support their parent in old age are very rare.

[73] As they argue in page S13, "Many attempts to explain why some countries have had the best economic performance in the past several centuries give too little attention to accidents and good fortune".

argue that a major shock shifted economies from the low-output high-fertility steady-state equilibrium towards the high-output low-fertility steady-state equilibrium, triggering a demographic transition.

This theory suffers from critical deficiencies in the micro-structure and it generates predictions that are inconsistent with the evidence.[74] Moreover, even if economically plausible micro-foundations for the presence of multiple steady-state equilibria would be established, a major shock that would shift the economy from the basin of attraction of a high-fertility to a low-fertility steady-state equilibrium would not account for the main characteristics of the demographic transition and the transition to modern growth. In contrast to existing evidence that shows that for a large number of countries population growth rates increased prior to their decline in the course of the demographic transition and that the rise in income per capita preceded the decline in fertility,.a major shock that would shift the economy from the basin of attraction of a high-fertility to a low-fertility steady-state equilibrium would generate, counterfactually, a monotonic decline in fertility rates along with a simultaneous rise in income per capita.

4 Unified Growth Theory

The inconsistency of exogenous and endogenous neoclassical growth models with the process of development along most of human history, induced growth theorists to develop a unified theory of economic growth that would capture in a single framework the epoch of Malthusian stagnation, the era of modern growth, and the principal factors that brought about the transition between these regimes.[75]

The establishment of a unified growth theory has been a great intellectual challenge, requiring major methodological innovations in the construction of dynamical systems that would capture the complexity that has characterized the evolution of economies from a Malthusian epoch to a state of sustained economic growth. Historical evidence suggests that the take-off from the Malthusian epoch to a state of sustained economic growth, rapid as it may appear, was a gradual process and thus could not plausibly (and meaningfully) be viewed as the outcome of a major exogenous shock that shifted the economy from the basin of attraction of the Malthusian epoch into the basin of attraction of the Modern growth regime.[76] The simplest methodology for the generation of this phase transition - a major shock in an environment characterized by multiple locally stable equilibria - is therefore not applicable for the generation of the transition from stagnation to growth.

An alternative methodology, however, was rather difficult to establish since a unified growth

[74]The source of multiplicity of equilibria in their model is the implausible assumption that the return to education increases with the aggregate level of education in society. (Browing, Hansen and Heckman (1998), for instance, show that there is weak empirical evidence in favor of this assumption.) Moreover, they define erroneously the low-output, high population growth, steady-state as a Malthusian steady-state equilibrium. Their "Malthusian" steady-state, however, has none of the features of a Malthusian equilibrium. In contrast to the historical evidence about the Malthusian era, in this equilibrium (in the absence of technological change) population growth rate is not at the reproduction level. Moreover, counter-factually population growth in their "Malthusian" steady-state is *higher* than the that in the beginning of the demographic transition. Furthermore, a small positive shock to income when the economy is in the "Malthusian" steady-state initially decreases fertility in contrast to the central aspect of the Malthusian equilibrium.

[75]Growth theories that capture the evolution of population, technology, and output from stagnation to sustained economic growth have been established by Galor and Weil (1999, 2000), Galor and Moav (2002), Hansen and Prescott (2002), Jones (2001), Kogel and Prskawetz. (2001), Hazan and Berdugo (2002), Tamura (2002), Lagerlof (2003a, 2003b), Fernandez-Vilaverde (2003), Doepke (2004), as well as others. The Great Divergence and its association with the transition from stagnation to growth was explored in a unified setting by Galor and Mountford (2003).

[76]As established in section 2, and consistently with the revisionist view of the Industrial Revolution, neither the take-off of the currently developed world in the 19th century, nor the recent take-off of less developed economies provide evidence for an unprecedented shock that generated a quantum leap in income per-capita. Moreover, technological progress could not be viewed as a shock to the system. As argued by Mokyr (2002) technological progress during the Industrial Revolution was an outcome of a gradual endogenous process that took place over this time period. Moreover, technological progress in less developed economies was an outcome of a deliberate decision by entrepreneurs to adopt existing advanced technologies.

theory in which economies take-off gradually but swiftly from an epoch of a stable Malthusian stagnation would necessitate a *gradual* escape from an absorbing (stable) steady-state equilibrium, in contradiction to the essence of a stable steady-state equilibrium. Ultimately, it has become apparent that the observed gradual, rapid, and continuos phase transition would be captured by a single dynamical system, only if the set of steady-state equilibria and their stability would be altered qualitatively in the process of development. As proposed by Galor and Weil (2000), during the Malthusian epoch, the dynamical system would have to be characterized by a stable Malthusian steady-state equilibrium, but ultimately due to the evolution of latent state variables in this epoch, the Malthusian steady-state equilibrium would vanish endogenously leaving the arena to the gravitational forces of the emerging Modern Growth Regime.

Unified growth theories that permit a phase transition and do not rely on the existence of a major exogenous shock, have to be founded on a dynamical system in which economies are for an epoch in the vicinity of a temporary stable Malthusian steady-state equilibrium, but the evolution of latent state variables (i.e., the rise in a latent demand for human capital in Galor and Weil (2000) and the evolution of the distribution of genetic characteristics in Galor and Moav (2002)) ultimately generates a structural change in the dynamical system that causes this Malthusian steady state to vanish endogenously, permitting the economy to take-off and to converge to a modern growth steady-state equilibrium.

The role of the demographic transition in the transition from the Post-Malthusian Regime to the Sustained Growth Regime adds to the complexity of the desirable dynamical system. Capturing this additional transition would require the unified theory to generate endogenously a reversal in the positive Malthusian effect of income on population once the take-off occurs and to provide the reduction in fertility a special role in the transition to a state of sustained economic growth.

This section explores mechanisms that can account for the complexities of these long transitions from stagnation to growth and the emergence of the Great Divergence, focusing on the role of population, technology, income distribution and education in this intricate process. It describes several unified growth theories that encompass the transition between three distinct regimes that have characterized the process of economic development: The Malthusian Epoch, The Post-Malthusian Regime, and the Sustained Growth Regime.[77] Imposing the constraint that a unified theory would account for the entire intricate process of development in the last thousands of years is a discipline that would enhance the viability of growth theory. A unified theory of economic growth would reveal the underlying micro-foundations that are consistent with the process of economic development along the entire spectrum of human history, rather that with the last century only. It would therefore enhance the confidence in the viability of growth theory, its predictions and policy implications, while improving the understanding of the origin of the recent transition from stagnation to growth and the associated phenomenon of the great divergence.

4.1 From Stagnation to Growth

The first unified growth theory in which the endogenous evolution of population, technology, and income per capita is consistent with the process of development in the last thousands of years was advanced by Galor and Weil (2000). The theory captures the three regimes that have characterized the process of

[77] Although the emphasis is on the experience of Europe and its offshoots, since these were the areas that completed the transition from the Malthusian regime to modern growth, these theories could be modified to account for the incomplete transition of the less developed countries, integrating the drastic influence of the import of pre-existing production and health technologies.

development as well as the fundamental driving forces that generated the transition from an epoch of Malthusian stagnation to a state of sustained economic growth.

The theory proposes that in early stages of development the economy was in a stable Malthusian steady state equilibrium. Technology advanced rather slowly, and generated proportional increases in output and population. The inherent positive interaction between population and technology in this epoch, however, gradually increased the pace of technological progress and the delayed adjustment of population permitted output per capita to creep forward at a miniscule rate. The slow pace of technological progress in the Malthusian epoch provided a limited scope for human capital in the production process and parents therefore had no incentive to reallocate resources towards child quality during this era.

The Malthusian interaction between technology and population accelerated the pace of technological progress permitting a take-off to the Post-Malthusian regime. The expansion of resources was partially counterbalanced by the enlargement of population and the economy was characterized by rapid growth rates of income per capita and population. The acceleration in technological progress increased the demand for human capital, while having two opposing effects on population growth. On the one hand, it eased households' budget constraints, allowing the allocation of more resources for raising children. On the other hand, it induced a reallocation of these additional resources toward child quality. In the Post-Malthusian regime, due to the limited demand for human capital, the first effect dominated and the rise in real income permitted households to increase their family size as well the quality of each child.

As investment in human capital took place the Malthusian steady state equilibrium vanished and the economy started to be attracted by the gravitational forces of the Modern Growth Regime. The interaction between investment in human capital and technological progress generated a virtuous circle: human capital generated faster technological progress, which in turn further raised the demand for human capital, inducing further investment in child quality, and ultimately initiating a demographic transition.[78] The offsetting effect of population growth on the growth rate of income per capita was eliminated and the interaction between human capital accumulation and technological progress permitted a transition to a state of sustained economic growth.

The theory suggests that the transition from stagnation to growth is an inevitable by-product of the Malthusian interaction between population and technology and its ultimate impact on the demand for human capital and the demographic transition . The timing of the transition differ however across countries and regions due to initial variations in geographical factors and historical accidents and their manifestation in variations in institutional, demographic, and cultural factors, trade patterns, colonial status, as well as in disparity in public policy.[79]

4.1.1 Central Building Blocks

The theory is based upon the interaction between the several building blocks: the Malthusian elements, the engines of technological progress, the origin of human capital formation, and the determinants of parental choice regarding the quantity and quality of offspring.

First, the Malthusian elements. Individuals are subjected to a subsistence consumption constraint and as long as the constraint is binding, an increase in income results in an increase in population growth. Technological progress, which brings about temporary gains in income per capita , triggers

[78] In less developed countries the stock of human capital determines the pace of adaptation of existing technologies whereas in developed countries it determined the pace of the advancement of the technological frontier.

[79] A fertile land in a Malthusian environment, for instance, would generate a larger population density and a scale effect.

therefore in early stages of development an increase in the size of the population that offsets the gain in income per capita due to the existence of decreasing returns to labor. Growth in income per capita is generated ultimately, despite decreasing returns to labor, since technological progress outpaces the rate of population growth.

Second, the forces behind technological progress in the process of development. The size of the population stimulates technological progress in early stages of development (Boserup (1965)), whereas investment in human capital is the prime engine of technological progress in more advanced stages of development. In the Malthusian era, the technological frontier was not distant from the working environment of most individuals, and the scale of the population affected the rate of technological progress due to its effect on: (a) the supply of innovative ideas, (b) the demand for new technologies, (c) technological diffusion, (d) the division of labor, and (e) trade.[80] As the distance from the technological frontier gets larger, however, the role of human capital becomes more significant in technological advancement (e.g., Nelson and Phelps (1966)) and individuals with high levels of human capital are more likely to advance the technological frontier.

Third, the origin of human capital formation. The introduction of new technologies is mostly skill-biased although in the long run, these technologies may be either "skill biased" or "skill saving." The "disequilibrium" brought about by technological change raises the demand for human capital.[81] Technological progress reduces the adaptability of existing human capital for the new technological environment and educated individuals have a comparative advantage in adapting to the new technological environment.[82]

Fourth, the determination of paternal decisions regarding the quantity and quality of their offspring. Individuals choose the number of children and their quality in the face of a constraint on the total amount of time that can be devoted to child-raising and labor market activities. The rise in the demand for human capital induces parents to substitute quality for quantity of children.[83]

4.1.2 The Basic Structure of the Model

Consider an overlapping-generations economy in which activity extends over infinite discrete time. In every period the economy produces a single homogeneous good using land and efficiency units of labor as inputs. The supply of land is exogenous and fixed over time whereas the number of efficiency units of labor is determined by households' decisions in the preceding period regarding the number and level of human capital of their children.

[80]The positive effect of the scale of the population on technological progress in the Malthusian epoch is supported by Boserup (1965) and recent evidence (e.g., Kremer (1993)). The role of the scale of the population in the modern era is, however, controversial. The distance to the technological frontier is significantly larger and population size per-se may have an ambiguous effect on technological progress, if it comes on the account of population quality.

[81]If the return to education rises with the *level* of technology the qualitative results would not be affected. Adopting this mechanism, however, would be equivalent to assuming that changes in technology were skill-biased throughout human history. Although on average technological change may have been skilled biased, Galor and Weil's mechanism is consistent with periods in which the characteristics of new technologies could be defined as unskilled-biased (most notably, the first phase of the industrial revolution).

[82]Schultz (1975) cites a wide range of evidence in support of this theory. Similarly, Foster and Rosenzweig (1996) find that technological change during the green revolution in India raised the return to schooling, and that school enrollment rates responded positively to this higher return. This element is central in the analysis of Galor and Tsiddon (1997), Galor and Moav (2000), and Hassler and Mora (2000).

[83]The existence of a trade-off between quantity and quality of children is supported empirically (e.g., Hanushek (1992) and Rosenzweig and Wolpin (1980)).

Production of Final Output Production occurs according to a constant-returns-to-scale technology that is subject to endogenous technological progress. The output produced at time t, Y_t, is

$$Y_t = H_t^{\alpha}(A_t X)^{1-\alpha}, \tag{1}$$

where H_t is the aggregate quantity of efficiency units of labor employed in period t, X is land employed in production in every period t, A_t represents the endogenously determined technological level in period t, $A_t X$ are therefore the "effective resources" employed in production in period t, and $\alpha \in (0,1)$.

Output per worker produced at time t, y_t, is

$$y_t = h_t^{\alpha} x_t^{1-\alpha}, \tag{2}$$

where $h_t \equiv H_t/L_t$ is the level of efficiency units of labor per worker, and $x_t \equiv (A_t X)/L_t$ is the level of effective resources per worker at time t.

Suppose that there are no property rights over land.[84] The return to land is therefore zero, and the wage per efficiency unit of labor is therefore equal to the output per efficiency unit of labor.

$$w_t = (x_t/h_t)^{1-\alpha}. \tag{3}$$

Preferences and Budget Constraints In each period t, a generation that consists of L_t identical individuals joins the labor force. Each individual has a single parent. Members of generation t (those who join the labor force in period t) live for two periods. In the first period of life (childhood), $t-1$, individuals consume a fraction of their parental unit time endowment. The required time increases with children's quality. In the second period of life (parenthood), t, individuals are endowed with one unit of time, which they allocate between child rearing and labor force participation. They choose the optimal mixture of quantity and quality of (surviving) children and supply their remaining time in the labor market, consuming their wages.

Individuals' preferences are represented by a utility function defined over consumption above a subsistence level $\tilde{c} > 0$, as well as over the quantity and quality (measured by human capital) of their (surviving) children.[85]

$$u^t = (c_t)^{1-\gamma}(n_t h_{t+1})^{\gamma} \qquad \gamma \in (0,1), \tag{4}$$

where c_t is the consumption of individual of generation t, n_t is the number of children of individual t, and h_{t+1} is the level of human capital of each child.[86] The utility function is strictly monotonically increasing and strictly quasi-concave, satisfying the conventional boundary conditions that assure that, for a sufficiently high income, there exists an interior solution for the utility maximization problem.

[84] The modeling of the production side is based upon two simplifying assumptions. First, capital is not an input in the production function, and second the return to land is zero. Alternatively it could have been assumed that the economy is small and open to a world capital market in which the interest rate is constant. In this case, the quantity of capital will be set to equalize its marginal product to the interest rate, while the price of land will follow a path such that the total return on land (rent plus net price appreciation) is also equal to the interest rate. Allowing for capital accumulation and property rights over land would complicate the model to the point of intractability, but would not affect the qualitative results.

[85] For simplicity parents derive utility from the expected number of surviving offspring and the parental cost child rearing is associated only with surviving children. A more realistic cost structure would not affect the qualitative features of the theory.

[86] Alternatively, the utility function could have been defined over consumption above subsistence rather than over a consumption set that is truncated from below by the subsistence consumption constraint. In particular, if $u^t = (c_t - \tilde{c})^{(1-\gamma)}(n_t h_{t+1})^{\gamma}$. the qualitative analysis would not be affected, but the complexity of the dynamical system would be greatly enhanced. The income expansion path would be smooth, transforming continuously from being nearly vertical for low levels of potential income to asymptotically horizontal for high levels of potential income. The subsistence consumption constraint would therefore generate the Malthusian effect of income on population growth at low income levels.

However, for a sufficiently low level of income the subsistence consumption constraint is binding and there is a corner solution with respect to the consumption level.[87]

Individuals choose the number of children and their quality in the face of a constraint on the total amount of time that can be devoted to child-raising and labor market activities. For simplicity, only time is required in order to produce child quantity and quality.[88] Let $\tau + e_{t+1}$ be the time cost for a member i of generation t of raising a child with a level of education (quality) e_{t+1}. That is, τ is the fraction of the individual's unit time endowment that is required in order to raise a child, regardless of quality, and e_{t+1} is the fraction of the individual's unit time endowment that is devoted for the education of each child.[89]

Consider members of generation t who are endowed with h_t efficiency units of labor at time t. Define potential income, z_t, as the potential earning if the entire time endowment is devoted to labor force participation, earning the competitive market wage, w_t, per efficiency unit. The potential income, $z_t \equiv w_t h_t$, is divided between consumption, c_t, and expenditure on child rearing (quantity as well as quality), evaluated according to the value of the time cost, $w_t h_t[\tau + e_{t+1}]$, per child. Hence, in the second period of life (parenthood), the individual faces the budget constraint

$$w_t h_t n_t(\tau + e_{t+1}) + c_t \leq w_t h_t \equiv z_t. \tag{5}$$

The Production of Human Capital Individuals' level of human capital is determined by their quality (education) as well as by the technological environment. Technological progress is assumed to raise the value of education in the production of human capital.[90] Technological progress reduces the adaptability of existing human capital for the new technological environment (the 'erosion effect'). Education, however, lessens the adverse effects of technological progress. That is, skilled individuals have a comparative advantage in adapting to the new technological environment. In particular, the time required for learning the new technology diminishes with the level of education and increases with the rate of technological change.

The level of human capital of children of a member i of generation t, h^i_{t+1}, is an increasing strictly concave function of their parental time investment in education, e^i_{t+1}, and a decreasing strictly convex function of the rate of technological progress, g_{t+1} :

$$h_{t+1} = h(e_{t+1}, g_{t+1}), \tag{6}$$

where $g_{t+1} \equiv (A_{t+1} - A_t)/A_t$. Education lessens the adverse effect of technological progress. That is, technology complements skills in the production of human capital (i.e., $h_{eg}(e^i_{t+1}, g_{t+1}) > 0$). In the absence of investment in quality, each individual has a basic level human capital that is normalized to 1 in a stationary technological environment, i.e., $h(0,0) = 1$.[91]

[87] The subsistence consumption constraint generates the positive income elasticity of population growth at low income levels, since higher income allows individuals to afford more children.

[88] If both time and goods are required in order to produce child quality, the process we describe would be intensified. As the economy develops and wages increase, the relative cost of a quality child will diminish and individuals will substitute quality for quantity of children.

[89] τ is assumed to be sufficiently small so as to assure that population can have a positive growth rate. That is, $\tau < \gamma$.

[90] Schultz [1975] cites a wide range of evidence in support of this assumption. More recently, Foster and Rosenzweig [1996] find that technological change during the green revolution in India raised the return to schooling, and that school enrollment rate responded positively to this higher return. The effect of technological transition on the return to human capital is at the center of the theoretical approach of Galor and Tsiddon (1997), Caselli (1999), Galor and Moav (2000), and Hassler and Rodriguez Mora (2002).

[91] For simplicity, investment in quality is not beneficial in a stationary technological environment, i.e., $h_e(0,0) = 0$, and in the absence of investment in education, there exists a sufficiently rapid technological progress, that due to the erosion effect renders the existing human capital obsolete (i.e., $\lim_{g\to\infty} h(0, g_{t+1}) = 0$). Furthermore, although the potential

Optimization Members of generation t choose the number and quality of their children, and therefore their own consumption, so as to maximize their intertemporal utility function subject to the subsistence consumption constraint. Substituting (5)-(6) into (4), the optimization problem of a member of generation t is:

$$\{n_t, e_{t+1}\} = argmax\{w_t h_t[1 - n_t(\tau + e_{t+1})]\}^{1-\gamma}\{(n_t h(e_{t+1}, g_{t+1})\}^{\gamma} \tag{7}$$

Subject to:

$$w_t h_t[1 - n_t(\tau + e_{t+1})] \geq \tilde{c};$$
$$(n_t, e_{t+1}) \geq 0.$$

Hence, as long as potential income at time t is sufficiently high so as to assure that $c_t > \tilde{c}$ (i.e., as long as $z_t \equiv w_t h_t$, is above the level of potential income at which the subsistence constraint is just binding, (i.e., $z_t > \tilde{z} \equiv \tilde{c}/(1-\gamma)$)), the fraction of time spent by individual t raising children is γ, while $1-\gamma$ is devoted for labor force participation. However, if $z_t \leq \tilde{z}$, the subsistence constraint is binding, the fraction of time necessary to assure subsistence consumption, $\tilde{c}$, is larger than $1-\gamma$ and the fraction of time devoted for child rearing is therefore below γ. That is,

$$n_t[\tau + e_{t+1}] = \begin{cases} \gamma & \text{if} \quad z_t \geq \tilde{z} \\ \\ 1 - [\tilde{c}/w_t h_t] & \text{if} \quad z_t \leq \tilde{z}. \end{cases} \tag{8}$$

Figure 4.1 shows the effect of an increase in potential income z_t on the individual's allocation of time between child rearing and consumption. The income expansion path is vertical as long as the subsistence consumption constraint is binding. As the wage per efficiency unit of labor increases in this income range, the individual can generate the subsistence consumption with a smaller labor force participation and the fraction of time devoted to child rearing increases. Once, the level of income is sufficiently high such that the subsistence consumption constraint is not binding, the income expansion path becomes horizontal at a level γ in terms of time devoted for child rearing.

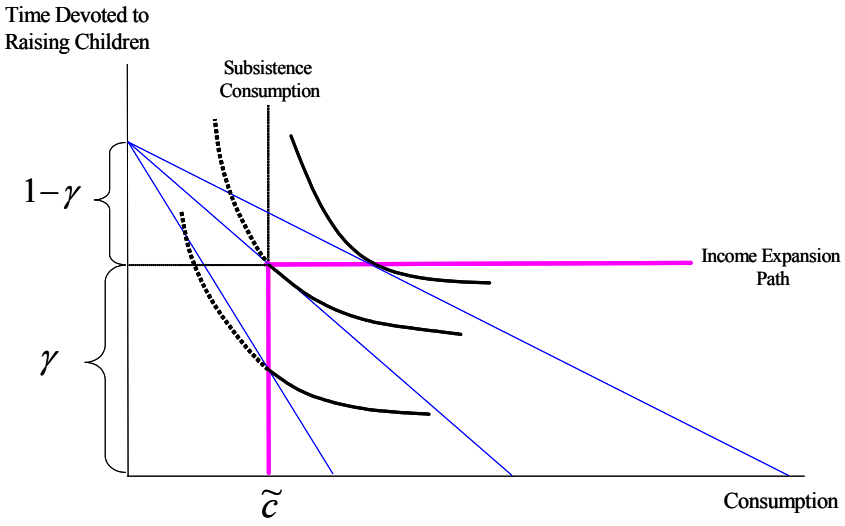

Figure 4.1. Preferences, Constraints, and Income Expansion Path

number of efficiency units of labor is diminished due to the transition from the existing technological state to a superior one (due to the erosion effect), each individual operates with a superior level of technology and the productivity effect is assumed to dominate. That is, $\partial y_t/\partial g_t > 0$.

Furthermore, the optimization with respect to e_{t+1} implies that the level of education chosen by members of generation t for their children, e_{t+1}, is an increasing function of g_{t+1}.

$$e_{t+1} = e(g_{t+1}) \quad \begin{cases} = 0 & \text{if} \quad g_{t+1} \leq \hat{g} \\ \\ > 0 & \text{if} \quad g_{t+1} > \hat{g} \end{cases} \tag{9}$$

where $e'(g_{t+1}) > 0$ and $e''(g_{t+1}) < 0 \ \ \forall g_{t+1} > \hat{g} > 0$.[92] Hence, regardless of whether potential income is above or below $\tilde{z}$, increases in wages will not change the division of child-rearing time between quality and quantity. However, the division between time spent on quality and time spent on quantity is affected by the rate of technological progress, which changes the return to education.

Furthermore, substituting (9) into (8), it follows that n_t is:

$$n_t = \begin{cases} \frac{\gamma}{\tau + e(g_{t+1})} \equiv n^b(g_{t+1}) & \text{if} \quad z_t \geq \tilde{z} \\ \\ \frac{1-[\tilde{c}/z_t]}{\tau + e(g_{t+1})} \equiv n^a(g_{t+1}, z(e_t, g_t, x_t)) & \text{if} \quad z_t \leq \tilde{z}. \end{cases} \tag{10}$$

where $z_t \equiv w_t h_t = z(e_t, g_t, x_t)$ as follows from (3) and (6)

Hence, as follows from the properties of $e(g_{t+1}), n^b(g_{t+1})$, and $n^a(g_{t+1}, z_t)$:
(a) An increase in the rate of technological progress reduces the number of children and increases their quality, i.e.,

$$\partial n_t / \partial g_{t+1} \leq 0 \text{ and } \partial e_{t+1} / \partial g_{t+1} \geq 0.$$

(b) If the subsistence consumption constraint is binding (i.e., if parental potential income is below $\tilde{z}$), an increase in parental potential income raises the number of children, but has no effect on their quality, i.e.,

$$\partial n_t / \partial z_t > 0 \text{ and } \partial e_{t+1} / \partial z_t = 0 \quad \text{if } z_t < \tilde{z}.$$

(c) If the subsistence consumption constraint is not binding (i.e., if parental potential income is above $\tilde{z}$), an increase in parental potential income does not affect the number of children or their quality, i.e.,

$$\partial n_t / \partial z_t = \partial e_{t+1} / \partial z_t = 0 \quad \text{if } z_t > \tilde{z}.$$

Technological Progress Suppose that technological progress, g_{t+1}, that takes place between periods t and $t+1$ depends upon the education per capita among the working generation in period t, e_t, and the population size in period t, L_t.[93]

$$g_{t+1} \equiv \frac{A_{t+1} - A_t}{A_t} = g(e_t, L_t), \tag{11}$$

where for $e_t \geq 0$ and a sufficiently large population size L_t, $g(0, L_t) > 0$, $g_i(e_t, L_t) > 0$, and $g_{ii}(e_t, L_t) < 0$, $i = e_t, L_t$.[94] Hence, for a sufficiently large population size, the rate of technological progress between

[92] $e''(g_{t+1})$ depends upon the third derivatives of the production function of human capital. $e''(g_{t+1})$ is assumed to be concave, which appears plausible.

[93] While the role of the scale effect in the Malthusian epoch, is essential, none of the existing results depend on the presence or the absence of the scale effect in the modern era. The functional form of technological progress given in (11) can capture both the presence and the absence of the scale effect in the modern era. In particular, the scale effect can be removed, once investment in education is positive, assuming for instance that $lim_{L \to \infty} g_L(e_t, L) = 0$ for $e_t > 0$.

[94] For a sufficiently small population the rate of technological progress is strictly positive only every several periods. Furthermore, the number of periods that pass between two episodes of technological improvement declines with the size of population. These assumptions assure that in early stages of development the economy is in a Malthusian steady-state with zero growth rate of output per capita, but ultimately the growth rates is positive and slow. If technological progress would occur in every time period at a pace that increases with the size of population, the growth rate of output per capita would always be positive, despite the adjustment in the size of population.

time t and $t+1$ is a positive, increasing, strictly concave function of the size and level of education of the working generation at time t. Furthermore, the rate of technological progress is positive even if labor quality is zero.

The state of technology at time $t+1$, A_{t+1}, is therefore

$$A_{t+1} = (1 + g_{t+1})A_t, \tag{12}$$

where the state of technology at time 0 is given at a level A_0.

Population The size of population at time $t+1$, L_{t+1}, is

$$L_{t+1} = n_t L_t, \tag{13}$$

where L_t is the size of population at time t and n_t is the number of children per person; L_0 is given. Hence, given (10), the evolution of population over time is

$$L_{t+1} = \begin{cases} n^b(g_{t+1})L_t & \text{if} \quad z_t \geq \tilde{z} \\ \\ n^a(g_{t+1}, z(e_t, g_t, x_t))L_t & \text{if} \quad z_t \leq \tilde{z}. \end{cases} \tag{14}$$

Effective Resources The evolution of effective resources per worker, $x_t \equiv (A_t X)/L_t$, is determined by the evolution of population and technology. The level of effective resources per worker in period $t+1$ is

$$x_{t+1} = \frac{1 + g_{t+1}}{n_t} x_t, \tag{15}$$

where $x_0 \equiv A_0 X/L_0$ is given. Furthermore, as follows from (10) and (11)

$$x_{t+1} = \begin{cases} \frac{[1+g(e_t,L_t)][\tau+e(g(e_t,L_t))]}{\gamma} x_t \equiv \phi^b(e_t, L_t)x_t & \text{if} \quad z_t \geq \tilde{z} \\ \\ \frac{[1+g(e_t,L_t)][\tau+e(g(e_t,L_t))]}{1-[\tilde{c}/z(e_t,g_t,x_t)]} x_t \equiv \phi^a(e_t, g_t, x_t, L_t)x_t & \text{if} \quad z_t \leq \tilde{z}, \end{cases} \tag{16}$$

where $\phi^b_e(e_t, L_t) > 0$, and $\phi^a_x(e_t, g_t, x_t, L_t) < 0 \ \ \forall e_t \geq 0$.

4.1.3 The Dynamical System

The development of the economy is fully determined by a sequence $\{e_t, g_t, x_t, L_t\}_{t=0}^{\infty}$ that satisfies (9), (11), 14), and (16), in every period t and describe the joint evolution of education, technological progress, effective resources per capita, and population over time.

The dynamical system is characterized by two regimes. In the first regime the subsistence consumption constraint is binding and the evolution of the economy is governed by a four dimensional non-linear first-order autonomous system:

$$\begin{cases} x_{t+1} = \phi^a(e_t, g_t, x_t; L_t)x_t \\ e_{t+1} = e(g(e_t; L_t)) \\ g_{t+1} = g(e_t, L_t) \\ L_{t+1} = n^a(g(e_t, L_t),\ z(e_t, g_t, x_t))L_t, \end{cases} \quad \text{for } z_t \leq \tilde{z} \tag{17}$$

where the initial conditions e_0, g_0, x_0 are historically given.

In the second regime the subsistence consumption constraint is not binding and the evolution of the economy is governed by a three dimensional system:

$$\begin{cases} x_{t+1} = \phi^b(e_t, x_t; L)x_t \\ e_{t+1} = e(g(e_t; L)) \qquad \text{for } z_t \geq \tilde{z} \\ L_{t+1} = n^b(g(e_t, L_t))L_t. \end{cases} \tag{18}$$

In both regimes, however, the analysis of the dynamical system is greatly simplified by the fact that the evolution of e_t and g_t is independent of whether the subsistence constraint is binding, and by the fact that, for a given population size L, the joint evolution of e_t and g_t is determined independently of the x_t. The education level of workers in period $t+1$ depends only on the level of technological progress expected between period t and period $t+1$, while technological progress between periods t and $t+1$ depends only on the level of education of workers in period t. Thus the dynamics of technology and education can be analyzed independently of the evolution resources per capita.

A. The Dynamics of Technology and Education The evolution of technology and education, for a given population size L, is characterized by the sequence $\{g_t, e_t; L\}_{t=0}^{\infty}$ that satisfies in every period t the equations $g_{t+1} = g(e_t; L)$, and $e_{t+1} = e(g_{t+1})$. Although this dynamical sub-system consists of two independent one dimensional, non-linear first-order difference equations, it is more revealing to analyze them jointly.

In light of the properties of the functions $e(g_{t+1})$ and $g(e_t; L)$ this dynamical sub-system is characterized by three qualitatively different configurations, which are depicted in Figures 4.2.A, 4.3.A and 4.4.A. The economy shifts endogenously from one configuration to another as population increases and the curve $g(e_t; L)$ shifts upward to account for the effect of an increase in population.

In Figure 4.2.A, for a range of small population size, the dynamical system is characterized by globally stable steady-state equilibria, $(\bar{e}(L), \bar{g}(L)) = (0, g^l(L))$, where $g^l(L)$ increases with the size of the population while the level of education remains unchanged. In Figure 4.3.A, for a range of moderate population size, the dynamical system is characterized by three steady state equilibria, two locally stable steady-state equilibria: $(\bar{e}(L), \bar{g}(L)) = (0, g^l(L))$ and $(\bar{e}(L), \bar{g}(L)) = (e^h(L), g^h(L))$, and an interior unstable steady-state $(\bar{e}(L), \bar{g}(L)) \equiv (e^u(L), g^u(L))$, where $(e^h(L), g^h(L))$ and $g^l(L)$ increase monotonically with the size of the population. Finally, in Figure 4.4.A, for a range of large population sizes, the dynamical system is characterized by globally stable steady-state equilibria, $(\bar{e}(L), \bar{g}(L)) = (e^h(L), g^h(L))$,where $e^h(L)$ and $g^h(L)$ increases monotonically with the size of the population.

B. Global Dynamics This section analyzes the evolution of the economy from the Malthusian Regime, through the Post-Malthusian Regime, to the demographic transition and Modern Growth. The global analysis is based a sequence of phase diagrams that describe the evolution of the system, within each regime, for a given population size, and the transition between these regimes as population increases in the process of development. Each of the phase diagrams is a two dimensional projection in the plain $(e_t, x_t; L)$,of the three dimensional system in the space $\{e_t, g_t, x_t; L\}$.

The phase diagrams, depicted in Figure 4.2.B, 4.4.B, and 4.5.B contain three elements: the Malthusian Frontier, which separates the regions in which the subsistence constraint is binding from those where it is not; the XX locus, which denotes the set of all triplets $(e_t, g_t, x_t; L)$ for which effective resources per worker are constant; and the EE locus, which denotes the set of all pairs $(e_t, g_t; L)$ for which the level of education per worker is constant.

The Malthusian Frontier

As was established in (17) and (18) the economy exits from the subsistence consumption regime when potential income, z_t, exceeds the critical level $\tilde{z}$. This switch of regime changes the dimensionality of the dynamical system from three to two.

Let the *Malthusian Frontier* be the set of all triplets of $(e_t, x_t, g_t; L)$ for which individuals' income equal $\tilde{z}$.[95] Using the definitions of z_t and $\tilde{z}$, it follows from (3) and (6) that the The Malthusian Frontier, $MM \equiv \{(e_t, x_t, g_t; L) : x_t^{1-\alpha} h(e_t, g_t)^{\alpha} = \tilde{c}/(1-\gamma)\}$.

Let the *Conditional Malthusian Frontier* be the set of all pairs $(e_t, x_t; L)$ for which, conditional on a given technological level g_t, individuals incomes equal $\tilde{z}$. Following the definitions of z_t and $\tilde{z}$, equations (3) and (6) imply that the Conditional Malthusian Frontier, $MM_{|g_t}$, is $MM_{|g_t} \equiv \{(e_t, x_t; L) : x_t^{(1-\alpha)} h(e_t, g_t)^{\alpha} = \tilde{c}/(1-\gamma) \mid g_t\}$, where x_t *is a decreasing strictly convex function of* e_t along the $MM_{|g_t}$locus.

Hence, the Conditional Malthusian Frontier, as depicted in Figures 4.2.B-4.4.B, is a strictly convex, downward sloping, curve in the (e_t, x_t) space. Furthermore, it intersects the x_t axis and approaches asymptotically the e_t axis as x_t approaches infinity. The frontier shifts upward as g_t increases in the process of development.

The XX Locus

Let XX be the locus of all triplets $(e_t, g_t, x_t; L)$ such that the effective resources per worker, x_t, is in a steady-state: $XX \equiv \{(e_t, x_t, g_t; L) : \ x_{t+1} = x_t\}$.

As follows from (15), along the XX locus the growth rates of population and technology are equal. Above the Malthusian frontier, the fraction of time devoted to child-rearing is independent of the level of effective resources per worker. In this case, the growth rate of population will just be a negative function of the growth rate of technology, since for higher technology growth, parents will spend more of their resources on child quality and thus less on child quantity. Thus there will be a particular level of technological progress which induces an equal rate population growth. Since the growth rate of technology is, in turn, a positive function of the level of education, this rate of technology growth will correspond to a particular level of education, denoted $\hat{e}$. Below the Malthusian Frontier, the growth rate of population depends on the level of effective resources per capita, x, as well as on the growth rate of technology. The lower is x, the smaller the fraction of the time endowment devoted to child-rearing, and so the lower is population growth. Thus, below the Malthusian frontier, a lower value of effective resources per capita would imply that lower values of technology growth (and thus education) would be consistent with population growth being equal to technology growth. Thus, as drawn in Figures 4.2.B, 4.3.B, and 4.4.B, lower values of x are consistent with lower values of e on the part of the XX locus that is below the Malthusian Frontier.

If the subsistence consumption constraint is not binding, it follows from (16) that for $z_t \geq \tilde{z}$, there exists a unique value $0 < \hat{e}(L) < e^h(L)$, such that $x_t \in XX$.[96]

$$x_{t+1} - x_t \begin{cases} > 0 & \textit{if} \quad e_t > \hat{e}(L) \\ = 0 & \textit{if} \quad e_t = \hat{e}(L) \\ < 0 & \textit{if} \quad e_t < \hat{e}(L) \end{cases} \tag{19}$$

Hence, the XX Locus, as depicted in Figures 4.2.B, 4.3.B, and 4.4.B is a vertical line above the Condi-

[95] Below the Malthusian Frontier, the effect of income on fertility will be positive, while above the frontier there will be no effect of income on fertility. Thus the Malthusian Frontier separates the Malthusian and Post-Malthusian regimes, on the one hand, from the Modern Growth regime, on the other, and crossing this frontier is associated with the demographic transition.

[96] In order to simplify the exposition without affecting the qualitative nature of the dynamical system, the parameters of the model are restricted so as to assure that the XX Locus is non-empty when $z_t \geq \tilde{z}$. That is, $\hat{g} < (\gamma/\tau) - 1 < g(e^h(L_0), L_0)$.

tional Malthusian Frontier at a level $\hat{e}(L)$.

If the subsistence constraint is binding, the evolution of x_t, is based upon the rate of technological change, g_t, the effective resources per-worker, x_t as well as the quality of the labor force, e_t. Let $XX_{|g_t}$ be the locus of all pairs $(e_t, x_t; L)$ such that $x_{t+1} = x_t$, for a given level of g_t. That is, $XX_{|g_t} \equiv \{(e_t, x_t; L) : x_{t+1} = x_t \mid g_t\}$ It follows from (16 that *for* $z_t \leq \tilde{z}$, *and for* $0 \leq e_t \leq \hat{e}(L)$, *there exists a single-valued function* $x_t = x(e_t)$ *such that* $(x(e_t), e_t) \in XX_{|g_t}$.

$$x_{t+1} - x_t \begin{cases} < 0 & \textit{if} \quad (e_t, x_t) > (e_t, x(e_t)) \quad \textit{for} \quad 0 \leq e_t \leq \hat{e}(L), \\ = 0 & \textit{if} \quad x_t = x(e_t) \quad \textit{for} \quad 0 \leq e_t \leq \hat{e}(L), \\ > 0 & \textit{if} \quad [(e_t, x_t) < (e_t, x(e_t)) \quad \textit{for} \quad 0 \leq e_t \leq \hat{e}(L),] \quad \textit{or} \quad [e_t > \hat{e}(L)] \end{cases} \tag{20}$$

Hence, without loss of generality, the locus $XX_{|g_t}$ is depicted in Figure 4.2, as an upward slopping curve in the space (e_t, x_t), defined for $e_t \leq \hat{e}(L)$. $XX_{|g_t}$ is strictly below the Conditional Malthusian Frontier for value of $e_t < \hat{e}(L)$, and the two coincides at $\hat{e}(L)$. Moreover, the Conditional Malthusian Frontier, the XX Locus, and the $XX_{|g_t}$ Locus, coincide at $(\hat{e}(L), \hat{x}(L))$.

The EE Locus

Let EE be the locus of all triplets $(e_t, g_t, x_t; L)$ such that the quality of labor, e_t, is in a steady-state: $EE \equiv \{(e_t, x_t, g_t; L) : e_{t+1} = e_t\}$.

As follows from (9) and (11), $e_{t+1} = e(g(e_t; L)$ and thus, for a given population size, the steady-state values of e_t are independent of the values of x_t and g_t. The locus EE evolves through three phases in the process of development, corresponding to the three phases that describe the evolution of education and technology, as depicted in Figures 4.2.A, 4.3.A, and 4.4.A.

In early stages of development, when population size is sufficiently small, the joint evolution of education and technology is characterized by a globally stable temporary steady-state equilibrium, $(\bar{e}(L), \bar{g}(L)) = (0, g^l(L))$, as depicted in Figure 4.2.A. The corresponding EE Locus, depicted in the space $(e_t, x_t; L)$ in Figure 4.2.B, is vertical at the level $e = 0$, for a range of small population sizes. Furthermore, for this range, the global dynamics of e_t are given by:

$$e_{t+1} - e_t \begin{cases} = 0 & \textit{if} \quad e_t = 0 \\ < 0 & \textit{if} \quad e_t > 0. \end{cases} \tag{21}$$

In later stages of development as population size increases sufficiently, the joint evolution of education and technology is characterized by multiple locally stable temporary steady-state equilibria, as depicted in Figure 4.3.A. The corresponding EE Locus, depicted in the space $(e_t, x_t; L)$ in Figure 4.3.B, consists of 3 vertical lines corresponding the three steady-state equilibria for the value of e_t. That is, $e = 0$, $e = e^u(L)$, and $e = e^h(L)$. The vertical lines $e = e^u(L)$, and $e = e^h(L)$ shift rightward as population size increases. Furthermore, the global dynamics of e_t in this configuration are given by:

$$e_{t+1} - e_t \begin{cases} < 0 & \textit{if} \quad 0 < e_t < e^u(L) \quad \textit{or} \quad e_t > e^h(L) \\ = 0 & \textit{if} \quad e_t = (0,\ e^u(L),\ e^h(L)) \\ > 0 & \textit{if} \quad e^u(L) < e_t < e^h(L). \end{cases} \tag{22}$$

In mature stages of development when population size is sufficiently large, the joint evolution of education and technology is characterized by a globally stable steady-state equilibrium, $(\bar{e}(L), \bar{g}(L)) = (e^h(L), g^h(L))$, as depicted in Figure 4.4.A. The corresponding EE Locus, as depicted in Figure 4.4.B in the space $(e_t, x_t; L)$, is vertical at the level $e = e^h(L)$. This vertical line shifts rightward as population size increases. Furthermore, the global dynamics of e_t in this configuration are given by:

$$e_{t+1} - e_t \begin{cases} > 0 & if \quad 0 \leq e_t < e^h(L) \\ = 0 & if \quad e_t = e^h(L). \\ < 0 & if \quad e_t > e^h(L). \end{cases} \tag{23}$$

Conditional Steady-State Equilibria

In early stages of development, when population size is sufficiently small, the dynamical system, as depicted in Figure 4.2.B is characterized by a unique and globally stable conditional steady-state equilibrium.[97] It is given by a point of intersection between the EE Locus and the $x_{t+1} = x_t$ Locus. That is, conditional on a given technological level, g_t, the Malthusian steady-state $(0, \bar{x}(L))$ is globally stable.[98] In later stages of development as population size increases sufficiently, the dynamical system as depicted in Figure 4.3.B is characterized by two conditional steady-state equilibria. The Malthusian conditional steady-state equilibrium is locally stable, whereas the steady-state equilibrium $(e^u(L), x^u(L))$ is a saddle point.[99] For education levels above $e^u(L)$ the system converges to a stationary level of education $e^h(L)$ and possibly to a steady-state *growth rate* of x_t. In mature stages of development when population size is sufficiently large, the system convergence globally to an educational level $e^h(L)$ and possibly to a steady-state *growth rate* of x_t.

4.1.4 From Malthusian Stagnation to Sustained Growth

The economy evolves from an epoch of Malthusian stagnation through the Post-Malthusian regime to the demographic transition and a Modern Growth regime. This pattern and the prime driving forces in this transition emerge from the phase diagrams depicted in Figures 4.2-4.4.

Consider an economy in early stages of development. Population size is relatively small and the implied slow rate of technological progress does not provide an incentive to invest in the education of children. As depicted in Figure 4.2.A,the interaction between education, e_t, and the rate of technological change, g_t, for a constant small population, L^l, is characterized by a globally stable steady-state equilibrium $(0, g^l(L))$, where education is zero and the rate of technological progress is slow. This steady-state equilibrium corresponds to a globally stable conditional Malthusian steady-state equilibrium, depicted in Figure 4.2.B. For a constant small population, L^l,and for a given rate of technological progress, effective resources per capita, as well as the level of education are constant, and output per capita is therefore constant as well. Moreover, shocks to population or resources will be resolved in a classic Malthusian fashion.

As population grows slowly in reaction to technological progress, the $g(e_{t+1}, L^l)$ locus, depicted in Figure 4.2.A, gradually shifts upward and the steady-state equilibrium shifts vertically upward reflecting small increments in the rate of technological progress, while the level of education remains constant at a zero level. Similarly, the conditional Malthusian steady-state equilibrium drawn in Figure 4.2.B shifts vertically upward , as the XX locus shifts upward. However, output per capita remains initially constant at the subsistence level and ultimately creeps forward at a miniscule rate.

[97] Since the dynamical system is discrete, the trajectories implied by the phase diagrams do not necessarily approximate the actual dynamic path, unless the state variables evolve monotonically over time. As shown, the evolution of e_t is monotonic, whereas the evolution and convergence of x_t may be oscillatory. Non-monotonicity in the evolution of x_t may arise only if $e < \hat{e}$ and it does not affect the qualitative description of the system. Furthermore, if $\phi_x^a(e_t, g_t, x_t)x_t > -1$ the conditional dynamical system is locally non-oscillatory. The phase diagrams in Figures 4.3.A-4.5.A are drawn under the assumptions that assure that there are no oscillations.

[98] The local stability of the steady-state equilibrium $(0, \overline{x}(g_t))$ can be derived formally. The eigenvalues of the Jacobian matrix of the conditional dynamical system evaluated at the conditional steady-state equilibrium are both smaller than one (in absolute value)

[99] Convergence to the saddle point takes place only if the level of education is e^u. That is, the saddle path is the entire vertical line that corresponds to $e_t = e^u$.

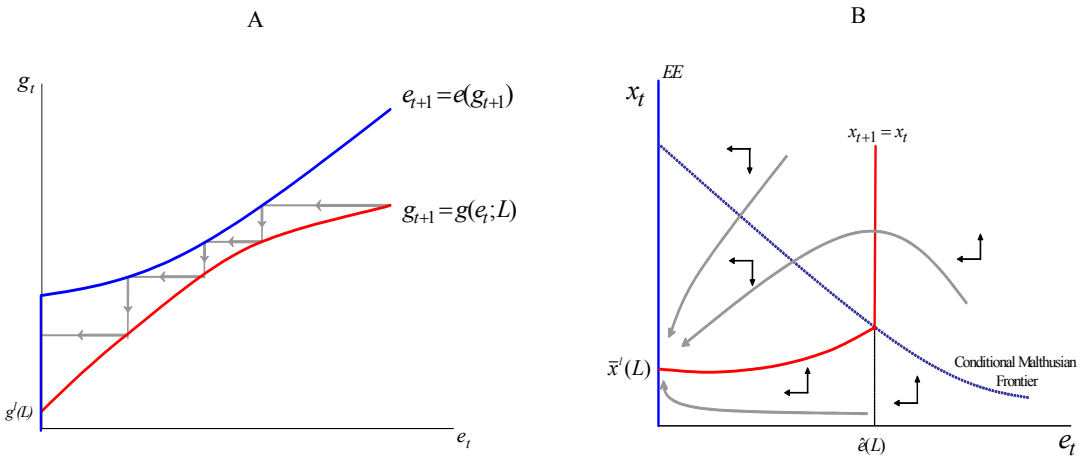

Figure 4.2. The Evolution of Technology, g_t, Education, e_t, and Effective Resources, x_t
Small Population

Over time, the slow growth in population that takes place in the Malthusian regime raises the rate of technological progress and shift the $g(e_{t+1}, L^l)$ locus in Figure 4.2.A sufficiently upward, generating a qualitative change in the dynamical systems depicted in Figure 4.3.A.

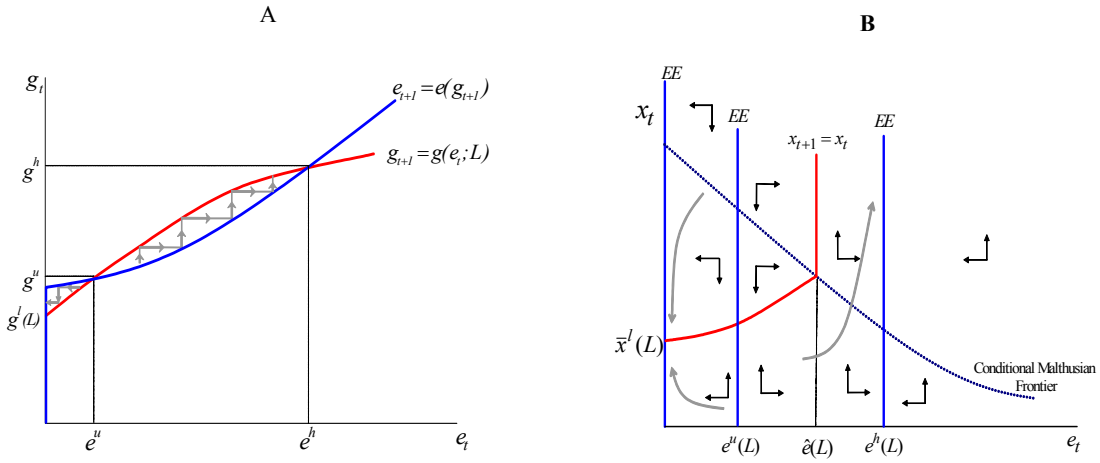

Figure 4.3. The Evolution of Technology, g_t, Education, e_t, and Effective Resources, x_t :
Moderate Population

The dynamical system of education and technology, for a moderate population, is characterized by multiple, history-dependent, stable steady state equilibria: The steady-state equilibria $(0, g^l(L))$ and $(e^h(L), g^h(L))$ are locally stable, whereas $(e^u(L), g^u(L))$ is unstable. Given the initial conditions, in the absence of large shocks the economy remains in the vicinity of the low steady-state equilibrium $(0, g^l(L))$, where education is still zero but the rate of technological progress is moderate. This steady-state equilibria correspond to a multiple locally stable conditional Malthusian steady-state equilibrium, depicted in Figure 4.3.B. A Malthusian steady-state, characterized by constant resources per capita, slow

technological progress, and no education, and a modern growth steady state, characterized by a high level of education, rapid technological progress, growing income per capita, and moderate population growth. However, since the economy starts in the vicinity of Malthusian steady state, it remains there.[100]

As the rate of technological progress continue to rise in reaction to the increasing population size, the $g(e_{t+1}, L_t)$ locus shifts upward further and ultimately, as depicted in Figure 4.4, the dynamical system experiences another qualitative change. The Malthusian steady state equilibrium vanishes, and the economy is the system is characterized by a unique globally stable modern steady-state equilibrium $(e^h(L), g^h(L))$ characterized by high levels of education and technological progress.

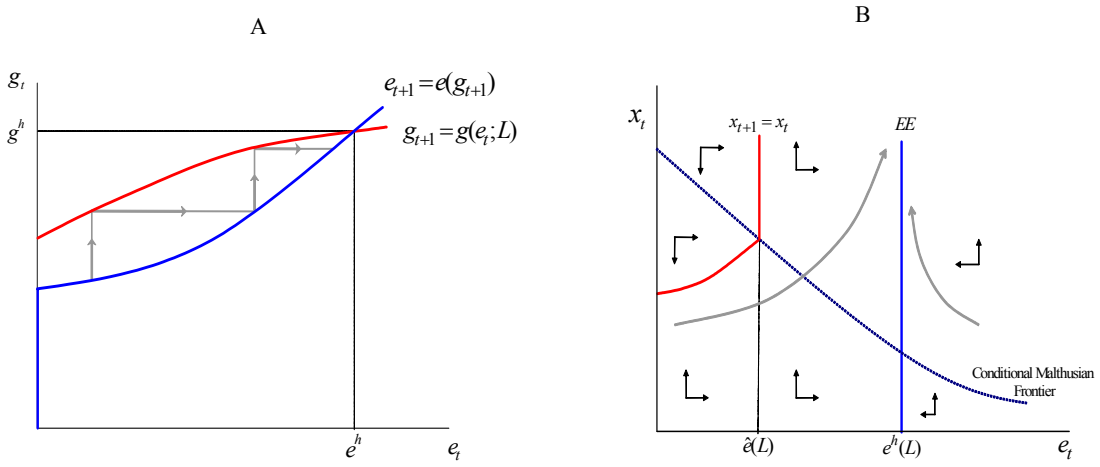

Figure 4.4. The Evolution of Technology, g_t, Education, e_t, and Effective Resources, x_t
Large Population

Increases in the rate of technological progress and the level of education feed back on each other until the economy converges rapidly to the stable modern steady state equilibrium. The increase in the pace of technological progress has two opposing effects on the evolution of population. On the one hand, it eased households' budget constraints, allowing the allocation of more resources for raising children. On the other hand, it induced a reallocation of these additional resources toward child quality. In the Post-Malthusian regime, due to the limited demand for human capital, the first effect dominated and the rise in real income permitted households to increase their family size as well the quality of each child.[101] The interaction between investment in human capital and technological progress generate a virtuous circle: human capital formation prompted faster technological progress, which in turn further raised the demand for human capital, inducing further investment in child quality, and ultimately, as the economy crosses the Malthusian frontier triggering a demographic transition. The offsetting effect of population growth on the growth rate of income per capita is eliminated and the interaction between human capital accumulation and technological progress permitted a transition to a state of sustained economic growth.

[100]Large shock to education or technological progress would permit the economy to jump to the Modern Growth steady state, but this possibility appears inconsistent with the evidence.

[101]Literally, income per capita does not change during the Post-Malthusian regime. It remains fixed at the subsistence level. This is an artifact of the assumption that the only input into child (quality and quantity) is parental time, and that this time input does not produce measured output. If child-rearing, especially the production of quality, requires goods or time supplied through a market (e.g., schooling), the shift toward higher child quality that takes place during the post-Malthusian regime would be reflected in higher market expenditures (as opposed to parental time expenditures) and rising measured income.

In the modern growth regime, resources per capita rise, as technological progress outstrips population growth. Provided that population size is constant (i.e., population growth is zero), the levels of education and technological progress and the growth rates of resources per capita, and thus the output per capita are constant in the modern growth steady state equilibrium.[102]

4.1.5 Major Hypotheses and their Empirical Validity

The theory generates several hypotheses about the evolution of population, human capital and income per capita in the process of development, underlying the roles of the inherent interaction between population and technology in the Malthusian epoch, as well as the formation of human capital in the second phase of the Industrial Revolution and the associated demographic transition, in the emergence of a state of sustained economic growth.

Main Hypotheses:

- During the initial phases of the Malthusian epoch the growth rate of output per capita is nearly zero and the growth rate of population is miniscule, reflecting the sluggish pace of technological progress and the full adjustment of population to the expansion of resources. In the later phases of the Malthusian epoch, the increasing rate of technological progress, along with the inherent delay in the adjustment of population to the rise in income per capita, generated a positive but very small growth rates of output per capita and population.

The hypothesis is consistent with the evidence provided in section 2.1 about the evolution of the world economy in the Malthusian epoch. In particular, the infinitesimal pace of resource expansion in the first millennium was reflected in a miniscule increase in the Western European population from 24.7 million people in the year 1 to 25.4 million in the year 1000, along with a zero average growth rate of output per capita. The more rapid (but still very slow) expansion of resources in the period 1000-1500, permitted the Western European population to grow at a slow average rate of 0.16% per year, from 25 million in the year 1000 to 57 million in the year 1500, along with a slow average growth rate of income per capita at a rate of about 0.13% per year. Resource expansion over the period 1500-1820 had a more significant impact on the Western European population that grew at an average pace of 0.26% per year, from 57 million in the year 1500 to 133 million in the year 1820, along with a slightly faster average growth rate of income per capita at a rate of about 0.15% per year.

- The reinforcing interaction between population and technology during the Malthusian epoch, increased the size of the population sufficiently so as to support a faster pace of technological progress, generating the transition to the Post-Malthusian Regime. The growth rates of output per capita increased significantly, but the positive Malthusian effect of income per capita on population growth was still maintained, generating a sizeable increase in population growth, and offsetting some of the potential gains in income per capita. Moreover, human capital accumulation did not play a significant role in the transition to the Post-Malthusian Regime and thus in the early take-off in the first phase of the Industrial Revolution. It emerged in the midst of the Post-Malthusian Regime, inducing further technological progress.

[102] If population growth is positive in the Modern Growth regime, then education and technological progress continue to rise, and, similarly, if population growth is negative they fall. In fact, the model makes no firm prediction about what the growth rate of population will be in the Modern Growth regime, other than that population growth will fall once the economy exits from the Malthusian region. If the growth rate of technology is related to the growth rate of population, rather than to its level, then there exists a steady state modern growth regime in which the growth rates of population and technology would be constant. Further, such a steady state would be stable: if population growth fell, the rate of technological progress would also fall, inducing a rise in fertility.

The hypothesis is consistent with the evidence provided in section 2.2 about the evolution of the world economy in the Post-Malthusian regime. In particular, the acceleration in the pace of resource expansion in the period 1820-1870 increased the Western European population from 133 million people in the year 1820 to 188 million in the year 1870, and the average growth rate of output per capita over this period increased significantly to 0.95% per year. Furthermore, the evidence suggest that the industrial demand for human capital increased only in the second phase of the of the Industrial Revolution. As shown by Clark (2003) human capital formation prior to the Industrial Revolution as well as in its first phase occurred in an era in which the market rewards for skill acquisition were at historically low levels.[103]

- The acceleration in the rate of technological progress increased the demand for human capital in the Post-Malthusian Regime, inducing significant investment in human capital, and triggering the demographic transition and a rapid pace of economic growth.

The hypotheses is consistent with the evidence, provided in section 2.3 and depicted partly in Figure 4.5, about the significant rise in the industrial demand for human capital in the second phase of the Industrial Revolution and a marked increased in educational attainment, in association with a decline in fertility rates, and a transition to a state of sustained economic growth. In particular, it is consistent with the revisionist view on the British Industrial Revolution (e.g., Crafts and Harley 1992, Clark 2001, and Voth 2003) that argue that the first phase of the Industrial Revolution in England was characterized by a moderate increase in the growth rate of output per capita, and the standard of living and the "take-off", as depicted in Figure 4.5, occurred only in 1860s.

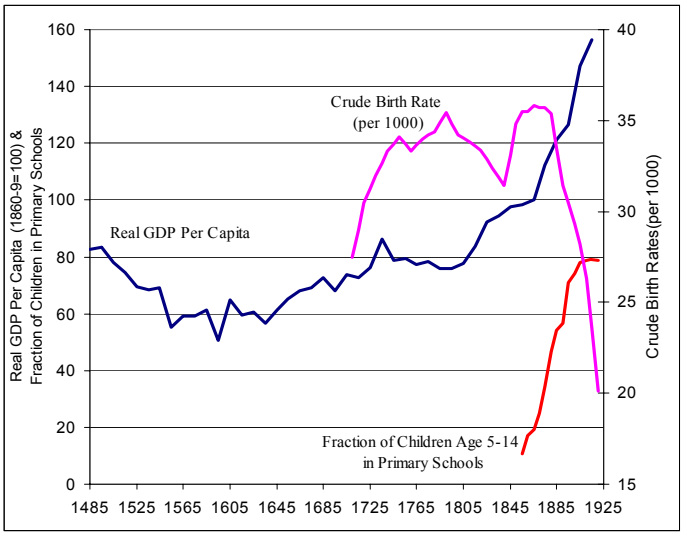

Figure 4.5. The Sharp Rise in Real GDP Per Capita and it association with Investment in Education and Fertility Decline: England 1865-1920
Source: Clark (2001), Feinstein (1972), Flora et al. (1983), Wrigley and Schofield (1981)

Furthermore, quantitative analysis of unified growth theories by Fernandez-Vilaverde (2003), Doepke (2004), and Pereira (2004) suggests that indeed the rise in the demand for human capital was a significant force behind the demographic transition and the emergence of a state of sustained economic growth[104]

[103]The rise in human capital formation over this period may reflect religious, cultural and social forces, as well as the rise in valuation for offspring quality due to the forces of natural selection, as discussed in section 5.2.

[104]The rise in the demand for human capital in Fernandez-Vilaverde (2003) is based on capital-skill complementarity, and is indistinguishable from the complementarity between technology and skills (in the short run) that is maintained by Galor and Weil (2000).

Moreover, the theory is consistent with the observed simultaneous onset of the demographic transition across Western European countries that differed significantly in their income per capita. It suggests that a universal rise in the demand for human capital in Western Europe (as documented in section 2.3.3) generated this simultaneous transition. It should be noted that the lack of clear evidence about the increase in the return to human capital in the second phase of the Industrial Revolution does not indicate the absence of a significant increase in the demand for human capital over this period. The significant increase in schooling that took place in the 19th century and in particular the introduction of public education (e.g., The Education Act of 1870) that lowered the cost of education, generated significant increase in the supply of educated workers that may have prevented a significant rise in the return to education.[105]

- a. The growth process is characterized by stages of development and the evolution of the growth rates of output per capita is nonlinear. Technological leaders experienced a monotonic increase in the growth rates of their income per capita. Their growth was rather slow in early stages of development, it increased rapidly during the take-off from the Malthusian epoch, and then continued to rise at a lower pace, possibly stabilizing at higher level. Technological followers that made the transition to sustained economic growth, in contrast, experienced a non-monotonic increase in the growth rates of their income per capita. Their growth rates rather slow in early stages of development, it increased rapidly in the early stages of the take-off from the Malthusian epoch and was boosted by the adoption of technologies from the existing technological frontier, and then once the economy reached the technological frontier, the growth rates dropped to the level of the technological leaders.

  b. The differential timing of the take-off between economies generated convergence clubs characterized by a group of poor countries in the vicinity of the Malthusian equilibrium, a group of rich countries in the vicinity of the sustained growth equilibrium, and others that are in the attempting to shift from one camp to another.[106]

These hypotheses are consistent the Maddison (2001)'s evidence about the growth process in the last 2000 years, as well as with contemporary cross section evidence that suggest that the growth process is characterized by multiple growth regimes (e.g., Duraluf and Johnson 1995) and thus with non-linearities in the growth process (e.g., Duraluf and Quah 1998, and Bloom, Canning and Silva 2003), and that divergence along with a twin peak have emerged in the distribution of income across countries in the world (Quah 1996, 1997, Jones 1997, and Prichett 1997).[107]

4.2 Complementary Theories

Subsequent theories of economic growth in the very long run demonstrate that the unified theory of economic growth can be augmented and fortified by additional characteristics of the transition from stagnation to growth without altering the fundamental hypothesis regarding the central roles played by the emergence of human capital formation and the demographic transition in this process. Various qualitative and quantitative unified theories explore plausible mechanisms for the emergence of human capital and the onset of the demographic transition such as, the rise in the demand for human capital

[105]Some of this supply response was a direct reaction of the potential increase in the return to human capital, and thus may only operate to partially offset the increase in the return to human capital, but the reduction in the cost of education via public schooling, generated an additional force that operated towards a reduction in the return to human capital.

[106]For the definition and the theory of club convergence see Azariadis (1996) and Galor (1996).

[107]Other studies that focused on nonlinearity of the growth process includes Fiaschi and Lavezzi (2003). Other research on the emergence of twin peak is Feyrer (2003).

(due to: technological acceleration, capital-skill complementarity, skilled biased technological change, and reallocation of resources towards skilled intensive sectors), the decline in child and infant mortality, the rise in life expectancy, the emergence of public education, the decline in child labor, as well as cultural and genetic evolution in the valuation of human capital. They suggest that indeed the emergence of human capital formation, and the onset of the demographic transition played a central role in the shift from stagnation to growth.

4.2.1 Alternative Mechanisms for the Emergence of Human Capital Formation

The emergence of human capital formation and its impact on the demographic transition and the technological frontier is a central element in the transition from the Post-Malthusian Regime to the state of sustained economic growth in all unified theories of economic growth in which population, technology and income per capita are endogenously determined.[108] Various complementary mechanisms that generate or reinforce the rise in human capital formation have been proposed and examined quantitatively, demonstrating the robustness and the empirical plausibility of this central hypothesis.

The Rise in the Industrial Demand for Human Capital

The rise in industrial demand for human capital in advanced stages of industrialization, as documented in section 2.3.3, and its impact on human capital formation led researchers to incorporate it as a central feature in unified theories of economic growth.

The link between industrial development and the demand for human capital have been modeled in various complementary ways. Galor and Weil (2000) modeled the rise in the demand for human capital as an outcome of the acceleration in technological progress, underlying the role of educated individuals in coping with a rapidly changing technological environment. Their mechanism is founded on the premise that the introduction of new technologies increases the demand for skilled labor in the short-run, although in some periods the characteristics of new technologies may be complementarity to unskilled labor, as was the case in the first phase of the Industrial Revolution.[109]

Subsequent unified theories of economic growth have demonstrated that the rise in the demand for human capital in association with advanced stages of industrialization could emerge from alternative mechanisms, without altering the fundamental insights of the theory. Fernandez-Vilaverde (2003) bases his quantitative unified theory on capital-skill complementarity, Doepke (2004) constructs his unified theory on the basis of a rising *level* of skilled-intensive industrial technology, and Galor and Mountford (2003) generate the rise in the demand for human capital via an increased specialization in the production of skilled-intensive goods due to international trade.

The rise in the demand for human capital stimulated public policy designed to enhance investment in human capital. In particular, as established in the quantitative unified theory of Doepke (2004), educational policy and child labor laws in England played an important role in human capital formation and the demographic transition.

Mortality Decline, the Rise in Life Expectancy, and Human Capital Formation

Several unified theories of economic growth demonstrated that the basic mechanism for the emergence of human capital proposed by Galor and Weil (2000) can be augmented and reinforced by the incorporation of the effect of the decline in mortality rates and the rise in life expectancy (as

[108] Even in the multiple-regime structure of Lucas (2002) a shock to the return to human capital is suggested in order to generate the switch from the Malthusian Regime to the Modern Growth Regime.

[109] Evidence for the complementarity between technological progress (or capital) and skills is provided by Katz and Goldin (1988) and on the basis of cross-section studies by Duffy, Papageorgiou and Perez-Sebastain (2004).

documented in section 2.3.2) on the rise in human capital formation, the decline in the desirable number of surviving offspring, and thus on the transition from stagnation to growth.[110]

The significant decline in mortality rates in developed countries since the 18th century, as depicted in Figure 2.24, and the recent decline in mortality rates in less developed countries, as depicted in Figure 2.25, corresponded to an acceleration in the rise in life expectancy and a significant rise in human capital formation, towards the end of the 19th century in developed countries (Figures 2.26 and 2.28) and towards the middle of the 20th century in less developed countries (Figures 2.27 and 2.31). The rise in the expected length of the productive life may have increased the potential rate of return to investments in children's human capital, and thus could have induced an increase in human capital formation along with a decline in fertility. However, despite the gradual rise in life expectancy in developed and less developed countries, investment in human capital has been insignificant as long as the industrial demand for human capital has not emerged. Thus, it appears that the industrial demand for human capital, as documented in section 2.3.3, provided the inducement for investment in education and the associated reduction in fertility rates, whereas the prolongation of life may have re-enforced and complemented this process.

Galor and Weil (1999) argue that the Malthusian interaction between technology and population accelerated the pace of technological progress, improving industrial technology as well as medical and health technologies. Consistent with the historical evidence provided in section 2.3.3, the improvements in the industrial technology increased the demand for human capital, whereas the development of medical technology and health infrastructure generated a significant rise in life expectancy. The expected rate of return to human capital investment increased therefore due to the prolongation of life, as well as the rise in industrial demand for human capital, enhancing the positive interaction between schooling and technological progress, bringing about a demographic transition and the emergence of the state of sustained economic growth.

Various theories formally examined mechanisms that capture the interaction between human capital formation, the decline in mortality rate, and the rise in life expectancy, in the process of development.[111] Cervellati and Sunde (2003) and Boucekkine, de la Croix and Licandro (2003) focus on the plausible role of the reinforcing interaction between life expectancy and human capital formation in the transition from stagnation to growth, abstracting from its effect on fertility decisions. Others suggest that a decline in mortality rates increased the return to investment in human capital via: (a) increased population density and thus efficiency of the transmission of human capital (Lagerlof 2003a), (b) increased population growth and the advancement of skill-biased technologies (Weisdorf 2004), and (c) improved healthiness and thus the capacity to absorb human capital (Hazan and Zoabi 2004), generating a substitution of quality for quantity, a demographic transition and a transition to a state of sustained economic growth.[112]

Capital-Skill Complementarity and the Emerging Incentives for Capitalists to Support Education Reforms

The accumulation of physical capital in the early stages of industrialization enhanced the importance of human capital in the production process and generated an incentive for the capitalists to support the provision of public education for the masses.[113] Consistent with the evidence provided in

[110]The effect of an increase in life expectancy on the incentive of individuals to invest in their own human capital is well established since Ben-Porath (1967). See Kalemli-Ozcan, Ryder and Weil (2000), as well.

[111]As argued in section 3.2.3, qualitative and quantitative evidence do not lend credence to the theory that a decline in infant and child mortality rates *triggered* the decline in the number of surviving offspring and the increase in the investment in offspring's human capital.

[112]See Iyigun (2003) as well.

[113]Attentively, other argued that increased polarization induced the elite to enact costly educational reforms. Grossman

section 2.3.3, Galor and Moav (2004) argue that due to capital-skill complementarity, the accumulation of physical capital by the capitalists in the first phase of the Industrial Revolution increased the importance of human capital in sustaining the rate of return to physical capital inducing capitalists to support the provision of public education for the masses.[114]

The Decline in Child Labor

Other theories that focused on the transition from stagnation to growth suggested that the central role of human capital formation and the demographic transition can be augmented and reinforced by the incorporation of the adverse effect of the rise in the demand for human capital on child labor. Hazan and Berdugo (2002) suggest that technological change increased the wage differential between parental labor and child labor inducing parents to reduce the number of their children and to further invest in their quality, stimulating human capital formation, a demographic transition, and a shift to a state of sustained economic growth.[115] Alternatively, the rise in the importance of human capital in the production process, as documented in section 2.3.3, induced industrialists to support laws that abolish child labor (Doepke and Zilibotti (2003)), inducing a reduction in child labor, and stimulating human capital formation and a demographic transition.

Cultural and Genetic Evolution in the Valuation of Human Capital

Human capital formation and its impact on the decline in the desirable number of surviving offspring may have been reinforced by cultural or genetic evolution in the attitude of individuals towards human capital formation. Consistent with the gradual rise in literacy rates prior to the Industrial Revolution, Galor and Moav (2002), argue that during the epoch of Malthusian stagnation that had characterized most of human existence, individuals with a higher valuation for offspring quality generated an evolutionary advantage and their representation in the population gradually increased. The increase in the rate of return to human capital along with the increase in the bias towards quality in the population reinforced the substitution towards child quality, setting the stage for a significant increase in human capital formation along with a rapid decline in fertility.

4.2.2 Alternative Triggers for the Demographic Transition

The demographic transition that separated the Post-Malthusian Regime and the Sustained Growth Regime is a central element in quantitative and qualitative unified theories of economic growth in which population, technology and income per capita are endogenously determined. As discussed in section 2.3.2, the demographic transition brought about a reversal in the unprecedented increase in population growth that occurred during the Post-Malthusian Regime, leading to a significant reduction in fertility rates and population growth in various regions of the world, and enabling economies to convert a larger share of the fruits of factor accumulation and technological progress into growth of output per capita.[116] The demographic transition enhanced the growth process reducing the dilution of the stock of capital and land, enhancing the investment in the human capital of the population, and alternating the age

and Kim (1999) argue that education decreases predation, and Bowles and Gintis (1975) suggest that educational reforms are designed to *sustain* the existing social order, by displacing social problems into the school system. In contrast, Bourguignon and Verdier (2000) suggest that if political participation is determined by the education (socioeconomic status) of citizens, the elite may not find it beneficial to subsidize universal public education despite the existence of positive externalities from human capital.

[114]Since firms have limited incentive to invest in the general human capital of their workers, in the presence of credit market imperfections, the level of education would be suboptimal unless it would be financed publicly (Galor and Zeira (1993), Duraluf (1996), Fernandez and Rogerson (1996) Benabou (2000), Mookherjee and Ray (2003), and Galor and Moav (2004)). Moreover, a mixture of vocational and general education would be enacted (Bertocchi and Spagat 2004).

[115]The decline in the relative wages of children is documented empirically (e.g., Horrell and Humphries (1995)).

[116]Demographic shocks generate a significant effect on economic growth in Connolly and Peretto (2003) as well.

distribution of the population, increasing temporarily the size of the labor force relative to the population as a whole.[117]

Various complementary mechanisms for the demographic transition have been proposed in the context of unified growth theories, establishing, theoretically and quantitatively the importance of this central hypothesis in the understanding of the transition from stagnation to growth.[118]

The Emergence of Human Capital Formation

The gradual rise in the demand for human capital in the process of industrialization, as documented in section 2.3.3, and its close association with the timing of the demographic transition has led researchers to argue that the increasing role of human capital in the production process induced households to increase their investment in the human capital of their offspring, ultimately leading to the onset of the demographic transition.

The link between the rise in the demand for human capital and the demographic transition have been modeled in various complementaries ways. Galor and Weil (2000) argue that the gradual rise in the demand for human capital induced parents to invest in the human capital of their offspring. In the early stages of the transition from the Malthusian regime, the effect of technological progress on parental income permitted the rise in population growth as well as the average quality. Further increases in the rate of technological progress ultimately induced a reduction in fertility rates, generating a demographic transition in which the rate of population growth declined along with an increase in the average level of education. Thus, consistent with historical evidence, the theory suggests that prior to the demographic transition, population growth increased along with investment in human capital, whereas the demographic transition brought about a decline in population growth along with a further increase in human capital formation.

Other unified theories examine several reinforcing mechanisms that could have triggered the demographic transition and the transition to sustained economic growth, such as the decline in child labor (Hazan and Berdugo 2002, Doepke 2004 and Doepke and Zilibotti 2003), the decline in mortality rates and the rise in life expectancy (Lagerlof 2003a, and Weisdorf 2004), and the evolution of preferences for offspring quality (Galor and Moav 2002)), as discussed in section 4.1. The quantitative unified theories of Fernandez-Villaverde (2003) and Doepke (2004) confirm the significance of these various channels in originating the demographic transition and the shift from stagnation to growth.

The Decline in the Gender Gap

The observed decline in the gender gap in the last two centuries, as discussed in section 3.3.4, is an alternative mechanism that could have triggered a demographic transition and human capital formation in other unified theories.

A unified theory based upon the decline in the gender wage gap and the associated increase in female labor force participation and fertility decline was explored by Galor and Weil (1996, 1999), as elaborated in section 3.3.4. They argue that technological progress and capital accumulation complemented mental intensive tasks and substituted for physical-intensive tasks in the industrial production process. In light of the comparative physiological advantage of men in physical-intensive tasks and women in mental-intensive tasks, the demand for women's labor input gradually increased in the industrial sector, decreasing monotonically the wage deferential between men and women. In early stages of

[117] Bloom and Williamson (1998) suggest that the cohort effect played a significant role in the growth "miracle" of East Asian countries in the time period 1960-1990.

[118] As established in section 3.3, some mechanisms that were proposed for the demographic transition, such as the decline in infant and child mortality, as well as the rise in income, are inconsistent with the evidence. These mechanisms were excluded in the formulation of unified growth theory.

industrialization, wages of men and women increased, but the rise in female's relative wages was insufficient to induce a significant increase in women's labor force participation. Fertility, therefore increased due to the income effect that was generated by the rise in men's absolute wages. Ultimately, however, the rise in women's relative wages was sufficient to induce a significant increase in labor force participation, increasing the cost of child rearing proportionally more that households income and triggering a demographic transition and a shift from stagnation to growth.

Similarly, a transition from stagnation to growth based upon a declining gender gap in human capital formation was proposed by Lagerlof (2003b). He argues that the process of development permitted a gradual improvement in the relative level of female education, raising the opportunity cost of children and initiating a fertility decline.[119]

4.2.3 Alternative Modeling of the Transition from Agricultural to Industrial Economy

The shift from agriculture to industry that accompanied the transition from stagnation to growth, as described in section 2.2.3, influenced the specifications of the production structure of most unified theories of economic growth. In some unified theories (e.g., Galor and Weil (2000)) the structure of the aggregate production function and its interaction with technological progress, reflects implicitly a transition from an agricultural to an industry economy in the process of development. In other theories (e.g., Hansen and Prescott 2002, Kogel and Prskawetz 2001, Hazan and Berdugo 2002, Tamura 2002, Doepke 2004, Galor and Mountford 2003, Bertocchi 2003, and Galor, Moav and Vollrath 2003) the process of development generates explicitly a transition from an agricultural sector to an industrial sector.

In Galor and Weil (2000) production occurs according to a constant-returns-to-scale technology that is subject to endogenous technological progress. The output produced at time t, is $Y_t = H_t^{\alpha}(A_t X)^{1-\alpha}$, where H_t is the aggregate quantity of efficiency units of labor employed in period t, X is land employed in production in every period t, and A_t represents the endogenously determined technological level in period t. Hence $A_t X$ are the "effective resources" employed in production in period t. In early stages of development, the economy is agricultural (i.e., the fixed amount of land is a binding constraint on the expansion of the economy). Population growth reduces labor productivity since the rate of technological progress is not sufficiently high to compensate for the land constraint. However as the rate of technological progress intensifies in the process of development the economy becomes industrial. Technological progress counterbalanced the land constraint, the role of land gradually diminishes, and "effective resources" are expanding at a rate that permit sustained economic growth.

Hansen and Prescott (2002) develop a model that captures explicitly the shift from an agricultural sector to an industrial sector in the transition from stagnation to growth. In early stages of development, the industrial technology is not sufficiently productive and production takes place solely in an agricultural sector, where population growth (that is *assumed* to increase with income) offset increases in productivity. An *exogenous* technological progress in the latent industrial technology ultimately makes the industrial sector economically viable and the economy gradually shifts resources from the agricultural sector to the industrial one. Assuming that the positive effect of income on population is reversed, the rise in productivity in the industrial sector is not counterbalanced by population growth permitting the transition to a state of sustained economic growth.

[119] Alternatively, one could have adopted the mechanism proposed by Fernandez, Fogli and Olivetti (2004) for the gradual decline in the education gap and labor force participation between men and women. They suggest that it reflects a dynamic process in which the home experience of sons of working, educated mothers makes them more likely to prefer educated and working wives, inducing a gradual increase in investment in education as well as labor force participation among women.

Unlike most unified theories in which the time paths of technological progress, population growth, and human capital formation are endogenously determined and are determined on the basis on explicit micro-foundations, in Hansen and Prescott (2002) technological progress is exogenous, population growth is assumed to follow the hump-shaped pattern that is observed along human history and human capital formation that appears central in the transition is absent. Based upon this reduced form approach, they demonstrate that there exists a rate of technological progress in the latent industrial sector and a well specified reduced form relationship between population and output under which the economy will shift from Malthusian stagnation to sustained economic growth. Unfortunately, however, this methodology does not advance us in identifying the underlying micro-foundations that led to the transition from stagnation to growth - the ultimate goal of unified growth theory.

Formally, the transition from stagnation to growth in Hansen and Prescott (2002) does not rely on the forces of human capital in the transition. However, the lack of a role for human capital in their structure is an artifact of the reduced form analysis that does not identify the economic factors behind the process of technological change in the latent industrial technology, as well as the forces behind the assumed hump shaped pattern of population dynamics. If the micro-foundations of these critical factors behind the transition would have been properly established, human capital would have played a central role sustaining the rate of technological progress in the industrial sector and in generating the demographic transition that is assumed in their setting.

Thus, no major insight has been generated from this explicit modeling of the transition from agriculture to industry in a closed economy setting. In contrast, the two-sector framework is instrumental in the exploring of the effect of international trade on the differential timing of the transition from stagnation to growth and the associate phenomenon of the great divergence (Galor and Mountford 2003), as discussed in section 6.1. Moreover, this two-sector setting would be necessary in order to examine the incentives of land owners to block education reforms and the process of industrialization (Galor, Moav, and Vollrath 2003), and the evolution of property rights and their impact on political reforms (Bertocchi 2003).

5 Unified Evolutionary Growth Theory

"It is not the strongest of the species that survive, nor the most intelligent, but the one most responsive to change." Charles Darwin

5.1 Human Evolution and Economic Development

This section explores the dynamic interaction between human evolution and the process of economic development. It focuses on a recent development of a unified evolutionary growth theory that, based on historical evidence, generates innovative hypotheses about the interplay between the process of development and human evolution, shedding new light about the origin of modern economic growth and the observed intricate evolution of health, life expectancy, human capital, and population growth since the Neolithic revolution.

The unified evolutionary growth theory advances a novel analytical methodology that is designed to capture the complexity of the dynamic interaction between the economic, social, and behavioral aspects of the process of development and evolutionary processes in the human population. The proposed hybrid between Darwinian methodology and the methodology of unified theories of economic growth permits the exploration of the dynamic reciprocal interaction between the evolution of the distribution of genetic traits and the process of economic development. It captures potential non-monotonic

evolutionary processes that were triggered by major socioeconomic transitions, and may have played a significant role in the observed time path of health, life expectancy, human capital, and population growth.[120]

Humans were subjected to persistent struggle for existence for most of their history. The Malthusian pressure affected the size of the population (as established in section 2.1.2), and conceivably via natural selection, the composition of the population as well. Lineages of individuals whose traits were complementary to the economic environment generated higher income, a larger number of surviving offspring and the representation of their traits in the population gradually increased, contributing significantly to the process of development.

Consistent with the historical evidence presented in section 2, the proposed unified evolutionary growth theory demonstrates that the Malthusian epoch that characterized most of human existence stimulated a process of natural selection that generated an evolutionary advantage to human traits that were complementary to the growth process, and ultimately generating a take-off from an epoch of Malthusian stagnation to a state of sustained economic growth.

Evidence suggests that evolutionary processes in the composition of existing genetic traits may be rather rapid and the time period between the Neolithic Revolution and the Industrial Revolution that lasted about 10,000 years is sufficient for significant evolutionary changes. There are numerous examples of rapid evolutionary changes among various species.[121] In particular, evidence establishes that evolutionary changes occurred in the Homo sapiens within the time period that is the focus of our analysis. For instance, lactose tolerance was developed among European and Near Easterners since the domestication of dairy animals in the course of the Neolithic revolution, whereas in regions that were exposed to dairy animals in later stages a larger proportion of the adult population suffers from lactose intolerance. Furthermore, genetic immunity to malaria provided by the sickle cell trait is prevalent among descendents of Africans whose engagement in agriculture improved the breeding ground for mosquitoes and thereby raised the incidence of malaria, whereas this trait is absent among descendents of nearby populations that have not made the transition to agriculture.[122]

Despite the existence of compelling evidence about the interaction between human evolution and the process of economic development, only few attempts have been made to explore the reciprocal interaction between the process of development and human evolution.[123] This exploration is likely to revolutionize our understanding of the process of economic development as well as the process of human

[120]The conventional methodology of *evolutionary stable strategies* that has been employed in various fields of economics, ignores the dynamics of the evolutionary process, and is thus inappropriate for the understanding of the "short-run" interaction between human evolution and the process of development since the Neolithic revolution. As will become apparent the dynamics of the evolutionary process are essential for the understanding of the interaction between human evolution and economic growth since the Neolithic revolution that was marked by fundamental non-monotonic evolutionary processes.

[121]The color change that peppered moths underwent during the 19th century is a classic example of evolution in nature [See Kettlewell 1973]. Before the Industrial Revolution light-colored English peppered moths blended with the lichen-covered bark of trees. By the end of the 19th century a black variant of the moth, first recorded in 1848, became far more prevalent than the lighter varieties in areas in which industrial carbon removed the lichen and changed the background color. Hence, a significant evolutionary change occurred within a time period that correspond to only hundreds of generations. Moreover, evidence from Daphne Major in the Galapagos suggests that significant evolutionary changes in the distribution of traits among Darwin's Finches occurred within few generations due to a major drought [Grant and Grant 1989]. Other evidence, including the dramatic changes in the color patterns of guppies within 15 generations due to changes in the population of predators, are surveyed by Endler [1986].

[122]See Levingston [1958], Weisenfeld [1967] and Durham [1982].

[123]Notable exceptions are Galor and Moav (2002)'s exploration of the interaction between human evolution and the transition from stagnation to growth, Saint Paul (2003)'s examination of the effect of the emergence of markets on the evolution of heterogeneity in the human population , Clark and Hamilton (2003) analysis of the relationship between the evolution of time preference and the sharp decline in interest rate in England in the 14th and 15th centuries, and Galor and Moav (2004)'s exploration of the effect of an increased population density in the process of development on the evolution of life expectancy.

evolution.

5.2 Natural Selection and the Origin of Economic Growth

The first evolutionary growth theory that captures the interplay between human evolution and the process of economic development in various phases of development, was developed by Galor and Moav (2002). The theory suggests that during the epoch of Malthusian stagnation that had characterized most of human existence, traits of higher valuation for offspring quality generated an evolutionary advantage and their representation in the population gradually increased. This selection process and its effect on investment in human capital stimulated technological progress and ultimately initiated a reinforcing interaction between investment in human capital and technological progress that brought about the demographic transition and the state of sustained economic growth.[124]

The theory maintains that during the Malthusian epoch, the distribution of valuation for quality lagged behind the evolutionary optimal level. The evolution of the human brain in the transition to Homo sapiens and the complementarity between brain capacity and the reward for human capital has increased the evolutionary optimal investment in the quality of offspring (i.e., the level that maximizes reproduction success).[125] Moreover, the increase in the return to human capital in the aftermath of the Neolithic revolution increased the evolutionary optimal levels of investment in child quality. The agricultural revolution facilitated the division of labor and fostered trade relationships across individuals and communities, enhancing the complexity of human interaction and raising the return to human capital. Thus, individuals with traits of higher valuation for offspring's quality generated higher income and, in the Malthusian epoch when child rearing was positively affected by aggregate resources, a larger number of offspring. Traits of higher valuation for quality gained the evolutionary advantage and their representation in the population increased over time.

The Malthusian pressure increased the representation of individuals whose preferences are biased towards child quality, positively affecting investment in human capital and ultimately the rate of technological progress. In early stages of development, the proportion of individuals with higher valuation for quality was relatively low, investment in human capital was minimal, resources above subsistence were devoted primarily to child rearing, and the rate of technological progress was rather slow. Technological progress therefore generated proportional increases in output and population and the economy was in the vicinity of a Malthusian equilibrium, where income per capita is constant, but the proportion of individuals with high valuation for quality was growing over time.[126]

As the fraction of individuals with high valuation for quality continued to increase, technological progress intensified, raising the rate of return to human capital. The increase in the rate of technological progress generated two effects on the size and the quality of the population. On the one hand, improved

[124]The theory is applicable for either social or genetic intergenerational transmission of traits. A cultural transmission is likely to be more rapid and may govern some of the observed differences in fertility rates across regions. The interaction between cultural and genetic evolution is explored by Boyd and Richardson (1985) and Cavalli-Sforza and Feldman (1981), and a cultural transmission of preferences is examined by Bisin and Verdier (2000).

[125]The evolutionary process in valuation for quality that was triggered by the evolution of the human brain has not reached a new evolutionary stable state prior to the Neolithic period because of the equality that characterized resource allocation among hunter-gatherers tribes. Given this tribal structure, a latent attribute of preferences for quality, unlike observable attributes such as strength and intelligence, could not generate a disproportionate access to sexual mates and resources that could affect fertility rates and investment in offspring's quality, delaying the manifestation of the potential evolutionary advantage of these traits. It was the emergence of the nuclear family in the aftermath of the agricultural revolution that fostered intergenerational links, and thereby enhanced the manifestation of the potential evolutionary advantage of this trait.

[126]Unlike Galor and Weil (2000) in which the adverse effect of limited resources on population growth delays the process of development, in the proposed theory the Malthusian constraint generates the necessary evolutionary pressure for the ultimate take-off.

technology eased households' budget constraints and provided more resources for quality as well as quantity of children. On the other hand, it induced a reallocation of these increased resources toward child quality. In the early stages of the transition from the Malthusian regime, the effect of technological progress on parental income dominated, and the rate of population growth as well as the average quality increased, further accelerating technological progress. Ultimately, the rate of technological progress induced universal investment in human capital along with a reduction in fertility rates, generating a demographic transition in which the rate of population growth declined along with an increase in the average level of education. The positive feedback between technological progress and the level of education reinforced the growth process, setting the stage for the transition to a state of sustained economic growth.[127]

During the transition from the Malthusian epoch to the sustained growth regime, once the economic environment improved sufficiently, the significance of quality for survival (fertility) declined, and traits of higher valuation for quantity gained the evolutionary advantage. Namely, as technological progress brought about an increase in income, the Malthusian pressure relaxed and the domination of wealth in fertility decisions diminished. The inherent advantage of higher valuation for quantity in reproduction has started to dominate, and individuals whose preferences are biased towards child quantity gained the evolutionary advantage. Nevertheless, the growth rate of output per worker has remained positive since the high rate of technological progress sustained an attractive return to investment in human capital even from the viewpoint of individuals whose valuation for quality is relatively low.

The transition from stagnation to growth is an inevitable by product of the interaction between the composition of the population and the rate of technological progress in the Malthusian epoch. However, for a given composition of population, the timing of the transition may differ significantly across countries and regions due to historical accidents, as well as variation in geographical, cultural, social and institutional factors, trade patterns, colonial status, and public policy, that have affected the relationship between human capital formation and technological progress.

5.2.1 Primary Ingredients

The theory is based upon the interaction between several building blocks: the Darwinian elements, the Malthusians elements, the nature of technological progress, the determinants of human capital formation, and the factors that affect parental choice regarding the quantity and quality of offspring.

The Darwinian elements. The theory incorporates the main ingredients of Darwinian evolution (i.e., variety, intergenerational transmission of traits, and natural selection) into the economic environment. Inspired by fundamental components of the Darwinian theory (Darwin 1859, 1871), individuals do not operate consciously so as to assure their evolutionary advantage. Nevertheless, their preferences (or strategies) assure that those individuals whose operations are most complementary to the environment would ultimately dominate the population.

Individuals' preferences are defined over consumption above a subsistence level as well as over the quality and the quantity of their children.[128] These preferences capture the Darwinian survival

[127]The theory suggests that waves of rapid technological progress in the Pre-Industrial Revolution era did not generate sustained economic growth due to the shortage of preferences for quality in the population. Although technological progress increased the return to quality temporarily, in these previous episodes, the level of human capital that was generated by the response of the existing population was insufficient to sustain technological progress and economic growth.

[128]The subsistence consumption constraint is designed to capture the fact that the physiological survival of the parent is a pre-condition for the survival of the lineage (dynasty). Resources allocated to parental consumption beyond the subsistence level may be viewed as a force that raises parental productivity and resistance to adverse shocks (e.g., famine and disease), generating a positive effect on the fitness of the parent and the survival of the lineage. This positive effect, however, is counterbalanced by the implied reduction in resources allocated to the offspring, generating a negative effect on the survival of the lineage.

strategy as well as the most fundamental trade-offs that exist in nature: namely, the trade-off between the resources allocated to the parent and the offspring, and the trade-off between the number of offspring and resources allocated to each offspring.[129] The economy consists of a variety of types of individuals distinguished by the weight given to child quality in their preferences.[130] This trait is assumed to be transmitted intergenerationally, the economic environment determines the type with the evolutionary advantage (i.e., the type characterized by higher fertility rates), and the distribution of preferences in the population evolves over time due to differences in fertility rates across types.[131]

The significance that individuals attribute to child quantity as well as to child quality reflects the well-known variety in the quality-quantity survival strategies (or in the K and r strategies) that exists in nature (e.g., MacArthur and Wilson 1967). Human beings, like other species, confront the basic trade-off between offspring's quality and quantity in their implicit Darwinian survival strategies. Although a quantity-biased preference has a positive effect on fertility rates and may therefore generate a direct evolutionary advantage, it adversely affects the quality of offspring, their income, and their fitness and may therefore generate an evolutionary disadvantage. "Increased bearing is bound to be paid for by less efficient caring." (Dawkins 1989, p. 116). As was established in the evolutionary biology literature since the seminal work of Lack (1954), the allocation of resources between offspring "caring" and "bearing" is subjected to evolutionary changes.[132]

The Malthusian elements. Individuals are subjected to a subsistence consumption constraint and as long as the constraint is binding, an increase in income results in an increase in population growth along with an increase in the average quality of a minor segment of the population. Technological progress, which brings about temporary gains in income per capita, triggered therefore in early stages of development an increase in the size of the population that offset the gain in income per capita due to the existence of diminishing returns to labor. Growth in income per capita is generated ultimately, despite decreasing returns to labor, since technological progress induces investment in human capital among a growing minority.

The determinants of technological progress. The composition of the population as reflected by the average level of human capital is the prime engine of technological progress.[133]

[129]Resources allocated to quality of offspring in different stages of development take different forms. In early stages of development it is manifested in investment in the durability of the offspring via better nourishment and parental guidance, whereas in mature stages, investment in quality may capture formal education.

[130]The analysis abstracts from heterogeneity in the degree of the trade-off between resources allocated to parent and offspring. The introduction of this element would not alter the qualitative results. On the evolution of preferences see the survey by Bowles (1998).

[131]Recent research across historical and modern data from the United States and Europe suggests that fertility behavior has a significant hereditary component [Rogdgers et al. 2001a]. For instance, as established recently by Kohler et al. (1999) and Rodgers et al. (2001b), based on the comparison of fertility rates among identical and fraternal twins born in Denmark during the periods 1870-1910 and 1953-1964, slightly more than one-quarter of the variance in completed fertility is attributable to genetic influence. These findings are consistent with those of Rodgers and Doughty [2000] based on kinship data from the United States.

[132]Lack (1954) suggests that clutch sizes (i.e., number of eggs per nest), among owls and other predatory vole-eating birds, for instance, are positively related to food abundance. He argues that the clutch size is selected such that under any feeding conditions fertility rates ensure the maximal reproductive success. Furthermore, Cody (1966) documents the existence of significant differences between clutch sizes of the same bird species on islands and nearby mainland localities of the same latitude. In temperate regions where food is more abundant in the mainland than on islands, the average clutch size is smaller on the islands. For instance, for *Cyanoramphus novaezelandeae*, the average mainland clutch is 6.5 whereas the average in the island is 4.

[133]This link between education and technological change was proposed by Nelson and Phelps (1966) and was supported empirically by Easterlin (1981), Doms et al. (1997), as well as others. Consistently with Mokyr (2002) who argues that the effect of human capital accumulation on technological progress became significant only in the course of the Scientific Revolution that preceded the Industrial Revolution, the effect of human capital accumulation on the rate of technological progress, need not be significant prior to the scientific revolution as long as it becomes significant prior to the Industrial Revolution. In order to focus on the role of the evolutionary process, the model abstracts from the potential positive effect of the size of the population on the rate of technological progress. Adding this scale effect would simply accelerate the

The origin of human capital formation. Technological change raises the demand for human capital. Technological progress reduces the adaptability of existing human capital for the new technological environment and educated individuals (and thus offspring of parent with high valuation for quality) have a comparative advantage in adapting to the new technological environment.[134]

The determination of paternal decision regarding offspring quantity and quality. Individuals choose the number of children and their quality based upon their preferences for quality as well as their time constraint.[135] The rise in the (genetic or cultural) bias towards quality in the population, as well as the rise in the demand for human capital, induce parents to substitute quality for quantity of children.[136]

5.2.2 Main Hypotheses and their Empirical Assessment

The theory generates several hypotheses about human evolution and the process of development, underlying the role of natural selection in: (i) the gradual process of human capital formation and thus technological progress prior to the Industrial Revolution, and (ii) the acceleration of the interaction between human capital and technological progress in the second phase of the Industrial Revolution, the associated demographic transition, and the emergence of a state of sustained economic growth.

The Main Hypotheses:

- During the initial phases of the Malthusian epoch, the growth rate of output per capita is nearly zero and the growth rate of population and literacy rates is minuscule, reflecting the sluggish pace of technological progress, the low representation of individuals with high valuation for child quality, and the slow pace of the evolutionary process.

This hypothesis is consistent with the characteristics of the Malthusian epoch, as described in section 2.1.

- In the pre-demographic transition era, traits for higher valuation for offspring quality generated an evolutionary advantage. Namely, individuals with higher valuation for the quality of children had a larger number of surviving offspring and their representation in the population increased over time. In contrast, in the post-demographic transition era, when income per capita has no longer been the binding constraint on fertility decisions, individuals with higher valuation for offspring quantity have had an evolutionary advantage, bearing a lager number of surviving offspring. Thus, in the pre-demographic transition era, the number of surviving offspring was affected positively by parental education and parental income whereas in the post-demographic transition era, in contrast, this pattern is reversed and more educated, higher income individuals have a smaller number of surviving offspring.

transition process (e.g., Galor and Weil 2000).

[134] See Schultz (1964) and Nelson and Phelps (1966). If the return to education rises with the level of technology rather than with the rate of technological progress, the qualitative analysis would not be affected. However, this alternative would imply that changes in technology were skill-biased throughout human history in contrast to those periods in which technological change was skilled-saving, notably, in the first phase of the Industrial Revolution.

[135] Anthropological evidence suggests that fertility control was indeed exercised even prior to the Neolithic Revolution. Reproductive control in hunter-gatherer societies is exemplified by "pacing birth" (e.g., birth every four years) conducted by tribes who live in small, semi nomadic bands in Africa, Southeast Asia, and New Guinea in order to prevent the burden of carrying several children while wandering. They abstained from sexual intercourse for a three-year period after each birth. Similarly, Nomadic women of the Kung (a group of the San people of Southern Africa), use no contraceptives but nurse their babies frequently, suppressing ovulation and menstruation for two to three years after birth, and reaching a mean interval between births of 44 months.

[136] The existence of a trade-off between quantity and quality of children is supported empirically (e.g., Rosenzweig and Wolpin (1980) and Hanushek (1992)).

Clark and Hamilton (2003) examine empirically this hypothesis on the basis of data that they have constructed from wills written in England in the time period 1620-1636. The wills that were written in a closed proximity to the death of a person in urban and rural areas, across a large variety of occupations and wealth, contain information about the number of surviving offspring, literacy of testator (measured by whether the will was signed), occupation of testator (if male), the amount of money bequeathed and to whom (spouse, children, the poor, unrelated persons), and houses and land that were bequeathed. Based on this data, Clark and Hamilton find a positive and statistically significant effect of literacy (and wealth) on the number of surviving offspring.[137] They confirm the hypothesis that literate people (born, according to the theory, to parents with quality-bias) had an evolutionary advantage in this (pre-demographic transition) period.[138] The negative relationship between education and fertility within a country in the post-demographic transition era was documented extensively.[139]

- The process of natural selection prior to the Industrial Revolution increased the representation of individuals with higher valuation for quality, gradually increasing the average level of investment in human capital,[140] permitting a slow growth of output per capita.

The prediction about the rise in literacy rates prior to the Industrial Revolution is consistent with historical evidence. Various measures of literacy rates demonstrate a significant rise in literacy rates in the 2 centuries that preceded the Industrial Revolution in England.[141] As depicted in Figure 5.1, male literacy rates increased gradually in the time period 1600-1760. Literacy rates for men doubled over this period, rising from about 30% in 1600 to over 60% in 1760. Similarly, as reported by Cipolla (1968), literacy rates of women more than tripled from less than 10% in 1640 to over 30% in 1760.[142]

[137] In addition, Boyer (1989) argues that in early nineteenth century England, agricultural laborers' income had a positive effect on fertility: birth rates increased by 4.4 percent in response to a 10 percent increase in annual income. Further evidence are surveyed by Lee (1997).

[138] Interestingly, in New France, where land was abundant, and thus fertility decisions were not constraint by the availability of resources, the number of surviving offspring was higher among less educated individuals. These findings are consistent with the theory as well. If resource constraint is not binding for fertility decisions (e.g., in the post-demographic transition era, or due to a positive shock to income in the Malthusian era), individuals with higher valuation for quantity gain an evolutionary advantage.

[139] See, for instance, Kremer and Chen (2002).

[140] In contrast to Galor and Weil (2000) in which the inherent positive interaction between population and technology during the Malthusian regime is the force behind the increase in the rate of technological progress that induced investments in human capital and led to further technological progress, a demographic transition, and sustained economic growth, Galor and Moav (2002) is structured such that the gradual change in the composition of the population (rather than by the size of the population) brings about the take-off from Stagnation to growth. Thus, a scale effect is not needed for the take-off. However, this is just a simplifying modelling devise and both forces could operated simultaneously in triggering the take-off.

[141] Moreover, this hypothesis appears consistent with the increase in the number and size of universities in Europe since the establishment of the first university in Bologna in the 11th century, significantly outpacing the growth rate of population.

[142] This pattern is robust and is observed in various diocese over this period. For instance Cressy (1981, table 6.3 p. 113) reports a gradual rise in average literacy rate of average of yeomen, husbandmen and tradesmen in Norwich from 30% in 1580 to nearly 61% in 1690, and Cressy (1980, table 7.1 p. 143) reports a gradual rise in Gentle literacy in the diocese of Durham over the period 1565 to 1624.

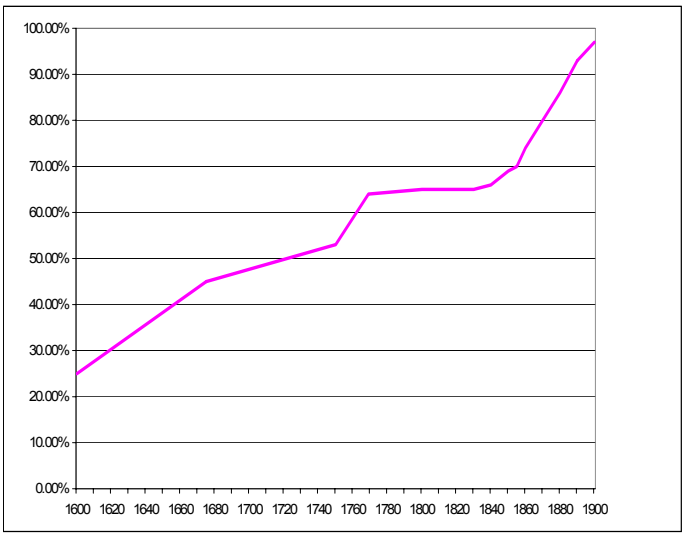

Figure 5.1 The Rise in Male Literacy Rates Prior and During the Industrial Revolution: England: 1600-1900
Sources: Cipolla (1969), Stone (1969) and Schofield (1973)

Moreover, as argued by Clark (2003), human capital accumulation in England began in an era when the market rewards to skill acquisition were at historically low levels, consistent with the argument that the rise in human capital reflected a rise in the preference for quality offspring.

- The acceleration in the rate of technological progress that was reinforced by the investment in human capital of individuals with high valuation for offspring quality, increased the demand for human capital in the Post-Malthusian Regime, generating a universal investment in human capital, a demographic transition and a rapid pace of economic growth.

The hypothesis is consistent with the evidence, provided in section 2.3 and depicted partly in Figure 4.1, about the significant rise in the demand for human capital in the second phase of the Industrial Revolution, the marked increased in educational attainment, and the emergence of universal education towards the end of the 19th century in association with a decline in fertility rates, and a transition to a state of sustained economic growth.

5.3 Complementary Mechanisms

The theory argues that during the Malthusian epoch hereditary human traits, physical or mental, that generate higher earning capacity, and thereby potentially larger number of offspring, would generate an evolutionary advantage and would dominate the population in the long run. Hereditary traits that stimulate technological progress or raise the incentive to invest in offspring's human capital (e.g., ability, longevity, and a preference for quality), may trigger a positive feedback loop between investment in human capital and technological progress that would bring about a take-off from an epoch of Malthusian stagnation, a demographic transition and a shift to a state of sustained economic growth. Hence, the struggle for existence that had characterized most of human history stimulated natural selection and generated an evolutionary advantage to individuals whose characteristics are complementary to the growth process, ultimately triggering a take-off from an epoch of stagnation to sustained economic growth. Galor and Moav (2002) focus on the evolution of the trade-off between resources allocated to

the quantity and the quality of offspring. Their framework of analysis can be modified to account for the interaction between economic growth and the evolution of other hereditary traits.

5.3.1 The Evolution of Ability and Economic Growth

Consider the model described earlier. Suppose that individual's preferences, are defined over consumption above a subsistent level and over child quality and quantity. Individuals are identical in their preferences, but differ in their hereditary innate ability. Suppose further that offspring's level of human capital is an increasing function of two complementary factors: innate ability and investment in quality. Thus, since the marginal return to investment in child quality increases with ability, higher ability individuals and hence dynasties would allocate a higher fraction of their resources to child quality.

In the Malthusian era individuals with a higher ability generate more income and hence are able to allocate more resources for child quality and quantity. High ability individuals, therefore, generate higher income due to fact that their innate ability as well as their quality are higher. In the Malthusian era fertility rates are positively affected by the level of income and (under plausible configurations) the high ability individuals have therefore an evolutionary advantage over individuals of lower ability. As the fraction of individuals of the high ability type increases, investment in quality rises, and technological progress intensified. Ultimately the dynamical system changes qualitatively, the Malthusian temporary steady-state vanishes endogenously and the economy takes-off from the Malthusian trap. Once the evolutionary process generates the positive feedback between the rate of technological progress and the level of education, technological progress is reinforced, the return to human capital increases further, setting the stage for the demographic transition and sustained economic growth.

5.3.2 The Evolution of Life Expectancy and Economic Growth

Suppose that individuals differ in their level of health due to hereditary factors. Suppose further that there exist a positive interaction between the level of health and economic well-being. Higher income generates a higher level of health, whereas higher level of health increases labor productivity and life expectancy. Parents that are characterized by high life expectancy and thereby expect their offspring to have a longer productive life, would allocate more resources toward child quality. In the Malthusian era fertility rates are positively affected by the level of income and individuals with higher life expectancy, and therefore higher quality and higher income, would have (under plausible configurations) an evolutionary advantage. Natural selection therefore, increases the level of health as well as the quality of the population. Eventually, this process generates a positive feedback loop between investment in child quality, technological progress and health, bringing about a transition to sustained economic growth with low fertility rates and high longevity.

Alternatively, Galor and Moav (2004b) hypothesize that major socioeconomic and environmental changes in the process of development that were associated with significant increases in population density (e.g., the Neolithic Revolution and the process of urbanization) triggered evolutionary processes that contributed significantly to the long lasting improvements in longevity. Consistent with historical evidence, the theory suggests that the rise in the extrinsic mortality rate, brought about by a denser population, led initially to a decline in life expectancy, as document for instance in Figure 2.8.[143] However, the evolutionary process that was originated by the rise in mortality, gradually increased the representation of traits associated with resistance to diseases and thus higher life expectancy, contributing

[143]Moreover, the evolutionary forces that major epidemics (e.g., the Black Death) and climatic changes have triggered, might have influenced the time path of human longevity and economic development in the subsequent centuries.

significantly to the observed rise in longevity. Moreover, this evolutionary process in life expectancy reinforced the interaction between investment in human capital, life expectancy, and technological progress thereby expediting the demographic transition and enhancing the economic transition from stagnation to growth.[144]

5.4 Assessment of the Various Mechanisms

The significance of the evolution of various genetic traits in the transition from an epoch of Malthusian stagnation to a state of sustained economic growth, ought to consider the possibility that some of these traits may have completed most of their evolutionary change tens of thousands of years before the take-off and may be therefore a pre-condition for the take-off rather than the trigger itself.

In particular, the conventional wisdom among evolutionary biologists is that intelligence has not evolved markedly since the emergence of Homo Sapience (i.e., intelligence may have reached a temporary evolutionary optimum, reflecting the trade-off between the benefits and the energy cost associated with a lager brain). In contrast, it is unlikely that preferences reflecting quality-bias would have reached a an evolutionary stable state very early in the evolution of mankind. Prior to the Neolithic period, the majority of people lived in tribes where resources as well as child rearing were shared by the community. Given this tribal structure, the latent attribute of preferences for quality, unlike observable attributes such as strength and intelligence, could not generate a disproportionate access to sexual mates and resources that could affect fertility rates and investment in offspring's quality, delaying the manifestation of the potential evolutionary advantage of individuals with a quality-bias. It was the emergence of the nuclear family in the aftermath of the agricultural revolution that fostered intergenerational links, and thereby enhanced the manifestation of the potential evolutionary advantage of individuals with a quality-bias.[145]

6 Differential Takeoffs and the Great Divergence

The last two centuries have witnessed dramatic changes in the distribution of income and population across the globe. The differential timing of the take-off from stagnation to growth across countries and the corresponding variations in the timing of the demographic transition have led to a great divergence in income as depicted in Figure 2.32 and to significant changes in the distribution of population around the globe, as depicted in Figure 2.33. Some regions have excelled in the growth of income per capita, while other regions have been dominant in population growth.[146]

Inequality in the world economy had been insignificant until the 19th century. The ratio of GDP per capita between the richest region and the poorest region in the world was only 1.1:1 in the year 1000, 2:1 in the year 1500 and 3:1 in the year 1820. In contrast, the past two centuries have been characterized

[144]The evolution of the human brain along with the evolution of life expectancy in the prior to the Neolithic revolution is examined by Robson and Kaplan (2003).

[145]An alternative explanation for the delay in the evolutionary process of the quality bias relative to the evolution of ability is based on the notion of punctuated equilibria (Gould 1977). A sequence of mutations, which result in a gradual increase in the variance in the distribution of the (latent) quality bias trait, had not affected investment in offspring's quality for a long period due to the low rate of return to human capital. Ultimately, however, mutations increased the variance sufficiently so as to induce investment in offspring's quality, despite the low return, and brought about an evolutionary advantage for the quality type. In contrast, a gradual increase in the variance of non-latent variables, such as ability, would have an immediate effect on the evolutionary process.

[146]Some researchers (e.g., Jones (1997) and Pritchett (1997)) have demonstrated that the great divergence that has been witnessed in the last two centuries has been maintained in the last decades as well, across countries. Interestingly, however, as established by Sala-i-Martin (2002), the phenomena has not been maintained across people in the world, (i.e., when national boundaries are removed).

by a 'Great Divergence' in income per capita among countries and regions. In particular, the ratio of GDP per capita between the richest and the poorest regions has widened considerably from a modest 3:1 ratio in 1820, to a large 18:1 ratio in 2001. An equally impressive transformation occurred in the distribution of world population across regions, as depicted in Figure 2.33. The earlier take-off of Western European countries generated a 16% increase in the share of their population in the world economy within the time period 1820-1870. However, the early onset in the Western European demographic transition, and the long delay in the demographic transition of less developed regions well into the second half of the twentieth century, led to a 55% decline in the share of Western European population in the world in the time period 1870-1998. In contrast, the prolongation of the Post-Malthusian period of less developed regions and the delay in their demographic transition, generated a 84% increase in Africa's share of world population, from 7% in 1913 to 12.9% in 1998, an 11% increase in Asia's share of world population from 51.7% in 1913 to 57.4% in 1998, and a four-fold increase in Latin American's share in world population from 2% in 1820 to 8.6% in 1998.

The phenomenon of the Great Divergence in income per capita across regions of the world in the past two centuries, that was associated with the take-off from the epoch of near stagnation to a state of sustained economic growth, presents intriguing questions about the growth process. How does one account for the sudden take-off from stagnation to growth in some countries in the world and the persistent stagnation in others? Why has the positive link between income per capita and population growth reversed its course in some economies but not in others? Why have the differences in per capita incomes across countries increased so markedly in the last two centuries? Has the transition to a state of sustained economic growth in advanced economies adversely affected the process of development in less-developed economies?

6.1 Non-Unified Theories

The origin of the Great Divergence has been a source of controversy. The relative role of geographical and institutions factors, ethnic, linguistic, and religious fractionalization, colonialism and globalization has been in the center of a debate about the origins of this remarkable change in the world income distribution in the past two centuries.

The role of institutional and cultural factors has been the focus of influential hypotheses regarding the origin of the great divergence. North (1981), Landes (1998), Mokyr (1990, 2002), Hall and Jones (1999), Parente and Prescott (2000), and Acemoglu, Johnson and Robinson (2002) have argued that institutions that facilitated the protection of property rights and enhanced technological research and the diffusion of knowledge, have been the prime factors that enabled the earlier European take-off and the great technological divergence across the globe.[147]

The effect of geographical factors on economic growth and the great divergence have been emphasized by Jones (1981), Diamond (1997) and Gallup, Sachs, and Mellinger (1998).[148] The geographical hypothesis suggests that advantageous geographical conditions made Europe less vulnerable to the risk associated with climate and diseases, leading to the early European take-off, whereas adverse geographical conditions (e.g. harsh climate, prevalence of diseases, scarcity of natural resources, high transportation costs, limited regional diffusion of knowledge and technology) in disadvantageous regions, generated permanent hurdles for the process of development, contributing to the great divergence.[149]

[147]Barriers to technological adoption that may lead to divergence are explored by Caselli and Coleman (2002), Howitt and Mayer-Foulkes (2002) and Acemoglu, Aghion and Zilibotti (2003) as well.

[148]See Hall and Jones (1999), Masters and McMillan (2001) and Hibbs and Olson (2004) as well.

[149]Bloom, Canning and Sevilla (2003) cross section analysis rejects the geographical determinism, but maintain nevertheless that favorable geographical conditions have mattered for economic growth since they increase the likelihood of an

Recent research by Engerman and Sokoloff (2000) and Acemoglu, Johnson and Robinson (2002) propose that initial geographical conditions had a persistent effect on the quality of institutions, leading to divergence and overtaking in economic performance. Engerman and Sokolof (2000) provide descriptive evidence that geographical conditions that led to income inequality, brought about oppressive institutions designed to preserve the existing inequality, whereas geographical characteristics that generated an equal distribution of income led to the emergence of growth promoting institutions. Acemoglu, Johnson and Robinson (2002) provide evidence that reversals in economic performance across countries have a colonial origin, reflecting institutional reversals that were introduced by European colonialism across the globe.[150] "Reversals of fortune" reflect the imposition of extractive institutions by the European colonialists in regions in which favorable geographical conditions led to prosperity, and the implementation of growth enhancing institutions in poorer regions.[151]

Furthermore, the role of ethnic, linguistic, and religious fractionalization in the emergence of divergence and "growth tragedies" has been linked to their effect on the quality of institutions. Easterly and Levine (1997) and Alesina et al. (2003) demonstrate that geopolitical factors brought about a high degree of fractionalization in some regions of the world, leading to the implementation of institutions that are not conducive for economic growth and thereby to diverging growth paths across regions.

Empirical research suggests that indeed initial geographical conditions affected the current economic performance primarily via their effect on institutions. Acemoglu, Johnson and Robinson (2002), Easterly and Levine (2003), and Rodrik, Subramanian and Trebbi (2004) provide evidence that variations in the contemporary growth processes across countries can be attributed to institutional factors whereas geographical factors are secondary, operating primarily via variations in institutions.

A theory that unifies the geographical and the institutional paradigms, capturing the transition from the domination of the geographical factors in the determination of productivity in early stages of development to the domination of the institutional factors in mature stages of development has been proposed by Galor, Moav and Vollrath (2003). The theory identifies and establishes the empirical validity of a novel channel through which favorable geographical conditions that were inherently associated with inequality affected the emergence of human capital promoting institutions (e.g., public schooling, child labor regulations, abolishment of slavery, etc.), and thus the pace of the transition from an agricultural to an industrial society.[152] They suggest that the distribution of land within and across countries affected the nature of the transition from an agrarian to an industrial economy, generating diverging growth patterns across countries. The accumulation of physical capital in the process of industrialization has raised the importance of human capital in the growth process, reflecting the complementarity between capital and skills. Investment in human capital, however, has been sub-optimal due to credit markets imperfections, and public investment in education has been growth enhancing. Nevertheless, human capital accumulation has not benefited all sectors of the economy. Due to a low degree of complementarity between human capital and land, universal public education has increased the cost of labor beyond the increase in average labor productivity in the agricultural sector, reducing the return to land. Landowners, therefore, had no economic incentives to support these growth enhancing educational policies as long as their stake in the productivity of the industrial sector was insufficient. Land abundance, which was beneficial in early stages of development, brought about a hurdle for human capital accu-

economy to escape a poverty trap.

[150] Additional aspects of the role of colonialism in comparative development are analyzed by Bertocchi and Canova (2002).

[151] Brezis, Krugman and Tsiddon (1993) attribute technological leapfrogging to the acquired comparative advantage (via learning by doing) of the current technological leaders in the use of the existing technologies.

[152] As established by Chanda and Dalgaard (2003), variations in the structural composition of economies and in particular the allocation of scarce inputs between the agriculture and the non-agriculture sectors are important determinants of international differences in TFP, accounting for between 30 and 50 percents of these variations.

mulation and economic growth among countries that were marked by an unequal distribution of land ownership.[153]

6.2 A Unified Theory - Globalization and the Great Divergence

Unified theories of economic growth generate direct hypotheses about the factors that determine the timing of the transition from stagnation to growth and thus the factors that contributed to the Great Divergence. The timing of the transition may differ significantly across countries and regions due to historical accidents, as well as variation in geographical, cultural, social and institutional factors, trade patterns, colonial status, and public policy, that have affected the relationship between human capital formation and technological progress.[154]

This section explores a unified growth theory that generates a transition from stagnation to growth along with a great divergence, focusing on the asymmetric effect of globalization on the timing of the take-off from the Malthusian epoch of developed and less developed countries. Galor and Mountford (2003) suggest that sustained differences in income and population growth across countries may be attributed to the contrasting effect of international trade on industrial and non-industrial nations. Consistent with the evidence provided in section 2, their theory suggests that the expansion of international trade in the 19th century and its effect on the pace of individualization has played a major role in the timing of demographic transitions across countries and has thereby been a significant determinant of the distribution of world population and a prime cause of the 'Great Divergence' in income levels across countries in the last two centuries. International trade had an asymmetrical effect on the evolution of industrial and non-industrial economies**.** While in the industrial nations the gains from trade were directed primarily towards investment in education and growth in output per capita, a significant portion of the gains from trade in non-industrial nations was channeled towards population growth.[155]

In the second phase of the Industrial Revolution, international trade enhanced the specialization of industrial economies in the production of industrial, skilled intensive, goods. The associated rise in the demand for skilled labor has induced a gradual investment in the quality of the population, expediting a demographic transition, stimulating technological progress and further enhancing the comparative advantage of these industrial economies in the production of skilled intensive goods. In non-industrial economies, in contrast, international trade has generated an incentive to specialize in the production of unskilled intensive, non-industrial, goods. The absence of significant demand for human capital has provided limited incentives to invest in the quality of the population and the gains from trade have been utilized primarily for a further increase in the size of the population, rather than the income of the existing population. The demographic transition in these non-industrial economies has been significantly delayed, increasing further their relative abundance of unskilled labor, enhancing their comparative dis-

[153] An alternative mechanism is explored by Berdugo, Sadik and Sussman (2003).

[154] Related to the unified paradigm, Pomeranz (2000) has suggested that the discovery of the New World enabled Europe, via Atlantic trade, to overcome 'land constraints' and to take-off technologically. The inflow of grain and other commodities as well as the outflow of migrants during the Nineteenth century may have played a crucial role in Europe's development. By easing the land constraint at a crucial point — when income per capita had begun to rise rapidly, but before the demographic transition had gotten under way — the "ghost acres" of the New World provided a window of time which allowed Europe to pull decisively away from the Malthusian equilibrium.

[155] In contrast to the recent literature on the dynamics of comparative advantage (e.g., Findlay and Kierzkowski (1983), Grossman and Helpman (1991) Matsuyama (1991), Young (1991), Mountford (1998), and Baldwin et. al (2001) the focus on the interaction between population growth and comparative advantage and the persistent effect that this interaction may have on the distribution of population and income in the world economy generates an important new insight regarding the distribution of the gains from trade. The theory suggests that even if trade affects output growth of the trading countries at the same rate, (due to the terms of trade effect) income *per capita* of developed and less developed economies will diverge since in less developed economies growth of total output will be generated primarily by population growth, whereas in developed economies it will be generated by an increase in output per capita.

advantage in the production of skilled intensive goods and delaying their process of development. The research suggests, therefore, that international trade affected persistently the distribution of population, skills, and technologies in the world economy, and has been a significant force behind the 'Great Divergence' in income per capita across countries.[156]

The historical evidence described in section 2 suggests that the fundamental hypothesis of this theory is consistent with the process of development of the last two centuries. As implied by the trade patterns reported in Table 2.1, and the evolution of industrialization depicted in Figure 2.14, trade over this period induced the specialization of industrialized economies in the production of industrial goods whereas non-industrial economies specialize in the production of primary goods. The asymmetric effect of international trade on the process of industrialization of developed and less developed economies, as depicted in Figure 2.14, affected the demand for human capital as analyzed in section 2.3.3, and thus the timing of the demographic transition in developed and less-developed economies, generating a great divergence in output per capita as well as significant changes in the distribution of world population, as depicted in Figure 2.33.[157]

The diverging process of development of the UK and India since the 19th century in terms of the levels of income per capita and population growth is consistent with the theory of Galor and Mountford (2003) and provides an interesting case study. During the nineteenth century the UK traded manufactured goods for primary products with India.[158] Trade with Asia constituted over 20% of UK total exports and 23.2% of total imports throughout the nineteenth century (Bairoch 1974). [159] Consistent with the proposed hypothesis, as documented in Figure 2.14, industrialization in the UK accelerated, leading to a significant increase in the demand for skilled labor in the second phase of the Industrial Revolution, a demographic transition and a transition to a state of sustained economic growth.

For India, however, international trade played the reverse role. The period 1813-1850 was characterized by a rapid expansion in the volume of exports and imports which gradually transformed India from being an exporter of manufactured products – largely textiles – into a supplier of primary commodities (Chaudhuri 1983). Trade with the UK was fundamental in this process, with the UK supplying over two thirds of its imports for most of the nineteenth century and being the market for over a third of India's exports. As depicted in Figure 2.14, the rapid industrialization in the UK in the nineteenth century was associated with a decline in the per capita level of industrialization in India.[160] The delay in the process of industrialization and consequently the lack of demand for skilled labor delayed the de-

[156]Consistent with the thesis that human capital has reinforced the existing patterns of comparative advantage, Taylor (1999) argues that human capital accumulation during the late Nineteenth Century was not a source of convergence even among the advanced ' Greater Atlantic' trading economies. The richer economies - U.S.A. and Australia – had greater levels of school enrollments than the poorer ones, Denmark and Sweden.

[157]Consistent with the viewpoint the trade has not been uniformly beneficial across time and regions, recent research by Rodriguez and Rodrik (2001) has indicated that the relationship between openness and growth changed in the last century. Moreover, Clemens and Williamson (2004) find a positive relationship between average tariff levels and growth for the period 1870-1913 and a negative relationship for the period 1970-1998. Similarly Vamvakadis (2002) finds a positive relationship between several measures of openness and growth after 1970 and some evidence of a negative relationship in the period 1870-1910.

[158]The colonial power of the UK may have encouraged the specialization of India in the production of primary goods beyond the degree dictated by market forces. However, these forces would have just reinforced the adverse effects described in this paper.

[159]In contrast, trade with Asia constituted only 5% or less of French, German or Italian exports and 12.1% of total imports of continental Europe.

[160]Furthermore, Bairoch (1974) found that industries that employed new technologies made up between 60 and 70 percent of the UK manufacturing industry in 1860 but less than 1 percent of manufacturing industries in the developing countries. This contrasts with the experience of the non-UK European economies which produced more of the 'new technology' goods and which traded with themselves to a greater extent, (Bairoch, 1974).

mographic transition and the process of development.[161] Thus, while the gains from trade were utilized in the UK primarily towards an increase in output per capita, in India they were channeled towards an increase in the size of the population. The ratio of output per capita in the UK relative to India grew from 3:1 in 1820 to 11:1 in 1998, whereas the ratio of India's population relative to the UK's population grew from 8:1 in 1870 to 16:1 in 1998.[162]

7 Concluding Remarks

The transition from stagnation to growth and the associated phenomenon of the great divergence have been the subject of an intensive research in the growth literature in recent years. The discrepancy between of exogenous and endogenous neoclassical growth models and the process of development along most of human history, induced growth theorists to advance an alternative theory that captures in a single unified framework the contemporary era of sustained economic growth, the epoch of Malthusian stagnation that had characterized most of human history, and the fundamental driving forces of the recent transition between these distinct regimes.

The understanding of the contemporary growth process is fragile and incomplete unless growth theory would be based on proper micro-foundations that would reflect the qualitative aspects of the growth process in its entirety. Moreover, a comprehensive understanding of the hurdles faced by less developed economies in reaching a state of sustained economic growth would be futile unless the origin the transition of the currently developed economies into a state of sustained economic growth would be identified and their implications would be modified to account for the differences in the structure of less developed economies in an interdependent world.

Imposing the constraint that a single unified theory account for the entire intricate process of development in the last thousands of years is a discipline that enhances the viability of growth theory. A unified theory of economic growth reveals the underlying micro foundations that are consistent with the process of economic development along the entire spectrum of human history, rather than with the last century only, enhancing the confidence in the viability of growth theory, its predictions and policy implications, while improving the understanding of the sources of the recent transition from stagnation to growth and the associated phenomenon of the great divergence.

Unified growth theory suggests that the transition from stagnation to growth is an inevitable by-product of the inherent Malthusian interaction between population and technology and its ultimate impact on the demand for human capital and thereby on the onset of the demographic transition . Variations in the timing of the transition across countries and regions reflect initial differences in geographical

[161] Unlike the rise in the industrial demand for education in the UK, education was not expanded to a similar degree in India in the 19th Century. As noted by Aparna Basu (1974), during the nineteenth century the state of education in India was characterized by a relatively large university sector, aimed at producing skilled bureaucrats rather than industrialists, alongside widespread illiteracy of the masses. The literacy rate was very low, (e.g., 10% in Bengal in 1917-8) but nevertheless, attempts to expand primary education in the twentieth century were hampered by poor attendance and high drop out rates, which may suggest that the rate of return to education was relatively low. The lack of broad based education in India can also be seen using the data of Barro and Lee (2000). Despite an expansion of education throughout the twentieth century Barro and Lee report that in 1960 72.2 percent of Indians aged 15 and above had "no schooling" compared with 2 percent in the UK.

[162] Another interesting case study providing supporting evidence for the proposed hypothesis is the economic integration of the Israeli and the West Bank economies in the aftermath of the 1967 war. Trade and factor mobility between the skilled abundant economy of Israel and the unskilled abundant economy of the West Bank shifted the West Bank economy toward further specialization in the production of primary goods, and possibly triggered the astonishing increase in crude births rates from 22 per 1000 people in 1968 to 42 per 1000 in 1990, despite a decline in mortality rates. The gains from trade and development in the West Bank economy were converted primarily into an increase in population size, nearly doubling the population in those two decades. Estimates of the growth rates of output per capita over this period are less reliable and suggest that the increase was about 30%. Consistent with the proposed theory, the Palestinian uprising in the early 1990s and the gradual disintegration of the two economies resulted in the reduction in the crude birth rates.

factors and historical accidents and their manifestation in variations in institutional, demographic, and cultural factors, trade patterns, colonial status, and public policy.

> In the problem of economic development, a phrase that crops up frequently is 'the vicious circle of poverty.' It is generally treated as something obvious, too obvious to be worth examining. I hope I may be forgiven if I begin by taking a look at this obvious concept. (R. Nurkse, 1953)

1 Introduction

Despite the considerable amount of research devoted to economic growth and development, economists have not yet discovered how to make poor countries rich. As a result, poverty remains the common experience of billions. One half of the world's people live on less than $2 per day. One fifth live on less than $1. [1] If modern production technologies are essentially free for the taking, then why is it that so many people are still poor?

⋆ This chapter draws on material contained in two earlier surveys by the first author (Azariadis 1996, 2004). Support from the Program of Dynamic Economics at UCLA is acknowledged with thanks, as is research assistance from Athanasios Bolmatis, and discussions with David de la Croix, Chris Edmond, Cleo Fleming, Oded Galor, Karla Hoff, Kirdan Lees and Yasusada Murata. The second author thanks the Center for Operations Research and Econometrics at Université Catholique de Louvain for their hospitality during a period when part of this survey was written. All simulations and estimations use the open source programming language R.

Email addresses: azariadi@ucla.edu (Costas Azariadis),
j.stachurski@econ.unimelb.edu.au (John Stachurski).

[1] Figures are based on Chen and Ravallion (2001). Using national surveys they calculate a total head-count for the $1 and $2 poverty lines of 1.175 and 2.811

The literature that we survey here contains the beginnings of an answer to this question. First, it is true that technology is the primary determinant of a country's income. However, the most productive techniques will not always be adopted: There are self-reinforcing mechanisms, or "traps," that act as barriers to adoption. Traps arise both from market failure and also from "institution failure;" that is, from traps within the set of institutions that govern economic interaction. Institutions—in which we include the state, legal systems, social norms, conventions and so on—are determined endogenously within the system, and may be the direct cause of poverty traps; or they may interact with market failure, leading to the perpetuation of an inefficient status quo.

There is no consensus on the view that we put forward. Some economists regard institutions such as the state or policy as largely exogenous. Many argue that the primary suspect for the unfortunate growth record of the least developed countries should be bad domestic policy. Bad policy can be changed directly, because it is exogenous, rather than determined within the system. Sound governance and free market forces are held to be not only necessary but also *sufficient* to revive the poor economies, and to catalyze their convergence. Because good policy is available to all, there are no poverty traps.

The idea that good policy and the invisible hand are sufficient for growth is at least vacuously true, in the sense that an all-seeing and benevolent social planner who completes the set of markets can succeed where developing country governments have failed. But this is not a theory of development, and of course benevolent social planners are not what the proponents of good governance and liberalization have in mind. Rather, their argument is that development can be achieved by the poor countries if only governments allow the market mechanism to function effectively—to get the prices right—and permit economic agents to fully exploit the available gains from trade. This requires not just openness and non-distortionary public finance, but also the enforcement of property rights and the restraint of predation. [2]

In essence, this is the same story that the competitive neoclassical benchmark economy tells us: Markets are complete, entry and exit is free, transaction costs are negligible, and technology is convex at an efficient scale relative to

billion respectively in 1998. Their units are 1993 purchasing power adjusted US dollars.

[2] Development theory then reduces to Adam Smith's famous and compelling dictum, that "Little else is requisite to carry a state to the highest degree of opulence from the lowest barbarism but peace, easy taxes, and a tolerable administration of justice."

the size of the market. As a result, the private and social returns to production and investment are equal. A complete set of "virtual prices" ensures that all projects with positive net social benefit are undertaken. Diminishing returns to the set of reproducible factor inputs implies that when capital is scarce the returns to investment will be high. The dynamic implications of this benchmark were summarized by Solow (1956), Cass (1965), and Koopmans (1965). Even for countries with different endowments, the main conclusion is convergence.

There are good reasons to expect this benchmark will have relevance in practice. The profit motive is a powerful force. Inefficient practices and incorrect beliefs will be punished by lost income. Further, at least one impetus shaping the institutional environment in which the market functions is the desire to mitigate or correct perceived social problems; and one of the most fundamental of all social problems is scarcity. Over time institutions have often adapted so as to relieve scarcity by addressing sources of market inefficiency. [3]

In any case, the intuition gained from studying the neoclassical model has been highly influential in the formulation of development policy. A good example is the structural adjustment programs implemented by the International Monetary Fund. The key components of the Enhanced Structural Adjustment Facility—the centerpiece of the IMF's strategy to aid poor countries and promote long run growth from 1987 to 1999—were prudent macroeconomic policies and the liberalization of markets. Growth, it was hoped, would follow automatically.

Yet the evidence on whether or not non-distortionary policies and diminishing returns to capital will soon carry the poor to opulence is mixed. Even relatively well governed countries have experienced little or no growth. For example, Mali rates as "free" in recent rankings by Freedom House. Although not untroubled by corruption, it scores well in measures of governance relative to real resources (Radlet 2004; Sachs et al. 2004). Yet Mali is still desperately poor. According to a 2001 UNDP report, 70% of the population lives on less than $1 per day. The infant mortality rate is 230 per 1000 births, and household final consumption expenditure is down 5% from 1980.

Mali is not an isolated case. In fact for all of Africa Sachs et al. (2004) argue that

> With highly visible examples of profoundly poor governance, for example in Zim-

[3] See Greif, Milgrom and Weingast (1994) for one of many possible examples.

babwe, and widespread war and violence, as in Angola, Democratic Republic of Congo, Liberia, Sierra Leone and Sudan, the impression of a continent-wide governance crisis is understandable. Yet it is wrong. Many parts of Africa are well governed, and yet remain mired in poverty. Governance is a problem, but Africa's development challenges are much deeper.

There is a further problem. While the sufficiency of good policy and good governance for growth is still being debated, what can be said with certainty is that they are both elusive. The institutions that determine governance and other aspects of market interaction are difficult to reform. Almost everyone agrees that corruption is bad for growth, and yet corruption remains pervasive. Some institutions important to traditional societies have lingered, inhibiting the transition to new techniques of production. The resistance of norms and institutions to change is one reason why the outcome of liberalization and governance focused adjustment lending by the IMF has often been disappointing.

We believe that in practice there are serious problems with direct application of the benchmark story. First, for reasons outlined below, numerous deviations from the neoclassical benchmark generate market failure. Because of these failures, good technologies are not always adopted, and productive investments are not always undertaken. Inefficient equilibria exist. Second, as Hoff (2000) has emphasized, the institutional framework in which market interaction takes place is not implemented "from above." Rather it is determined within the system. Bounded rationality, imperfect information, and costly transactions make institutions and other "rules of the game" critical to economic performance; and the equilibria for institutions may be inefficient.

Moreover, as we shall see, inefficient equilibria have a bad habit of *reinforcing* themselves. Corrupt institutions can generate incentives which reward more corruption. Workers with imperfectly observed skills in an unskilled population may be treated as low skilled by firms, and hence have little incentive to invest large sums in education. Low demand discourages investment in increasing returns technology, which reduces productivity and reinforces low demand. That these inefficient outcomes are self-reinforcing is important—were they not then presumably agents would soon make their way to a better equilibrium.

Potential departures from the competitive neoclassical benchmark which cause market failure are easy to imagine. One is increasing returns to scale, both internal and external. Increasing returns matter because development is almost synonymous with industrialization, and with the adoption of modern pro-

duction techniques in agriculture, manufacturing and services. These modern techniques involve both fixed costs—internal economies—and greater specialization of the production process, the latter to facilitate application of machines.

The presence of fixed costs for a *given* technology is more troubling for the neoclassical benchmark in poor countries because there market scale is relatively small. If markets are small, then the neoclassical assumption that technologies are convex at an efficient scale may be violated. The same point is true for market scale and specialization, in the sense that for poor countries a given increase in market scale may lead to considerably more opportunity to employ indirect production. [4]

Another source of increasing returns follows from the fact that modern production techniques are knowledge-intensive. As Romer (1990) has emphasized, the creation of knowledge is associated with increasing returns for several reasons. First, knowledge is non-rival and only partially excludable. Romer's key insight is that in the presence of productive non-rival inputs, *the entire replication-based logical argument for constant returns to scale immediately breaks down.* Thus, knowledge creation leads to positive technical externalities and increasing returns. Second, new knowledge tends in the aggregate to complement existing knowledge.

If scale economies, positive spillovers and other forms of increasing returns are important, then long run outcomes may not coincide with the predictions of the neoclassical benchmark. The essence of the problem is that when returns are increasing a rise in output *lowers* unit cost, either for the firm itself or for other firms in the industry. This sets in motion a chain of positive self-reinforcement. Lower unit cost encourages production, which further lowers unit cost, and so on. Such positive feedbacks can strongly reinforce either poverty *or* development.

[4] Domestic markets *are* small in many developing countries, despite the possibility of international trade. In tropical countries, for example, roads are difficult to build and expensive to maintain. In Sub-Saharan Africa, overland trade with European and other markets is cut off by the Sahara. At the same time, most Sub-Saharan Africans live in the continent's interior highlands, rather than near the coast. To compound matters, very few rivers from the interior of this part of the continent are ocean-navigable, in contrast to the geography of North America, say, or Europe (Limao and Venables 2001; Sachs et al. 2004). The potential for international trade to mitigate small market size is thus far lower than for a country with easy ocean access, such as Singapore or the UK.

Another deviation from the competitive neoclassical benchmark that we discuss at length is failure in credit and insurance markets. Markets for loans and insurance suffer more acutely than most from imperfections associated with a lack of complete and symmetric information, and with all the problems inherent in anonymous trading over time. Borrowers may default or try not to pay back loans. The insured may become lax in protecting their own possessions.

One result of these difficulties is that lenders usually require collateral from their borrowers. Collateral is one thing that the poor always lack. As a result, the poor are credit constrained. This can lead to an inefficient outcome which is self-reinforcing: Collateral is needed to borrow funds. Funds are needed to take advantage of economic opportunities—particularly those involving fixed costs. The ability to take advantage of opportunities determines income; and through income is determined the individual's wealth, and hence their ability to provide collateral. Thus the poor lack access to credit markets, which is in turn the cause of their own poverty.

An important aspect of this story for us is that many modern sector occupations and production techniques have indivisibilities which are not present in subsistence farming, handicraft production or other traditional sector activities. Examples include projects requiring fixed costs, or those needing large investments in human capital such as education and training. The common thread is that through credit constraints the uptake of new technologies is inhibited.

With regards to insurance, it has been noted that—combined with limited access to credit—a lack of insurance is more problematic for the poor than the rich, because the poor cannot self-insure by using their own wealth. As a result, a poor person wishing to have a smooth consumption path may be forced to choose activities with low variance in returns, possibly at the cost of lower mean. Over time, lower mean income leads to more poverty.

Credit and insurance markets are not the only area of the economy where limited information matters. Nor is lack of information the only constraint on economic interaction: The world we seek to explain is populated with economic actors who are boundedly rational, not rational. The fact that people are neither all-knowing nor have unlimited mental capability is important to us for several reasons.

One is that transactions become costly; and this problem is exacerbated as societies become larger and transactions more impersonal. Interaction with large societies requires more information about more people, which in turn requires

more calculation and processing (North 1993, 1995). Second, if we concede that agents are boundedly rational then we must distinguish between the objective world and each agent's subjective interpretation of the world. These interpretations are formed on the basis of individual and local experience, of individual inference and deduction, and of the intergenerational transmission of knowledge, values and customs. The product of these inputs is a mental model or belief system which drives, shapes and governs individual action (Simon 1986; North 1993).

These two implications of bounded rationality are important. The first (costly transactions) because when transactions are costly institutions matter. The second (local mental models and subjective beliefs) because these features of different countries and economies shape their institutions.

In this survey we emphasize two related aspects of institutions and their connection to poverty traps. The first is that institutions determine how well inefficiencies arising within the market are resolved. A typical example would be the efforts of economic and political institutions to solve coordination failure in a given activity resulting from some form of complementary externalities. The second is that institutions themselves can have inefficient equilibria. Moreover, institutions are *path dependent*. In the words of Paul A. David, they are the "carriers of history" (David 1994).

Why are institutions characterized by multiple equilibria and path dependence? Although human history often shows a pattern of negotiation towards efficient institutions which mitigate the cost of transactions and overcome market failure, it is also true that institutions are created and perpetuated by those with political power. As North (1993, p. 3) has emphasized, "institutions are not necessarily or even usually created to be socially efficient; rather they, or at least the formal rules, are created to serve the interests of those with the bargaining power to create new rules."

Moreover, the institutional framework is path dependent because those who currently hold power almost always have a stake in its perpetuation. Consider for example the current situation in Burundi, which has been mired in civil war since its first democratically elected president was assassinated in 1993. The economic consequences have not been efficient. Market-based economic activity has collapsed along with income. Life expectancy has fallen from 54 years in 1992 to 41 in 2000. Household final consumption expenditure is down 35% from 1980. Nevertheless, the military elite have much to gain from continuation of the war. The law of the gun benefits those with most guns. Curfew and

identity checks provide opportunities for extortion. Military leaders continue to subvert a peace process that would lead to reform of the army.

Path dependence is strengthened by positive feedback mechanisms which *reinforce* existing institutions. For example, the importance of strong property rights for growth has been extensively documented. Yet Acemoglu, Johnson and Robinson (this volume) document how in Europe during the Middle Ages monarchs consistently failed to ensure property rights for the general population. Instead they used arbitrary expropriation to increase their wealth and the wealth of their allies. Increased wealth closed the circle of causation by reinforcing their own power. Engerman and Sokoloff (2004) discuss how initial inequality in some of Europe's colonial possessions led to policies which hindered broad participation in market opportunities and strengthened the position of a small elite. Such policies tended to reinforce existing inequality (while acting as a break on economic growth).

Path dependence is also inherent in the way that informal norms form the foundations of community adherence to legal stipulations. While the legal framework can be changed almost instantaneously, social norms, conventions and other informal institutions are invariably persistent (otherwise they could hardly be conventions). Often legislation is just the first step a ruling body must take when seeking to alter the de facto rules of the game. [5]

Finally, bounded rationality can be a source of self-reinforcing inefficient outcomes independent of institutions. For example, even in an otherwise perfect market a lack of global knowledge can cause agents to choose an inefficient technology, which is then reinforced by herd effects. [6] When there are market frictions or nonconvexities such outcomes may be exacerbated. For example, if technology is nonconvex then initial poor choices by boundedly rational agents can be locked in (Arthur 1994).

In summary, the set of all self-reinforcing mechanisms which can potentially cause poverty is large. Even worse, the different mechanisms can interact, and reinforce one another. Increasing returns may cause investment complementarities and hence coordination failure, which is then perpetuated by pessimistic beliefs and conservative institutions. Rent-seeking and corruption may discour-

[5] For example, Transparency International's 2004 Global Corruption Report notes that in Zambia courts have been reluctant to hand down custodial sentences to those convicted of corruption, "principally because it was felt that white-collar criminals *did not deserve* to go to jail." (Emphasis added.)

[6] This example is due to Karla Hoff.

age investment in new technology, which lowers expected wages for skilled workers, decreasing education effort and hence the pool of skilled workers needed by firms investing in technology. The disaffected workers may turn to rent-seeking. Positive feedbacks reinforce other feedbacks. In these kinds of environments the relevance of the neoclassical benchmark seems tenuous at best.

Our survey of poverty traps proceeds as follows. Section 2 reviews key development facts. Section 3 considers several basic models associated with persistent poverty, and their implications for dynamics and the data. Section 4 looks at the empirics of poverty traps. Our survey of microfoundations is in Sections 5–8. Section 9 concludes.

There are already a number of surveys on poverty traps, including two by the first author (Azariadis 1996, 2004). The surveys by Hoff (2000) and Matsuyama (1995, 1997) are excellent, as is Easterly (2001). See in addition the edited volumes by Bowles, Durlauf and Hoff (2004) and Mookherjee and Ray (2001). Parente and Prescott (this volume) also focus on barriers to technology adoption as an explanation of cross-country variation in income levels. In their analysis institutions are treated as exogenous.

2 Development Facts

In Section 2.1 we briefly review key development facts, focusing on the vast and rising differences in per capita income across nations. Section 2.2 reminds the reader how these disparities came about by quickly surveying the economic history behind income divergence.

2.1 Poverty and riches

What does it mean to live on one or two dollars per day? Poverty translates into hunger, lack of shelter, illness without medical attention. Calorie intake in the poorest countries is far lower than in the rich. The malnourished are less productive and more susceptible to disease than those who are well fed. Infant mortality rates in the poorest countries are up to 40 or 50 times higher than the OECD average. Many of the common causes, such as pneumonia or dehydration from diarrhea, cost very little to treat.

The poor are more vulnerable to events they cannot control. They are less able to diversify their income sources. They are more likely to suffer from famine, violence and natural disasters. They have lower access to credit markets and insurance, with which to smooth out their consumption. Their children risk exploitation, and are less likely to become educated.

The plight of the poor is even more striking when compared to the remarkable wealth of the rich. Measured in 1996 US dollars and adjusted for purchasing power parity, average yearly income per capita in Luxembourg for 2000 was over $46,000.[7] In Tanzania, by contrast, average income for 2000 was about $500. In other words, people in Luxembourg are nearly 100 times richer on average than those living in the very poorest countries.[8] Luxembourg is rather exceptional in terms of per capita income, but even in the US average income is now about 70 times higher than it is in Tanzania.

How has the gap between the richest and the poorest evolved over time? The answer is simple: It has increased dramatically, even in the postwar era. In 1960, per capita income in Tanzania was $478. After rising somewhat during the 1960s and 1970s it collapsed again in the 1980s. By 2000 it was $457. Many other poor countries have had similar experiences, with income hovering around the $500–1,000 mark. Meanwhile, the rich countries continued exponential growth. Income in the US grew from $12,598 in 1960 (26 times that of Tanzania) to $33,523 in 2000 (73 times). Other rich industrialized countries had similar experiences. In Australia over the same period per capita GDP rose from $10,594 to $25,641. In France it rose from $7,998 to $22,253, and in Canada from $10,168 to $26,983.

Figure 1 shows how the rich have gotten richer relative to the poor. The left hand panel compares an average of real GDP per capita for the 5 richest countries in the Penn World Tables with an average of the same for the 5 poorest. The comparison is at each point in time from 1960 to the year 2000. The right panel does the same comparison with groups of 10 countries (10 richest vs 10 poorest) instead of 5. Both panels show that by these measures

[7] Unless otherwise stated, all income data in the remainder of this section is from the Penn World Tables Version 6.1 (Heston, Summers and Aten 2002). Units are PPP and terms of trade adjusted 1996 US dollars.

[8] Some countries record per capita income even lower than the figure given above for Tanzania. 1997 average income in Zaire is measured at $276. Sachs et al. (2004) use the World Bank's 2003 World Development Indicators to calculate a population-weighted average income for Sub-Saharan Africa at 267 PPP-adjusted US dollars, or 73 cents a day.

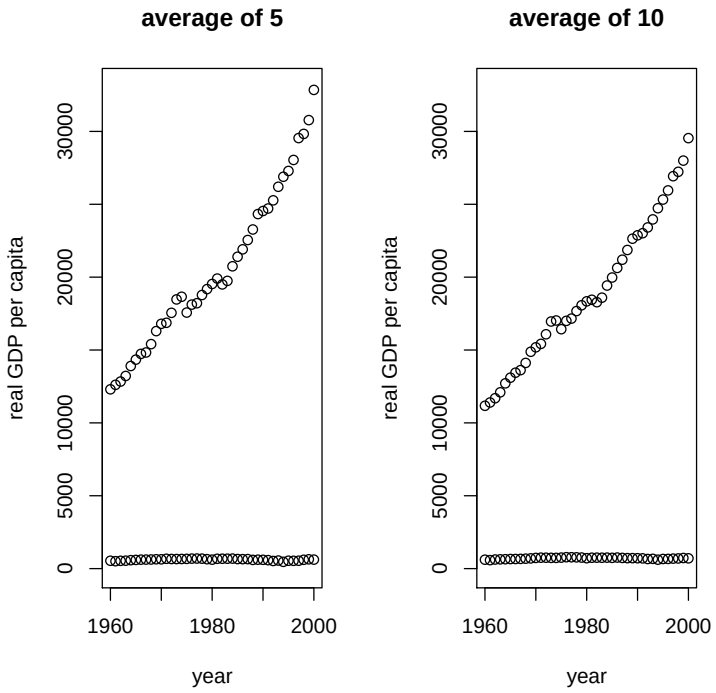

Fig. 1. The rich get richer

income disparity has widened dramatically in the postwar era, and the rate of divergence is, if anything, increasing. The vast and growing disparity in output per person shown in Figure 1 is what growth and development theorists are obliged to explain. [9]

2.2 A brief history of economic development

How did the massive disparities in income shown in Figure 1 arise? It is worth reviewing the broad history of economic development in order to remind ourselves of key facts. [10]

Although the beginnings of agriculture some ten thousand years ago marked the start of rapid human progress, for most of the subsequent millennia all but a tiny fraction of humanity was poor as we now define it, suffering regularly from hunger and highly vulnerable to adverse shocks. Early improvements

[9] Of course the figure says nothing about mobility. The poor this year could be the rich next year. See Section 4.1 for some discussion of mobility.

[10] The literature on origins of modern growth is too extensive to list here. See for example the monographs of Rostow (1975) and Mokyr (2002).

in economic welfare came with the rise of premodern city-states. Collective organization of irrigation, trade, communications and security proved more conducive to production than did autarky. Handicraft manufacture became more specialized over time, and agriculture more commercial. (Already the role of increasing returns and the importance of institutions are visible here.)

While such city-states and eventually large empires rose and fell over time, and the wealth of their citizens with them, until the last few hundred years no state successfully managed the transition to what we now call modern, self-sustaining growth. Increased wealth was followed by a rise in population. Malthusian pressure led to famine and disease.

The overriding reason for lack of sustained growth was that in the premodern world production technology improved only slowly. While the scientific achievements of the ancient Mediterranean civilizations and China were remarkable, in general there was little attempt to apply science to the economic problems of the peasants. Scientists and practical people had only limited interaction. Men and women of ability usual found that service to the state—or predation against other states—was more rewarding than entrepreneurship and invention.

Early signs of modern growth appeared in Western Europe around the middle of the last millennium. Science from the ancient world had been preserved, and now began to be extended. The revolutionary ideas of Copernicus led to intensive study of the natural world and its regularities. The printing press and movable type dramatically changed the way ideas were communicated. Innovations in navigation opened trade routes and new lands. Gunpowder and the cannon swept away local fiefdoms based on feudal castles.

These technological innovations led to changes in institutions. The weakening of local fiefdoms was followed in many countries by a consolidation of central authority, which increased the scale of markets and the scope for specialization.[11] Growing trade with the East and across the Atlantic produced a rich and powerful merchant class, who subsequently leveraged their political muscle to gain strengthened property and commercial rights.

Increases in market size, institutional reforms and progress in technology at

[11] For example, in 1664 Louis XIV of France drastically reduced local tolls and unified import customs. In 1707 England incorporated Scotland into its national market. Russia abolished internal duties in 1753, and the German states instituted similar reforms in 1808.

first lead to steady but unspectacular growth in incomes. In 1820 the richest countries in Europe had average per capita incomes of around $1,000 to $1,500—some two or three times that of the poorest countries today. However, in the early 19th Century the vast majority of people were still poor.

In this survey we compare productivity in the poor countries with the economic triumphs of the rich. Richness in our sense begins with the Industrial Revolution in Britain (although the rise in incomes was not immediate) and, subsequently, the rest of Western Europe. Industrialization—the systematic application of modern science to industrial technology and the rise of the factory system—led to productivity gains *entirely different in scale from those in the premodern world.*

In terms of proximate causes, the Industrial Revolution in Britain was driven by a remarkable revolution in science that occurred during the period from Copernicus through to Newton, and by what Mokyr (2002) has called the "Industrial Enlightenment," in which traditional artisanal practices were systematically surveyed, cataloged, analyzed and generalized by application of modern science. Critical to this process was the interactions of scientists with each other and with the inventors and practical men who sought to profit from innovation.

Science and invention led to breakthroughs in almost all areas of production; particularly transportation, communication and manufacturing. The structure of the British economy was massively transformed in a way that had never occurred before. Employment in agriculture fell from nearly 40% in 1820 to about 12% in 1913 (and to 2.2% in 1992). The stock of machinery, equipment and non-residential structures per worker increased by a factor of five between 1820 and 1890, and then doubled again by 1913. The literacy rate also climbed rapidly. Average years of education increased from 2 in 1820 to 4.4 in 1870 and 8.8 in 1913 (Maddison 1995).

As a result of these changes, per capita income in the UK jumped from about $1,700 in 1820 to $3,300 in 1870 and $5,000 in 1913. Other Western European countries followed suit. In the Netherlands, income per capita grew from $1,600 in 1820 to $4,000 in 1913, while for Germany the corresponding figures are $1,100 and $3,900. [12]

Looking forward from the start of the last century, it might have seemed likely that these riches would soon spread around the world. The innovations and

[12] The figures are from Maddison (1995). His units are 1990 international dollars.

inventions behind Britain's productivity miracle were to a large extent public knowledge. Clearly they were profitable. Adaptation to new environments is not costless, but nevertheless one suspects it was easy to feel that already the hard part had been done.

Such a forecast would have been far too optimistic. Relatively few countries besides Western Europe and its off-shoots have made the transition to modern growth. Much of the world remains mired in poverty. Among the worst performers are Sub-Saharan Africa and South Asia, which together account for some 70% of the 1.2 billion people living on less than $1 per day. But poverty rates are also high in East Asia, Latin America and the Carribean. Why is it that so many countries are still poorer than 19th Century Britain? Surely the different outcomes in Britain and a country such as Mali can—at least from a modeler's perspective—be Pareto ranked. What deviation from the neoclassical benchmark is it that causes technology growth in these countries to be retarded, and poverty to persist?

3 Models and Definitions

We begin our attempt to answer the question posed at the end of the last section with a review of the convex neoclassical growth model. It is appropriate to start with this model because it is the benchmark from which various deviations will be considered. Section 3.2 explains why the neoclassical model *cannot* explain the vast differences in income per capita between the rich and poor countries. Section 3.3 introduces the first of two "canonical" poverty trap models. These models allow us to address issues common to all such models, including dynamics and implications for the data. Section 3.4 introduces the second.

3.1 Neoclassical growth with diminishing returns

The convex neoclassical model (Solow 1956) begins with an aggregate production function of the form

$$Y_t = K_t^{\alpha}(A_t L_t)^{1-\alpha}\xi_{t+1}, \quad \alpha \in (0,1), \tag{1}$$

where Y is output of a single composite good, A is a productivity parameter, K is the aggregate stock of tangible and intangible capital, L is a measure of

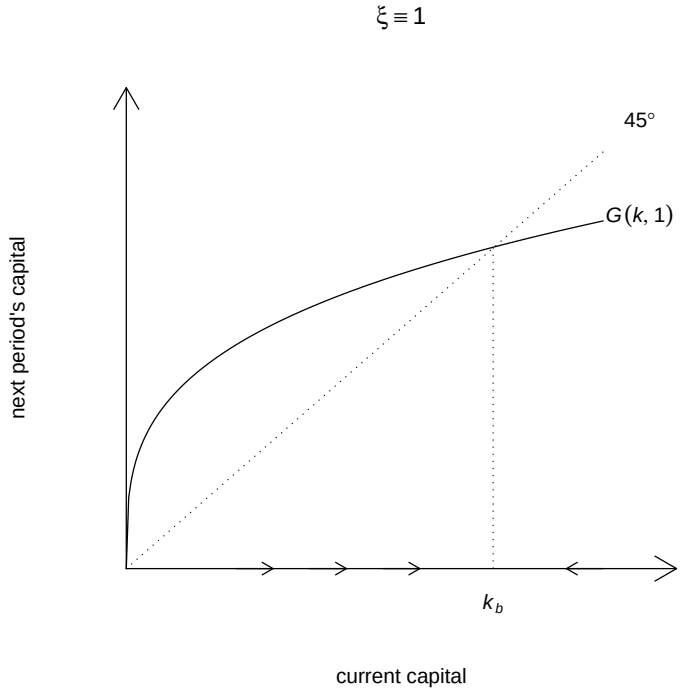

Fig. 2. Deterministic neoclassical dynamics

labor input, and ξ is a shock. In this formulation the sequence $(A_t)_{t\geq 0}$ captures the persistent component of productivity, and $(\xi_t)_{t\geq 0}$ is a serially uncorrelated innovation.

The production function on the right hand side of (1) represents maximum output for a given set of inputs. That output is maximal follows from competitive markets, profit seeking and free entry. (Implicit is the assumption of no significant indivisibilities or nonconvexities.) The Cobb-Douglas formulation is suggested by relative constancy of factor shares with respect to the level of worker output.

Savings of tangible and intangible capital from current output occurs at constant rate s; in which case K evolves according to the rule

$$K_{t+1} = sY_t + (1-\delta)K_t. \tag{2}$$

Here $\delta \in (0, 1]$ is a constant depreciation rate. The savings rate can be made endogenous by specifying intertemporal preferences. However the discussion in this section is purely qualitative; endogenizing savings changes little. [13]

[13] See, for example, Brock and Mirman (1972) or Nishimura and Stachurski (2004) for discussion of dynamics when savings is chosen optimally.

If, for example, labor L is undifferentiated and grows at exogenous rate n, and if productivity A is also exogenous and grows at rate γ, then the law of motion for capital per effective worker $k_t := K_t/(A_t L_t)$ is given by

$$k_{t+1} = \frac{s k_t^\alpha \xi_{t+1} + (1-\delta)k_t}{\theta} =: G(k_t, \xi_{t+1}), \tag{3}$$

where $\theta := 1 + n + \gamma$. The evolution of output per effective worker $Y_t/(A_t L_t)$ and output per capita Y_t/L_t are easily recovered from (1) and (3).

Because of diminishing returns, capital poor countries will extract greater marginal returns from each unit of capital stock invested than will countries with plenty of capital. The result is convergence to a long-run outcome which depends only on fundamental primitives (as opposed to beliefs, say, or historical conditions).

Figure 2 shows the usual deterministic global convergence result for this model when the shock ξ is suppressed. The steady state level of capital per effective worker is k_b. Figure 3 illustrates stochastic convergence with three simulated series from the law of motion (3), one with low initial income, one with medium initial income and one with high initial income. Part (a) of the figure gives the logarithm of output per effective worker, while (b) is the logarithm of output per worker. All three economies converge to the balanced growth path. [14]

Average convergence of the sample paths for $(k_t)_{t\geq 0}$ and income is mirrored by convergence in probabilistic laws. Consider for example the sequence of marginal distributions $(\psi_t)_{t\geq 0}$ corresponding to the sequence of random variables $(k_t)_{t\geq 0}$. Suppose for simplicity that the sequence of shocks is independent, identically distributed and lognormal; and that $k_0 > 0$. It can then be shown that (a) the distribution ψ_t is a density for all $t \geq 1$, and (b) the sequence $(\psi_t)_{t\geq 0}$ obeys the recursion

$$\psi_{t+1}(k') = \int_0^\infty \Gamma(k, k')\psi_t(k)dk, \quad \text{for all } t \geq 1, \tag{4}$$

where the *stochastic kernel* Γ in (4) has the interpretation that $\Gamma(k, \cdot)$ is the probability density for $k_{t+1} = G(k_t, \xi_{t+1})$ when k_t is taken as given and equal to k. [15] The interpretation of (4) is straightforward. It says (heuristically) that

[14] In the simulation the sequence of shocks $(\xi_t)_{t\geq 0}$ is lognormal, independent and identically distributed. The parameters are $\alpha = 0.3$, $A_0 = 100$, $\gamma = .025$, $n = 0$, $s = 0.2$, $\delta = 0.1$, and $\ln \xi \sim N(0, 0.1)$. Here and in all of what follows $X \sim N(\mu, \sigma)$ means that X is normally distributed with mean μ and standard deviation σ.

[15] See the technical appendix for details.

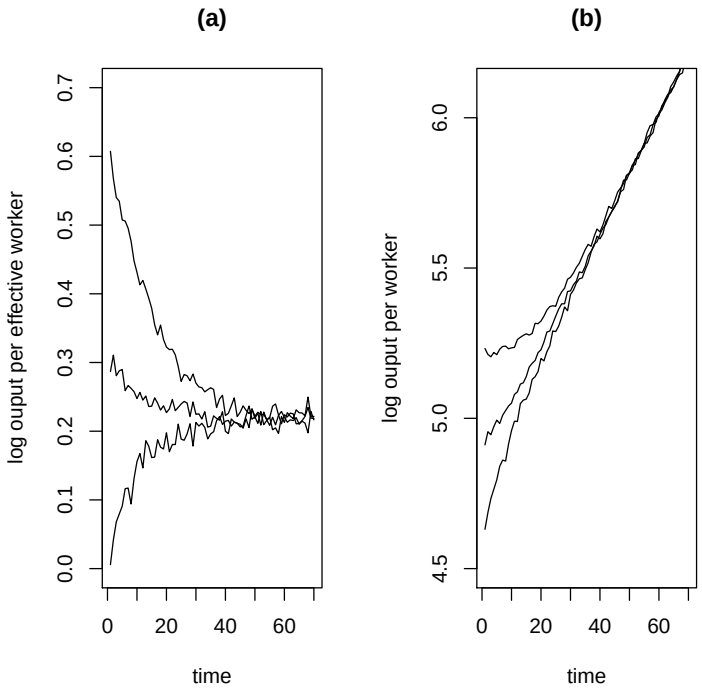

Fig. 3. Convergence to the balanced growth path

$\psi_{t+1}(k')$, the probability that k takes the value k' next period, is equal to the probability of taking value k' next period given that the current state is k, summed across all k, and weighted by $\psi_t(k)dk$, which is the probability that the current state actually takes the value k.

Here the conditional distribution $\Gamma(k, \cdot)$ of k_{t+1} given $k_t = k$ is easily calculated from (3) and the familiar change-of-variable rule that if ξ is a random variable with density φ and $Y = h(\xi)$, where h is smooth and strictly monotone, then Y has density $\varphi(h^{-1}(y)) \cdot [dh^{-1}(y)/dy]$. Applying this rule to (3) we get

$$\Gamma(k, k') := \varphi\left[\frac{\theta k' - (1-\delta)k}{sk^\alpha}\right]\frac{\theta}{sk^\alpha}, \tag{5}$$

where φ is the lognormal density of the productivity shock ξ. [16]

All Markov processes have the property that the sequences of marginal distributions they generate satisfies a recursion in the form of (4) for some stochastic kernel Γ. [17] Although the state variables usually do not themselves become

[16] Precisely, $z \mapsto \varphi(z)$ is this density when $z > 0$ and is equal to zero when $z \leq 0$.

[17] See the technical appendix for definitions. Note that we are working here with processes that generate sequences of *densities*. If the marginal distributions are not densities, and the conditional distribution contained in Γ is not a density, then the

stationary (due to the ongoing presence of noise), the sequence of probabilities $(\psi_t)_{t\geq 0}$ may. In particular, the following behavior is sometimes observed:

Definition 3.1 (Ergodicity) *Let a growth model be defined by some stochastic kernel* Γ*, and let* $(\psi_t)_{t\geq 0}$ *be the corresponding sequence of marginal distributions generated by* (4)*. The model is called* ergodic *if there is a unique probability distribution* ψ^* *supported on* $(0, \infty)$ *with the property that* (i)

$$\psi^*(k') = \int_0^\infty \Gamma(k, k')\psi^*(k)dk \quad \textit{for all } k';$$

and (ii) *the sequence* $(\psi_t)_{t\geq 0}$ *of marginal distributions for the state variable satisfies* $\psi_t \to \psi^*$ *as* $t \to \infty$ *for all non-zero initial states.* [18]

It is easy to see that (i) and (4) together imply that if $\psi_t = \psi^*$ (that is, $k_t \sim \psi^*$), then $\psi_{t+1} = \psi^*$ (that is, $k_{t+1} \sim \psi^*$) also holds (and if this is the case then $k_{t+2} \sim \psi^*$ follows, and so on). A distribution with this property is called a stationary distribution, or ergodic distribution, for the Markov chain. Property (ii) says that, conditional on a strictly positive initial stock of capital, the marginal distribution of the stock converges in the long run to the ergodic distribution.

Under the current assumptions it is relatively straightforward to prove that the Solow process (3) is ergodic. (See the technical appendix for more details.) Figures 4 and 5 show convergence in the neoclassical model (3) to the ergodic distribution ψ^*. In each of the two figures an initial distribution ψ_0 has been chosen arbitrarily. Since the process is ergodic, in both figures the sequence of marginal distributions $(\psi_t)_{t\geq 0}$ converges to the same ergodic distribution ψ^*. This distribution ψ^* is determined purely by fundamentals, such as the propensity to save, the rate of capital depreciation and fertility. [19]

---

formula (4) needs to be modified accordingly. See the technical appendix. Other references include Stokey, Lucas and Prescott (1989), Futia (1982) and Stachurski (2004).

[18] Convergence refers here to that of measures in the total variation norm, which in this case is just the L_1 norm. Convergence in the norm topology implies convergence in distribution in the usual sense.

[19] The algorithms and code for computing marginal and ergodic distributions are available from the authors. All ergodic distributions are calculated using Glynn and Henderson's (2001) look-ahead estimator. Marginals are calculated using a variation of this estimator constructed by the authors. The parameters in (3) are chosen—rather arbitrarily—as $\alpha = 0.3$, $\gamma = .02$, $n = 0$, $s = 0.2$, $\delta = 1$, and $\ln \xi \sim N(3.6, 0.11)$.

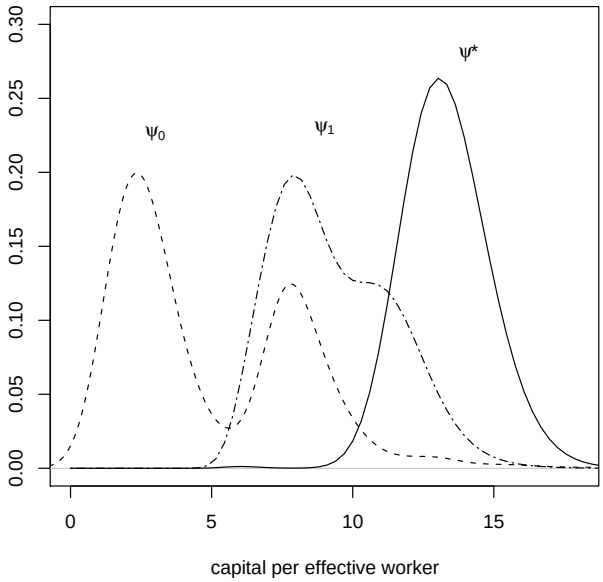

Fig. 4. Convergence to the ergodic distribution

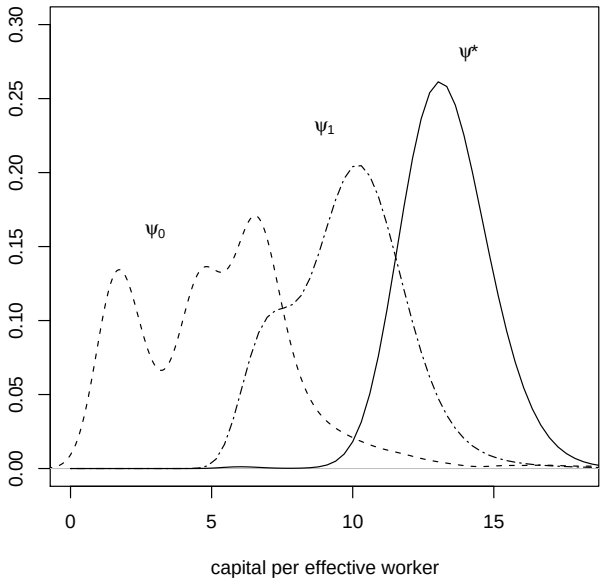

Fig. 5. Convergence to the ergodic distribution

Notice in Figures 4 and 5 how initial differences are moderated under the convex neoclassical transition rule. We will see that, without convexity, initial differences often persist, and may well be amplified as the system evolves through time.

The convex neoclassical growth model described in the previous section predicts that per capita incomes will differ across countries with different rates of physical and human capital formation or fertility. Can the model provide a reasonable explanation then for the fact that per capita income in the US is more than 70 times that in Tanzania or Malawi?

The short answer to this question is no. First, rates at which people accumulate reproducible factors of production or have children (fertility rates) are endogenous—in fact they are choice variables. To the extent that factor accumulation and fertility are important, we need to know *why* some individuals and societies make choices that lead them into poverty. For poverty is suffering, and, all things being equal, few people will choose it.

This same observation leads us to suspect that the choices facing individuals in rich countries and those facing individuals in poor countries are very different. In poor countries, the choices that collectively would drive modern growth—innovation, investment in human and physical capital, etc.—must be perceived by individuals as *worse* than those which collectively lead to the status quo. [20]

A second problem for the convex neoclassical growth model as an explanation of level differences is that even when we regard accumulation and fertility rates as exogenous, they must still account for all variation in income per capita across countries. However, as many economists have pointed out, the differences in savings and fertility rates are not large enough to explain real income per capita ratios in the neighborhood of 70 or 100. A model ascribing output variation to these few attributes alone is insufficient. A cotton farmer in the US does not produce more cotton than a cotton farmer in Mali simply because he has saved more cotton seed. The production techniques used in these two countries are utterly different, from land clearing to furrowing to planting to irrigation and to harvest. A model which does not address the vast differences in production technology across countries cannot explain the observed differences in output.

Let us very briefly review the quantitative version of this argument. [21] To

[20] For this reason, endogenizing savings by specifying preferences is not very helpful, because to get poverty in optimal growth models we must assume that the poor are poor because they prefer poverty.

[21] The review is brief because there are many good sources. See, for example, Lucas (1990), King and Rebelo (1993), Prescott (1998), Hall and Jones (1999) or Easterly

begin, recall the aggregate production function (1), which is repeated here for convenience:

$$Y_t = K_t^{\alpha}(A_t L_t)^{1-\alpha}\xi_{t+1}. \tag{6}$$

All of the components are more or less observable besides A_t and the shock.[22] Hall and Jones (1999) conducted a simple growth accounting study by collecting data on the observable components for the year 1988. They calculate that the geometric average of output per worker for the 5 richest countries in their sample was 31.7 times that of the 5 poorest countries. Taking L to be a measure of human capital, variation in the two inputs L and K contributed only factors of 2.2 and 1.8 respectively. This leaves all the remaining variation in the productivity term A.[23]

This is not a promising start for the neoclassical model as a theory of level differences. Essentially, it says that there is no single map from total inputs to aggregate output that holds for every country. Why might this be the case? We know that the aggregate production function is based on a great deal of theory. Output is maximal for a given set of inputs because of perfect competition among firms. Free entry, convex technology relative to market size, price taking and profit maximization mean that the best technologies are used—and used efficiently. Clearly some aspect of this theory must deviate significantly from reality.

Now consider how this translates into predictions about level differences in income per capita. When the shock is suppressed ($\xi_t = 1$ for all t), output per capita converges to the balanced path

$$y_t := \frac{Y_t}{L_t} = A_t(s/\kappa)^{\alpha/(1-\alpha)}, \tag{7}$$

where $\kappa := n + \gamma + \delta$.[24] Suppose at first that the path for the productivity residual is the same in all countries. That is, $A_t^i = A_t^j$ for all i, j and t. In this

and Levine (2000).

[22] The parameter α is the share of capital in the national accounts. Human capital can be estimated by collecting data on total labor input, schooling, and returns to each year of schooling as a measure of its productivity.

[23] The domestic production shocks $(\xi_t)_{t\geq 0}$ are not the source of the variation. This is because they are very small relative to the differences in incomes across countries, and, by definition, not persistent. (Recall that in our model they are innovations to the permanent component $(A_t)_{t\geq 0}$.)

[24] When considering income *levels* it is necessary to assume that countries are in the neighborhood of the balanced path, for this is where the model predicts they will be. Permitting them to be "somewhere else" is not a theory of variations in income levels.

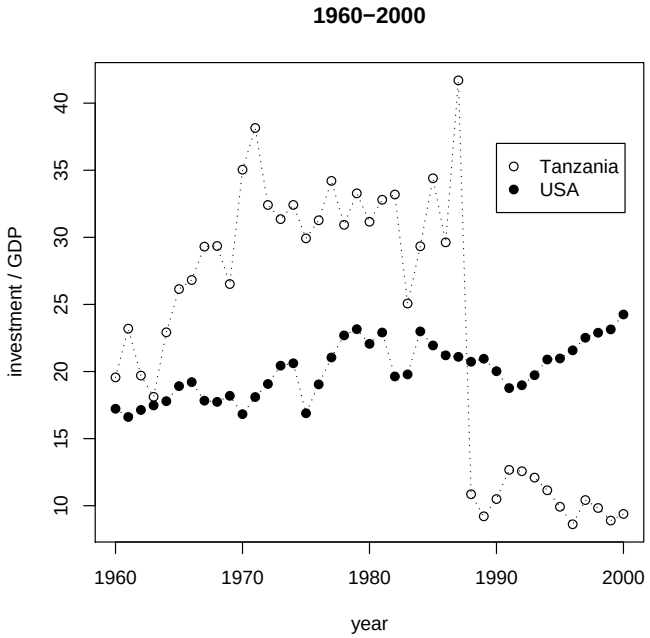

Fig. 6. Investment rates in Tanzania and the US

case, the ratio of output per capita in country i relative to that in country j is constant and equal to

$$\frac{y^i}{y^j} = \left(\frac{s^i \kappa^j}{s^j \kappa^i}\right)^{\alpha/(1-\alpha)}. \tag{8}$$

The problem for the neoclassical model is that the term inside the brackets is usually not very large. For example, if we compare the US and Tanzania, say, and if we identify capital with physical capital, then average investment as a fraction of GDP between 1960 and 2000 was about 0.2 in the US and 0.24 in Tanzania. (Although the rate in Tanzania varied a great deal around this average. See Figure 6.) The average population growth rates over this period were about 0.01 and 0.03 respectively. Since $A_t^i = A_t^j$ for all t we have $\gamma^i = \gamma^j$. Suppose that this rate is 0.02, say, and that $\delta^i = \delta^j = 0.05$. This gives $s^i \kappa^j / (s^j \kappa^i) \approx 1$. Since payments to factors of production suggest that $\alpha/(1-\alpha)$ is neither very large nor very small, output per worker in the two countries is predicted to be roughly equal.

This is only an elementary calculation. The computation of investment rates in Tanzania is not very reliable. There are issues in terms of the relative ratios of consumption and investment good prices in the two countries which may distort the data. Further, we have not included intangible capital—most notably human capital. The rate of investment in human capital and training

in the US is larger than it is in Tanzania. Nevertheless, it is difficult to get the term in (8) to contribute a factor of much more than 4 or 5—certainly not 70.[25]

However the calculations are performed, it turns out that to explain the ratio of incomes in countries such as Tanzania and the US, productivity residuals must absorb most of the variation. In other words, the convex neoclassical growth model cannot be reconciled with the cross-country income data *unless we leave most of the variation in income to an unexplained residual term about which we have no quantitative theory.* And surely *any* scientific theory can explain *any* given phenomenon by adopting such a strategy.

Different authors have made this same point in different ways. Lucas (1990) points out that if factor input differences *are* large enough to explain cross-country variations in income, the returns to investment in physical and human capital in poor countries implied by the model will be huge compared to those found in the rich. In fact they are not. Also, productivity residuals are growing quickly in countries like the US.[26] On the other hand, in countries like Tanzania, growth in the productivity residual has been very small.[27] Yet the convex neoclassical model provides no theory on why these different rates of growth in productivity should hold.

On balance, the importance of productivity residuals suggests that the poor countries are not rich because for one reason or another they have failed or not been able to adopt modern techniques of production. In fact production technology in the poorest countries is barely changing. In West Africa, for example, almost 100% of the increase in per capita food output since 1960 has come from expansion of harvest area (Baker 2004). On the other hand, the rich countries are becoming ever richer because of continued innovation.

[25] See in particular Prescott (1998) for detailed calculations. He concludes that convex neoclassical growth theory "fails as a theory of international income differences, even after the concept of capital is broadened to include human and other forms of intangible capital. It fails because differences in savings rates cannot account for the great disparity in per capita incomes unless investment in intangible capital is implausibly large."

[26] One can compute this directly, or infer it from the fact that interest rates in the US have shown no secular trend over the last century, in which case transitional dynamics can explain little, and therefore growth in output per worker and growth in the residual can be closely identified (King and Rebelo 1993).

[27] Again, this can be computed directly, or inferred from the fact that if it had been growing at a rate similar to the US, then income in Tanzania would have been at impossibly low levels in the recent past (Pritchett 1997).

Of course this only pushes the question one step back. Technological change is only a proximate cause of diverging incomes. What economists need to explain is why production technology has improved so quickly in the US or Japan, say, and comparatively little in countries such as Tanzania, Mali and Senegal.

We end this section with some caveats. First, the failure of the simple convex neoclassical model does *not* imply the existence of poverty traps. For example, we may discover successful theories that predict very low levels of the residual based on exogenous features which tend to characterize poor countries. (Although it may turn out that, depending on what one is prepared to call exogenous, the map from fundamentals to outcomes is not uniquely defined. In other words, there are multiple equilibria. In Section 4.2 some evidence is presented on this point.)

Further, none of the discussion in this section seeks to deny that factor accumulation matters. Low rates of factor accumulation are certainly correlated with poor performance, and we do not wish to enter the "factor accumulation versus technology" debate—partly because this is viewed as a contest between neoclassical and "endogenous" growth models, which is tangential to our interests, and partly because technology and factor accumulation are clearly interrelated: technology drives capital formation and investment boosts productivity. [28]

Finally, it should be emphasized that our ability to reject the elementary convex neoclassical growth model as a theory of level differences between rich and poor countries is precisely because of its firm foundations in theory and excellent quantitative properties. All of the poverty trap models we present in this survey provide far less in terms of quantitative, testable restrictions that can be confronted with the data. The power of a model depends on its falsifiability, not its potential to account for every data set.

3.3 Poverty traps: historical self-reinforcement

How then are we to explain the great variation in cross-country incomes such as shown in Figure 1? In the introduction we discussed some deviations from the neoclassical benchmark which can potentially account for this variation by endogenously reinforcing small initial differences. Before going into the

[28] However, as we stressed at the beginning of this section, to the extent that factor accumulation is important it may in fact turn out that low accumulation rates are mere symptoms of poverty, not causes.

specifics of different feedback mechanisms, this section formulates the first of two abstract poverty trap models. For both models a detailed investigation of microfoundations is omitted. Instead, our purpose is to establish a framework for the questions poverty traps raise about dynamics, and for their observable implications in terms of the cross-country income data.

The first model—a variation on the convex neoclassical growth model discussed in Section 3.1—is loosely based on Romer (1986) and Azariadis and Drazen (1990). It exemplifies what Mookherjee and Ray (2001) have called *historical* self-reinforcement, a process whereby initial conditions of the endogenous variables can shape long run outcomes. Leaving aside all serious complications for the moment, let us fix at $s > 0$ the savings rate, and at zero the rates of exogenous technological progress γ and population growth n. Let all labor be undifferentiated and normalize its total mass to 1, so that k represents both aggregate capital and capital per worker. Suppose that the productivity parameter A can vary with the stock of capital. In other words, A is a function of k, and aggregate returns $k_t \mapsto A(k_t)k_t^\alpha$ are potentially increasing. [29]

The law of motion for the economy is then

$$k_{t+1} = sA(k_t)k_t^\alpha \xi_{t+1} + (1-\delta)k_t. \tag{9}$$

Depending on the specification of the relationship between k and productivity, many dynamic paths are possible. Some of them will lead to poverty traps. Figure 7 gives examples of potential dynamic structures. For now the shock ξ is suppressed. The x-axis is current capital k_t and the y-axis is k_{t+1}. In each case the plotted curve is just the right hand side of (9), all with different maps $k \mapsto A(k)$.

In part (a) of the figure the main feature is non-ergodic dynamics: long run outcomes depend on the initial condition. Specifically, there are two local attractors, the basins of attraction for which are delineated by the unstable fixed point k_b. Part (b) is also non-ergodic. It shows the same low level attractor, but now no high level attractor exists. Beginning at a state above k_b leads to unbounded growth. In part (c) the low level attractor is at zero.

[29] In Romer (1986), for example, private investment generates new knowledge, some of which enters the public domain and can be used by other firms. In Azariadis and Drazen (1990) there are spillovers from human capital formation. See also Durlauf (1993) and Zilibotti (1995). See Matsuyama (1997) and references for discussion of how investment may feed back via pecuniary externalities into specialization and hence productivity. Our discussion of microfoundations begins in Section 5.

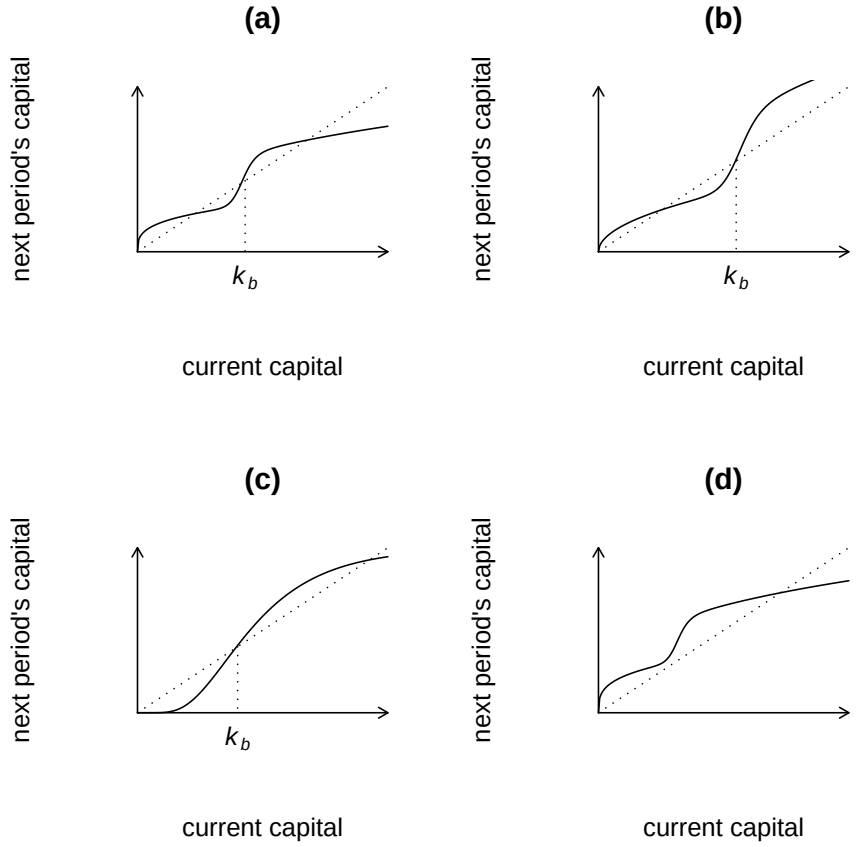

Fig. 7. Models with poverty traps

The figure in part (d) looks like an anomaly. Since the dynamics are formally ergodic, many researchers will not view this structure as a "poverty trap" model. Below we argue that this reading is too hasty: the model in (d) can certainly generate the kind of persistent-poverty aggregate income data we are hoping to explain.

In order to gain a more sophisticated understanding, let us now look at the stochastic dynamics of the capital stock. Deterministic dynamics are of course a special case of stochastic dynamics (with zero-variance shocks) but as in the case of the neoclassical model above, let us suppose that $(\xi_t)_{t\geq 0}$ is independently and identically lognormally distributed, with $\ln \xi \sim N(\mu, \sigma)$ and $\sigma > 0$. It then follows that the sequence of marginal distributions $(\psi_t)_{t\geq 0}$ for the capital stock sequence $(k_t)_{t\geq 0}$ again obeys the recursion (4) where the stochastic kernel Γ is now

$$\Gamma(k, k') := \varphi\left[\frac{k' - (1-\delta)k}{sA(k)k^\alpha}\right] \frac{1}{sA(k)k^\alpha}, \tag{10}$$

with φ the lognormal density on $(0, \infty)$ and zero elsewhere. All of the intuition for the recursion (4) and the construction of the stochastic kernel (10) is exactly the same as the neoclassical case.

How do the marginal distributions of the nonconvex growth model evolve? The following result gives the answer for most cases we are interested in.

Proposition 3.1 *Let $(\xi_t)_{t\geq 0}$ be an independent sequence with $\ln \xi_t \sim N(\mu, \sigma)$ for all t. If the function $k \mapsto A(k)$ satisfies the regularity condition*

$$0 < \inf_k A(k) \leq \sup_k A(k) < \infty,$$

then the stochastic nonconvex growth model defined by (9) *is ergodic.* [30]

Ergodicity here refers to Definition 3.1 on page 18, which, incidentally, is the standard definition used in growth theory and macroeconomics (see, for example, Brock and Mirman 1972; or Stokey, Lucas and Prescott 1989). In other words, there is a unique ergodic distribution ψ^*, and the sequence of marginal distributions $(\psi_t)_{t\geq 0}$ converges to ψ^* asymptotically, independent of the initial condition (assuming of course that $k_0 > 0$). A proof of this result is given in the technical appendix.

So why has a non-ergodic model become ergodic with the introduction of noise? The intuition is completely straightforward: Under our assumption of unbounded shocks there is always the potential—however small—to escape any basin of attraction. So in the long run initial conditions do not matter. (What *does* matter is how long this long run is, a point we will return to below.)

Figure 8 gives the ergodic distributions corresponding to two poverty trap models. [31] Both have the same structural dynamics as the model in part (a) of Figure 7. The left hand panels show this structure with the shock suppressed. The right hand panels show corresponding ergodic distributions under the independent lognormal shock process. Both ergodic distributions are bimodal, with modes concentrated around the deterministic local attractors.

Comparing the two left hand panels, notice that although qualitatively similar,

[30] In fact we require also that $k \mapsto A(k)$ is a Borel measurable function. But this condition is very weak indeed. For example, $k \mapsto A(k)$ need be neither monotone nor continuous.

[31] Regarding numerical computation see the discussion for the neoclassical case above.

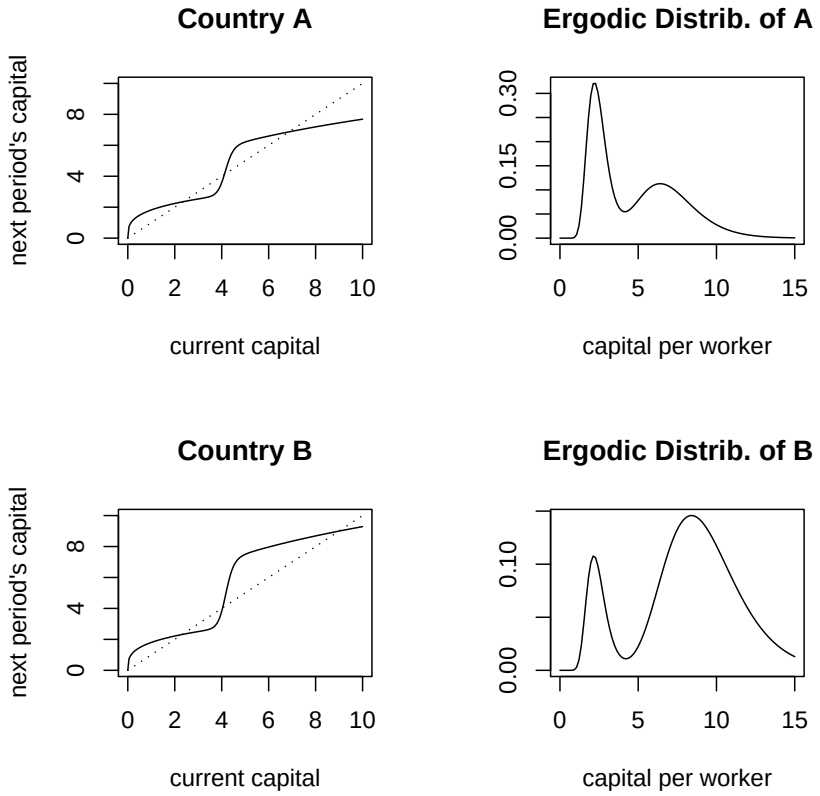

Fig. 8. Ergodic distributions under increasing returns

the laws of motion for Country A and Country B have different degrees of increasing returns. For Country B, the jump occurring around $k = 4$ is larger. As a result, the state is less likely to return to the neighborhood of the lower attractor once it makes the transition out of the poverty trap. Therefore the mode of the ergodic distribution corresponding to the higher attractor is large relative to that of Country A. Economies driven by law of motion B spend more time being rich.

Convergence to the ergodic distribution in a nonconvex growth model is illustrated in Figure 9. The underlying model is (a) of Figure 7.[32] As before, the ergodic distribution is bimodal. In this simulation, the initial distribution was chosen arbitrarily. Note how initial differences tend to be magnified over the medium term despite ergodicity. The initially rich diverge to the higher

[32] The specification of $A(k)$ used in the simulation is $A(k) = a \exp(h\Psi(k))$, where $a = 15$, $h = 0.52$ and the transition function Ψ is given by $\Psi(k) := (1 + \exp(-\ln(k/k_T)/\theta))^{-1}$. The parameter k_T is a "threshold" value of k, and is set at 6.9. The parameter θ is the smoothness of the transition, and is set at 0.09. The other parameters are $\alpha = 0.3$, $s = 0.2$, $\delta = 1$, and $\ln \xi \sim N(0, 0.1)$.

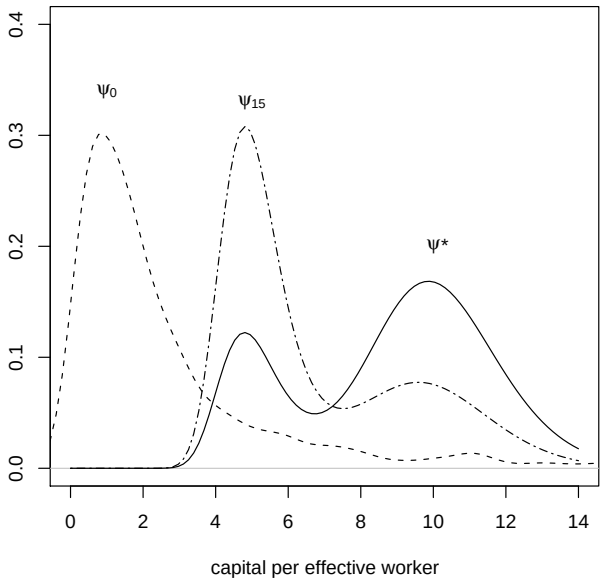

Fig. 9. Convergence under increasing returns

mode, creating the kind of "convergence club" effect seen in ψ_{15}, the period 15 marginal distribution. [33]

It is clear, therefore, that ergodicity is not the whole story. If the support of the shock ξ is bounded then ergodicity may not hold. Moreover, even with ergodicity, historical conditions may be arbitrarily persistent. Just how long they persist depends mainly on (i) the size of the basins of attraction and (ii) the statistical properties of the shock. On the other hand, the non-zero degree of mixing across the state space that drives ergodicity is usually more realistic than deterministic models where poverty traps are absolute and can never be overcome. Indeed, we will see that ergodicity is very useful for framing empirical questions in Section 4.2.

Figures 10 and 11 illustrate how historical conditions persist for individual time series generated by a model in the form of (a) of Figure 7, regardless of ergodicity. In both figures, the x-axis is time and the y-axis is (the log of) capital stock per worker. The dashed line through the middle of the figure corresponds to (the log of) k_b, the point dividing the two basins of attraction in (a) of Figure 7. Both figures show the simulated time series of four

[33] Incidentally, the change in the distributions from ψ_0 to ψ_{15} is qualitatively quite similar to the change in the cross-country income distribution that has been observed in the post war period.

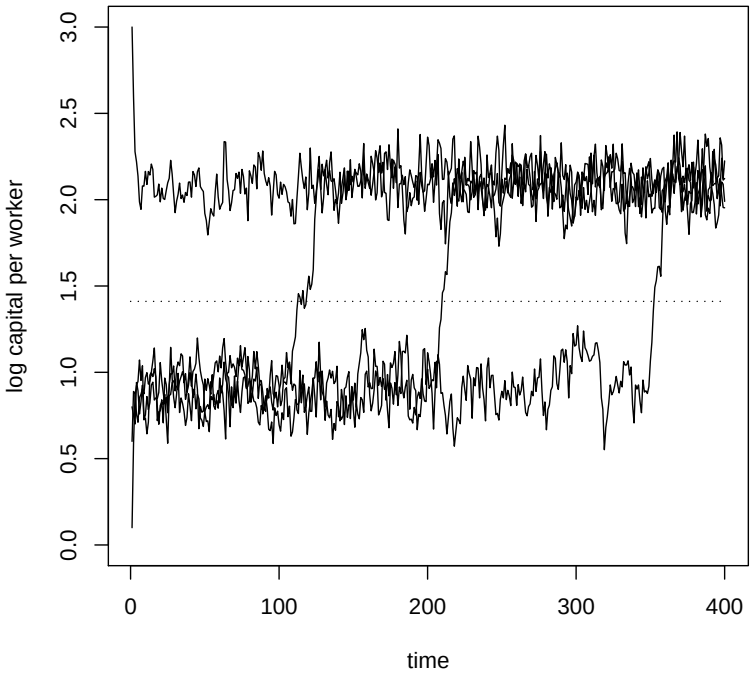

Fig. 10. Time series of 4 countries, high variance

economies. In each figure, all four economies are identical, apart from their initial conditions. One economy is started in the basin of attraction for the higher attractor, and three are started in that of the lower attractor. [34]

In the figures, the economies spend most of the time clustered in the neighborhoods of the two deterministic attractors. Economies starting in the portion of the state space (the y-axis) above the threshold are attracted on average to the high level attractor, while those starting below are attracted on average to the low level attractor. For these parameters, historical conditions are important in determining outcomes over the kinds of time scales economists are interested in, even though there are no multiple equilibria, and in the limit outcomes depend only on fundamentals.

In Figure 10, all three initially poor economies eventually make the transition out of the poverty trap, and converge to the neighborhood of the high attractor. Such transitions might be referred to as "growth miracles." In these

[34] The specification of $A(k)$ is as in Figure 9, where now $k_T = 4.1$, $\theta = 0.2$, $h = 0.95$, $\alpha = 0.3$, $s = 0.2$, $\delta = 1$. For Figure 10 we used $\ln \xi \sim N(0, 0.1)$, while for Figure 11 we used $\ln \xi \sim N(0, 0.05)$.

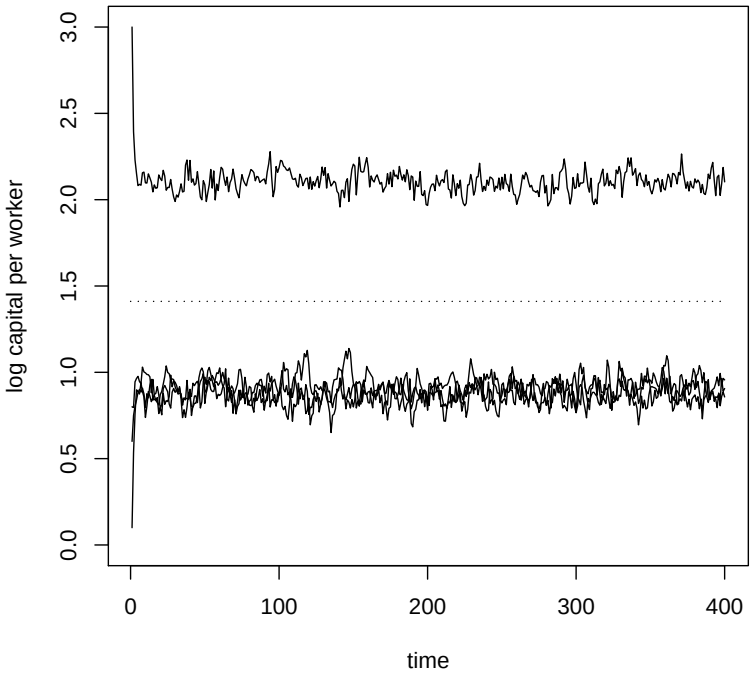

Fig. 11. Time series of 4 countries, low variance

series there are no "growth disasters" (transitions from high to low). The relative likelihood of growth miracles and growth disasters obviously depends on the structure of the model—in particular, on the relative size of the basins of attraction.

In Figure 10 the shock is distributed according to $\ln \xi \sim N(0, 0.1)$, while in Figure 11 the variance is smaller: $\ln \xi \sim N(0, 0.05)$. Notice that in Figure 11 no growth miracles occur over this time period. The intuition is clear: With less noise, the probability of a large positive shock—large enough to move into the basin of attraction for the high attractor—is reduced, and with it the probability of escaping from the poverty trap.

We now return to the model in part (d) of Figure 7, which is nonconvex, but at the same time is ergodic even in the deterministic case. This kind of structure is usually *not* regarded as a poverty trap model. In fact, since (d) is just a small perturbation of model (a), the existence of poverty traps is often thought to be very sensitive to parameters—a small change can cause a bifurcation of the dynamics whereby the poverty trap disappears. But, in fact, the phenomenon of persistence is more subtle. In terms of their medium run implications for cross-country income patterns, the two models (a) and

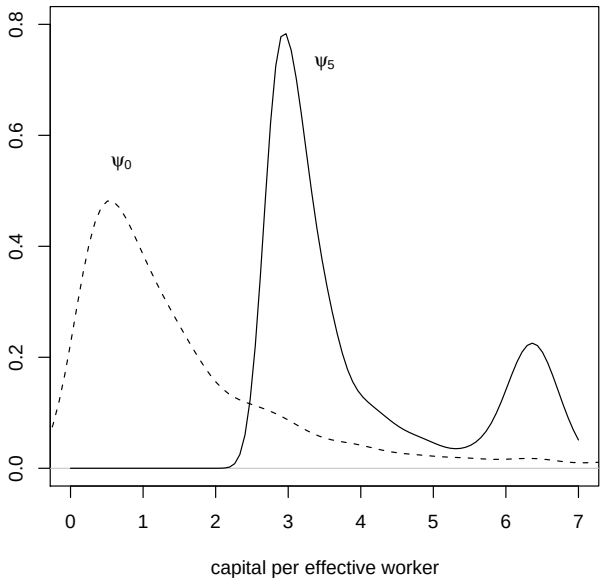

Fig. 12. Convergence under increasing returns

(d) are very similar.

To illustrate this, Figure 12 shows an arbitrary initial distribution and the resulting time 5 distribution for k under the law of motion given in (d) of Figure 7.[35] As in all cases we have considered, the stochastic model is ergodic. Now the ergodic distribution (not shown) is unimodal, clustered around the single high level attractor of the deterministic model. Thus the long run dynamics are different to those in Figure 9. *However,* during the transition, statistical behavior is qualitatively the same as that for models that *do* have low level attractors (such as (a) of Figure 7). In ψ_5 we observe amplification of initial differences, and the formation of a bimodal distribution with two "convergence clubs."

How long is the medium run, when the transition is in progress and the distribution is bimodal? In fact one can make this transition arbitrarily long without changing the basic qualitative features of (d), such as the non-existence of a low level attractor. Its length depends on the degree of nonconvexity and the variance of the productivity shocks $(\xi_t)_{t\geq 0}$. Higher variance in the shocks will tend to speed up the transition.

[35] The specification of $A(k)$ is as before, where now $k_T = 3.1$, $\theta = 0.15$, $h = 0.7$, $\alpha = 0.3$, $s = 0.2$, $\delta = 1$, and $\ln \xi \sim N(0, 0.2)$.

The last two examples have illustrated an important general principle: In economies with nonconvexities, the dynamics of key variables such as income can be highly sensitive to the statistical properties of the exogenous shocks which perturb activity in each period. [36] This phenomenon is consistent with the cross-country income panel. Indeed, several studies have emphasized the major role that shocks play in determining the time path of economic development (c.f., e.g., Easterly, Kremer, Pritchett and Summers 1993; den Haan 1995; Acemoglu and Zilibotti 1997; Easterly and Levine 2000). [37]

At the risk of some redundancy, let us end our discussion of the increasing returns model (9) by reiterating that persistence of historical conditions and formal ergodicity may easily coincide. (Recall that the time series in Figure 11 are generated by an ergodic model, and that (d) of Figure 7 is ergodic even in the deterministic case.) As a result, identifying history dependence with a lack of ergodicity can be problematic. In this survey we use a more general definition:

Definition 3.2 (Poverty trap) *A poverty trap is any self-reinforcing mechanism which causes poverty to persist.*

When considering a given quantitative model and its dynamic implications, the important question to address is, how persistent are the self-reinforcing mechanisms which serve to lock in poverty over the time scales that matter when welfare is computed? [38]

A final point regarding this definition is that the mechanisms which reinforce poverty may occur at any scale of social and spatial aggregation, from individuals to families, communities, regions, and countries. Traps can arise not just across geographical location such as national boundaries, but also within dispersed collections of individuals affiliated by ethnicity, religious beliefs or clan. Group outcomes are then summed up progressively from the level of the individual. [39]

[36] Such sensitivity is common to all dynamic systems where feedbacks can be positive. The classic example is evolutionary selection.

[37] This point also illustrates a problem with standard empirical growth studies. In general no information on the shock distribution is incorporated into calculation of dynamics.

[38] Mookherjee and Ray (2001) have emphasized the same point. See their discussion of "self-reinforcement as slow convergence."

[39] This point has been emphasized by Barrett and Swallow (2003) in their discussion of "fractal" poverty traps.

Next we turn to our second "canonical" poverty trap model, which again is presented in a very simplistic form. (For microfoundations see Sections 5–8.) The model is static rather than dynamic, and exhibits what Mookherjee and Ray (2001) have described as *inertial* self-reinforcement. [40] Multiple equilibria exist, and selection of a particular equilibrium can be determined purely by beliefs or subjective expectations.

In the economy a unit mass of agents choose to work either in a traditional, rural sector or a modern sector. Labor is the only input to production, and each agent supplies one unit in every period. All markets are competitive. In the traditional sector returns to scale are constant, and output per worker is normalized to zero. The modern sector, however, is knowledge-intensive, and aggregate output exhibits increasing returns due perhaps to spillovers from agglomeration, or from matching and network effects.

Let the fraction of agents working in the modern sector be denoted by α. The map $\alpha \mapsto f(\alpha)$ gives output per worker in the modern sector as a function of the fraction employed there. Payoffs are just wages, which equal output per worker (marginal product). Agents maximize individual payoffs taking the share α as exogenously given.

We are particularly interested in the case of strategic complementarities. Here, entry into the modern sector exhibits complementarities if the payoff to entering the modern sector increases with the number of other agents already there; in other words, if f is increasing. We assume that $f' > 0$, and also that returns in the modern sector dominate those in the traditional sector only when the number of agents in the modern sector rises above some threshold. That is, $f(0) < 0 < f(1)$. This situation is shown in Figure 13. At the point α_b returns in the two sectors are equal.

Equilibrium distributions of agents are values of α such that $f(\alpha) = 0$, as well as "all workers are in the traditional sector," or "all workers are in the modern sector" (ignoring adjustments on null sets). The last two of these are clearly Pareto-ranked: The equilibrium $\alpha = 0$ has the interpretation of a poverty trap.

Immediately the following objection arises. Although the lower equilibrium is to be called a poverty trap, is there really a self-reinforcing mechanism here

[40] By "static" we mean that there are no explicitly specified interactions between separate periods.

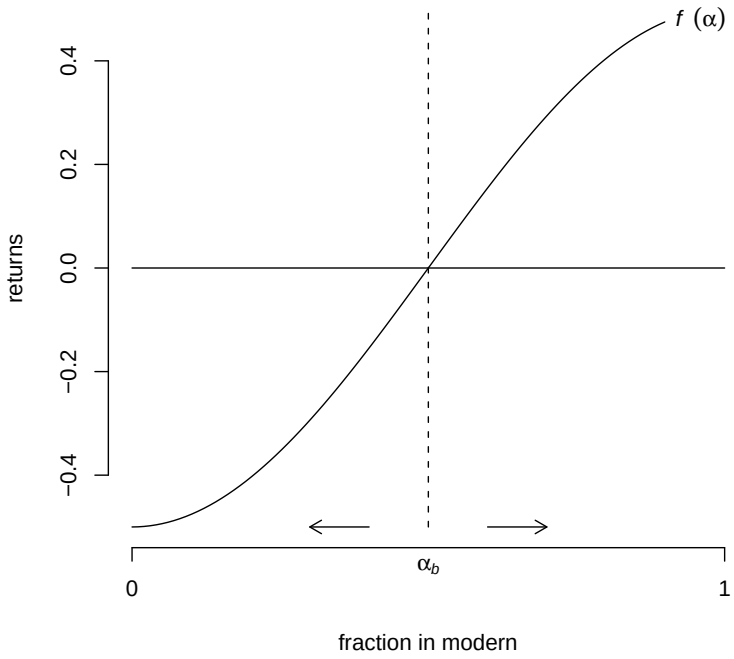

Fig. 13. Returns in traditional and modern sectors

which causes poverty to persist? After all, it seems that as soon as agents coordinate on the good equilibrium "poverty" will disappear. And there are plenty of occasions where societies acting collectively have put in place the institutions and preconditions for successful coordination when it is profitable to do so.

Although the last statement is true, it seems that history still has a role to play in equilibrium selection. This argument has been discussed at some length in the literature, usually beginning with myopic Marshallian dynamics, under which factors of production move over time towards activities where returns are higher. In the case of our model, these dynamics are given by the arrows in Figure 13. If $(\alpha_0)_{t\geq 0}$ is the sequence of modern sector shares, and if initially $\alpha_0 < \alpha_b$, then $\alpha_t \to 0$. Conversely, if $\alpha_0 > \alpha_b$, then $\alpha_t \to 1$.

But, as many authors have noted, this analysis only pushes the question one step back. Why should the sectoral shares only evolve slowly? And if they can adjust instantaneously, then why should they depend on the initial condition at all? What are the sources of inertia here that prevent agents from immediately

coordinating on good equilibria? [41]

Adsera and Ray (1997) have proposed one answer. Historical conditions may be decisive if—as seems quite plausible—spillovers in the modern sector arise only with a lag. A simplified version of the argument is as follows. Suppose that the private return to working in the modern sector is r_t, where now $r_0 = f(\alpha_0)$ and r_t takes the lagged value $f(\alpha_{t-1})$ when $t \geq 1$. Suppose also that at the end of each period agents can move costlessly between sectors. Agent j chooses location in order to maximize a discounted sum of payoffs given subjective beliefs $(\alpha_t^j)_{t\geq 0}$ for the time path of shares, where to be consistent we require that $\alpha_0^j = \alpha_0$ for all j.

Clearly, if $\alpha_0 < \alpha_b$, then switching to or remaining in the traditional sector at the end of time zero is a dominant strategy regardless of beliefs, because $r_1 = f(\alpha_0) < f(\alpha_b) = 0$. The collective result of these individual decisions is that $\alpha_1 = 0$. But then $\alpha_1 < \alpha_b$, and the whole process repeats. Thus $\alpha_t = 0$ for all $t \geq 1$. This outcome is interesting, because even the most optimistic set of beliefs lead to the low equilibrium when $f(\alpha_0) < 0$. To the extent that Adsera and Ray's analysis is correct, history must always determine outcomes. [42]

Another way that history can re-enter the equation is if we admit some deviation from perfect rationality and perfect information. As was stressed in the introduction, this takes us back to the role of institutions, through which history is transmitted to the present.

It is reasonable to entertain such deviations here for a number of reasons. First and foremost, assumptions of complete information and perfect rationality are usually justified on the basis of experience. Rationality obtains by repeated observation, and by the punishment of deviant behavior through the carrot and stick of economic payoff. Rational expectations are justified by appealing to *induction*. Agents are assumed to have had many observations from a stationary environment. Laws of motion and hence conditional expectations are inferred on the basis of repeated transition sampling *from every relevant state/action pair* (Lucas 1986). When attempting to break free from a poverty trap, however, agents have most likely *never* observed a transition to the high level equilibrium. On the basis of what experience are they to assess its like-

[41] See, for example, Krugman (1991) or Matsuyama (1991).

[42] There are a number of possible criticisms of the result, most of which are discussed in detail by the authors. If, for example, there are congestion costs or first mover advantages, then moving immediately to the modern sector might be rational for some optimistic beliefs and specification of parameters.

lihood from each state and action? How will they assess the different costs or benefits?

In a boundedly rational environment with limited information, outcomes will be driven by norms, institutions and conventions. It is likely that *these* factors are among the most important in terms of a society's potential for successful coordination on good equilibria. In fact for some models we discuss below the equilibrium choice is not between traditional technology and the modern sector, but rather is a choice between predation (corruption) and production, or between maintaining kinship bonds and breaking them. In some sense these choices are inseparable from the social norms and institutions of the societies within which they are framed. [43]

The central role of institutions may not prevent rapid, successful coordination on good equilibria. After all, institutions and conventions are precisely how societies solve coordination problems. As was emphasized in the introduction, however, norms, institutions and conventions are path dependent by definition. And, in the words of Matsuyama (1995, p. 724), "coordinating expectations is much easier than coordinating changes in expectations." Because of this, economies that start out in bad equilibria may find it difficult to break free.

Why should a convention that locks an economy into a bad equilibrium develop in the first place? Perhaps this is just the role of historical accident. Or perhaps, as Sugden (1989) claims, conventions tend to spread on the basis of versatility or analogy. [44] If so, the conventions that propagate themselves most successfully may be those which are most versatile or susceptible to analogy—not necessarily those which lead to "good" or efficient equilibria.

Often the debate on historical conditions and coordination is cast as "history versus expectations." We have emphasized the role of history, channeled through social norms and institutions, but without intending to say that beliefs are not important. Rather, beliefs are no doubt crucial. At the same time,

[43] More traditional candidates for coordinating roles among the set of institutions include interventionist states promoting industrialization through policy-based financing, or (the cultural component of) large business groups, such as Japan's keiretsu and South Korea's chaebol. In Section 5.2, we discuss the potential for large banks with significant market power to drive "big push" type investments by the private sector.

[44] A versatile convention works reasonably well against many strategies, and hence is advantageous when facing great uncertainty. Analogy means that a rule for a particular situation is suggested by similar rules applied to different but related situations.

beliefs and expectations are shaped by history. And they in turn combine with value systems and local experience to shape norms and institutions. The latter then determine how successful different societies are in solving the particular coordination problems posed by interactions in free markets.

If beliefs and expectations are shaped by history, then the "history versus expectations" dichotomy is misleading. The argument that beliefs and expectations are indeed formed by a whole variety of historical experiences has been made by many development theorists. In an experiment investigating the effects of the Indian caste system, Hoff and Pandey (2004) present evidence that individuals view the world through their own lens of "historically created social identities," which in turn has a pronounced effect on expectations. Rostow (1990, p. 5) writes that "the value system of [traditional] societies was generally geared to what might be called a long run fatalism; that is, the assumption that the range of possibilities open to one's grandchildren would be just about what it had been for one's grandparents." Ray (2003, p. 1) argues that "poverty and the failure of aspirations may be reciprocally linked in a self-sustaining trap."

Finally, experimental evidence on coordination games with multiple Pareto-ranked equilibria suggests that history is important: Outcomes are strongly path dependent. For example, Van Huyck, Cook and Battalio (1997) study people's adaptive behavior in a generic game of this type, where multiple equilibria are generated by strategic complementarities. In each experiment, eight subjects participated in a sequence of between 15 and 40 plays. The authors find sensitivity to initial conditions, defined here as the median of the first round play. In their view, "the experiment provides some striking examples of coordination failure growing from small historical accidents."

4 Empirics of Poverty Traps

Casual observation of the cross-country income panel tends to be suggestive of mechanisms which reinforce wealth or poverty. In Section 4.1 we review the main facts. Section 4.2 considers tests for the empirical relevance of poverty trap models. While the results of the tests support the hypothesis that the map from fundamentals to economic outcomes is not unique, it gives no indication as to what forces might be driving multiplicity. Section 4.3 begins the difficult task of addressing this issue in a macroeconomic framework. Finally, Section 4.4 gives references to empirical tests of specific microeconomic

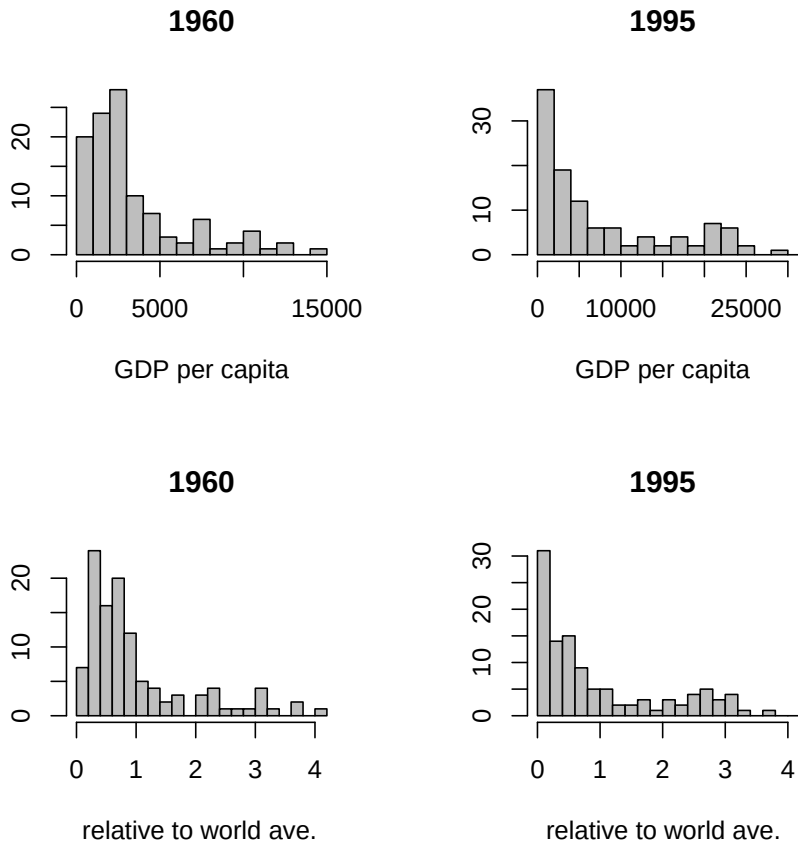

Fig. 14. Absolute and relative GDP per capita

mechanisms that can reinforce poverty at the individual or group level.

4.1 Bimodality and convergence clubs

A picture of the evolving cross-country income distribution is presented in Figure 14. For both the top and bottom histograms the y-axis measures frequency. For the top pair (1960 and 1995) the x-axis is GDP per capita in 1996 PPP adjusted dollars. This is the standard histogram of the cross-country income distribution. For the bottom pair the x-axis represents income as a fraction of the world average for that year.

The single most striking feature of the absolute income histograms for 1960 and 1995 is that over this period a substantial fraction of poor countries have grown very little or not at all. At the same time, a number of middle income countries have grown rapidly, in some cases fast enough to close in on the rich. Together, these forces have caused the distribution to become somewhat

thinner in the middle, with probability mass collecting at the extremes. Such an outcome is consistent with mechanisms that accentuate differences in initial conditions, and reinforce wealth or poverty. Related empirical studies include Azariadis and Drazen (1990), Quah (1993, 1996), Durlauf and Johnson (1995), Bianchi (1997), Pritchett (1997), Desdoigts (1999) and Easterly and Levine (2000).

As well as observing past and present distributions, Quah (1993) also used the Penn World Tables to estimate a transition probability matrix by discretizing the state space (income per capita), treating all countries as observations from the same Markovian probability law, and measuring transition frequency. This matrix provides information on mobility. Also, by studying the ergodic distribution, and by multiplying iterations of the matrix with the current cross-country income distribution, some degree of inference can be made as to where the income distribution is heading.

In his calculation, Quah uses per capita GDP relative to the world average over the period 1962 to 1984 in a sample of 118 countries. Relative income is discretized into state space $S := \{1, 2, 3, 4, 5\}$ consisting of 5 "bins," with states corresponding to values for relative GDP of 0–0.25, 0.25–0.5, 0.5–1, 1–2 and 2–∞ respectively. The transition matrix $\mathbf{P} = (p_{ij})$ is computed by setting p_{ij} equal to the fraction of times that a country, finding itself in state i, makes the transition to state j the next year. The model is assumed to be stationary, so all of the transitions can be pooled when calculating transition probabilities. The result of this calculation (Quah 1993, p. 431) is

$$\mathbf{P} = \begin{pmatrix} 0.97 & 0.03 & 0.00 & 0.00 & 0.00 \\ 0.05 & 0.92 & 0.03 & 0.00 & 0.00 \\ 0.00 & 0.04 & 0.92 & 0.04 & 0.00 \\ 0.00 & 0.00 & 0.04 & 0.94 & 0.02 \\ 0.00 & 0.00 & 0.00 & 0.01 & 0.99 \end{pmatrix}.$$

The Markov chain represented by $\mathbf{P}$ is easily shown to be ergodic, in the sense that there is a unique $\psi^* \in \mathscr{P}(S)$, the distributions on S, with the property that $\psi^*\mathbf{P} = \psi^*$, and $\psi\mathbf{P}^t \to \psi^*$ as $t \to \infty$ for all $\psi \in \mathscr{P}(S)$.[45] Quah calculates this ergodic distribution ψ^* to be $(0.24, 0.18, 0.16, 0.16, 0.27)$.

[45] Following Markov chain convention we are treating the distributions in $\mathscr{P}(S)$ as row vectors. Also, $\mathbf{P}^t$ is t compositions of $\mathbf{P}$ with itself. For more discussion of ergodicity see the technical appendix, or Stachurski (2004).

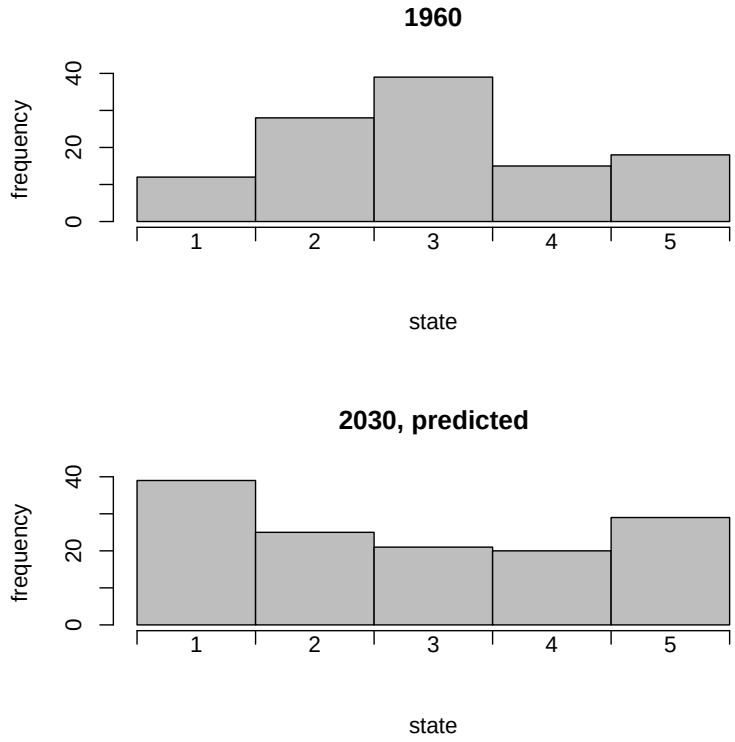

Fig. 15. Discrete projection

The ergodic distribution is quite striking, in that the world is divided almost symmetrically into two convergence clubs of rich and poor at either end of the income distribution.

It is not immediately clear just how long the long run is. To get some indication, we can apply $\mathbf{P}^t$ to the current distribution for different values of t. Figure 15 shows the results of applying $\mathbf{P}^{30}$ to the year 2000 income distribution from the Penn World Tables. This gives a projection for the 2030 distribution. Contrasted with the 1960 distribution the prediction is strongly bimodal.

As Quah himself was at pains to emphasize, the projections carried out above are only a first pass at income distribution dynamics, with many obvious problems. One of those is that the dynamics generated by a discretized version of a continuous state Markov chain can deviate very significantly from the true dynamics generated by the original chain, and error bounds are difficult to quantify. [46] Also, since the estimation of $\mathbf{P}$ is purely nonparametric, the projections do not contain any of the restrictions implied by growth theory.

[46] Compare, for example, Feyrer (2003) and Johnson (2004).

Quah (1996) addressed the first of these problems by estimating a continuous state version. In the language of this survey, he estimates a stochastic kernel Γ, of which $\mathbf{P}$ is a discretized representation. The estimation is nonparametric, using a Parzen-window type density smoothing technique. The kernel is suggestive of considerable persistence.

Azariadis and Stachurski (2004) make some effort to address both the discretization problem and the lack of economic theory simultaneously, by estimating Γ *parametrically*, using a theoretical growth model. In essence, they estimate equation (9), where $k \mapsto A(k)$ is represented by a three-parameter logistic function. The logistic function nests a range of growth models, from the convex model in Figure 2 to the nonconvex models in Figure 7, panels (a), (b) and (d). Once the law of motion (9) is estimated, the stochastic kernel Γ is calculated via equation (10), and the projection of distributions is computed by iterating (4).

The resulting 2030 prediction is shown in Figure 16, with the 1960 distribution drawn above for comparison. The x-axis is log of real GDP per capita in 1996 US dollars. The 1960 density is just a smoothed density estimate using Gaussian kernels, with data from the Penn World Tables. The same data was used to estimate the parameters in the law of motion (9). As in Figure 15, a unimodal distribution gives way to a bimodal distribution.

These findings do lend some support to Quah's convergence club hypothesis. Much work remains to be done. For example, in all of the methodologies discussed above, nonstationary data is being fitted to a stationary Markov chain. This is clearly a source of bias. Furthermore, all of these models are too small, in the sense that the state space used in the predictions are only one-dimensional. [47]

[47] In fact within each economy there are many interacting endogenous variables, only one of which is income. Even if the process as a whole is stationary and Markov, projection of the system onto one dimension will yield a process which is not generally Markovian. Moreover, there are interactions between countries that affect economic performance, and these interactions are important. A first-best approach would be to treat the world economy as an $N \times M$-dimensional Markov process, where N is the number of countries, and M is the number of endogenous variables in each country. One would then estimate the stochastic kernel Γ for this process, a map from $\mathbb{R}_+^{N \times M} \times \mathbb{R}_+^{N \times M} \to [0, \infty)$. Implications for the cross-country income distribution could be calculated by computing marginals.

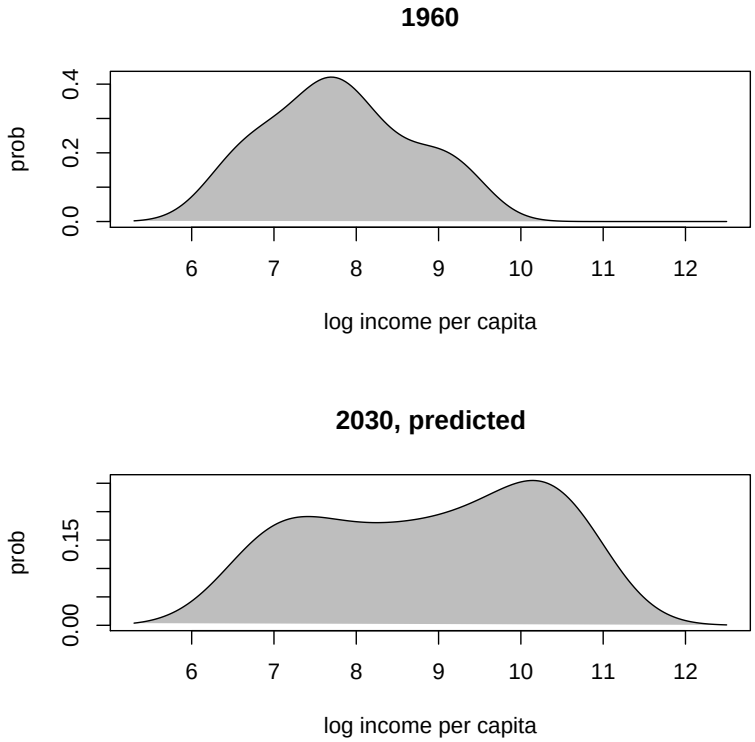

Fig. 16. Parametric projection

4.2 Testing for existence

Poverty trap models tend to be lacking in testable quantitative implications. Where there are multiple equilibria and sensitive dependence to initial conditions, outcomes are much harder to pin down than when the map from parameters to outcomes is robust and unique. This has led many economists to question the empirical significance of poverty trap models. [48] In this section, we ask whether or not there is any evidence that poverty traps exist.

In answering this question, one must be very careful to avoid the following circular logic: First, persistent poverty is observed. Poverty traps are then offered as the explanation. But how do we know there are poverty traps? Because (can't you see?) poverty persists. [49] This simple point needs to be kept in mind when interpreting the data with a view to assessing the empirical relevance of the models in this survey. Persistent poverty, emergent bimodality and the dispersion of cross-country income are the phenomena we seek to explain. They cannot themselves be used as proof that poverty traps explain

[48] See Matsuyama (1997) for more discussion of this point.
[49] This is a version of Karl Popper's famous tale about Neptune and the sea.

the data.

Also, a generalized convex neoclassical model can certainly be the source of bimodality and dispersion if we accept that the large differences in total factor productivity residuals across countries are due to some exogenous force, the precise nature of which is still waiting to be explained. In this competing explanation, the map from fundamentals to outcomes is unique, and shocks or historical accidents which perturb the endogenous variables can safely be ignored.

The central question, then, is *whether or not the poverty trap explanation of cross-country income differentials survives if we control for the exogenous forces which determine long run economic performance.* In other words, do self-reinforcing and path dependent mechanisms imply that economies populated by fundamentally similar people in fundamentally similar environments can support very different long run outcomes? What empirical support is there for such a hypothesis?

One particularly interesting study which addresses this question is that of Bloom, Canning and Sevilla (2003). Their test is worth discussing in some detail. To begin, consider again the two multiple equilibria models shown in Figure 8 (page 28), along with their ergodic distributions. As can be seen in the left hand panels, when the shock is suppressed both Country A and Country B have two locally stable equilibria for capital per worker—and therefore two locally stable equilibria for income. Call these two states y_1^* and y_2^*, the first of which is interpreted as the poverty trap.

In general, y_1^* and y_2^* will depend on the vector of exogenous fundamentals, which determine the exact functional relationships in the model, and hence become parameters in the law of motion. Let this vector be denoted by $\mathbf{x}$. Consider a snapshot of the economy at some point in time t. We can write income per capita as

$$y = \begin{cases} y_1^*(\mathbf{x}) + u_1 & \text{with probability } p(\mathbf{x}); \\ y_2^*(\mathbf{x}) + u_2 & \text{with probability } 1 - p(\mathbf{x}). \end{cases} \tag{R2}$$

Here $p(\mathbf{x})$ is the probability that the country in question is in the basin of attraction for the lower equilibrium $y_1^*(\mathbf{x})$ at time t. This probability is determined by the time t marginal distribution of income. The shock u_i represents deviation from the deterministic attractor at time t.

Figure 8 (page 28) helps to illustrate how y_1^* and y_2^* might depend on the

exogenous variables. Imagine that Countries A and B have characteristics $\mathbf{x}_A$ and $\mathbf{x}_B$ respectively. These different characteristics account for the different shapes of the laws of motion shown in the left hand side of the figure. As drawn, $y_2^*(\mathbf{x}_A)$, the high level attractor for Country A, is less than $y_2^*(\mathbf{x}_B)$, the high level attractor for Country B, while $y_1^*(\mathbf{x}_A)$ and $y_1^*(\mathbf{x}_B)$ are roughly equal.

In addition, we can see how the probability $p(\mathbf{x})$ of being in the poverty trap basin depends on these characteristics. For time t sufficiently large, ergodicity means that the time t marginal distribution—which determines this probability—can be identified with the ergodic distribution. The ergodic distribution in turn depends on the underlying structure, which depends on $\mathbf{x}$. This is illustrated by the different sizes of the distribution modes for Countries A and B in Figure 8. For Country A the left hand mode is relatively large, and hence so is $p(\mathbf{x})$.

Using a maximum likelihood ratio test, the specification (R2) is evaluated against a single regime alternative

$$y = y^*(\mathbf{x}) + u, \tag{R1}$$

which can be thought of for the moment as being generated by a convex Solow model. The great benefit of the specification (R1) and (R2)—as emphasized by the authors—is that long run output depends only on exogenous factors. The need to specify the precise system of endogenous variables and their interactions is circumvented. [50]

In conducting the test of (R1) against (R2), it is important *not* to include as exogenous characteristics any variable which is in fact endogenously determined. For to do so might result in conditioning on the *outcomes* of the underlying process which generates multiple equilibria. In the words of the authors, "Including such variables may give the impression of a unique equilibrium relationship [for the economic system] when in reality they are a function of the equilibrium being observed. Fundamental forces must be characteristics that determine a country's economic performance but are not determined by it."

In the estimation of Bloom, Canning and Sevilla, only geographic features are included in the set of exogenous variables. These include data on distance from equator, rainfall, temperature, and percentage of land area more than 100km from the sea. For this set of variables, the likelihood ratio test rejects the single regime model (R1) in favor of the multiple equilibria model (R2).

[50] Ergodicity is critical in this respect, for without it p will depend not just on $\mathbf{x}$ but also on the lagged values of endogenous variables.

They find evidence for a high level equilibrium which does not vary with $\mathbf{x}$, and a low level equilibrium which does. In particular, $y_1^*(\mathbf{x})$ tends to be smaller for hot, dry, land-locked countries (and larger for those with more favorable geographical features). In addition, $p(\mathbf{x})$ is larger for countries with unfavorable geographical features. In other words, the mode of the ergodic distribution around $y_1^*(\mathbf{x})$ is relatively large. For these economies escape from the poverty trap is more difficult.

Overall, the results of the study support the poverty trap hypothesis. They also serve to illustrate the importance of distinguishing between variables which are exogenous and those which have feedback from the system. If one conditions on "explanatory" variables which deviate significantly from fundamental forces, the likelihood of observing multiple equilibria in the map from those variables to outcomes will be lower. For example, one theme of this survey is that institutions can be an important source of multiplicity, either directly or indirectly through their interactions with the market. If institutions are endogenous, and if traps in institutions drive the disparities in cross-country incomes, then conditioning on institutions may give spurious convergence results entirely disconnected from long run outcomes generated by the system.

4.3 Model calibration

One of the advantages of the methodology proposed by Bloom, Canning and Sevilla is that estimation and testing can proceed without fully specifying the underlying model. The exacting task of determining the relevant set of endogenous variables and the laws by which they interact is thereby circumvented. But there are two sides to this coin. While the results of the test suggest that poverty traps matter, they give no indication as to their source, or to the appropriate framework for formulating them as models.

Graham and Temple (2004) take the opposite approach. They give the results of a numerical experiment starting from a specific poverty trap model, somewhat akin to the inertial self-reinforcement model of Section 3.4. The question they ask is whether or not the model in question has the potential to explain observed cross-country variation in per capita income for a reasonable set of parameters. We briefly outline their main findings, as well as their technique for calibration, which is of independent interest.

As in Section 3.4, there is both a traditional agricultural sector and a modern sector with increasing social returns due to technical externalities. The

agricultural sector has a decreasing returns technology

$$Y_a = A_a L_a^{\gamma}, \quad \gamma \in (0,1), \tag{11}$$

where Y_a is output, A_a is a productivity parameter and L_a is labor employed in the agricultural sector. The j-th firm in the modern sector has technology

$$Y_{m,j} = A_m L_{m,j} L_m^{\lambda}, \quad \lambda > 0, \tag{12}$$

where $Y_{m,j}$ is output of firm j, A_m is productivity, $L_{m,j}$ is labor employed by firm j, and L_m is total employment in the modern sector. The firm ignores the effect of its hiring decisions on L_m, thus setting the stage for multiplicity. We set $L_a + L_m = L$, a fixed constant, and, as usual, $\alpha := L_m/L$.

The relative price of the two goods is fixed in world markets and normalized to one by appropriate choice of units. Wages are determined by marginal cost pricing: $w_a = \gamma A_a L_a^{\gamma-1}$ and $w_m = A_m L_m^{\lambda}$. Setting these factor payments equal gives the set of equilibrium modern sector shares α as solutions to the equation

$$(1-\alpha)^{1-\gamma}\alpha^{\lambda} = \frac{A_a \gamma L^{\gamma-1-\lambda}}{A_m}. \tag{13}$$

Regarding calibration, γ is a factor share, and the increasing returns parameter λ has been calculated in several econometric studies.[51] Relative productivity is potentially more problematic. However, it turns out that (13) has precisely two solutions for reasonable parametric values. Since both solutions α_1 and α_2 satisfy (13) we have

$$(1-\alpha_1)^{1-\gamma}\alpha_1^{\lambda} - (1-\alpha_2)^{1-\gamma}\alpha_2^{\lambda} = 0. \tag{14}$$

In which case, assuming that current observations are in equilibrium, one can take the observed share as α_1, calculate α_2 as the other solution to (14), and set the poverty trap equilibrium equal to $\alpha_1^* := \min\{\alpha_1, \alpha_2\}$. The high productivity equilibrium is $\alpha_2^* := \max\{\alpha_1, \alpha_2\}$. Figure 17 illustrates this procedure for $\alpha_1 = 0.1$, $\gamma = 0.7$ and $\lambda = 0.3$.

When α_1^*, α_2^*, γ and λ are known, a little algebra shows that the ratio of output in the high equilibrium to output in the low equilibrium can also be computed. In this way it is possible to evaluate the relative impact of the poverty trap on individual countries and the cross-country income distribution.

Using this strategy and a more elaborate model (including both capital and land), Graham and Temple's main findings are as follows. First, for reasonable

[51] See, for example, Cabarello and Lyons (1992).

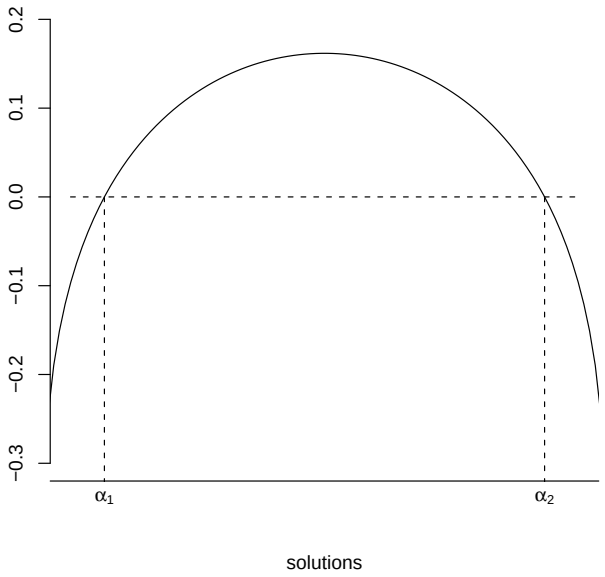

Fig. 17. Multiple equilibria

parameter values some 1/4 of the 127 countries in their 1988 data set are in the poverty trap α_1^*. Second, after calculating the variance of log income across countries when all are in their high output equilibrium and comparing it to the actual variance of log income, they find that the poverty trap model can account for some 2/5 to one half of all observed variation in incomes.

Overall, their study suggests that the model can explain some properties of the data, such as the difference between poor, agrarian economies and low to middle income countries. On the other hand, it cannot account for the huge differences between the very poorest and the rich industrialized countries. In the model, the largest ratios of low to high equilibrium production are in the region of two to three. As we saw in Section 2.1, however, actual per capita output ratios between rich and poor countries are much larger.

4.4 Microeconomic data

There has also been research in recent years on poverty traps that occur at the individual or group level. For example, Jalan and Ravallion (2002) fit a microeconomic model of consumption growth with localized spillovers from capital to farm-household panel data in rural China. Their results are consistent with empirical significance of geographical poverty traps. Other authors

have studied particular trap mechanisms. For example, Bandiera and Rasul (2003) and Conley and Udry (2003) consider the effects of positive network externalities on technology adoption in Mozambique and Ghana respectively. Barrett, Bezuneh and Aboud (2001) consider the dynamic impact of credit constraints on the poor in Côte d'Ivoire and Kenya. Morduch (1990) studies the effect of risk on income in India, as does Dercon (1998) for Tanzania.

5 Nonconvexities, Complementarities and Imperfect Competition

Increasing returns production under imperfect competition is a natural framework to think about multiple equilibria. Imperfect competition leads directly to externalities transmitted through the price system, because monopolists themselves, rather than Walrasian auctioneers, set prices, and presumably they do so with their own profit in mind. At the same time, their pricing and production decisions impinge on other agents. These general equilibrium effects can be a source of multiplicity.

Section 5.1 illustrates this idea using the big push model of Murphy, Shleifer and Vishny (1989); a model which formalizes an earlier discussion in Rosenstein-Rodan (1943). Rosenstein-Rodan argued that modern industrial technology is freely available to poor countries, but has not been adopted because the domestic market is too small to justify the fixed costs it requires. If all sectors industrialize simultaneously, however, the market may potentially be expanded to the extent that investment in modern technology is profitable.

Thus the big push model of Section 5.1 helps to clarify the potential challenges posed by coordination for the industrialization process. We shall see that the major coordination problem facing monopolists cannot be resolved by the given market structure. In this situation, the ability of a society to successfully coordinate entrepreneurial activity—and thereby realize the social benefits available in modern production technologies—will depend in general on such structures as its institutions, political organizations, the legal framework, and social and business conventions.

In countries such as South Korea, the state has been very active in attempting to overcome coordination problems associated with industrialization. In Western Europe, the state was typically much less active, and the role of the private sector was correspondingly larger. For example, Da Rin and Hellmann (2002) have recently emphasized the important role played by banks in coordinating industrialization. Section 5.2 reviews their model.

A theme of this survey is traps that prevent economies as a whole from adopting modern production technologies. One aspect of this transformation to modernity is the need for human capital. If investment in human capital has a high economic payoff then a skilled work-force should spontaneously arise. Put differently, if the poor are found to invest little in schooling or training then this suggests to us that returns to these investments are relatively low. Section 5.3 reviews Kremer's (1993) matching model, where low investment in schooling sustains itself in a self-reinforcing trap.

Finally, Section 5.4 gives references to notable omissions on the topic of increasing returns.

5.1 Increasing returns and imperfect competition

Murphy, Shleifer and Vishny's (1989) formalization of Rosenstein-Rodan's (1943) big push is something of a watershed in development economics. Their model turns on demand spillovers which create complementarities to investment. They point out that for the economy to generate multiple equilibria, it must be the case that investment simultaneously (i) increases the size of other firms' markets, or otherwise improves the profitability of investment; and (ii) has negative net present value. This means that profits alone cannot be the direct source of the market size effects; otherwise (i) and (ii) would be contradictory.

In the first model they present, higher wages in the modern sector are the channel through which demand spillovers increase market size. Although investment is not individually profitable, it raises labor income, which in turn raises the demand for other products. If the spillovers are large enough, multiple equilibria will occur. In their second model, investment in the modern technology changes the composition of aggregate demand across time. In the first period, the single monopolistic firm in each sector decides whether to invest or not. Doing so incurs a fixed cost F in the first period, and yields output ωL in the second, where $\omega > 1$ is a parameter and L is labor input. The cost in the second period is just L, as wages are the numeraire. If, on the other hand, the monopolist chooses not to invest, production in that sector will take place in a "competitive fringe" of atomistic firms using constant returns to scale technology. For these firms, one unit of labor input yields one unit of output. The price for each unit so produced is unity.

All wages and profits accrue to a representative consumer, who supplies L

units of labor in both periods, and maximizes the undiscounted utility of his consumption, that is,

$$\max\left\{\int_0^1 \ln c_1(\alpha)d\alpha + \int_0^1 \ln c_2(\alpha)d\alpha \;\Big|\; c_t\colon [0,1] \ni \alpha \mapsto c_t(\alpha) \in [0,\infty)\right\}$$

subject to the constraints $\int_0^1 c_1 p_1 \leq y_1$ and $\int_0^1 p_2 c_2 \leq y_2$. Here $\alpha \in [0,1]$ indexes the sector, $c_t(\alpha)$ and $p_t(\alpha)$ are consumption and price of good α at time t respectively, and y_t is income (wages plus profits) at time t. [52]

In the first period only the competitive fringe produces, and $p_1(\alpha) = 1$ for all α. In the second, monopolists face unit elastic demand curves $c_2(\alpha) = y_2/p_2(\alpha)$. Given these curves and the constraints imposed by the competitive fringe, monopolists set $p_2(\alpha) = 1$ for all α. Their profits are $\pi = ay_2 - F$, where $a := 1 - 1/\omega$ is the mark-up.

Consider profitability when all entrepreneurs corresponding to sectors $[0,\alpha]$ decide to invest. (The number α can also be thought of as the fraction of the total number of monopolists who invest.) It turns out that for some parameter values both $\alpha = 0$ and $\alpha = 1$ are equilibria. To see this, consider first the case $\alpha = 0$, so that $y_1 = y_2 = L$. It is not profitable for a firm acting alone to invest if $\pi = aL - F \leq 0$. On the other hand, if $\alpha = 1$, then $y_1 = L - F$ and $y_2 = \omega L$, so monopolists make positive profits when $a\omega L - F \geq 0$. Multiple equilibria exist if these inequalities hold simultaneously. In Figure 18 multiple equilibria obtain for all $L \in [L_1, L_2]$.

As was mentioned in the introduction, coordination problems and other mechanisms that reinforce the status quo can interact with each other and magnify their individual impact. Murphy, Shleifer and Vishny (1989) provide a simple example of this in the context of the model outlined above. They point out that the coordination problem for the monopolists is compounded if industrialization requires widespread development of infrastructure and intermediate inputs, such as railways, road networks, port facilities and electricity grids. All of these projects will themselves need to be coordinated with industrialization.

For example, suppose that n infrastructure projects must be undertaken in the first period to permit industrialization in the second. Each project has a fixed

[52] To simplify the exposition we assume that consumers can neither save nor dissave from current income. For the moment we also abstract from the existence of a financial sector. Firms which invest simply pay all wages in the second period at a zero rate of interest. See the original for a more explicitly general equilibrium formulation.

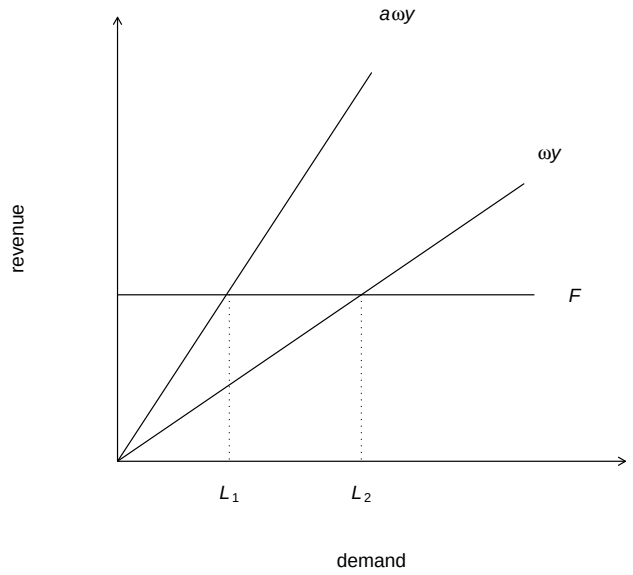

Fig. 18. Multiple equilibria

cost R_n, and operates in the second period at zero marginal cost. Leaving aside the issue of how the spoils of industrialization will be divided among the owners of the projects and the continuum of monopolists, it is clear that industrialization has the potential to be profitable for all only when $a\omega L - F$, the profits of the monopolists when $\alpha = 1$, exceed total infrastructure costs $\sum_{i=1}^{n} R_i$.

If the condition $aL - F \leq 0$ continues to hold, however, individual monopolists investing alone will be certain to lose money. Realizing this, investors in infrastructure face extrinsic uncertainty as to whether or not industrialization will actually take place. Given their subjective evaluation, they may choose not to start their infrastructure projects. In turn, the monopolists are aware that investors in infrastructure face uncertainty, and may themselves refrain from starting projects. This makes monopolists even more uncertain as to whether or not the conditions for successful industrialization will eventuate. The fixed point of this infinite regression of beliefs may well be inaction. In either case, the addition of more actors adds to the difficulty of achieving coordination.

As Da Rin and Hellmann (2002) have recently emphasized, one candidate within the private sector for successfully coordinating a big push type industrialization is the banks. Banks are the source of entrepreneurs' funds, and shape the terms and conditions under which capital may be raised. In addition, banks interact directly with many entrepreneurs. Finally, banks can potentially profit from coordinating industrialization if their market power is large.

Da Rin and Hellmann find that the structure and legal framework of the banking sector are important determinants of its ability to coordinate successful industrialization. To illustrate their ideas, consider again the big push model of Section 5.1. In order to make matters a little easier, let us simply define the second period return of monopolists (entrepreneurs) to be $f(\alpha)$, where α is the fraction of entrepreneurs who decide to set up firms and the function $f\colon [0,1] \to \mathbb{R}$ is strictly increasing. As before, there is a fixed cost F to be paid in the first period, which we set equal to 1. The future is not discounted.

It is convenient to think of the number of entrepreneurs as some large but finite number N.[53] In addition to these N entrepreneurs, there is now a financial sector, members of whom are referred to as either "banks" or "investors." There are $B \in \mathbb{N}$ banks, the first $B-1$ of which have an intermediation cost of r per unit of investment. The last bank has an intermediation cost of zero, but can lend to only $\ell \leq N$ firms. The number ℓ can be thought of as a measure of the last bank's market power.

The equilibrium lending rate at which firms borrow in the first period is determined by the interaction of the monopolists and the banks. In the first stage of the game, each bank b offers a schedule of interest rates to the N firms. This strategy will be written as $\sigma_b := \{i_n^b : 1 \leq n \leq N\}$. The collection of these strategies across banks will be written as $\sigma := \{\sigma_b : 1 \leq b \leq B\}$. Let Σ be the set of all such σ.

In the second stage, each entrepreneur either rejects all offers and does not set up the firm, or selects the minimum interest rate, pays the fixed cost and enters the market. In what follows we write $m_n(\sigma)$ to mean $\min_b i_n^b$, the minimum interest rate offered to firm n in σ. If a fraction α accepts contracts then firm

[53] In particular, entrepreneurs do not take into account their influence on α when evaluating whether to set up firms or not.

n makes profits

$$\pi(\alpha, m_n(\sigma)) = f(\alpha) - (1 + m_n(\sigma)). \tag{15}$$

For bank $b < B$, profits are given by

$$\Pi_b(\sigma_b) = \sum_{n=1}^{N} (i_n^b - r) \mathbb{1}\{\text{firm } n \text{ accepts}\}, \tag{16}$$

where here and elsewhere $\mathbb{1}\{Q\}$ is equal to one when the statement Q is true and zero otherwise. For $b = B$, profits are

$$\Pi_b(\sigma_b) = \sum_{n=1}^{N} i_n^b \mathbb{1}\{\text{firm } n \text{ accepts}\}. \tag{17}$$

In equilibrium, banks never offer interest rates strictly greater than r, because should they do so other banks will always undercut them. As a result, we can and do assume in all of what follows that $m_n(\sigma) \leq r$ for all n. Also, to make matters interesting, we assume that $f(0) < 1 + r < f(1)$, or, equivalently,

$$\pi(0, r) < 0 < \pi(1, r). \tag{18}$$

Firms' actions will depend on their beliefs—in particular, on what fraction α of the N firms they believe will enter. Clearly beliefs will be contingent on the set of contracts offered by banks. Thus a belief for firm n is a map α_n^e from Σ into $[0, 1]$. Given this belief, firm n enters if and only if

$$\pi(\alpha_n^e(\sigma), m_n(\sigma)) \geq 0. \tag{19}$$

Given σ, the set of self-supporting equilibria for the second stage subgame is

$$\Omega(\sigma) := \left\{ \alpha \in [0, 1] \quad : \quad \frac{1}{N} \sum_{n=1}^{N} \mathbb{1}\{\pi(\alpha, m_n(\sigma)) \geq 0\} = \alpha \right\}. \tag{20}$$

In other words, $\alpha \in \Omega(\sigma)$ if, given the set of offers σ and the belief on the part of all firms that the fraction of firms entering will be α, exactly $\alpha \times 100\%$ of firms find it optimal to enter.

Beliefs are required to be consistent in the sense that $\alpha_n^e(\sigma) \in \Omega(\sigma)$ for all σ and all n. Beliefs are called *optimistic* if $\alpha_n^e = \alpha^{\text{opt}}$ for all n, where $\alpha^{\text{opt}}(\sigma) := \max \Omega(\sigma)$ for all $\sigma \in \Sigma$. In other words, all agents believe that as many firms will enter as are consistent with offer σ, and this is true for every $\sigma \in \Sigma$. Beliefs are defined to be *pessimistic* if the opposite is true; that is, if $\alpha_n^e = \alpha^{\text{pes}}$ for all n, where $\alpha^{\text{pes}}(\sigma) := \min \Omega(\sigma)$ for all $\sigma \in \Sigma$.

Da Rin and Hellmann first observe that if $\ell = 0$, then the outcome of the game will be determined by beliefs. In particular, if beliefs are pessimistic, then the low equilibrium $\alpha = 0$ will obtain. If beliefs are optimistic, then the high equilibrium $\alpha = 1$ will obtain. The interpretation is that when $\ell = 0$, so that the market for financial services is entirely competitive (in the sense of Bertrand competition with identical unit costs described above), the existence of the financial sector will not alter the primary role of beliefs in determining whether industrialization will take place.

Let us verify this observation in the case of pessimistic beliefs. To do so, it is sufficient to show that if $\sigma \in \Sigma$ is optimal, then $0 \in \Omega(\sigma)$. The reason is that if $0 \in \Omega(\sigma)$, then by (20) we have $\pi(0, m_n(\sigma)) < 0$ for all n. Also, beliefs are pessimistic, so $\alpha_n^e(\sigma) = \min \Omega(\sigma) = 0$. In this case no firms enter by (19).

To see that $0 \in \Omega(\sigma)$ for all optimal σ, suppose to the contrary that $\sigma \in \Sigma$ is optimal, but $0 \notin \Omega(\sigma)$. Then $\pi(0, m_k(\sigma)) \geq 0$ for some k, in which case (18) implies that $m_k(\sigma) < r$. Because firms only accept contracts at rates less than r (that is, $m_n(\sigma) \leq r$ for all n), it follows from (16) that the bank which lent to k looses money, and σ is not optimal. The intuition is that no bank has market power, and cannot recoup losses sustained when encouraging firms to enter by offering low interest rates.

More interesting is the case where the last bank B has market power. With sufficient market power, B will induce industrialization (the high equilibrium where $\alpha = 1$) even when beliefs are pessimistic:

Proposition 5.1 (Da Rin and Hellmann) *Suppose beliefs are pessimistic. In this case, there exists an $\bar{\alpha} \in [0, 1]$ depending on r and f such that industrialization will occur whenever ℓ, the market power of B, satisfies $\ell/N \geq \bar{\alpha}$.*

The result shows that rather than relying on spontaneous coordination of beliefs, financial intermediaries may instead be the source of coordination. The key intuition is that a financial intermediary may have a profit motive for inducing industrialization. But to achieve this, two things are necessary: size and market power. Size (as captured by ℓ) is necessary to induce a critical mass of entrepreneurs to invest. Market power (as captured by the cost advantage r) is necessary to recoup the costs of mobilizing that critical mass. We sketch Da Rin and Hellmann's proof in the appendix.

Until now we have considered only the possibility that the banks offer pure debt contracts. Da Rin and Hellmann also study the case where the banks may hold equity as well (i.e., universal banking). They show that in this case

the threshold level at which the lead bank B has sufficient market power to mobilize the critical mass is lower. Industrialization is unambiguously more likely to occur. The reason is that equity permits B to partake in the ex post profits of the critical mass, who benefit from low interest rates on one hand and complete entry ($\alpha = 1$) on the other. With a lower cost of mobilizing firms, B requires less market power to recoup these losses. In Da Rin and Hellmann's words,

> Our model provides a rationale for why a bank may want to hold equity that has nothing to do with the standard reasons of providing incentives for monitoring. Instead, equity allows a bank to participate in the gains that it creates when inducing a higher equilibrium.

In summary, the theory suggests that large universal banks with a high degree of market power can play a central role in the process of industrialization. This theory is consistent with the evidence from countries such as Belgium, Germany and Italy, where a few oligopolist banks with strong market positions played a pivotal role. Some were pioneers of universal banking, and many directly coordinated activity across sectors by participation in management. The theory may also explain why other countries, such as Russia, failed to achieve significant industrialization in the 19th Century. There banks were small and dispersed, their market power severely restricted by the state.

5.3 Matching

The next model we consider is due to Kremer (1993), and has the following features. A production process consists of n distinct tasks, organized within a firm. For our purposes n can be regarded as exogenous. The tasks are undertaken by n different workers, all of whom have their own given skill level $h_i \in [0, 1]$. Here the skill level will be thought of as the probability that the worker performs his or her task successfully. We imagine that if one worker fails in their task the entire process is ruined and output is zero. If all are successful, the outcome of the process is n units of the product. [54] That is,

$$y = n \prod_{i=1}^{n} \mathbb{1}\{\text{worker } i \text{ successful}\}, \quad \mathbb{P}\{\text{worker } i \text{ successful}\} = h_i, \tag{21}$$

[54] Assuming one unit might seem more natural than n, but the latter turns out to be more convenient.

where as before $\mathbb{1}\{Q\} = 1$ if the statement Q is true and zero otherwise. All of the success probabilities are independent, so that $\mathbb{E}(y) = n \prod_i h_i$.

Consider an economy with a unit mass of workers. The distribution of skills across workers is endogenous, and will be discussed at length below. Kremer's first point is that in equilibrium, firms will match workers of equal skill together to perform the process. The intuition is that (i) firms will not wish to pair a work-force of otherwise skilled employees with one relatively unskilled worker, who may ruin the whole process; and (ii) firms with a skilled work-force will be able to bid more for skilled workers, because the marginal value of increasing the last worker's skill is increasing in the skill of the other workers. Thus, for each firm,

$$\mathbb{E}(y) = nh^n, \quad h \text{ the firm's common level of worker skill.} \tag{22}$$

The first thing to notice about this technology is that the expected marginal return to skill is increasing. As a result, small differences in skill can have relatively large effects on output. This may go some way to explaining the extraordinarily large wage differentials between countries. Moreover, for economies with such technology, positive feedback dynamics of the kind considered in Section 3.3 may result, even if the technology for creating human capital is concave.

Another channel for positive feedbacks occurs when matching is imperfect, perhaps because it is costly or the population is finite. Exact matches may not be possible. In that case, there are potentially returns to agglomeration: Skilled people clustering together will decrease the cost of matching, and increase the likelihood of good matches. Also, an initial distribution of skills will tend to persist, because workers will choose skills so as to be where the distribution is thickest. This maximizes their chances of finding good matches. But this is self-reinforcing: Their choices perpetuate the current shape of the distribution.

There is yet another channel that Kremer suggests may lead to multiple equilibrium distributions of skill. This is the situation where skill levels are imperfectly *observed*. We present a simple (and rather extremist) version of Kremer's model. In the first period, workers decide whether to undertake "schooling" or not. This education involves a common cost $c \in (0, 1)$. In the second, firms match workers, produce, and pay out wages. Both goods and labor markets are competitive, and total wages exhaust revenue. Specifically, it is assumed that each worker's wage w is $1/n$-th of firm's output.

Not all of those who undertake schooling become skilled. We assume that the

educated receive a skill level $h = 1$ with probability $p > 1/2$ and $h = 0$ with probability $1 - p$. Those who do not undertake schooling have the skill level $h = 0$. Further, h is not observable, even for workers. Instead, all workers take a test, which indicates their true skill with probability p and the reverse with probability $1 - p$.[55] That is,

$$t := \text{test score} = \begin{cases} h & \text{with probability } p; \\ 1 - h & \text{with probability } 1 - p. \end{cases} \tag{23}$$

Firms then match workers according to the test score t rather than h.

Let $\alpha \in [0, 1]$ denote the fraction of workers who choose to undertake schooling. We will show that for certain values of the parameters p and c, both $\alpha = 0$ and $\alpha = 1$ are equilibria. In doing so, we assume that p is known to all. Also, workers and firms are risk neutral.

Consider first the case where $\alpha = 0$. If the worker undertakes schooling, then, regardless of his skill and test score, his expected wage is $1/n$-th of $n \prod_i h_i$, where his co-workers are drawn from a pool in which the skilled workers have measure zero. That is, $\mathbb{P}\{h_i = 0\} = 1$. It follows that expected output and wage are zero. Since $c > 0$, it is optimal to avoid schooling.[56]

Now consider the agent's problem when $\alpha = 1$. In the second period, the agent will be matched with other workers having the same test score. In either case, computing expected wages is a signal extraction problem. First, using the fact that agents in the pool of potential co-workers have chosen schooling with probability one, the agent can calculate probable skills of a co-worker chosen at random from the population, given their test score:

$$\mathbb{P}\{h = 1 \,|\, t = 1\} = \frac{\mathbb{P}\{h = 1 \text{ and } t = 1\}}{\mathbb{P}\{t = 1\}} = \frac{p^2}{p^2 + (1 - p)^2} =: \theta_p, \tag{24}$$

and,

$$\mathbb{P}\{h = 1 \,|\, t = 0\} = \frac{\mathbb{P}\{h = 1 \text{ and } t = 0\}}{\mathbb{P}\{t = 0\}} = \frac{p(1 - p)}{p(1 - p) + p(1 - p)} = \frac{1}{2}. \tag{25}$$

The worker can use these probabilities to compute expected output and hence wages given the different outcomes of his own test score. In particular, $\mathbb{E}(w \,|\, t =$

[55] We are using the same p as before just to simplify notation.

[56] On the other hand, if skills are perfectly observable, workers who acquire skills will be matched with n workers from the measure zero set of agents having $h = 1$. In that case $w = 1$. Since $c < 1$ it is optimal to choose schooling, and $\alpha = 0$ is not an equilibrium. The same logic works for any $\alpha < 1$

$1) = \theta_p^n$ and $\mathbb{E}(w \,|\, t = 0) = (1/2)^n$. It follows that the expected return to schooling for the agent is

$$\begin{aligned}\mathbb{E}(w \,|\, \text{schooling}) &= \mathbb{E}(w \,|\, t = 0)\mathbb{P}\{t = 0\} + \mathbb{E}(w \,|\, t = 1)\mathbb{P}\{t = 1\} \\ &= \frac{1}{2^n}(1 - p) + \theta_p^n p.\end{aligned}$$

Conversely, $\mathbb{E}(w \,|\, \text{no schooling}) = \frac{1}{2^n}p + \theta_p^n(1 - p)$. Schooling is optimal if

$$\begin{aligned}c < \mathbb{E}(w \,|\, \text{schooling}) - \mathbb{E}(w \,|\, \text{no schooling}) \\ = (2p - 1)(\theta_p^n - (1/2)^n) := c^*(p).\end{aligned}$$

It is easy to see that $c^*(p) > 0$ whenever $p > 1/2$, which is true by assumption. As a result, schooling will be optimal for some sufficiently small c, and $\alpha = 1$ is an equilibrium too. [57]

What are the sources of multiple equilibria in the model? The first is pecuniary externalities in the labor market: When more agents become educated, the probability that the marginal worker can successful match with a skilled co-worker increases. In turn, this increases the returns to education. [58] Second, there is imperfect information: Skilled workers cannot readily match with other skilled workers. Instead, matching is probabilistic, and depends on the overall distribution of skills. Finally, the increasing expected marginal reward for skill inherent in the production function means that the wage spillovers from the decisions of other agents are potentially large.

Another important model of human capital investment with multiple equilibria is Acemoglu (1997). He shows how labor market frictions can induce a situation where technology adoption is restricted by a lack of appropriately skilled workers. Low adoption in turn reduces the expected return to training, further exacerbating the scarcity of workers who are trained. In other words, poor technology adoption and low capital investment are self-reinforcing, because they cause the very shortage of skilled workers necessary to make such investments profitable.

[57] It may seem that if $p = 1$ and observation is perfect, then $\mathbb{E}(w \,|\, \text{schooling}) - \mathbb{E}(w \,|\, \text{no schooling})$ should be zero, so that no multiple equilibria are possible. But under this assumption the above derivation of $c^*(p)$ is not valid, because we would be conditioning on sets with probability zero.

[58] In fact the expected wage is increased for all, but those who become skilled benefit more.

Young's (1928) famous paper on increasing returns notes that not only does the degree of specialization depend on the size of the market, but the size of the market also depends on the degree of specialization. In other words, there are efficiency gains from greater division of labor, primarily due to application of machines. Greater specialization increases productivity, which then expands the market, leading back into more specialization, and so on. As a result, there are complementarities in investment. These complementarities can be the source of poverty traps. A detailed discussion of this process is omitted from the present survey, but only because excellent surveys already exist. See in particular Matsuyama (1995) and Matsuyama (1997). Other references include Matsuyama and Ciccone (1996), Rodríguez-Clare (1996) and Rodrik (1996).

Increasing returns are also associated with geographical agglomeration. Starrett (1978) points out that agglomerations *cannot* form as the equilibria of perfectly competitive economies set in a homogeneous space. Thus all agglomerations must be caused either by exogenous geographical features or by some market imperfection. An obvious candidate is increasing returns. (It is difficult to see what geographical features could explain the extent of concentration witnessed in places such as Tokyo or Hong Kong.) This survey does not treat geography and its possible connections with poverty traps in much detail. Interested readers might start with the review of Ottaviano and Thisse (2004). [59]

Another source of complementarities partly related to geography is positive network externalities in technology adoption. These are often thought to arise from social learning: Local experience with a technology allows the cost of adoption to decrease as the number of adopters in some network gets larger. As well as information spillovers, more adopters of a given technology may lead to the growth of local supply networks for intermediate inputs, repairs and servicing, skilled labor and so on. See, for example, Beath, Katsoulacos and Ulph (1995), Bandiera and Rasul (2003), Conley and Udry (2003), and Baker (2004).

Finally, an area that we have not treated substantially in this survey is *optimal* growth under nonconvexities, as opposed to the fixed savings rate model

[59] See also Limao and Venables (2001) or Redding and Venables (2004) for the empirics of geography and international income variation.

considered in Section 3.3. In other words, how do economies evolve when (i) agents choose investment optimally by dynamic programming, given a set of intertemporal preferences; and (ii) the aggregate production function is nonconvex?

There are two main cases. One is that increasing returns are taken to be external, perhaps as a feedback from aggregate capital stock to the productivity residual, and agents perceive the aggregate production function to be *convex*. In this case there is a subtle issue: In order to optimize, agents must have a belief about how the productivity residual evolves. This may or may not coincide with its actual evolution as a result of their choices. An equilibrium transition rule is a specification of savings and investment behavior such that (a) agents choose this rule given their beliefs; and (b) those choices cause aggregate outcomes to meet their expectations. Existence of such an equilibrium is far from assured. See Mirman, Morand and Reffett (2004) and references therein. Dynamics are still actively being investigated.

The second case is where increasing returns are internal, and agents perceive aggregate production possibilities exactly as they are. These models generate similar poverty traps as were found for fixed savings rates in Section 3.3. The literature is large. An early investigation is Skiba (1978). See also Dechert and Nishimura (1983), who consider a per capita production function $k \mapsto f(k)$ which is convex over a lower region of the state space (capital per worker), and concave over the remainder; and Amir, Mirman and Perkins (1991), who study the same problem using lattice programming. Majumdar, Mitra and Nyarko (1989) study optimal growth for stochastic nonconvex models, as do Nishimura and Stachurski (2004). Dimaria and Le Van (2002) analyze the dynamics of deterministic models with R&D and corruption. [60]

6 Credit Markets, Insurance and Risk

In terms of informational requirements necessary for efficient free market operation and low transaction costs, one of the most problematic of all markets is the intertemporal trade in funds. Here information is usual asymmetric, and lenders face the risk of both voluntary and involuntary default (Kehoe and Levine 1993). Voluntary default is strategic default by borrowers who judge

[60] One should be cautious about interpreting these nonconvex models as aggregative studies of development. The Second Fundamental Welfare Theorem does not apply, so decentralization is problematic.

the expected rewards of repayment to be lower than those of not repaying the loan. Involuntary default occurs when ex post returns are insufficient to cover total loans.

Facing these risks, a standard response of lenders is to make use of collateral (Kiyotaki and Moore 1997). But the poor lack collateral almost by definition; as a result they are credit constrained. Credit constraints in turn restrict participation by the poor in activities with substantial set up costs, as well as those needing large amounts of working capital. For the poor, then, the range of feasible income-generating activities is reduced. Thus, the vicious circle of poverty: Income determines wealth and low wealth restricts collateral. This trap is discussed in Section 6.1. [61]

The market for insurance is similar to the market for credit, in that information is asymmetric and transaction costs are high. This can lead to poverty traps in several ways. In Section 6.2, we study a model where poor agents, lacking access to insurance or credit, choose low risk strategies at the cost of low mean income. These choices reinforce their poverty.

In Section 6.3 we review Matsuyama's (2004) world economy model, where all countries must compete for funds in a global financial market. On one hand, diminishing returns imply that rewards to investment in the poor countries are large. High returns attract funds and investment, and high investment provides a force for convergence. On the other hand, credit markets are imperfect, and rich countries have more collateral. This puts them in a strong position vis-a-vis the poor when competing for capital. The inability of the poor to guarantee returns with collateral is a force for divergence.

6.1 Credit markets and human capital

Consider an economy producing only one good and facing a risk free world interest rate of zero. Agents live for one period. Each has one and only one child. From their parent, the child receives a bequest x. At the beginning of life, each agent chooses between two occupations. The first is to work using a constant returns technology $Y = \bar{w}L$, where Y is output, L is total labor input in this sector, and w is a productivity parameter. The agent supplies all

[61] See also Tsiddon (1992) for a poverty trap model connected to the market for credit. In his model, asymmetric information leads to a moral hazard problem, which restricts the ability of investors to raise money. The market solution involves quantity constraints on loans, the severity of which depends on the level of income.

of his or her labor endowment ℓ_t, and we define $w_t := \bar{w}\ell_t$ as the return to this choice of occupation. We admit the possibility that ℓ_t varies stochastically, so w_t may be random.

Alternatively, the agent may set up a project at cost F. The gross payoff from the project is equal to Q_t. Agents with wealth $x_t < F$ may borrow to cover the costs of the project beyond which they are able to self-finance. They face interest rate $i > 0$, where the excess of the borrowing rate over the risk free rate reflects a credit market imperfection. In this case we have in mind costs imposed on lenders due to the need for supervision and contract enforcement (c.f., e.g., Galor and Zeira 1993, p. 39). These costs are then passed on to the borrower.

The two stochastic productivity parameters w_t and Q_t are draws from joint distribution φ. We assume that $\mathbb{E}\ell_t = 1$, and that $\mathbb{E}w_t = \bar{w} < \mathbb{E}Q_t - F$. Thus, the net return to setting up the project is higher on average than the wage. However, the agent may still choose to work at wage rate w_t if his or her income is relatively low. The reason is that for the poor setting up a project requires finance at the borrowing rate $i > 0$, which may offset the differential return between the two occupations.

Consider the employment decisions and wealth dynamics for each dynasty. Omitting time subscripts, an agent with bequest x has

$$y := \text{lifetime income } = \begin{cases} x + w & \text{if do not set up project;} \\ (x - F)(1 + i) + Q & \text{if set up project, } x < F; \\ (x - F) + Q & \text{if set up project, } x \geq F. \end{cases}$$

Preferences are given by $u(c, b) = (1 - \theta) \ln c + \theta \ln b$, where $\theta \in (0, 1)$ is a parameter, c is consumption and b is bequest to the child. As a result, each agent bequeaths a fraction θ of y; the remainder is consumed. Indirect utility is $v(y) = \gamma + \delta \ln y$, where $\gamma, \delta > 0$ are constants.

To abstract temporarily from the issue of risk aversion let us suppose that each agent can observe his or her idiosyncratic shocks (w_t, Q_t) prior to choosing a field of employment. As a result, agents with $x \geq F$ will choose to set up projects iff $Q - F \geq w$. Agents with $x < F$ will choose the same iff $(x - F)(1 + i) + Q \geq x + w$; in other words, iff

$$x \geq \hat{x} := \frac{w - Q + F(1 + i)}{i}.$$

It follows that dynamics for each dynasty's wealth in this economy are given

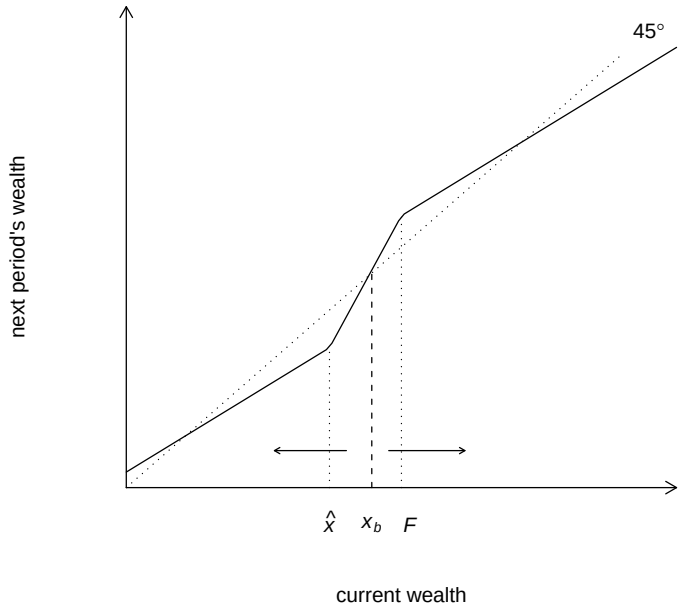

Fig. 19. Deterministic dynamics

by the transition rule

$$x_{t+1} = S_t(x_t); \quad S_t(x_t) = \theta \times \begin{cases} x_t + w_t & \text{if } x_t \leq \hat{x}_t; \\ (x_t - F)(1+i) + Q_t & \text{if } x_t \in (\hat{x}_t, F); \\ x_t - F + Q_t & \text{if } x_t \geq F. \end{cases}$$

Figure 19 illustrates a transition rule S and hence the dynamics of this economy when the two rates of return are constant and equal to their means.[62] For this particular parameterization there are multiple equilibria. Agents with initial wealth less than the critical value x_b will converge to the lower attractor, while those with greater wealth will converge to the high attractor. Given any initial distribution ψ_0 of wealth in the economy, the fraction of agents converging to the lower attractor will be $\int_0^{x_b} \psi_0$. If this fraction is large, average long run income in the economy will be small.

A more realistic picture can be obtained if the productivity parameters are permitted to vary stochastically around their means. This will allow at least some degree of income mobility—perhaps very small—which we tend to observe over time in almost all societies. To this end, suppose that for each agent

[62] The parameters here are set to $\theta = 0.7$, $w = 0.06$, $Q_t \equiv 1.05$, $i = 2$ and $F = 0.65$.

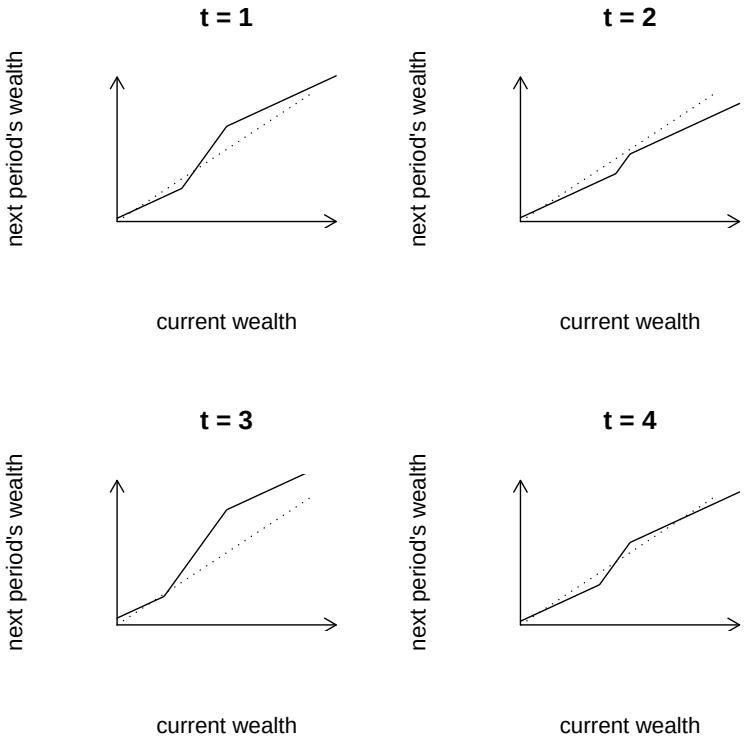

Fig. 20. Stochastic law of motion

and at each point in time the parameters w_t and Q_t are drawn independently across time and agents from a bivariate lognormal distribution. In this case the transition law is itself random, and varies for each agent at each point in time.

Figure 20 shows a simulated sequence of transition rules facing a given agent starting at $t = 1$. At $t = 2$ a negative shock to the project return Q causes the high level attractor to disappear. A *series* of such negative shocks would cause a rich dynasty to loose its wealth. In this case, however, the shocks are iid and such an outcome is unlikely. It turns out that the time 3 shocks are strongly positive.

If the number of agents is large, then the sequence of cross-sectional distributions for wealth over time can be identified with the sequence of marginal probability laws $(\psi_t)_{t\geq 0}$ generated by the Markov process $x_{t+1} = S_t(x_t)$. It is not difficult to prove that this Markov process is ergodic. The intuition and the dynamics are more or less the same as for the nonconvex growth model of Section 3.3. [63] We postpone further details on dynamics until the next section,

[63] As we discussed at length in that section, it would be a mistake to claim that this

which treats another version of the same model.

There are several interpretations of the two sector story with fixed costs described above. One is to take the notion of a project or business literally, in which case F is the cost of set up and working capital which must be paid up before the return is received. Alternatively F might be the cost of schooling, and Q is the payoff to working for skilled individuals.[64] As emphasized by Loury (1981) and others, human capital is particularly problematic for collateral-backed financing, because assets produced by investment in human capital cannot easily be bonded over to cover the risk of default.

Whatever the precise interpretation, the "project" represents an opportunity for the poor to lift themselves out of poverty, while the fixed cost F and the credit market imperfection captured here by i constitute a barrier to taking it. Microeconometric studies suggests that the effects of this phenomenon are substantial. For example, Barrett, Bezuneh and Aboud (2001) analyze the effects of a large devaluation of the local currency that occurred in Côte d'Ivoire in 1994 on rural households. They find that "A macro policy shock like an exchange rate devaluation seems to create real income opportunities in the rural sector. But the chronically poor are structurally impeded from seizing these opportunities due to poor endowments and liquidity constraints that restrict their capacity to overcome the bad starting hand they have been dealt." (Barrett et al. 2001, p. 12)

The same authors also study a local policy shock associated with food aid distribution in Keyna. According to this study, "The wealthy are able to access higher-return niches in the non-farm sector, increasing their wealth and reinforcing their superior access to strategies offering better returns. Those with weaker endowments ex ante are, by contrast, unable to surmount liquidity barriers to entry into or expansion of skilled non-farm activities and so remain

---

ergodicity result in some way overturns the poverty trap found in the deterministic version.

[64] For these and related stories see Ray (1990), Ray and Streufert (1993), Banerjee and Newman (1993), Galor and Zeira (1993), Ljungqvist (1993), Freeman (1996), Quah (1996), Aghion and Bolton (1997), Piketty (1997), Matsuyama (2000) Mookherjee and Ray (2003) and Banerjee (2003). Yet another possible interpretation of the model is that F is the cost of moving from a rural to an urban area in order to find work. In the presence of imperfect capital markets, such costs—interpreted broadly to include any extra payments incurred when switching to the urban sector—may help to explain the large and growing differentials between urban and rural incomes in some modernizing countries.

trapped in lower return...livelihood strategies." (Barrett et al. 2001, p. 15).

6.2 Risk

For the poor another possible source of historical self-reinforcement is risk. In the absence of well-functioning insurance and credit markets, the poor find ways to mitigate adverse shocks and to smooth out their consumption. One way to limit exposure is to pass up opportunities which might seem on balance profitable but are thought to be too risky. Another strategy is to diversify activities; and yet another is to keep relatively large amounts of assets in easily disposable form, rather than investing in ventures where mean return is high. All of these responses of the poor to risk have in common the fact that they tend to lower mean income and reinforce long run poverty.

A simple variation of the model from the previous section illustrates these ideas.[65] Let the framework of the problem be the same, but current shocks are no longer assumed to be previsible. In other words, each agent must decide his or her career path before observing the shocks w_t and Q_t which determine individual returns in each sector. Given that preferences are risk averse (indirect utility is $v(y) = \gamma + \delta \ln y$), the agent makes these decisions as a function not only of mean return but of the whole joint distribution. Regarding this distribution, we assume that both shocks are lognormal and may be correlated.

Lenders also cannot observe these variables at the start of time t, and hence the borrowing rate $i = i(x)$ reflects the risk of default, which in turn depends on the wealth x of the agent. In particular, default occurs when Q_t is less than the debtor's total obligations $(F - x)(1 + i(x))$. In that case the debtor pays back what he or she is able. Lifetime income is therefore

$$y = \begin{cases} x + w & \text{if do not set up project;} \\ \max\{0, (x - F)(1 + i(x)) + Q\} & \text{if set up project, } x < F; \\ (x - F) + Q & \text{if set up project, } x \geq F. \end{cases}$$

It turns out that in our very simplistic environment agents will never borrow, because when shocks are lognormal agents with $x < F$ who borrow will have $\mathbb{P}\{y = 0\} > 0$, in which case $\mathbb{E}v(y) = -\infty$. (If $x \geq F$ agents may still choose to work for a wage, depending on the precise joint distribution.) The result that agents never borrow is clearly unrealistic. For more sophisticated

[65] What follows is loosely based on Banerjee (2003).

versions of this model with similar dynamics see Banerjee (2003) or Checchi and García-Peñalosa's (2004).

Because agents never borrow, the dynamics for the economy are just

$$x_{t+1} = \theta(x_t + w_t) \cdot \mathbb{1}\{x_t \in D\} + \theta(x_t - F + Q_t) \cdot \mathbb{1}\{x_t \notin D\},$$

where $D := \{x : \mathbb{E}\, v(x + w_t) \geq \mathbb{E}\, v(x - F + Q_t)\}$. (As before, $\mathbb{1}$ is the indicator function.) The stochastic kernel Γ for this process can be calculated separately for the two cases $x \in D$ and $x \notin D$ using the same change-of-variable technique employed in Section 3.1. The calculation gives

$$\Gamma(x, x') = \varphi_w \left(\frac{x' - \theta x}{\theta} \right) \frac{1}{\theta} \cdot \mathbb{1}\{x \in D\} + \varphi_Q \left(\frac{x' - \theta(x - F)}{\theta} \right) \frac{1}{\theta} \cdot \mathbb{1}\{x \notin D\},$$

where φ_w and φ_Q are the marginal densities of w and Q respectively.

A two-dimensional plot of the kernel is given in Figure 21, where the parameters are $F = 1$, $\theta = 0.45$, $\ln w \sim N(0.1, 1)$, and $\ln Q \sim N(1.4, 0.2)$. The dark unbroken line is the 45^o line. Lighter areas indicate greater elevation, in this case associated with a collection of probability mass. For the parameters chosen, agents work precisely when $x < F$, and set up projects when $x \geq F$ (so that $D = [0, F]$), despite the fact that mean returns to the project are higher than those of working. The concentration of probability mass along the 45^o line in the region $D = [0, F]$ implies that poverty will be strongly self-reinforcing.

Nevertheless, lognormal shocks give poor individuals a non-zero probability of becoming rich at every transition; and the rich can eventually become poor, although it might take a sequence of negative shocks. The rate of mixing depends on the parameters that make up the law of motion and the variance of the shock. Usually some small degree of mixing is a more natural assumption than none. The mixing causes the corresponding Markov chain to be ergodic. This is the case regardless of how small the tails of the shocks are made. [66] For more details on ergodicity see the technical appendix.

To summarize, the poor are not wealthy enough to self-insure, and as a result choose income streams that minimize risk at the expense of mean earnings. The effect is to reinforce poverty. A number of country studies provide evidence of this behavior. [67] Dercon (2003) finds that the effects on mean income are substantial. In a review of the theoretical and empirical literature, he estimates

[66] But not necessarily so if the shocks have bounded support.
[67] See, for example, Morduch (1990) and Dercon (1998).

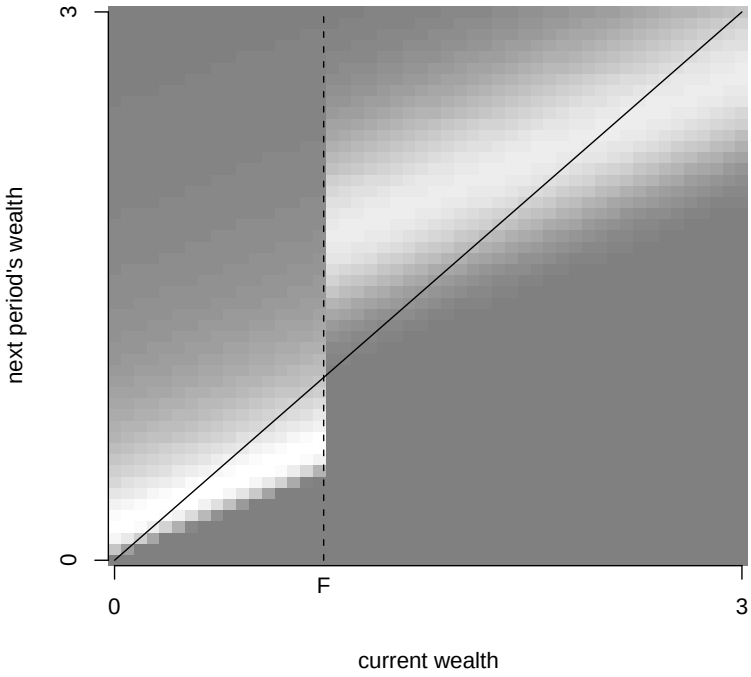

Fig. 21. Stochastic kernel

that incomes of the poor could be 25–50% higher on average if they had the same protection against shocks that the rich had as a result of their wealth (Dercon 2003, p. 14).

A more sophisticated model of the relationship between risk and development is Acemoglu and Zilibotti (1997). In their study, indivisibilities in technology imply that diversification possibilities are tied to income. An increase in investment raises output, which then improves the extent of diversification. Since agents are risk averse, greater diversification encourages more investment. In the decentralized outcome investment is too small, because agents do not take into account the effect of their investment on the diversification opportunities of others.

6.3 Credit constraints and endogenous inequality

Next we consider a world economy model with credit market imperfections due to Matsuyama (2004). For an individual country, the formulation of the problem is as follows. A unit mass of agents live for two periods each, supplying

one unit of labor in the first period of life and consuming all their wealth in the second. Per capita output of the consumption good is given by $y_t = f(k_t)\xi_t$, where f is a standard concave production function, k_t is the capital stock and $(\xi_t)_{t\geq 0}$ is a noise process. Once the current shock ξ_t is realized production then takes place. Factor markets are competitive, so that labor and capital receive payments $w_t = [f(k_t) - k_t f'(k_t)]\xi_t =: w(k_t, \xi_t)$ and $\varrho_t = f'(k_t)\xi_t$ respectively.

Current wages w_t are invested by young agents to finance consumption when old. Funds can be invested in a competitive capital market at gross interest rate R_{t+1}, or in a project which transforms one unit of the final good into Q units of the capital good at the start of next period. It is assumed that projects are discrete and indivisible: Each agent can run one and only one project. [68] They will need to borrow $1 - w_t$, the excess cost of the project over wages.

Our agents are risk neutral. Time t information is summarized by the information set $\mathscr{F}_t$, and we normalize $\mathbb{E}[\xi_{t+1} \,|\, \mathscr{F}_t] = 1$. In the absence of borrowing constraints, agents choose to start a project if $\mathbb{E}[\varrho_{t+1}Q - R_{t+1}(1 - w_t) \,|\, \mathscr{F}_t] \geq \mathbb{E}[R_{t+1}w_t \,|\, \mathscr{F}_t]$. This is equivalent to

$$\mathbb{E}[R_{t+1} \,|\, \mathscr{F}_t] \leq \mathbb{E}[\varrho_{t+1}Q \,|\, \mathscr{F}_t]. \tag{26}$$

However, it is assumed that borrowers can credibly commit to repay only a fraction λ of revenue $\varrho_{t+1}Q$. Thus $\lambda \in [0, 1]$ parameterizes the degree of credit market imperfection faced by borrowers in this economy. As a result, agents can start a project only when $\mathbb{E}[\lambda\varrho_{t+1}Q \,|\, \mathscr{F}_t]$ exceeds $\mathbb{E}[R_{t+1}(1 - w_t) \,|\, \mathscr{F}_t]$, the cost of funds beyond those which the agent can self-finance. In other words, when $w_t = w(k_t, \xi_t) < 1$, we must have

$$\mathbb{E}[R_{t+1} \,|\, \mathscr{F}_t] \leq \Lambda(k_t, \xi_t)\mathbb{E}[\varrho_{t+1}Q \,|\, \mathscr{F}_t], \tag{27}$$

where $\Lambda(k_t, \xi_t) := \lambda/(1 - w_t)$ Given the profitability constraint (26), the borrowing constraint (27) binds only when $\Lambda(k_t, \xi_t) < 1$. [69]

In the case of autarky it turns out that adjustment of the domestic interest rate can always equilibrate domestic savings and domestic investment. Since each generation of agents has unit mass, total domestic savings is just w_t. If $w_t \geq 1$, then all agents run projects and total output of the capital good is

[68] Put differently, we imagine that output is Q units of capital good for all investment levels greater than or equal to one. See the original model for a more general technology.

[69] Of course if $w_t \geq 1$ then all agents can self-finance and the borrowing constraint never binds.

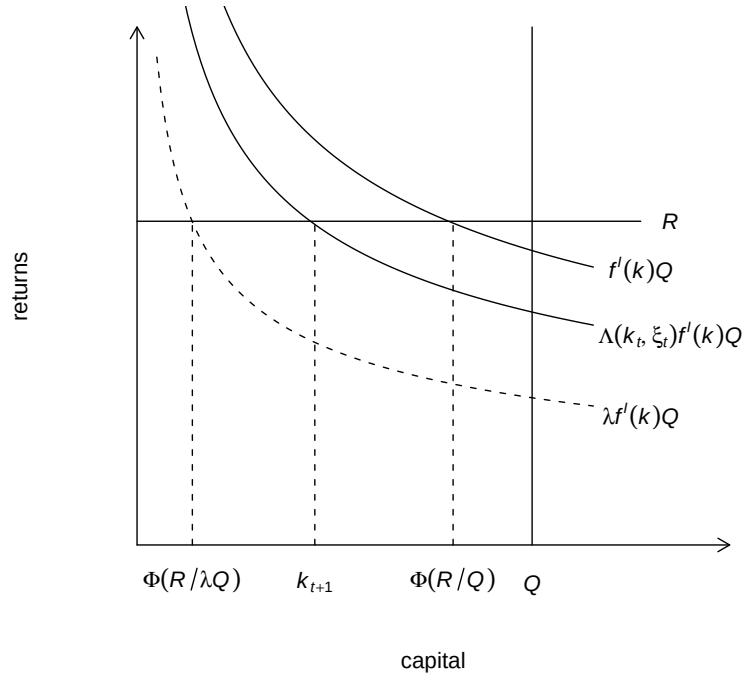

Fig. 22. Domestic investment

Q. If $w_t < 1$, then w_t is equal to the fraction of agents who can start projects. Output of the capital good is $w_t Q$. Assuming that capital depreciates totally in each period, we get $k_{t+1} = \min\{w(k_t, \xi_t)Q, Q\}$. If, for example, technology in the final good sector is Cobb-Douglas, so that $f(k) = Ak^\alpha$, where $\alpha < 1$, then $w(k_t, \xi_t) = (1-\alpha)Ak^\alpha \xi_t$. For $\xi_t \equiv 1$ there is a unique and globally stable steady state k^*.

A more interesting case for us is the small open economy. Here a world interest rate of R is treated as fixed and given. The final good is tradable, so international borrowing and lending are allowed. However, the project must be run in the home country (no foreign direct investment) and factors of production are nontradable.

In the open economy setting there is a perfectly elastic supply of funds at the world interest rate R. The effective demand for funds on the part of domestic projects is determined by (26) and (27). The right hand side of (26) is the expected marginal product of capital in this sector, $\mathbb{E}[\varrho_{t+1}Q \,|\, \mathscr{F}_t]$. Since $\mathbb{E}[\xi_{t+1}|\mathscr{F}_t] = 1$ we have $\mathbb{E}[\varrho_{t+1}Q \,|\, \mathscr{F}_t] = f'(k_{t+1})Q$. Absent borrowing constraints, investment adjusts to equalize $f'(k_{t+1})Q$ with R. Figure 22 shows the intersection of the curve $k \mapsto f'(k)Q$ with the horizontal supply curve R at

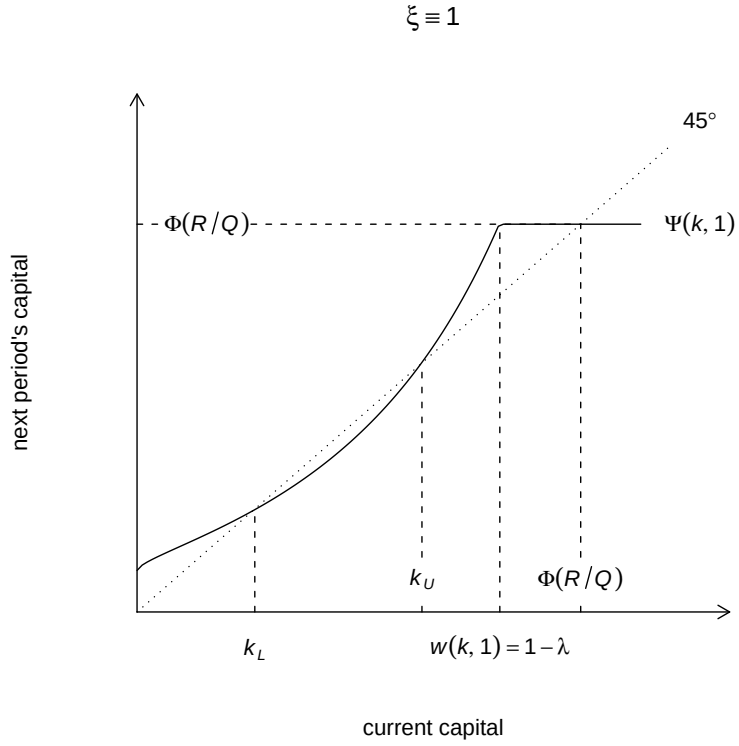

Fig. 23. Deterministic dynamics

$\Phi(R/Q)$, where Φ is the inverse function of f'.

As the figure is drawn, however, $\Lambda(k_t, \xi_t) < 1$, perhaps because the capital stock is small, or because of an adverse productivity shock. As a result, the borrowing constraint is binding, and next period's capital stock k_{t+1} is given by the intersection of the effective demand curve $k \mapsto \Lambda(k_t, \xi_t) f'(k) Q$ and the supply curve R.

Assuming that $\Phi(R/Q) < Q$ as drawn in the figure, the law of motion for the capital stock is $k_{t+1} = \Psi(k_t, \xi_t)$, where

$$\Psi(k, \xi) := \begin{cases} \Phi[R/\Lambda(k, \xi)Q] & \text{if } w(k, \xi) < 1 - \lambda; \\ \Phi(R/Q) & \text{if } w(k, \xi) \geq 1 - \lambda. \end{cases} \tag{28}$$

For $w(k_t, \xi_t) < 1 - \lambda$ we have $\Lambda(k_t, \xi_t) < 1$ and the borrowing constraint binds. Domestic investment is insufficient to attain the unconstrained equilibrium $\Phi(R/Q)$. In this region of the state space, the law of motion $k \mapsto \Psi(k, \xi)$ is increasing in k. Behind this increase lies a credit multiplier effect: Greater domestic investment increases collateral, which alleviates the borrowing constraint. This in turn permits more domestic investment, which increases col-

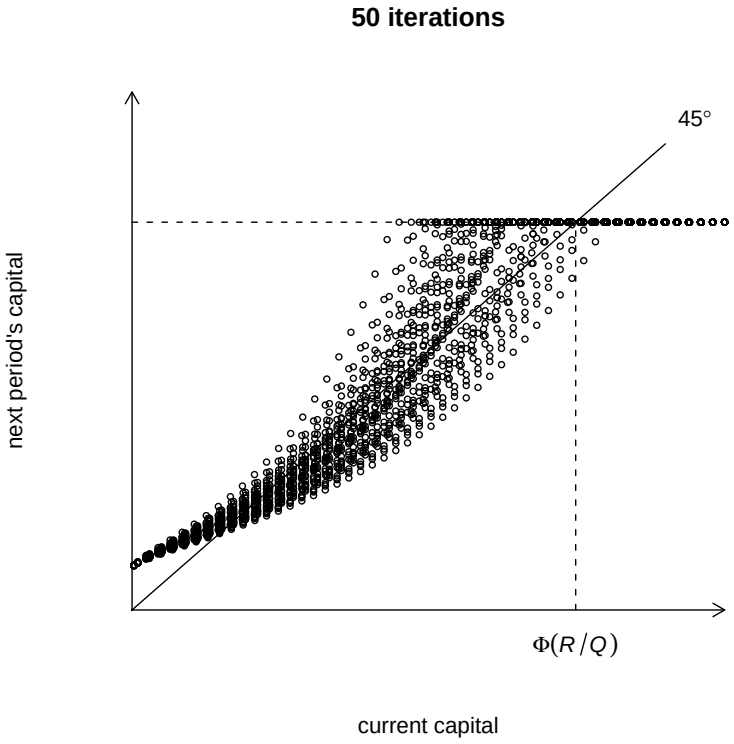

Fig. 24. Stochastic dynamics

lateral, and so on. Individual agents do not take into account the effect of their actions on the borrowing constraint.

Figure 23 shows the law of motion when $\xi_t \equiv 1$. As drawn, there is a poverty trap at k_L and another attractor at $\Phi(R/Q)$. Countries with $k_t > k_U$ tend to $\Phi(R/Q)$, while those with $k_t < k_U$ tend to k_L. Figure 24 shows stochastic dynamics by superimposing the first 50 laws of motion from a simulation on the 45^o diagram. The shocks $(\xi_t)_{t\geq 0}$ are independent and identically distributed. [70] Notice that for particularly good shocks the lower attractor k_L disappears, while for particularly bad shocks the higher attractor at $\Phi(R/Q)$ vanishes.

Figure 25 shows a simulated time series for the same parameters as Figure 24 over 400 periods. At around $t = 290$ the economy transitions to the higher attractor $\Phi(R/Q)$. Subsequent fluctuations away from this equilibrium are due to shocks so negative that $\Phi(R/Q)$ ceases to be an attractor (see Figure 24).

The story does not end here. What is particularly interesting about Matsuyama's study is his analysis of symmetry-breaking. He shows the following

[70] The production function is $f(k) = k^\alpha$. The shock is lognormal. The parameters are $\alpha = 0.59$, $Q = 2.4$, $\lambda = 0.40$, $R = 1$ and $\ln \xi \sim N(0.01, 0.08)$.

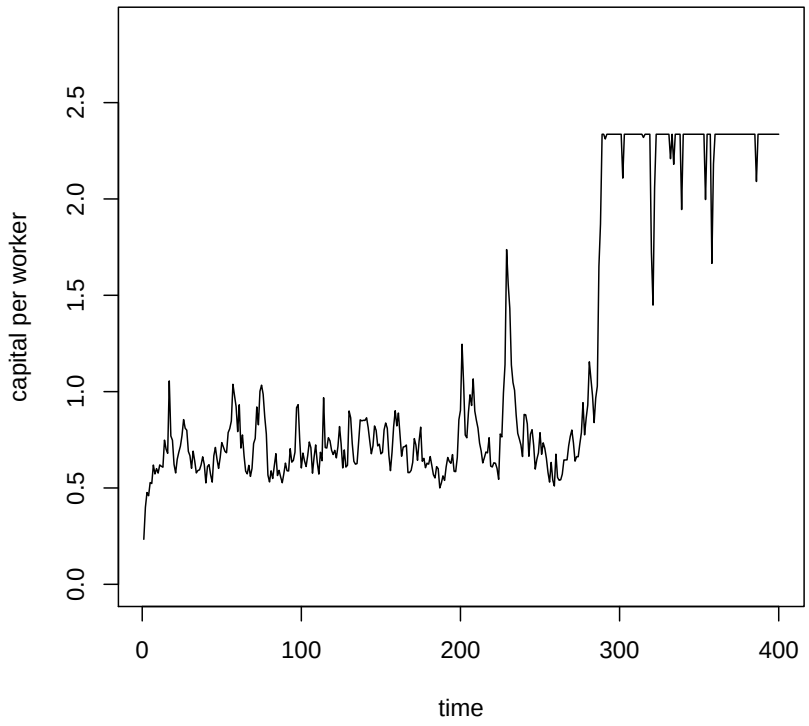

Fig. 25. Time series

for a large range of parameter values: For a world economy consisting of a continuum of such countries, the deterministic steady state for autarky, which is k^* defined by $k^* = w(k^*, 1)Q$, is precisely k_U, the *unstable* steady state for each country under open international financial markets and a world interest rate that has adjusted to equate world savings and investment. Figure 26 illustrates the situation.

Thus, the symmetric steady state after liberalization, where each country has capital stock k^*, is unstable and cannot be maintained under any perturbation. The reason is that countries which suffer from bad (resp., good) shocks are weakened (resp., strengthened) in terms of their ability to guarantee returns on loans, and therefore to compete in the world financial market. This leads to a downward (resp. upward) spiral. Under these dynamics the world economy is polarized *endogenously* into rich and poor countries.

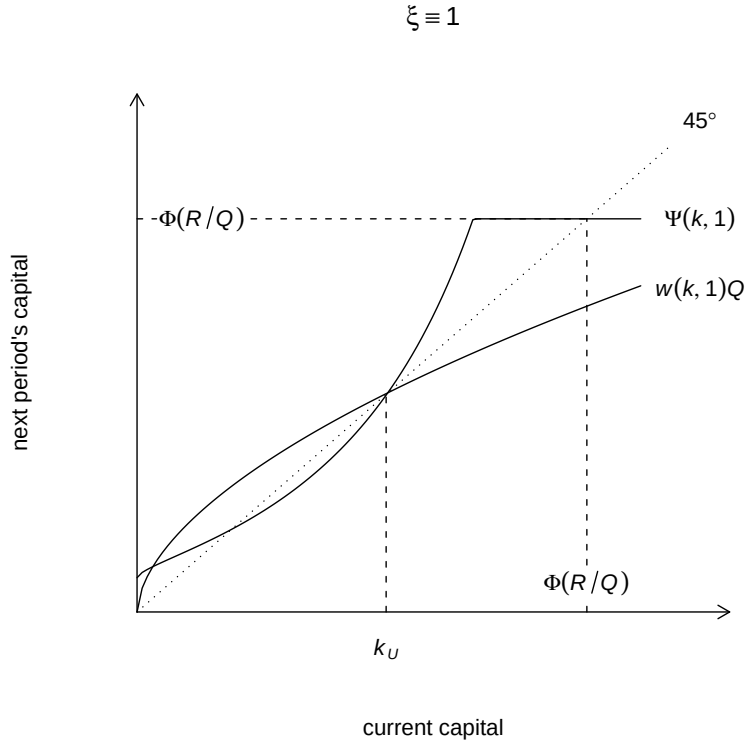

Fig. 26. Symmetry-breaking

7 Institutions and Organizations

The fundamental economic problem is scarcity. Since the beginning of life on earth, all organisms have engaged in competition for limited resources. The welfare outcomes of this competition have ranged from efficient allocation to war, genocide and extinction. It is the *rules of the game* which determine the social welfare consequences. More precisely, it is the long run interaction between the rules of the game and the agents who compete.

Institutions—which make up the rules of the game—were at one time thought to have strong efficiency properties in equilibrium. To a large extent, this is no longer the case (for an introduction to the literature, see, for example North 1993, 1995; or Hoff 2000). Institutions can either reinforce market failure or themselves be the source of inefficiency. Moreover, institutions are path dependent, so that bad equilibria forming from historical accident may be locked in, causing poverty to persist.

Among the set of institutions, the state is one of the most important determinants of economic performance; and one of the most common kinds of

"government failure" is corruption.[71] In Section 7.1 we review why corruption is thought to be not only bad for growth and development, but also self-reinforcing.

Section 7.2 then looks at the kinship system, a kind of institution that arises spontaneously in many traditional societies to address such market problems as lack of formal insurance. We consider how these systems may potentially form a local poverty trap, by creating hurdles to adoption of new techniques of production. Although the aggregate outcome is impoverishing, it is shown that the kinship system may nevertheless fail to be dismantled as a result of individual incentives.

7.1 Corruption and rent-seeking

Corruption is bad for growth. A number of ways that corruption retards development have been identified in the literature. First, corruption tends to reduce the incentive to invest by decreasing net returns and raising uncertainty. This effect impacts most heavily on increasing returns technologies with large fixed costs. Once costs are sunk, investors are subject to hold-up by corrupt officials, who can extort large sums. Also, governments and officials who have participated in such schemes find it difficult to commit credibly to new infrastructure projects.

Second, corruption diverts public expenditure intended for social overhead capital. At the same time, the allocation of such capital is distorted, because officials prefer infrastructure projects where large side payments are feasible. Corruption also hinders the collection of tax revenue, and hence the resource base of the government seeking to provide public infrastructure. Again, a lack of social overhead capital such as transport and communication networks tends to impact more heavily on the modern sector.

Third, innovators suffer particularly under a corrupt regime, because of their higher need for such official services as permits, patents and licenses (De Soto 1989; Murphy, Shleifer and Vishny 1993). The same is true for foreign investors, who bring in new technology. Lambsdorff (2003) finds that on average

[71] Following the excellent survey of Bardhan (1997), we define corruption to be "the use of public office for private gains, where an official (the agent) entrusted with carrying out a task by the public (the principal) engages in some sort of malfeasance for private enrichment which is difficult to monitor for the principal" (Bardhan 1997, p. 1321).

a 10% worsening in an index of transparency and corruption he constructs leads to a fall of 0.5 percentage points the ratio of foreign direct investment to GDP.

Not only is corruption damaging to growth, but it also tends to breed more corruption. In other words, there are complementarities in corruption and other rent-seeking activities. It is this increasing returns nature of corruption which may serve to lock in poverty. Some equilibria will be associated with high corruption and low income, where many rent-seekers prey on relatively few producers. Others will have the reverse.

The decision of one official to seek bribes will increase expected net rewards to bribe taking in several ways. The most obvious of these complementarities is that when many agents are corrupt, the probability of detection and punishment for the marginal official is lowered. A related point is that if corruption is rampant then detection will not entail the same loss of reputation or social stigma as would be the case in an environment where corruption is rare. In other words, corruption is linked to social norms, and is one of the many reasons why they matter for growth. [72] Third, greater corruption tends to reduce the search cost for new bribes.

Murphy, Shleifer and Vishny (1993) point out yet another source of potential complementarities in rent-seeking. Their idea is that even if returns to predation are decreasing in an absolute sense, they may still be increasing *relative* to production. This would occur if the returns to productive activities—the alternative when agents make labor supply decisions—fall *faster* than those to rent-seeking as the number of rent-seekers increases. The general equilibrium effect is that greater rent-seeking decreases the (opportunity) cost of an additional rent-seeker.

In their model there is a modern sector, where output by any individual is equal to a, and a subsistence technology with which agents can produce output $c < a$. Alternatively, agents can prey on workers, obtaining for themselves an amount no more than b per person, but limited by the amount of output available for predation. This in turn depends on the number of people working in the productive sectors. The authors assume, in addition, that only modern

[72] Transparency International's 2004 Global Corruption Report cites a statement by the president of the Government Action Observatory in Burundi that "corruption has spread, openly and publicly, to such an extent that those who practice it have become stronger than those who are fighting against it. This has led to a kind of *reversal of values*." (Emphasis added.)

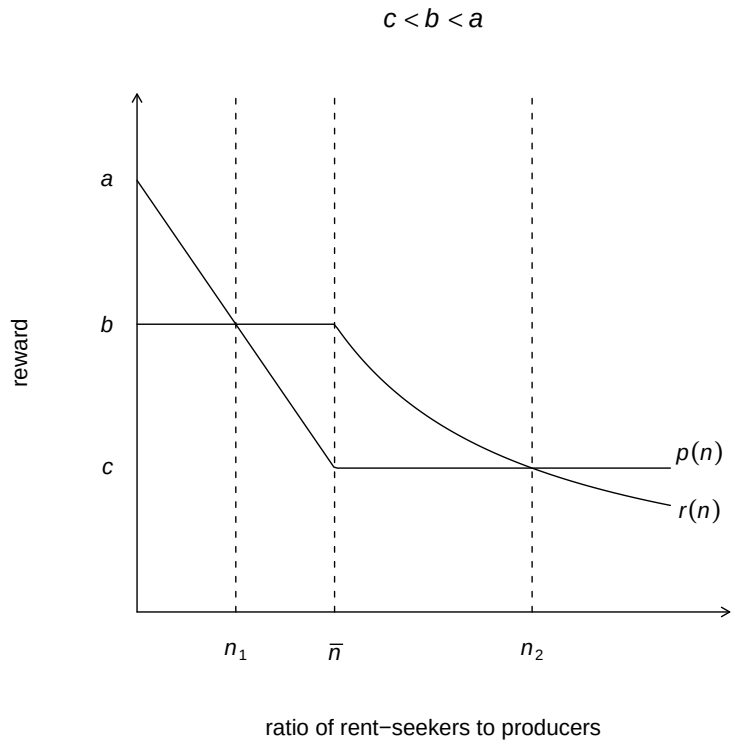

Fig. 27. Rewards to rent-seeking and production

sector output can be appropriated by rent-seekers, so returns to subsistence farming are always equal to c.

An equilibrium is an allocation of labor across the different occupations such that returns to all are equal, and no individual agent can increase their reward by acting unilaterally. To locate equilibria, we now discuss returns to working in the different sectors as a function of n, which is defined to be the number of rent seekers for each modern sector producer.

Returns to employment in the subsistence sector are always given by c. Rent-seekers all take a slice b of the pie until their ratio to modern sector producers n satisfies $a - bn = c$. At this ratio, which we denote $\bar{n}$, the earnings of the modern sector producers fall to that of the subsistence producers, and the rent-seekers must reduce the size of their take (or earn nothing). After $\bar{n}$, the rent-seekers each take $(a - c)/n$, exactly equalizing returns to modern sector production and subsistence.

Let $p(n)$ and $r(n)$ be returns to modern sector production and rent-seeking respectively, so that $p(n) = (a - bn)\mathbb{1}\{n < \bar{n}\} + c\mathbb{1}\{n \geq \bar{n}\}$ and $r(n) = b\mathbb{1}\{n < \bar{n}\} + \frac{a-c}{n}\mathbb{1}\{n \geq \bar{n}\}$. These curves are drawn in Figure 27. The figure shows

that there are multiple equilibria whenever the parameters satisfy $c < b < a$. One is where all work in the modern sector. Then $n = 0$, and $p(n) = p(0) = a > r(n) = b > c$. This allocation is an equilibrium, where all agents earn the relatively high revenue available from modern sector production. In addition, because $b > c$, the payoff functions $n \mapsto p(n)$ and $n \mapsto r(n)$ intersect above $\bar{n}$, at n_2. This is again an equilibrium, where the payoffs to working in the subsistence sector, the modern sector and the rent-seeking sector are all equal and given by c.

Notice that b does not affect income in either of these two equilibria. However, it does affect which one is likely to prevail. If b declines below c, for example, then only the good equilibrium will remain. If it increases above a, then the bad equilibrium will be unique. When there are two equilibria, higher b increases the basin of attraction for the bad equilibrium under myopic Marshallian dynamics.

In summary, the model exhibits a general equilibrium complementarity to corruption, which helps illustrate why corruption tends to be self-reinforcing, therefore causing poverty to persist. These kind of stories are important, because in practice corruption and related crimes tend to show a great deal of variation across time and space, often without obvious exogenous characteristics that would cause such variation.

There are many other models which exhibit self-reinforcement and path dependence in corruption. One is Tirole (1996), who studies the evolution of individual and group reputation. In his model, past behavior provides information about traits, such as honesty, ability and diligence. However, individual behavior is not perfectly observed. As a result, actions of the group or cohort to which the individual belongs have predictive power when trying to infer the traits of the individual. It follows that outcomes and hence incentives for the individual are affected by the actions of the group.

In this case we can imagine the following scenario. Young agents progressively joint an initial cohort of workers, a large number of whom are known to be corrupt. Because the behavior of new agents is imperfectly observed, they inherit the suspicion which already falls on the older workers. As a result, they may have little incentive to act honestly, and drift easily to corruption. This outcome in turn perpetuates the group's reputation for corrupt action.

One can contemplate many more such feedback mechanisms. For example, it is often said that the low wages of petty officials drive them to corruption. But if corruption lowers national output and hence income, then this will reduce

the tax base, which in turn decreases the amount of resources with which to pay wages. For further discussion of corruption and poverty traps see Bardhan (1997). [73]

7.2 Kinship systems

All countries and economies are made up of people who at one time were organized in small tribes with their own experiences, customs, taboos and conventions. Over time these tribes were united into cities, states and countries; and the economies within which they operated grew larger and more sophisticated. Some of these economies became vibrant and strong. Others have stagnated. According to North (1993, p. 4),

> The reason for differing success is straightforward. The complexity of the environment increased as human beings became increasingly interdependent, and more complex institutional structures were necessary to capture the potential gains from trade. Such evolution required that the society develop institutions that will permit anonymous, impersonal exchange across time and space. But to the extent that "local experience" had produced diverse mental models and institutions with respect to the gains from such cooperation, the likelihood of creating the necessary institutions to capture the gains from trade of more complex contracting varied.

North and other development thinkers have emphasized that success depends on institutions rewarding efficient, productive activity; and having sufficient flexibility to cope with the structural changes experienced in the transition to modernity. The degree of flexibility and ability to adapt determines to what extent an economy can take advantage of the application of science, of new techniques, and of specialization and the effective division of labor.

To illustrate these ideas, in this section we review recent analysis of the "kin" system, an institution found in many traditional societies, usually defined as an informal set of shared rights and obligations between extended family and friends for the purpose of mutual assistance. [74] Where markets and state institutions are less developed, the kin system replaces formal insurance and

[73] For other kinds of poverty traps arising through interactions between the state and markets, see, for example, Hoff and Stiglitz (2004), or Gradstein (2004).
[74] A related form of local poverty traps is those generated by neighborhood effects. See Durlauf (2004).

social security by implementing various forms of community risk sharing, and by the provision of other social services (Hoff and Sen 2004). The question we ask in the remainder of this section is how, in the process of development, the kin system interacts with the nascent modern sector, and whether or not it may serve to *impede* the diffusion of new technologies and the exploitation of gains from trade.

An interesting example of such analysis is Baker (2004), who interprets Africa's lack of robust growth as a failure of technology diffusion caused by institutional barriers. She presents a model of a rural African village, and suggests two path dependent mechanisms related to the kin system which may serve to retard growth. Both of them involve community risk sharing, and indicate how technology adoption may have positive network externalities beyond simple social learning.

The first mechanism concerns risk sharing among kin members in the form of interest free "loans" with no fixed repayment schedule. Kin members in need can expect to receive these transfers from the better off, who in turn must comply or face various social sanctions (including, in the countries Baker studied, accusations of witchcraft as the source of their good fortune). Beyond the obvious incentive effects on those who might seek to improve their circumstances by using new technology, Baker suggests that a kin member who adopts new techniques may face significant additional uncertainty vis-a-vis income net of transfers if the kin group makes mistakes in estimating his or her true profits. Such a miscalculation may lead to excessive demands for "gifts" or other transfers.

As Baker points out, the uncertainty effect of the transfers will be larger for those who adopt new technology, where costs and revenue are harder for the other kin to estimate. For example, the kin may have difficulty in measuring the real costs of new techniques, such as fertilizer or more expensive seed, causing them to overestimate true profits. (New techniques are often associated with higher revenues combined with higher costs.)

On the other hand, cost and net profit will be easier to estimate if more kin members have experience of the new techniques. In other words, uncertainty will be mitigated for the marginal adopter if more of his or her fellow kin members adopt the same technology. As a result there are positive network externalities in terms of expected cost. This mechanism generates a coordination problem, whereby a critical mass of co-adopters may be necessary to make the new technology more attractive than the old. This need for coordination

may present a barrier to adoption.

At the same time, the coordination barrier would not seem to be insurmountable. Perhaps a kin group can negotiate to a better equilibrium when the gains are genuinely large? Baker suggests that in fact this will not be easy, because the risk sharing problem interacts with other path dependent institutions.

One of these concerns the nature of old age insurance among self-employed African farmers. Given the lack of state pensions and the difficulty of accumulating assets, support in old age may be contingent on the old providing some form of useful service to the household from which resources are to be acquired. And the most likely candidate for productive service from elderly farmers is the benefit of their experience. The problem here is that the value of this service provided by the old depends on a stagnant technology which does not change from generation to generation. Under new techniques the experience of old farmers may become redundant. If old farmers are able to resist the introduction of new techniques then it will be in their interests to do so. Once again, this is a source of multiple equilibria. The reason is that if the newer technology were already adopted then presumably it would be supported by old farmers, because this is then the methodology in which they have experience.

Another interesting study of the kin system has been conducted recently by Hoff and Sen (2004). They analyze the migration of kin members from rural areas to modern sector jobs, and show how network externalities arise in the migration decision. Even if kin members can coordinate on simultaneous migration, Hoff and Sen suggest that the kin group may put up barriers to prevent the loss of their most productive members. It is shown that even when the kin decisions are made by a majority, the barriers can be inefficient in terms of aggregate group welfare.

A simplified version of their story runs as follows. Kin members who do migrate may find themselves besieged by their less fortunate brethren. The latter come seeking not only "gifts" of cash transfers, but also help in finding jobs in the modern sector for themselves. Realizing this, employers will find it profitable to restrict employment of kin members. Here we assume these barriers are so high that migration while maintaining kin ties is never optimal. As a result, kin members choose between remaining in the rural sector or migrating while breaking their kin ties.

The kin group is thought of as a continuum of members with total mass of one. A fraction $\bar{\alpha} \in (0, 1)$ of the kin receive job offers in the modern sector.

The utility of remaining in the rural sector is

$$u_s(\alpha) = s_0 + b(1 - \alpha), \tag{29}$$

where here and elsewhere $\alpha \leq \bar{\alpha}$ is the fraction of the kin who break ties and move. The constant s_0 is a stand-alone payoff to rural occupation. The constant b is positive, so that utility of staying is higher when more kin members remain. On the other hand, the utility of moving to the modern sector is

$$u_m(\alpha) = m_0 - c(1 - \alpha), \tag{30}$$

where m_0 is a payoff to working in the modern sector and c is a positive constant. The function $\alpha \mapsto c(1 - \alpha)$ is the cost of ending kin membership (measured in the utility equivalent of various social sanctions which we will not describe). It is assumed that the cost of breaking kin ties for the marginal kin member decreases as more members leave the kin group and shift to the modern sector. [75]

Consider the interesting case, where $u_m(0) < u_s(0)$ and $u_m(\bar{\alpha}) > u_s(\bar{\alpha})$. A pair of curves for (29) and (30) which fit this pattern are depicted in Figure 28. If no kin members take modern sector jobs then it is not optimal to do so for an individual member. On the other hand, if all those with offers take up jobs, then their utility payoff will be higher than the payoff of those who remain.

If, as in the figure, we also have $u_m(\bar{\alpha}) > u_s(0)$, then it seems plausible that the kin members with job offers will coordinate their way to the equilibrium where all simultaneously move to modern sector jobs. Kin groups are not as diffuse as some other groups of economic actors, and coordination should prove correspondingly less problematic.

However, Hoff and Sen show that when kin members are heterogenous, a majority may take steps to forestall coordination by the productive critical mass on movement to the modern sector. Moreover, they may do so even when this choice is inefficient in terms of the kin's aggregate group payoff. In doing so, the kin group becomes a "dysfunctional institution," responsible for enforcing an inefficient status quo.

[75] Hoff and Sen cite Platteau (2000), who writes that to leave and enter the modern sector, a kin member "needs the protection afforded by the deviant actions of a sufficient number of other innovators in his locality. Rising economic opportunities alone will usually not suffice to generate dynamic entrepreneurs in the absence of a *critical mass* of cultural energies harnessed towards countering social resistance..." (Emphasis added.)

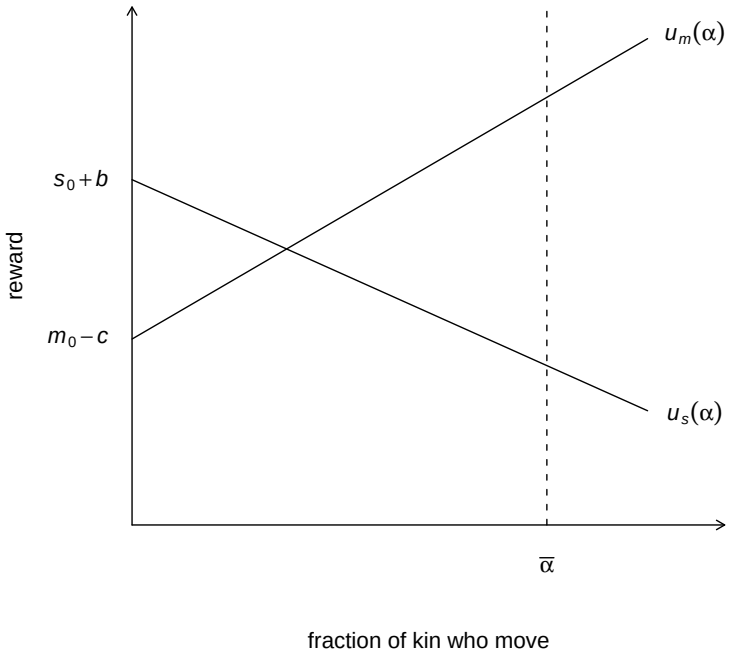

Fig. 28. Rewards to staying and moving

Their example works as follows. Consider a two stage game. First, the kin set the exit cost parameter c by majority vote. The two possible values are c^a and c^b, where $c^a < c^b$. Next, job offers are received, and kin members decide whether or not to move. Coordination always takes place in the situation where those with job offers together have a higher payoff in the modern sector.

There are now two types of kin members, those with high "ability" and those with low. The first type are of measure γ, and have probability α_H of getting a job offer from the modern sector. The second type are of measure $1 - \gamma$, and have probability α_L of getting a job offer from the modern sector, where $0 < \alpha_L < \alpha_H < 1$. We assume that $\gamma < 1/2$, so high ability types are in the minority. Also, we assume that $\gamma\alpha_H + (1-\gamma)\alpha_L = \bar{\alpha}$. Ex post, the law of large numbers implies that the fraction of kin members who get job offers will again be $\bar{\alpha}$.

Regarding parameters, we assume that $u_m^a(\alpha) := m_0 - c^a(1 - \alpha)$ satisfies $u_m^a(\bar{\alpha}) > u_s(0)$, but $u_m^b(\alpha) := m_0 - c^b(1-\alpha)$ satisfies $u_m^b(\bar{\alpha}) < u_s(0)$. The first inequality says that under the low cost regime, the payoff to working in the modern sector is greater than that of staying if all with job offers move. The second inequality says that under the high cost regime the opposite is true.

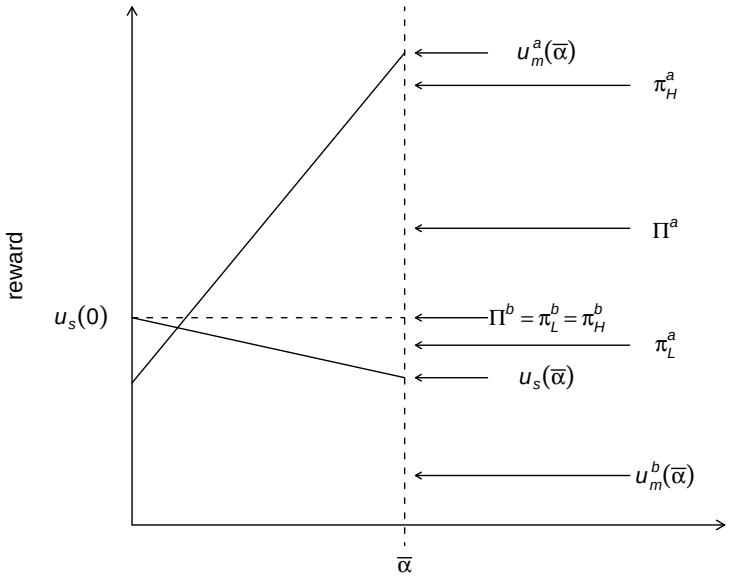

Fig. 29. Rewards

Because of coordination, under c^a all of those with job offers will move. The ex ante payoff of the high ability types is

$$\pi_H^a := \alpha_H u_m^a(\bar{\alpha}) + (1 - \alpha_H) u_s(\bar{\alpha}),$$

while that of low ability types is

$$\pi_L^a := \alpha_L u_m^a(\bar{\alpha}) + (1 - \alpha_L) u_s(\bar{\alpha}).$$

Under c^b all remain in the traditional sector, so the payoffs are $\pi_L^b := u_s(0) =: \pi_H^b$. Ex ante aggregate welfare measured as the sum of total payoffs is given under c^a by

$$\Pi^a := \bar{\alpha} u_m^a(\bar{\alpha}) + (1 - \bar{\alpha}) u_s(\bar{\alpha}).$$

Under c^b it is $\Pi^b := u_s(0)$.

What Hoff and Sen point out is that under some parameters it is possible to have

$$\pi_L^a < u_s(0) = \pi_L^b = \pi_H^b = \Pi^b < \Pi^a < \pi_H^a. \tag{31}$$

In this case $\pi_L^a < u_s(0) = \pi_L^b$, and since those with low ability are in the majority they will choose to set $c = c^b$. But then aggregate welfare is reduced,

because $\Pi^b < \Pi^a$. This situation is illustrated in Figure 29.[76] Incentives are such that the kinship institution perpetuates a low average income status quo.

8 Other Mechanisms

The poverty trap literature is vast, and even in a survey of this size many models must be neglected. A few of the more egregious omissions are listed in this section.

One of the earliest streams of literature on poverty traps is that related to endogenous fertility. A classic contribution is Nelson (1956), who shows how persistent underdevelopment can result from demographics. In his model, any increase in income lowers the death rate, which increases population and lowers capital stock per worker. If the population effect is stronger than diminishing returns then capital per worker cannot rise. See Azariadis (1996, Section 3.4) for other mechanisms and more references.

Other kinds of traps that arise in convex economies with complete markets include impatience traps and technology traps. Impatience traps typically involve subsistence levels of consumption, and sensitivity of consumption to income at low levels. See Magill and Nishimura (1984) or Azariadis (1996, Section 3.1). Technology traps are associated with low degrees of substitutability between capital and labor. See Azariadis (1996, Section 3.2).

See Dasgupta and Ray (1986) or Dasgupta (2003) for an introduction to the literature on malnutrition and underdevelopment. See also Basu and Van (1998) for a model of child labor with multiple equilibria.

9 Conclusions

The poor countries are not rich because they have failed to adopt the modern techniques of production which first emerged in Britain during the Industrial Revolution and then spread to some other nations in Western Europe and elsewhere. As a result, their economies have stagnated. By contrast, the rich countries possess market environments where the same techniques have been

[76] The parameters are $s_0 = 0.8$, $b = 0.2$, $m_0 = 2$, $c^a = 1.1$, $c^b = 2.3$, $\alpha_H = 0.9$, $\alpha_L = 0.1$ and $\gamma = 0.45$.

continuously refined, upgraded and extended, leading to what are now striking disparities between themselves and the poor.

Why would techniques not be adopted even when they are more efficient? Is it not the case that more efficient techniques are more profitable? The main objective of this survey has been to review a large number of studies which show why self-reinforcing traps may prevent the adoption of new technologies. For example, Section 5 showed how increasing returns can generate an incentive structure whereby agents avoid starting modern sector businesses, or invest little in their own training. Section 6 focused on credit market imperfections. Poor individuals lack collateral, which restricts their ability to raise funds. As a result, projects with large fixed costs are beyond the means of the poor, leaving them locked in low return occupations such as subsistence farming.

Recently many economists have highlighted the role of institutions in perpetuating poverty. Section 7 looked at why rent-seeking is both bad for growth and yet strongly self-reinforcing. Essentially similar societies may exhibit very different levels of predation simply as a result of historical accident, or some spontaneous coordination of beliefs. In addition, the role of kinship systems was analyzed as representative of the kinds of social conventions which may potentially harm formation of the modern sector.

Together, these mechanisms add up to a very different picture of development than the convex neoclassical benchmark model on which so much of modern growth theory has been based. Growth is not automatic. Small initial differences are magnified and then propagated through time. Poverty coexists with riches, much as it is observed to do in the cross-country income panel.

9.1 Lessons for economic policy

There is a real sense in which poverty trap models are optimistic. Poverty is not the result of some simple geographic or cultural determinism. The poor are not condemned to poverty by a set of unfavorable exogenous factors, or even a lack of resources. Temporary policy shocks will have large and permanent effects if one-off interventions can cause the formation of new and better equilibria.

In practice, however, engineering the emergence of more efficient equilibria seems problematic for a number of reasons. First, we have seen many examples of how bad equilibria can be stable and self-reinforcing. In this case small policy changes are not enough to escape from their grip. Large changes must

be made to the environment that people face, and the structure of their incentives. Such changes may be resisted by the forces that have perpetuated the inefficient equilibrium, such as a corrupt state apparatus fighting to preserve the status quo.

Second, coordinating changes in expectations and the status quo is difficult because norms and conventions are highly persistent. While it is possible to change policy and legislation almost instantaneously, it needs to be remembered that informal norms and conventions are often more important in governing behavior than the formal legalistic ones. Informal norms cannot be changed in the manner of interest rates, say, or tariffs. Rather they are determined within the system, and perpetuated by those forces that made them a stable part of the economy's institutional framework.

Third, policies can create new problems as a result of perverse incentives.[77] Successful policies will need to be carefully targeted, and operate more on the level of incentives than compulsion. These kinds of policies require a great deal of information. Traps which prevent growth and prosperity cannot be overcome without proper understanding and the careful design of policy.

A Technical Appendix

Section A.1 gives a general discussion of Markov chains and ergodicity. The proof of Proposition 3.1 is outlined. Section A.2 gives remaining proofs.

A.1 Markov chains and ergodicity

In the survey we repeatedly made use of a simple framework for treating Markov chains and ergodicity. The following is an elementary review. Our end

[77] For example, in South Korea the state is generally credited with solving many of the coordination problems associated with industrialization in that country through their organization and support of large industrial conglomerates, and through active policy-based lending. However, these actions also led to a moral hazard problem, as the industrial groups became highly leveraged with government-backed loans. In the 1970s, investment was increasingly characterized by a costly combination of duplication and poor choices. Losses were massive, and motivated subsequent liberalization.

objective is to sketch the proof of Proposition 3.1, but the review is intended to be more generally applicable.

Consider first a discrete time dynamical system evolving in state space $S \subset \mathbb{R}^n$. Just as for deterministic systems on S, which are represented by a *transition rule* associating each point in S with another point in S—the value of the state next period—a Markov chain is represented by a rule associating each point in S with a probability distribution over S. From this conditional distribution (i.e., distribution conditional on the current state $x \in S$) the next period state is drawn. In what follows the conditional distribution will be denoted by $\Gamma(x, dy)$, where $x \in S$ is the current state.

Because for Markov chains points in S are mapped into probability distributions rather than into individual points, it seems that the analytical methods used to study the evolution of these processes must be fundamentally different to those used to study deterministic discrete time systems. But this is not the case: Markov chains can always be reduced to deterministic systems.

To see this, note that since the state variable x_t is now a random variable, it must have some (marginal) distribution on S, which we call ψ_t. Suppose, as is often the case in economics, that ψ_t is a density on S, and that the distribution $\Gamma(x, dy)$ is in fact a density $\Gamma(x, y)dy$ for every $x \in S$. In that case the marginal distribution for x_{t+1} is a density ψ_{t+1}, and $\psi_{t+1}(y) = \int_S \Gamma(x, y)\psi_t(x)dx$. This last equality is just a version of the law of total probability: The probability of ending up at y is equal to the probability of going to y via x, weighted by the probability of being at x now, summed over all $x \in S$.

Now define map $\mathbf{M}\colon \mathscr{D} \to \mathscr{D}$, where $\mathscr{D} := \{\varphi \in L_1(S) \,|\, \varphi \geq 0 \text{ and } \int \varphi = 1\}$ is the space of densities on S, by

$$\mathbf{M}\colon \mathscr{D} \ni \psi \mapsto (\mathbf{M}\psi)(\cdot) := \int_S \Gamma(x, \cdot)\psi(x)dx \in \mathscr{D}. \tag{A.1}$$

With this definition our law of total probability rule for linking ψ_{t+1} and ψ_t can be written simply as $\psi_{t+1} = \mathbf{M}\psi_t$. Since the map $\mathbf{M}$ is deterministic, we have succeeded in transforming our stochastic system into a deterministic system to which standard methods of analysis may be applied. The only difficulty is that the state space is now $\mathscr{D}$ rather than S. The latter is finite dimensional, while the former clearly is not.

The map $\mathbf{M}$ is usually called the stochastic operator or Markov operator associated with Γ. There are many good expositions of Markov operators in economics, including Stokey, Lucas and Prescott (1989) and Futia (1982).

However those expositions treat the more general case, where $\Gamma(x, dy)$ does not necessarily have a density representation. Here it does, and it turns out that this extra structure is *very* useful for treating the models in this survey.

We wish to know when the difference equation $\psi_{t+1} = \mathbf{M}\psi_t$ has fixed points, and, more specifically, whether the system is globally stable in the sense that there is a unique fixed point ψ^*, and $\psi_t = \mathbf{M}^t\psi_0 \to \psi^*$ as $t \to \infty$ for all $\psi_0 \in \mathscr{D}$.[78] This is just ergodicity in the sense of Definition 3.1 on page 18.

Let $\|\cdot\|$ be the L_1 norm. Were $\mathbf{M}$ a uniform (Banach) contraction on $\mathscr{D}$, which is to say that $\exists\, \lambda < 1$ with $\|\mathbf{M}\psi - \mathbf{M}\psi'\| \leq \lambda\|\psi - \psi'\|$ for all $\psi, \psi' \in \mathscr{D}$, then ergodicity would hold because $\mathscr{D}$ is a closed subset of the complete metric space $L_1(S)$. Sadly, for continuous state Markov chains this uniform contraction property rarely holds. However it is often the case that $\mathbf{M}$ satisfies a weaker contraction condition:

Definition A.1 *Let $T\colon X \to X$, where (X, d) is a metric space. The map T is called a T2 contraction if $d(Tx, Tx') < d(x, x')$ for every $x \neq x'$ in X.*

T2 contractions maps distinct points strictly closer together. A sufficient condition for $\mathbf{M}\colon \mathscr{D} \to \mathscr{D}$ to satisfy the T2 property is given below. The essential requirement is communication across all regions of the state space. Although T2 contractions do not always have fixed points (examples in $\mathbb{R}$ are easy to construct), they do if the state space is compact! In fact if X is a compact set and $T\colon X \to X$ is a T2 contraction then T has unique fixed point $x^* \in X$ and $T^t x \to x^*$ as $t \to \infty$ for all $x \in X$. This is just what we require for ergodicity when $\mathbf{M}$ is thought of as a map on $\mathscr{D}$.

Now $\mathscr{D}$ is not itself a compact set in the L_1 norm topology, but it may be the case that every orbit $(\mathbf{M}^t\psi_0)_{t\geq 0}$ of $\mathbf{M}$ is compact when taken with its closure. (From now on, call a set with compact closure *precompact*). Such a property is called *Lagrange stability.*[79] And it turns out that Lagrange stability can substitute for compactness of the state space $\mathscr{D}$: If $\mathbf{M}$ is (a) a T2 contraction, and (b) Lagrange stable, then the associated Markov chain is ergodic.[80]

How to establish Lagrange stability? To check precompactness of orbits it

[78] Here $\mathbf{M}^t$ is t compositions of $\mathbf{M}$ with itself, and ψ_0 is the marginal distribution of x_0, so iterating the difference equation backwards gives $\psi_t = \mathbf{M}^t\psi_0$.
[79] That is, a self-mapping T on topological space X is called Lagrange stable if the set $\{T^t x \mid t \geq 0\}$ is precompact for every $x \in X$.
[80] The proof that Lagrange stability is sufficient is not hard. See Stachurski (2002, Theorem 5.2).

seems we must look at characterizations of compactness in L_1 (there is a famous one due to Kolmogorov), but Lasota (1994, Theorem 4.1) has proved that one need only check *weak* precompactness.[81] In fact it is sufficient to check weak precompactness of orbits starting from $\psi \in \mathscr{D}_0$, where $\mathscr{D}_0$ is a (norm) dense subset of $\mathscr{D}$. Weak compactness is much easier to work with than norm compactness. Several well-known conditions are available.

Using one such condition due to Dunford and Pettis, Mirman, Reffett and Stachurski (2004) show that Lasota's criterion for Lagrange stability is satisfied when (i) there exists a continuous "norm-like" function $V\colon S \to \mathbb{R}$ and constants $\alpha, \beta \in [0, \infty)$, $\alpha < 1$, such that

$$\int \Gamma(x, y)V(y)dy \leq \alpha V(x) + \beta, \quad \forall x \in S; \tag{A.2}$$

and (ii) there exists a continuous function $h\colon S \to \mathbb{R}$ such that $\sup_{x \in S} \Gamma(x, y) \leq h(y)$ for all $y \in S$. By V being norm-like is meant that V is nonnegative, and that the sets $\{x \in S : V(x) \leq a\}$ are precompact for all a. (For example, when $S = \mathbb{R}^n$ it is easy to convince yourself that $x \mapsto \|x\|$ is norm-like. Note that when S is a proper subset of $\mathbb{R}^n$ precompactness of sublevel sets refers to the *relative* Euclidean topology on S.)

Condition (i) is a standard drift condition, which pushes probability mass towards the center of the state space. This implies that orbits of the Markov process will be "tight." Tightness is a component of Dunford and Pettis' criterion for weak precompactness. Condition (ii) is just a technical condition which combines with (i) to fill out the requirements of the Dunford-Pettis criterion.

In the case of Proposition 3.1, we can take $S = (0, \infty)$, where $0 \notin S$ so that any stationary distribution we find is automatically nontrivial. One can then show that $V(x) = |\ln x|$ is norm-like on S, and a little bit of algebra shows that condition (i) holds for Γ given in (10). Also, one can show that (ii) holds when $h(y) := 1/y$.[82]

This takes care of Lagrange stability. Regarding T2 contractiveness, one can show that $\mathbf{M}$ is a T2 contraction whenever the set $\operatorname{supp} \mathbf{M}\psi \cap \operatorname{supp} \mathbf{M}\psi'$ has positive measure for all $\psi, \psi' \in \mathscr{D}$, where $\operatorname{supp} f := \{x \in S \,|\, f(x) \neq 0\}$. This

[81] Here is where the density structure is crucial. The operator $\mathbf{M}$ inherits nice properties from the fact that $\Gamma(x, dy)$ has a density representation. Also, we can work in L_1 rather than a space of measures. The former has a nice norm-dual space in L_∞—helpful when dealing with weak precompactness.

[82] For more details see Stachurski (2004).

basically says that probability mass is mixed across the state space—all areas of S communicate. In the case of (10) it is easy to show that $\operatorname{supp} \mathbf{M}\psi = (0, \infty) = S$ for every $\psi \in \mathscr{D}$. This is clearly sufficient for the condition.

A.2 Remaining proofs

The proof of Proposition 5.1 in Section 5.2 is now given. The first point is that the banks $b = 1, \ldots, B-1$ are equal-cost Bertrand competitors, and as a result always offer the interest rate r to all firms in equilibrium. The main issue is the optimal strategy of the last bank B. So consider the following strategy σ_B^* for B, which is illustrated with the help of Figure A.1. To firm n the bank offers i_n^* defined by $i_n^* = f[(n-1)/N] - 1$ if $n \leq \alpha_C N$. To the remaining firms B offers the interest rate r. (Without loss of generality, we suppose that the index of firms from 1 to N and the ranking of the offers made by B always coincide.) Let $\sigma^* \in \Sigma$ be the strategy where B offers σ_B^* and all other banks offer r.

For the strategy σ^* we have $\Omega(\sigma^*) = \{1\}$. The reason is that for $\alpha = n/N \leq \alpha_C$, firms $j = 1, \ldots, n+1$ all satisfy

$$\pi(n/N, m_j(\sigma^*)) \geq \pi(n/N, i_j^*) \geq \pi(n/N, i_{n+1}^*) = 0.$$

In which case $\alpha \notin \Omega(\sigma^*)$ by (20). Also, for $\alpha \in (\alpha_C, 1)$ we have $\pi(\alpha, m_n(\sigma^*)) \geq \pi(\alpha, r) \geq 0$ for all $n \in \{1, \ldots, N\}$, so again $\alpha \notin \Omega(\sigma^*)$. For the same reason, $1 \in \Omega(\sigma^*)$, because $\pi(1, m_n(\sigma^*)) \geq \pi(1, r) \geq 0$.

It follows that under this strategy $\alpha^{\text{pes}}(\sigma^*) = 1$. By (19) all firms enter. The profits of bank B are given by the sum of the regions P, Q and R, minus the region O, in Figure A.1. Here Q and $\bar{\alpha}$ are chosen so that $P+Q-O = 0$. Thus, $\bar{\alpha}$ is the break-even point for the bank, where it recoups all losses made by offering cheap loans to firms in the "critical mass" region $[0, \alpha_C]$. If $\ell/N \geq \bar{\alpha}$ and hence $R \geq 0$, the bank B makes positive profits.

It is not too hard to see that σ^* is indeed the optimal strategy in Σ for the banks. The banks $b = 1, \ldots, B-1$ always offer r. For B, strategy σ_B^* is optimal for the following reasons. First, if B offers interest rates to $n \in \{1, \ldots, N\}$ which are all less than or equal to those in σ_B^*, then all firms will enter as above, but B will make lower profits by (17). So suppose that B offers a schedule of rates $\{i_1^{**}, \ldots, i_N^{**}\}$ where $i_n^{**} > i_n^*$ for at least one n, and let k be the first such n. It is not difficult to see that the chain of logic whereby all firms enter now unravels: It must be that $k/N \leq \alpha_C$, because to other firms

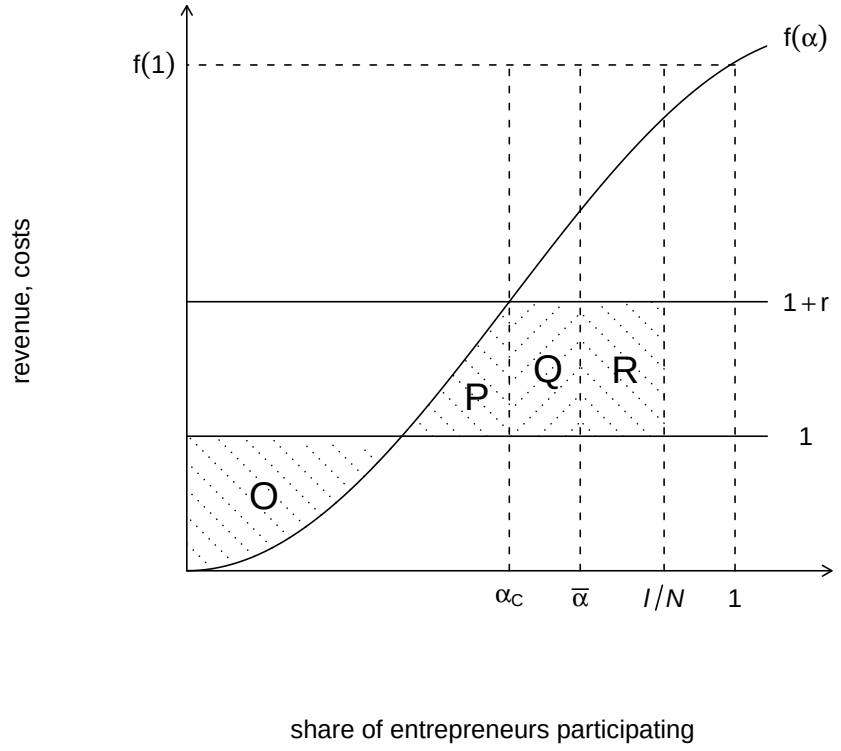

Fig. A.1. Coordination by the lead bank

B offers the rate r, which cannot be exceeded due to B's competitors. One can now check that $(k-1)/N \in \Omega(\sigma^{**})$, and in fact $(k-1)/N = \min \Omega(\sigma^{**})$. As a result, $\alpha^{\text{pes}}(\sigma^{**}) = (k-1)/N$, and precisely $k-1$ firms enter. Clearly the profits of B are lower for σ^{**} than for σ^{*}.

Abstract

This paper develops the empirical and theoretical case that differences in economic institutions are the fundamental cause of differences in economic development. We first document the empirical importance of institutions by focusing on two "quasi-natural experiments" in history, the division of Korea into two parts with very different economic institutions and the colonization of much of the world by European powers starting in the fifteenth century. We then develop the basic outline of a framework for thinking about why economic institutions differ across countries. Economic institutions determine the incentives of and the constraints on economic actors, and shape economic outcomes. As such, they are social decisions, chosen for their consequences. Because different groups and individuals typically benefit from different economic institutions, there is generally a conflict over these social choices, ultimately resolved in favor of groups with greater political power. The distribution of political power in society is in turn determined by political institutions and the distribution of resources. Political institutions allocate *de jure* political power, while groups with greater economic might typically possess greater *de facto* political power. We therefore view the appropriate theoretical framework as a dynamic one with political institutions and the distribution of resources as the state variables. These variables themselves change over time because prevailing economic institutions affect the distribution of resources, and because groups with de facto political power today strive to change political institutions in order to increase their de jure political power in the future. Economic institutions encouraging economic growth emerge when political institutions allocate power to groups with interests in broad-based property rights enforcement, when they create effective constraints on power-holders, and when there are relatively few rents to be captured by power-holders. We illustrate the assumptions, the workings and the implications of this framework using a number of historical examples.

1 Introduction

1.1 The question

The most trite yet crucial question in the field of economic growth and development is: Why are some countries much poorer than others? Traditional neoclassical growth models, following Solow (1956), Cass (1965) and Koopmans (1965), explain differences in income per capita in terms of different paths of factor accumulation. In these models, cross-country differences in factor accumulation are due either to differences in saving rates (Solow), preferences (Cass-Koopmans), or other exogenous parameters, such as total factor productivity growth. More recent incarnations of growth theory, following Romer (1986) and Lucas (1988), endogenize steady-state growth and technical progress, but their explanation for income differences is similar to that of the older theories. For instance, in the model of Romer (1990), a country may be more prosperous than another if it allocates more resources to innovation, but what determines this is essentially preferences and properties of the technology for creating 'ideas'.[1]

Though this theoretical tradition is still vibrant in economics and has provided many insights about the mechanics of economic growth, it has for a long time seemed unable to provide a *fundamental* explanation for economic growth. As North and Thomas (1973, p. 2) put it: "the factors we have listed (innovation, economies of scale, education, capital accumulation etc.) are not causes of growth; they *are* growth" (italics in original). Factor accumulation and innovation are only *proximate* causes of growth. In North and Thomas's view, the fundamental explanation of comparative growth is differences in *institutions*.

What are institutions exactly? North (1990, p. 3) offers the following definition: "Institutions are the rules of the game in a society or, more formally, are the humanly devised constraints that shape human interaction." He goes on to emphasize the key implications of institutions since, "In consequence they structure incentives in human exchange, whether political, social, or economic."

Of primary importance to economic outcomes are the *economic institutions* in society such as the structure of property rights and the presence and perfection of markets. Economic institutions are important because they influence the structure of economic

[1] Although some recent contributions to growth theory emphasize the importance of economic policies, such as taxes, subsidies to research, barriers to technology adoption and human capital policy, they typically do not present an explanation for why there are differences in these policies across countries.

incentives in society. Without property rights, individuals will not have the incentive to invest in physical or human capital or adopt more efficient technologies. Economic institutions are also important because they help to allocate resources to their most efficient uses, they determine who gets profits, revenues and residual rights of control. When markets are missing or ignored (as they were in the Soviet Union, for example), gains from trade go unexploited and resources are misallocated. Societies with economic institutions that facilitate and encourage factor accumulation, innovation and the efficient allocation of resources will prosper.

Central to this chapter and to much of political economy research on institutions is that economic institutions, and institutions more broadly, are *endogenous*; they are, at least in part, determined by society, or a segment of it. Consequently, the question of why some societies are much poorer than others is closely related to the question of why some societies have much "worse economic institutions" than others.

Even though many scholars including John Locke, Adam Smith, John Stuart Mill, Douglass North and Robert Thomas have emphasized the importance of economic institutions, we are far from a useful framework for thinking about how economic institutions are determined and why they vary across countries. In other words, while we have good reason to believe that economic institutions matter for economic growth, we lack the crucial *comparative static* results which will allow us to explain why equilibrium economic institutions differ (and perhaps this is part of the reason why much of the economics literature has focused on the proximate causes of economic growth, largely neglecting fundamental institutional causes).

This chapter has three aims. First, we selectively review the evidence that differences in economic institutions are a fundamental cause of cross-country differences in prosperity. Second, we outline a framework for thinking about why economic institutions vary across countries. We emphasize the potential comparative static results of this framework and also illustrate the key mechanisms through a series of historical examples and case studies. Finally, we highlight a large number of areas where future theoretical and empirical work would be very fruitful.

1.2 The Argument

The basic argument of this chapter can be summarized as follows:

1. Economic institutions matter for economic growth because they shape the incentives of key economic actors in society, in particular, they influence investments in physical and human capital and technology, and the organization of production. Al-

though cultural and geographical factors may also matter for economic performance, differences in economic institutions are the major source of cross-country differences in economic growth and prosperity. Economic institutions not only determine the aggregate economic growth potential of the economy, but also an array of economic outcomes, including the distribution of resources in the future (i.e., the distribution of wealth, of physical capital or human capital). In other words, they influence not only the size of the aggregate pie, but how this pie is divided among different groups and individuals in society. We summarize these ideas schematically as (where the subscript t refers to current period and $t+1$ to the future):

$$\text{economic institutions}_t \Longrightarrow \begin{cases} \text{economic performance}_t \\ \text{distribution of resources}_{t+1} \end{cases}.$$

2. Economic institutions are endogenous. They are determined as collective choices of the society, in large part for their economic consequences. However, there is no guarantee that all individuals and groups will prefer the same set of economic institutions because, as noted above, different economic institutions lead to different distributions of resources. Consequently, there will typically be a *conflict of interest* among various groups and individuals over the choice of economic institutions. So how are equilibrium economic institutions determined? If there are, for example, two groups with opposing preferences over the set of economic institutions, which group's preferences will prevail? The answer depends on the *political power* of the two groups. Although the efficiency of one set of economic institutions compared with another may play a role in this choice, political power will be the ultimate arbiter. Whichever group has more political power is likely to secure the set of economic institutions that it prefers. This leads to the second building block of our framework:

$$\text{political power}_t \Longrightarrow \text{economic institutions}_t$$

3. Implicit in the notion that political power determines economic institutions is the idea that there are conflicting interests over the distribution of resources and therefore indirectly over the set of economic institutions. But why do the groups with conflicting interests not agree on the set of economic institutions that maximize aggregate growth (the size of the aggregate pie) and then use their political power simply to determine the distribution of the gains? Why does the exercise of political power lead to economic inefficiencies and even poverty? We will explain that this is because there are commitment problems inherent in the use of political power. Individuals who have political power

cannot commit not to use it in their best interests, and this commitment problem creates an inseparability between efficiency and distribution because credible compensating transfers and side-payments cannot be made to offset the distributional consequences of any particular set of economic institutions.

4. The distribution of political power in society is also endogenous, however. In our framework, it is useful to distinguish between two components of political power, which we refer to as *de jure (institutional)* and *de facto political power*. Here de jure political power refers to power that originates from the *political institutions* in society. Political institutions, similarly to economic institutions, determine the constraints on and the incentives of the key actors, but this time in the political sphere. Examples of political institutions include the form of government, for example, democracy vs. dictatorship or autocracy, and the extent of constraints on politicians and political elites. For example, in a monarchy, political institutions allocate all de jure political power to the monarch, and place few constraints on its exercise. A constitutional monarchy, in contrast, corresponds to a set of political institutions that reallocates some of the political power of the monarch to a parliament, thus effectively constraining the political power of the monarch. This discussion therefore implies that:

$$\text{political institutions}_t \Longrightarrow \text{ de jure political power}_t$$

5. There is more to political power than political institutions, however. A group of individuals, even if they are not allocated power by political institutions, for example as specified in the constitution, may nonetheless possess political power. Namely, they can revolt, use arms, hire mercenaries, co-opt the military, or use economically costly but largely peaceful protests in order to impose their wishes on society. We refer to this type of political power as de facto political power, which itself has two sources. First, it depends on the ability of the group in question to solve its collective action problem, i.e., to ensure that people act together, even when any individual may have an incentive to free ride. For example, peasants in the Middle Ages, who were given no political power by the constitution, could sometimes solve the collective action problem and undertake a revolt against the authorities. Second, the de facto power of a group depends on its economic resources, which determine both their ability to use (or misuse) existing political institutions and also their option to hire and use force against different groups. Since we do not yet have a satisfactory theory of when groups are able to solve their collective action problems, our focus will be on the second source of de facto political

power, hence:

$$\text{distribution of resources}_t \Longrightarrow \text{de facto political power}_t$$

6. This brings us to the evolution of one of the two main *state variables* in our framework, political institutions (the other state variable is the distribution of resources, including distribution of physical and human capital stocks etc.). Political institutions and the distribution of resources are the state variables in this dynamic system because they typically change relatively slowly, and more importantly, they determine economic institutions and economic performance both directly and indirectly. Their direct effect is straightforward to understand. If political institutions place all political power in the hands of a single individual or a small group, economic institutions that provide protection of property rights and equal opportunity for the rest of the population are difficult to sustain. The indirect effect works through the channels discussed above: political institutions determine the distribution of de jure political power, which in turn affects the choice of economic institutions. This framework therefore introduces a natural concept of *a hierarchy of institutions*, with political institutions influencing equilibrium economic institutions, which then determine economic outcomes.

Political institutions, though slow changing, are also endogenous. Societies transition from dictatorship to democracy, and change their constitutions to modify the constraints on power holders. Since, like economic institutions, political institutions are collective choices, the distribution of political power in society is the key determinant of their evolution. This creates a tendency for persistence: political institutions allocate de jure political power, and those who hold political power influence the evolution of political institutions, and they will generally opt to maintain the political institutions that give them political power. However, de facto political power occasionally creates changes in political institutions. While these changes are sometimes discontinuous, for example when an imbalance of power leads to a revolution or the threat of revolution leads to major reforms in political institutions, often they simply influence the way existing political institutions function, for example, whether the rules laid down in a particular constitution are respected as in most functioning democracies, or ignored as in current-day Zimbabwe. Summarizing this discussion, we have:

$$\text{political power}_t \Longrightarrow \text{political institutions}_{t+1}$$

Putting all these pieces together, a schematic (and simplistic) representation of our

framework is as follows:

$$\left.\begin{array}{l} \text{political} \\ \text{institutions}_t \end{array} \Longrightarrow \begin{array}{c} \text{de jure} \\ \text{political} \\ \text{power}_t \end{array}\right\} \Longrightarrow \text{economic institutions}_t \Longrightarrow \left\{\begin{array}{c} \text{economic} \\ \text{performance}_t \\ \& \\ \text{distribution} \\ \text{of resources}_{t+1} \end{array}\right.$$

$$\left.\begin{array}{l} \text{distribution} \\ \text{of resources}_t \end{array} \Longrightarrow \begin{array}{c} \text{de facto} \\ \text{political} \\ \text{power}_t \end{array}\right\} \Longrightarrow \text{political institutions}_{t+1}$$

The two state variables are political institutions and the distribution of resources, and the knowledge of these two variables at time t is sufficient to determine all the other variables in the system. While political institutions determine the distribution of de jure political power in society, the distribution of resources influences the distribution of de facto political power at time t. These two sources of political power, in turn, affect the choice of economic institutions and influence the future evolution of political institutions. Economic institutions determine economic outcomes, including the aggregate growth rate of the economy and the distribution of resources at time $t+1$. Although economic institutions are the essential factor shaping economic outcomes, they are themselves endogenous and determined by political institutions and distribution of resources in society.

There are two sources of persistence in the behavior of the system: first, political institutions are durable, and typically, a sufficiently large change in the distribution of political power is necessary to cause a change in political institutions, such as a transition from dictatorship to democracy. Second, when a particular group is rich relative to others, this will increase its de facto political power and enable it to push for economic and political institutions favorable to its interests. This will tend to reproduce the initial relative wealth disparity in the future. Despite these tendencies for persistence, the framework also emphasizes the potential for change. In particular, "shocks", including changes in technologies and the international environment, that modify the balance of (de facto) political power in society and can lead to major changes in political institutions and therefore in economic institutions and economic growth.

A brief example might be useful to clarify these notions before commenting on some of the underlying assumptions and discussing comparative statics. Consider the development of property rights in Europe during the Middle Ages. There is no doubt that lack of property rights for landowners, merchants and proto- industrialists was detrimental to economic growth during this epoch. Since political institutions at the time placed political power in the hands of kings and various types of hereditary monarchies,

such rights were largely decided by these monarchs. Unfortunately for economic growth, while monarchs had every incentive to protect their own property rights, they did not generally enforce the property rights of others. On the contrary, monarchs often used their powers to expropriate producers, impose arbitrary taxation, renege on their debts, and allocate the productive resources of society to their allies in return for economic benefits or political support. Consequently, economic institutions during the Middle Ages provided little incentive to invest in land, physical or human capital, or technology, and failed to foster economic growth. These economic institutions also ensured that the monarchs controlled a large fraction of the economic resources in society, solidifying their political power and ensuring the continuation of the political regime.

The seventeenth century, however, witnessed major changes in the economic and political institutions that paved the way for the development of property rights and limits on monarchs' power, especially in England after the Civil War of 1642 and the Glorious Revolution of 1688, and in the Netherlands after the Dutch Revolt against the Hapsburgs. How did these major institutional changes take place? In England, for example, until the sixteenth century the king also possessed a substantial amount of de facto political power, and leaving aside civil wars related to royal succession, no other social group could amass sufficient de facto political power to challenge the king. But changes in the English land market (Tawney, 1941) and the expansion of Atlantic trade in the sixteenth and seventeenth centuries (Acemoglu, Johnson and Robinson, 2002b) gradually increased the economic fortunes, and consequently the de facto power of landowners and merchants. These groups were diverse, but contained important elements that perceived themselves as having interests in conflict with those of the king: while the English kings were interested in predating against society to increase their tax incomes, the gentry and merchants were interested in strengthening their property rights.

By the seventeenth century, the growing prosperity of the merchants and the gentry, based both on internal and overseas, especially Atlantic, trade, enabled them to field military forces capable of defeating the king. This de facto power overcame the Stuart monarchs in the Civil War and Glorious Revolution, and led to a change in political institutions that stripped the king of much of his previous power over policy. These changes in the distribution of political power led to major changes in economic institutions, strengthening the property rights of both land and capital owners and spurred a process of financial and commercial expansion. The consequence was rapid economic growth, culminating in the Industrial Revolution, and a very different distribution of

economic resources from that in the Middle Ages.

It is worth returning at this point to two critical assumptions in our framework. First, why do the groups with conflicting interests not agree on the set of economic institutions that maximize aggregate growth? So in the case of the conflict between the monarchy and the merchants, why does the monarchy not set up secure property rights to encourage economic growth and tax some of the benefits? Second, why do groups with political power want to change political institutions in their favor? For instance, in the context of the example above, why did the gentry and merchants use their de facto political power to change political institutions rather than simply implement the policies they wanted? The answers to both questions revolve around issues of *commitment* and go to the heart of our framework.

The distribution of resources in society is an inherently conflictual, and therefore political, decision. As mentioned above, this leads to major commitment problems, since groups with political power cannot commit to not using their power to change the distribution of resources in their favor. For example, economic institutions that increased the security of property rights for land and capital owners during the Middle Ages would not have been credible as long as the monarch monopolized political power. He could promise to respect property rights, but then at some point, renege on his promise, as exemplified by the numerous financial defaults by medieval kings (e.g., Veitch, 1986). Credible secure property rights necessitated a reduction in the political power of the monarch. Although these more secure property rights would foster economic growth, they were not appealing to the monarchs who would lose their rents from predation and expropriation as well as various other privileges associated with their monopoly of political power. This is why the institutional changes in England as a result of the Glorious Revolution were not simply conceded by the Stuart kings. James II had to be deposed for the changes to take place.

The reason why political power is often used to change political institutions is related. In a dynamic world, individuals care not only about economic outcomes today but also in the future. In the example above, the gentry and merchants were interested in their profits and therefore in the security of their property rights, not only in the present but also in the future. Therefore, they would have liked to use their (de facto) political power to secure benefits in the future as well as the present. However, commitment to future allocations (or economic institutions) was not possible because decisions in the future would be decided by those who had political power in the future with little reference to past promises. If the gentry and merchants would have been sure to maintain their de

facto political power, this would not have been a problem. However, de facto political power is often transient, for example because the collective action problems that are solved to amass this power are likely to resurface in the future, or other groups, especially those controlling de jure power, can become stronger in the future. Therefore, any change in policies and economic institutions that relies purely on de facto political power is likely to be reversed in the future. In addition, many revolutions are followed by conflict within the revolutionaries. Recognizing this, the English gentry and merchants strove not just to change economic institutions in their favor following their victories against the Stuart monarchy, but also to alter political institutions and the future allocation of de jure power. Using political power to change political institutions then emerges as a useful strategy to make gains more durable. The framework that we propose, therefore, emphasizes the importance of political institutions, and changes in political institutions, as a way of manipulating future political power, and thus indirectly shaping future, as well as present, economic institutions and outcomes.

This framework, though abstract and highly simple, enables us to provide some preliminary answers to our main question: why do some societies choose "good economic institutions"? At this point, we need to be more specific about what good economic institutions are. A danger we would like to avoid is that we define good economic institutions as those that generate economic growth, potentially leading to a tautology. This danger arises because a given set of economic institutions may be relatively good during some periods and bad during others. For example, a set of economic institutions that protects the property rights of a small elite might not be inimical to economic growth when all major investment opportunities are in the hands of this elite, but could be very harmful when investments and participation by other groups are important for economic growth (see Acemoglu, 2003b). To avoid such a tautology and to simplify and focus the discussion, throughout we think of good economic institutions as those that provide security of property rights and relatively equal access to economic resources to a broad cross-section of society. Although this definition is far from requiring equality of opportunity in society, it implies that societies where only a very small fraction of the population have well-enforced property rights do not have good economic institutions. Consequently, as we will see in some of the historical cases discussed below, a given set of economic institutions may have very different implications for economic growth depending on the technological possibilities and opportunities.

Given this definition of good economic institutions as providing secure property rights for a broad cross-section of society, our framework leads to a number of important com-

parative statics, and thus to an answer to our basic question. First, political institutions that place checks on those who hold political power, for example, by creating a balance of power in society, are useful for the emergence of good economic institutions. This result is intuitive; without checks on political power, power holders are more likely to opt for a set of economic institutions that are beneficial for themselves and detrimental for the rest of society, which will typically fail to protect property rights of a broad cross-section of people. Second, good economic institutions are more likely to arise when political power is in the hands of a relatively broad group with significant investment opportunities. The reason for this result is that, everything else equal, in this case power holders will themselves benefit from secure property rights.[2] Third, good economic institutions are more likely to arise and persist when there are only limited rents that power holders can extract from the rest of society, since such rents would encourage them to opt for a set of economic institutions that make the expropriation of others possible. These comparative statics therefore place political institutions at the center of the story, as emphasized by our term "hierarchy of institutions" above. Political institutions are essential both because they determine the constraints on the use of (de facto and de jure) political power and also which groups hold de jure political power in society. We will see below how these comparative statics help us understand institutional differences across countries and over time in a number of important historical examples.

1.3 Outline

In the next section we discuss how economic institutions constitute the basis for a fundamental theory of growth, and we contrast this with other potential fundamental theories. In section 3 we consider some empirical evidence that suggests a key role for economic institutions in determining long-run growth. We also emphasize some of the key problems involved in establishing a causal relationship between economic institutions and growth. We then show in section 4 how the experience of European colonialism can be used as a 'natural experiment' which can address these problems. Having established the central causal role of economic institutions and their importance relative to other factors in cross-country differences in economic performance, the rest of the paper focuses on developing a theory of economic institutions. Section 5 discusses four types of explanation for why countries have different institutions, and argues that

[2]The reason why we inserted the caveat of "a relatively broad group" is that when a small group with significant investment opportunities holds power, they may sometimes opt for an oligarchic system where their own property rights are protected, but those of others are not (see Acemoglu, 2003b).

the most plausible is the *social conflict view*. According to this theory, bad institutions arise because the groups with political power benefit from bad institutions. The emphasis on social conflict arises naturally from our observation above that economic institutions influence the distribution of resources as well as efficiency. Different groups or individuals will therefore prefer different institutions and conflict will arise as each tries to get their own way. Section 6 delves deeper into questions of efficiency and asks why a political version of the Coase Theorem does not hold. We emphasize the idea that commitment problems are intrinsic to the exercise of political power. In section 7 we argue that a series of historical examples of diverging economic institutions are best explained by the social conflict view. These examples illustrate how economic institutions are determined by the distribution of political power, and how this distribution is influenced by political institutions. Section 8 puts these ideas together to build our theory of institutions. In section 9 we then consider two more extended examples of the theory in action, the rise of constitutional rule in early modern Europe, and the creation of mass democracy, particularly in Britain, in the nineteenth and twentieth centuries. Section 10 concludes with a discussion of where this research program can go next.

2 Fundamental Causes of Income Differences

We begin by taking a step back. The presumption in the introduction was that economic institutions matter, and should in fact be thought of as one of the key fundamental causes of economic growth and cross-country differences in economic performance. How do we know this?

2.1 Three Fundamental Causes

If standard economic models of factor accumulation and endogenous technical change only provide proximate explanations of comparative growth, what types of explanations would constitute fundamental ones? Though there is no conventional wisdom on this, we can distinguish three such theories: the first set of theories, our main focus in this chapter, emphasize the importance of economic institutions, which influence economic outcomes by shaping economic incentives; the second emphasize geography, and the third emphasize the importance of culture (a fourth possibility is that differences are due to "luck," some societies were just lucky; however we do not believe that differences in luck by themselves constitute a sufficient fundamental causes of cross-country income differences).

2.1.1 Economic Institutions

At its core, the hypothesis that differences in economic institutions are the fundamental cause of different patterns of economic growth is based on the notion that it is the way that humans themselves decide to organize their societies that determines whether or not they prosper. Some ways of organizing societies encourage people to innovate, to take risks, to save for the future, to find better ways of doing things, to learn and educate themselves, solve problems of collective action and provide public goods. Others do not.

The idea that the prosperity of a society depends on its economic institutions goes back at least to Adam Smith, for example in his discussions of mercantilism and the role of markets, and was prominent in the work of many nineteenth century scholars such as John Stuart Mill (see the discussion in Jones, 1981): societies are economically successful when they have 'good' economic institutions and it is these institutions that are the *cause* of prosperity. We can think of these good economic institutions as consisting of an inter-related cluster of things. There must be enforcement of property rights for a broad cross-section of society so that all individuals have an incentive to invest, innovate and take part in economic activity. There must also be some degree of equality of opportunity in society, including such things as equality before the law, so that those with good investment opportunities can take advantage of them.[3]

One could think of other types of economic institutions, for instance markets. Traditional accounts of economic growth by historians, following the lead of Adam Smith, emphasized the spread of markets (Pirenne, 1937, Hicks, 1969) and more recent theories of comparative development are also based on differences in various economic institutions. Models of poverty traps in the tradition of Rosenstein-Rodan (1943), Murphy, Vishny and Shleifer (1989a,b) and Acemoglu (1995, 1997), are based on the idea that market imperfections can lead to the existence of multiple Pareto-ranked equilibria. As a consequence a country can get stuck in a Pareto inferior equilibrium, associated with poverty, but getting out of such a trap necessitates coordinated activities that the market cannot deliver. The literature initiated by Banerjee and Newman (1993) and Galor and Zeira (1993) is based on the idea that when capital markets are imperfect, the distribution of wealth matters for who can invest and societies with skewed income distributions can be stuck in poverty.

[3]In Acemoglu, Johnson and Robinson (2001), we coined the term *institutions of private property* for a cluster of would economic institutions, including the rule of law and the enforcement of property rights, and the term *extractive institutions* to designate institutions under which the rule of law and property rights are absent for large majorities of the population.

These theories provide interesting models of how incentives depend on expectations of others' behavior or the distribution of wealth given an underlying set of market imperfections. They take the market structure largely as given, however. We believe that the structure of markets is endogenous, and partly determined by property rights. Once individuals have secure property rights and there is equality of opportunity, the incentives will exist to create and improve markets (even though achieving perfect markets would be typically impossible). Thus we expect differences in markets to be an outcome of differing systems of property rights and political institutions, not unalterable characteristics responsible for cross-country differences in economic performance. This motivates our focus on economic institutions related to the enforcement of the property rights of a broad cross-section of society.

2.1.2 Geography

While institutional theories emphasize the importance of man-made factors shaping incentives, an alternative is to focus on the role of "nature", that is, on the physical and geographical environment. In the context of understanding cross-country differences in economic performance, this approach emphasizes differences in geography, climate and ecology that determine both the preferences and the opportunity set of individual economic agents in different societies. We refer to this broad approach as the "geography hypothesis". There are at least three main versions of the geography hypothesis, each emphasizing a different mechanism for how geography affects prosperity.

First, climate may be an important determinant of work effort, incentives, or even productivity. This idea dates back at least to the famous French philosopher, Montesquieu ([1748], 1989), who wrote in his classic book The Spirit of the Laws: "The heat of the climate can be so excessive that the body there will be absolutely without strength. So, prostration will pass even to the spirit; no curiosity, no noble enterprise, no generous sentiment; inclinations will all be passive there; laziness there will be happiness," and "People are ... more vigorous in cold climates. The inhabitants of warm countries are, like old men, timorous; the people in cold countries are, like young men, brave". One of the founders of modern economics Marshall is another prominent figure who emphasized the importance of climate, arguing: "vigor depends partly on race qualities: but these, so far as they can be explained at all, seem to be chiefly due to climate" (1890, p. 195).

Second, geography may determine the technology available to a society, especially in agriculture. This view is developed by an early Nobel Prize winner in economics,

Myrdal, who wrote "serious study of the problems of underdevelopment ... should take into account the climate and its impacts on soil, vegetation, animals, humans and physical assets—in short, on living conditions in economic development" (1968, volume 3, p. 2121). More recently, Diamond espouses this view, "... proximate factors behind Europe's conquest of the Americas were the differences in all aspects of technology. These differences stemmed ultimately from Eurasia's much longer history of densely populated ... [societies dependent on food production]," which was in turn determined by geographical differences between Europe and the Americas (1997, p. 358). The economist Sachs has been a recent and forceful proponent of the importance of geography in agricultural productivity, stating that "By the start of the era of modern economic growth, if not much earlier, temperate-zone technologies were more productive than tropical-zone technologies ..." (2001, p. 2).

The third variant of the geography hypothesis, especially popular over the past decade, links poverty in many areas of the world to their "disease burden," emphasizing that: "The burden of infectious disease is similarly higher in the tropics than in the temperate zones" (Sachs, 2000, p. 32). Bloom and Sachs (1998) claim that the prevalence of malaria, a disease which kills millions of children every year in sub-Saharan Africa, reduces the annual growth rate of sub-Saharan African economies by more than 1.3 percent a year (this is a large effect, implying that had malaria been eradicated in 1950, income per capita in sub-Saharan Africa would be double of what it is today).

2.1.3 Culture

The final fundamental explanation for economic growth emphasizes the idea that different societies (or perhaps different races or ethnic groups) have different cultures, because of different shared experiences or different religions. Culture is viewed as a key determinant of the values, preferences and beliefs of individuals and societies and, the argument goes, these differences play a key role in shaping economic performance.

At some level, culture can be thought to influence equilibrium outcomes for a given set of institutions. Possibly there are multiple equilibria connected with any set of institutions and differences in culture mean that different societies will coordinate on different equilibria. Alternatively, as argued by Greif (1993), different cultures generate different sets of beliefs about how people behave and this can alter the set of equilibria for a given specification of institutions (for example, some beliefs will allow punishment strategies to be used whereas others will not).

The most famous link between culture and economic development is that proposed by Weber (1930) who argued that the origins of industrialization in western Europe could be traced to the Protestant reformation and particularly the rise of Calvinism. In his view, the set of beliefs about the world that was intrinsic to Protestantism were crucial to the development of capitalism. Protestantism emphasized the idea of predestination in the sense that some individuals were 'chosen' while others were not. "We know that a part of humanity is saved, the rest damned. To assume that human merit or guilt play a part in determining this destiny would be to think of God's absolutely free decrees, which have been settled from eternity, as subject to change by human influence, an impossible contradiction" (Weber, 1930, p. 60).

But who had been chosen and who not? Calvin did not explain this. Weber (1930, p. 66) notes "Quite naturally this attitude was impossible for his followers ... for the broad mass of ordinary men ... So wherever the doctrine of predestination was held, the question could not be suppressed whether there was any infallible criteria by which membership of the *electi* could be known." Practical solutions to this problem were quickly developed, "... in order to attain that self-confidence intense worldly activity is recommended as the most suitable means. It and it alone disperses religious doubts and gives the certainly of grace" Weber (1930, pp. 66-67).

Thus "however useless good works might be as a means of attaining salvation ... nevertheless, they are indispensable as a sign of election. They are the technical means, not of purchasing salvation, but of getting rid of the fear of damnation" (p. 69). Though economic activity was encouraged, enjoying the fruits of such activity was not. "Waste of time is ... the first and in principle the deadliest of sins. The span of human life is infinitely short and precious to make sure of one's own election. Loss of time through sociability, idle talk, luxury, even more sleep than is necessary for health ... is worthy of absolute moral condemnation ... Unwillingness to work is symptomatic of the lack of grace" (pp. 104-105).

Thus Protestantism led to a set of beliefs which emphasized hard work, thrift, saving, and where economic success was interpreted as consistent with (if not actually signalling) being chosen by God. Weber contrasted these characteristics of Protestantism with those of other religions, such as Catholicism, which he argued did not promote capitalism. For instance on his book on Indian religion he argued that the caste system blocked capitalist development (Weber, 1958, p. 112).

More recently, scholars, such as Landes (1998), have also argued that the origins of Western economic dominance are due to a particular set of beliefs about the world and

how it could be transformed by human endeavor, which is again linked to religious differences. Although Barro and McCleary (2003) provide evidence of a positive correlation between the prevalence of religious beliefs, notably about hell and heaven, and economic growth, this evidence does not show a causal effect of religion on economic growth, since religious beliefs are endogenous both to economic outcomes and to other fundamental causes of income differences (points made by Tawney, 1926, and Hill, 1961b, in the context of Weber's thesis).

Ideas about how culture may influence growth are not restricted to the role of religion. Within the literature trying to explain comparative development there have been arguments that there is something special about particular cultural endowments, usually linked to particular nation states. For instance, Latin America may be poor because of its Iberian heritage, while North America is prosperous because of its Anglo-Saxon heritage (Véliz, 1994). In addition, a large literature in anthropology argues that societies may become 'dysfunctional' or 'maladapted' in the sense that they adopt a system of beliefs or ways or operating which do not promote the success or prosperity of the society (see Edgerton, 1992, for a survey of this literature). The most famous version of such an argument is due to Banfield (1958) who argued that the poverty of Southern Italy was due to the fact that people had adopted a culture of "amoral familiarism" where they only trusted individuals of their own families and refused to cooperate or trust anyone else. This argument was revived in the extensive empirical study of Putnam (1993) who characterized such societies as lacking "social capital". Although Putnam and others, for example, Knack and Keefer (1997) and Durlauf and Fafchamps (2003), document positive correlations between measures of social capital and various economic outcomes, there is no evidence of a causal effect, since, as with religious beliefs discussed above, measures of social capital are potentially endogenous.

3 Institutions Matter

We now argue that there is convincing empirical support for the hypothesis that differences in economic institutions, rather than geography or culture, *cause* differences in incomes per-capita. Consider first Figure 1.

This shows the cross-country bivariate relationship between the log of GDP per-capita in 1995 and a broad measure of property rights, "protection against expropriation risk", averaged over the period 1985 to 1995. The data on economic institutions come from Political Risk Services, a private company which assesses the risk that investments will be expropriated in different countries. These data, first used by Knack and Keefer

(1995) and subsequently by Hall and Jones (1999) and Acemoglu, Johnson and Robinson (2001, 2002a) are imperfect as a measure of economic institutions, but the findings are robust to using other available measures of economic institutions. The scatter plot shows that countries with more secure property rights, i.e., better economic institutions, have higher average incomes.

It is tempting to interpret Figure 1 as depicting a causal relationship (i.e., as establishing that secure property rights cause prosperity). Nevertheless, there are well known problems with making such an inference. First, there could be reverse causation – perhaps only countries that are sufficiently wealthy can afford to enforce property rights. More importantly, there might be a problem of omitted variable bias. It could be something else, e.g., geography, that explains both why countries are poor and why they have insecure property rights. Thus if omitted factors determine institutions and incomes, we would spuriously infer the existence of a causal relationship between economic institutions and incomes when in fact no such relationship exists. Trying to estimate the relationship between institutions and prosperity using Ordinary Least Squares, as was done by Knack and Keefer (1995) and Barro (1997) could therefore result in biased regression coefficients.

To further illustrate these potential *identification* problems, suppose that climate, or geography more generally, matters for economic performance. In fact, a simple scatterplot shows a positive association between latitude (the absolute value of distance from the equator) and income per capita. Montesquieu, however, not only claimed that warm climate makes people lazy and thus unproductive, but also unfit to be governed by democracy. He argued that despotism would be the political system in warm climates. Therefore, a potential explanation for the patterns we see in Figure 1 is that there is an omitted factor, geography, which explains both economic institutions and economic performance. Ignoring this potential third factor would lead to mistaken conclusions.

Even if Montesquieu's story appears both unrealistic and condescending to our modern sensibilities, the general point should be taken seriously: the relationship shown in Figure 1, and for that matter that shown in Figure 2, is not causal. As we pointed out in the context of the effect of religion or social capital on economic performance, these types of scatterplots, correlations, or their multidimensional version in OLS regressions, *cannot* establish causality.

What can we do? The solution to these problems of inference is familiar in microeconometrics: find a source of variation in economic institutions that should have no effect on economic outcomes, or depending on the context, look for a natural experiment.

As an example, consider first one of the clearest natural experiments for institutions.

3.1 The Korean Experiment

Until the end of World War II, Korea was under Japanese occupation. Korean independence came shortly after the Japanese Emperor Hirohito announced the Japanese surrender on August 15, 1945. After this date, Soviet forces entered Manchuria and North Korea and took over the control of these provinces from the Japanese. The major fear of the United States during this time period was the takeover of the entire Korean peninsular either by the Soviet Union or by communist forces under the control of the former guerrilla fighter, Kim Il Sung. U.S. authorities therefore supported the influential nationalist leader Syngman Rhee, who was in favor of separation rather than a united communist Korea. Elections in the South were held in May 1948, amidst a widespread boycott by Koreans opposed to separation. The newly elected representatives proceeded to draft a new constitution and established the Republic of Korea to the south of the 38th parallel. The North became the Democratic People's Republic of Korea, under the control of Kim Il Sung. These two independent countries organized themselves in very different ways and adopted completely different sets of institutions. The North followed the model of Soviet socialism and the Chinese Revolution in abolishing private property of land and capital. Economic decisions were not mediated by the market, but by the communist state. The South instead maintained a system of private property and the government, especially after the rise to power of Park Chung Hee in 1961, attempted to use markets and private incentives in order to develop the economy.

Before this "natural experiment" in institutional change, North and South Korea shared the same history and cultural roots. In fact, Korea exhibited an unparalleled degree of ethnic, linguistic, cultural, geographic and economic homogeneity. There are few geographic distinctions between the North and South, and both share the same disease environment. For example, the CIA Factbook describes the climate of North Korea as "temperate with rainfall concentrated in summer" and that of South Korea as "temperate, with rainfall heavier in summer than winter". In terms of terrain North Korea is characterized as consisting of "mostly hills and mountains separated by deep, narrow valleys; coastal plains wide in west, discontinuous in east," while South Korea is "mostly hills and mountains; wide coastal plains in west and south". In terms of natural resources North Korea is better endowed with significant reserves of coal, lead, tungsten, zinc, graphite, magnesite, iron ore, copper, gold, pyrites, salt, fluorspar, hydropower. South Korea's natural resources are "coal, tungsten, graphite, molybdenum,

lead, hydropower potential." Both countries share the same geographic possibilities in terms of access to markets and the cost of transportation.

Other man-made initial economic conditions were also similar, and if anything, advantaged the North. For example, there was significant industrialization during the colonial period with the expansion of both Japanese and indigenous firms. Yet this development was concentrated more in the North than the South. For instance, the large Japanese zaibatsu of Noguchi, which accounted for one third of Japanese investment in Korea, was centered in the North. It built large hydroelectric plants, including the Suiho dam on the Yalu river, second in the world only to the Boulder dam on the Colorado river. It also created Nippon Chisso, the second largest chemical complex in the world that was taken over by the North Korean state. Finally, in Ch'ongjin North Korea also had the largest port on the Sea of Japan. All in all, despite some potential advantages for the North,[4] Maddison (2001) estimates that at the time of separation, North and South Korea had approximately the same income per capita.

We can therefore think of the splitting on the Koreas 50 years ago as a natural experiment that we can use to identify the causal influence of a particular dimension of institutions on prosperity. Korea was split into two, with the two halves organized in radically different ways, and with geography, culture and many other potential determinants of economic prosperity held fixed. Thus any differences in economic performance can plausibly be attributed to differences in institutions.

Consistent with the hypothesis that it is institutional differences that drive comparative development, since separation, the two Koreas have experienced dramatically diverging paths of economic development: see Figure 3. By the late 1960's South Korea was transformed into one of the Asian "miracle" economies, experiencing one of the most rapid surges of economic prosperity in history while North Korea stagnated. By 2000 the level of income in South Korea was $16,100 while in North Korea it was only $1,000. By 2000 the South had become a member of the Organization of Economic Cooperation and Development, the rich nations club, while the North had a level of per-capita income about the same as a typical sub-Saharan African country. There is only one plausible explanation for the radically different economic experiences on the two Koreas after 1950: their very different institutions led to divergent economic outcomes. In this context, it is noteworthy that the two Koreas not only shared the same geography, but also the same culture.

[4]Such initial differences were probably eradicated by the intensive bombing campaign that the United States unleashed in the early 1950's on North Korea (see Cumings, 2004, chapter 1).

It is possible that Kim Il Sung and Communist Party members in the North believed that communist policies would be better for the country and the economy in the late 1940s. However, by the 1980s it was clear that the communist economic policies in the North were not working. The continued efforts of the leadership to cling to these policies and to power can only be explained by those leaders wishing to look after their own interests at the expense of the population at large. Bad institutions are therefore kept in place, clearly not for the benefit of society as a whole, but for the benefit of the ruling elite, and this is a pattern we encounter in most cases of institutional failure that we discuss in detail below.

However convincing on its own terms, the evidence from this natural experiment is not sufficient for the purposes of establishing the importance of economic institutions as the primary factor shaping cross-country differences in economic prosperity. First, this is only one case, and in the better-controlled experiments in the natural sciences, a relatively large sample is essential. Second, here we have an example of an extreme case, the difference between a market-oriented economy and a communist one. Few social scientists today would deny that a lengthy period of totalitarian centrally planned rule has significant economic costs. And yet, many might argue that differences in economic institutions among capitalist economies or among democracies are not the major factor leading to differences in their economic trajectories. To establish the major role of economic institutions in the prosperity and poverty of nations we need to look at a larger scale "natural experiment" in institutional divergence.

3.2 The Colonial Experiment

The colonization of much of the world by Europeans provides such a large scale natural experiment. Beginning in the early fifteenth century and massively intensifying after 1492, Europeans conquered many other nations. The colonization experience transformed the institutions in many diverse lands conquered or controlled by Europeans. Most importantly, Europeans imposed very different sets of institutions in different parts of their global empire, as exemplified most sharply by the contrast to the economic institutions in the northeast of America to those in the plantation societies of the Caribbean. As a result, while geography was held constant, Europeans initiated large changes in economic institutions, in the social organization of different societies. We will now show that this experience provides evidence which conclusively establishes the central role of economic institutions in development. Given the importance of this material and the details we need to provide, we discuss the colonial experience in the

next section.

4 The Reversal of Fortune

The impact of European colonialism on economic institutions is perhaps most dramatically conveyed by a single fact—historical evidence shows that there has been a remarkable Reversal of Fortune in economic prosperity within former European colonies. Societies like the Mughals in India, and the Aztecs and the Incas in the Americas were among the richest civilizations in 1500, yet the nation states that now coincide with the boundaries of these empires are among the poorer societies of today. In contrast, countries occupying the territories of the less-developed civilizations in North America, New Zealand and Australia are now much richer than those in the lands of the Mughals, Aztecs and Incas.

4.1 The reversal among the former colonies

The Reversal of Fortune is not confined to such comparisons. Using reasonable proxies for prosperity before modern times, we can show that it is a much more systematic phenomenon. Our proxies for income per capita in pre-industrial societies are urbanization rates and population density. Only societies with a certain level of productivity in agriculture and a relatively developed system of transport and commerce can sustain large urban centers and a dense population. Figure 4 shows the relationship between income per capita and urbanization (fraction of the population living in urban centers with greater than 5,000 inhabitants) today, and demonstrates that in the current period there is a significant relationship between urbanization and prosperity.

Naturally, high rates of urbanization do not mean that the majority of the population lived in prosperity. In fact, before the twentieth century urban centers were often centers of poverty and ill health. Nevertheless, urbanization is a good proxy for average income per capita in society, which closely corresponds to the measure we are using to look at prosperity.

Figures 5 and 6 show the relationship between income per capita today and urbanization rates and (log) population density in 1500 for the sample of European colonies.[5] We pick 1500 since it is before European colonization had an effect on any of these

[5]The sample includes the countries colonized by the Europeans between the 15th and the 19th centuries as part of their overseas expansion after the discovery of the New World and the rounding of the Cape of Good Hope. It therefore excludes Ireland, parts of the Russian Empire and also the Middle East and countries briefly controlled by European powers as U.N. Mondays during the 20th century.

societies. A strong negative relationship, indicating a reversal in the rankings in terms of economic prosperity between 1500 and today, is clear in both figures. In fact, the figures show that in 1500 the temperate areas were generally less prosperous than the tropical areas, but this pattern too was reversed by the twentieth century.

The urbanization data for these Figures come from Bairoch (1988), Bairoch, Batou and Chèvre (1988), Chandler (1987), and Eggimann (1999). The data on population density are from McEvedy and Jones (1978). Details and further results are in Acemoglu, Johnson and Robinson (2002a).

There is something extraordinary about this reversal. For example, after the initial spread of agriculture there was remarkable persistence in urbanization and population density for all countries, including those which were to be subsequently colonized by Europeans. In Figures 7 and 8 we show the relationships for urbanization plotting separately the relationship between urbanization in 1000 and in 1500 for the samples of colonies and all other countries. Both figures show persistence, not reversal. Although Ancient Egypt, Athens, Rome, Carthage and other empires rose and fell, what these pictures show is that there was remarkable persistence in the prosperity of regions.

Moreover, reversal was not the general pattern in the world after 1500. Figure 9 shows that within countries not colonized by Europeans in the early modern and modern period, there was no reversal between 1500 and 1995. There is therefore no reason to think that what is going on in Figures 5 and 6 is some sort of natural reversion to the mean.

4.2 Timing of the Reversal

When did the reversal occur? One possibility is that it arose shortly after the conquest of societies by Europeans but Figures 10 and 11 show that the previously-poor colonies surpassed the former highly-urbanized colonies starting in the late eighteenth and early nineteenth centuries, and this went hand in hand with industrialization. Figure 10 shows average urbanization in colonies with relatively low and high urbanization in 1500. The initially high-urbanization countries have higher levels of urbanization and prosperity until around 1800. At that time the initially low-urbanization countries start to grow much more rapidly and a prolonged period of divergence begins. Figure 11 shows industrial production per capita in a number of countries. Although not easy to see in the figure, there was more industry (per capita and total) in India in 1750 than in the United States. By 1860, the United States and British colonies with relatively good economic institutions, such as Australia and New Zealand, began to move ahead

rapidly, and by 1953, a huge gap had opened up.

4.3 Interpreting the Reversal

Which of the three broad hypotheses about the sources of cross-country income differences are consistent with the reversal and its timing? These patterns are clearly inconsistent with simple geography based views of relative prosperity. In 1500 it was the countries in the tropics which were relatively prosperous, in 2003 it is the reverse. This makes it implausible to base a theory of relative prosperity today, as Sachs (2000, 2001) does, on the intrinsic poverty of the tropics. This argument is inconsistent with the historical evidence.

Nevertheless, following Diamond (1997), one could propose what Acemoglu, Johnson and Robinson (2002a) call a "sophisticated geography hypothesis" which claims that geography matters but in a time varying way. For example, Europeans created "latitude specific" technology, such as heavy metal ploughs, that only worked in temperate latitudes and not with tropical soils. Thus when Europe conquered most of the world after 1492, they introduced specific technologies that functioned in some places (the United States, Argentina, Australia) but not others (Peru, Mexico, West Africa). However, the timing of the reversal, coming as it does in the nineteenth century, is inconsistent with the most natural types of sophisticated geography hypotheses. Europeans may have had latitude specific technologies, but the timing implies that these technologies must have been industrial, not agricultural, and it is difficult to see why industrial technologies do not function in the tropics (and in fact, they have functioned quite successfully in tropical Singapore and Hong Kong).[6]

Similar considerations weigh against the culture hypothesis. Although culture is slow-changing the colonial experiment was sufficiently radical to have caused major changes in the cultures of many countries that fell under European rule. In addition, the destruction of many indigenous populations and immigration from Europe are likely to have created new cultures or at least modified existing cultures in major ways (see Vargas Llosa, 1989, for a fictionalized account of just such a cultural change). Nevertheless, the culture hypothesis does not provide a natural explanation for the reversal, and has nothing to say on the timing of the reversal. Moreover, we discuss below how econometric models that control for the effect of institutions on income do not find any evidence of an effect

[6]A possible link is that proposed by Lewis (1978) who argued that tropical agriculture is less productive than temperate agriculture, and that an 'agricultural revolution' is a prerequisite to an industrial revolution because high agricultural productivity is needed to stimulate the demand for industrial goods.

of religion or culture on prosperity.

The most natural explanation for the reversal comes from the institutions hypothesis, which we discuss next.

4.4 Economic Institutions and the Reversal

Is the Reversal of Fortune consistent with a dominant role for economic institutions in comparative development? The answer is yes. In fact, once we recognize the variation in economic institutions created by colonization, we see that the Reversal of Fortune is exactly what the institutions hypothesis predicts.

In Acemoglu, Johnson and Robinson (2002a) we tested the connection between initial population density, urbanization, and the creation of good economic institutions. We showed that, others things equal, the higher the initial population density or the greater initial urbanization, the worse were subsequent institutions, including both institutions right after independence and today. Figures 12 and 13 show these relationships using the same measure of current economic institutions used in Figure 1, protection against expropriation risk today. They document that the relatively densely settled and highly urbanized colonies ended up with worse (or 'extractive') institutions, while sparsely-settled and non-urbanized areas received an influx of European migrants and developed institutions protecting the property rights of a broad cross-section of society. European colonialism therefore led to an institutional reversal, in the sense that the previously-richer and more-densely settled places ended up with worse institutions.[7]

To be fair, it is possible that the Europeans did not actively introduce institutions discouraging economic progress in many of these places, but inherited them from previous civilizations there. The structure of the Mughal, Aztec and Inca empires were already very hierarchical with power concentrated in the hands of narrowly based ruling elites and structured to extract resources from the majority for the benefit of a minority. Often Europeans simply took over these existing institutions. Whether this is so is secondary for our focus, however. What matters is that in densely-settled and relatively-developed places it was in the interests of Europeans to have institutions facilitating the extraction of resources thus not respecting the property rights of the majority, while in the sparsely-settled areas it was in their interests to develop institutions protecting

[7]The institutional reversal does not mean that institutions were necessarily better in the previously more densely-settled areas (see the next paragraph). It only implies a tendency for the relatively poorer and less densely-settled areas to end up with better institutions than previously-rich and more densely-settled areas.

property rights. These incentives led to an institutional reversal.

The institutional reversal, combined with the institutions hypothesis, predicts the Reversal of Fortune: relatively rich places got relatively worse economic institutions, and if these institutions are important, we should see them become relatively poor over time. This is exactly what we find with the Reversal of Fortune.

Moreover, the institutions hypothesis is consistent with the timing of the reversal. Recall that the institutions hypothesis links incentives to invest in physical and human capital and in technology to economic institutions, and argues that economic prosperity results from these investments. Therefore, economic institutions should become more important when there are major new investment opportunities. The opportunity to industrialize was the major investment opportunity of the nineteenth century. Countries that are rich today, both among the former European colonies and other countries, are those that industrialized successfully during this critical period.

4.5 Understanding the colonial experience

The explanation for the reversal that emerges from our discussion so far is one in which the economic institutions in various colonies were shaped by Europeans to benefit themselves. Moreover, because conditions and endowments differed between colonies, Europeans consciously created different economic institutions, which persisted and continue to shape economic performance. Why did Europeans introduce better institutions in previously-poor and unsettled areas than in previously-rich and densely-settled areas? The answer to this question relates to the comparative statics of our theoretical framework. Leaving a full discussion to later, we can note a couple of obvious ideas.

Europeans were more likely to introduce or maintain economic institutions facilitating the extraction of resources in areas where they would benefit from the extraction of resources. This typically meant areas controlled by a small group of Europeans, and areas offering resources to be extracted. These resources included gold and silver, valuable agricultural commodities such as sugar, but most importantly people. In places with a large indigenous population, Europeans could exploit the population, be it in the form of taxes, tributes or employment as forced labor in mines or plantations. This type of colonization was incompatible with institutions providing economic or civil rights to the majority of the population. Consequently, a more developed civilization and a denser population structure made it more profitable for the Europeans to introduce worse economic institutions.

In contrast, in places with little to extract, and in sparsely-settled places where the

Europeans themselves became the majority of the population, it was in their interests to introduce economic institutions protecting their own property rights.

4.6 Settlements, Mortality and Development

The initial conditions we have emphasized so far refer to indigenous population density and urbanization. In addition, the disease environments differed markedly among the colonies, with obvious consequences on the attractiveness of European settlement. As we noted above, when Europeans settled, they established institutions that they themselves had to live under. Therefore, whether Europeans could settle or not had an exogenous effect on the subsequent path of institutional development. In other words, if the disease environment 200 or more years ago affects outcomes today only through its effect on institutions today, then we can use this historical disease environment as an exogenous source of variation in current institutions. From an econometric point of view we have a valid instrument which will enable us to pin down the casual effect of economic institutions on prosperity.[8]

We developed this argument in Acemoglu, Johnson and Robinson (2001) and investigated it empirically. We used initial conditions in the European colonies, particularly data from Curtin (1989, 1998) and Gutierrez (1986) on the mortality rates faced by Europeans (primarily soldiers, sailors, and bishops), as instruments for current economic institutions. The justification for this is that, outside of its effect on economic institutions during the colonial period, historical European mortality has no impact on current income levels. Figures 14 and 15 give scatter plots of this data against contemporaneous economic institutions and GDP per-capita. The sample is countries which were colonized by Europeans in the early modern and modern periods and thus excludes, among others, China, Japan, Korea, Thailand.

Figure 14 shows the very strong relationship between the historical mortality risk faced by Europeans and the current extent to which property rights are enforced. A bivariate regression has an R^2 of 0.26. It also shows that there were very large differences in European mortality. Countries such as Australia, New Zealand and the United States were very healthy with life expectancy typically greater than in Britain. On the other hand mortality was extremely high in Africa, India and South-East Asia. Differential

[8]Although European mortality is potentially correlated with indigenous mortality, which may determine income today, in practice local populations have developed much greater immunity to malaria and yellow fever. Thus the historical experience of European mortality is a valid instrument for institutional development. See Acemoglu, Johnson and Robinson (2001).

mortality was largely due to tropical diseases such as malaria and yellow fever and at the time it was not understood how these diseases arose nor how they could be prevented or cured.

In Acemoglu, Johnson and Robinson (2001) we showed, using European mortality as an instrument for the current enforcement of property rights, that most of the gap between rich and poor countries today is due to differences in economic institutions. More precisely, we showed (p. 1387) that if one took two typical—in the sense that they both lie on the regression line—countries with high and low expropriation risk, like Nigeria and Chile, then almost the entire difference in incomes per-capita between them could be explained by the differences in the security of property rights. We also presented regression evidence that showed that once the effect of economic institutions on GDP per-capita was properly controlled for, geographical variables, such as latitude, whether or not a country is land-locked and the current disease environment, have no explanatory power for current prosperity.

These ideas and results provide an interpretation of why there are strong correlations between geographical variables such as latitude and income per-capita. Basically this is because Europeans did not have immunity to tropical diseases during the colonial period and thus settler colonies tended, other things equal, to be created in temperate latitudes. Thus the historical creation of economic institutions was correlated with latitude. Without considering the role of economic institutions it is easy to find a spurious relationship between latitude and income per-capita. However, once economic institutions are properly controlled for, these relationships go away. There is no causal effect of geography on prosperity today, though geography may have been important historically in shaping economic institutions.

What about the role of culture? On the face of it, the Reversal of Fortune is consistent with cultural explanations of comparative growth. The Europeans not only brought new institutions, they also brought their own cultures. There seem to be three main ways to test this idea. First, cultures may be systematically related to the national identity of the colonizing power. For example, the British may have implanted a 'good' Anglo-Saxon culture into colonies such as Australia and the United States, while the Spanish may have condemned Latin America by endowing it with a Hispanic or Iberian culture (the academic literature is full of ideas like this, for recent versions see Véliz, 1994, North, Summerhill and Weingast, 2000, and Wiarda, 2001). Second, following Landes (1998), Europeans may have had a culture, for example a work ethic or set of beliefs, which was uniquely propitious to prosperity. Finally, following Weber (1930),

Europeans also brought different religions with different implications for prosperity. Such a hypothesis could explain why Latin America is relatively poor since its citizens are primarily Roman Catholic, while North America is relatively rich because its citizens are mostly Protestant.

However, the econometric evidence in Acemoglu, Johnson and Robinson (2001) is not consistent with any these views. Once we control properly for the effects of economic institutions, neither the identity of the colonial power, nor the contemporary fraction of Europeans in the population, nor the proportions of the populations of various religions, are significant determinants of income per capita.

These econometric results are supported by historical examples. For instance, with respect to the identity of the colonizing power, in the 17th century the Dutch had perhaps the best domestic economic institutions in the world but the colonies they created in South-East Asia ended up with institutions designed for the extraction of resources, providing little economic or civil rights to the indigenous population.

It is also be clear that the British in no way simply re-created British institutions in their colonies. For example, by 1619 the North American colony of Virginia had a representative assembly with universal male suffrage, something that did not arrive in Britain itself until 1919. Another telling example is due to Newton (1914) and Kupperman (1993), who showed that the Puritan colony in Providence Island in the Caribbean quickly became just like any other Caribbean slave colony despite the Puritanical inheritance. Although no Spanish colony has been as successful economically as British colonies such as the United States, it is also important to note that Britain had many unsuccessful colonies (in terms of per capita income), such as in Africa, India and Bangladesh (see Acemoglu, Johnson and Robinson, 2004).

To emphasize that the culture or the religion of the colonizer was not at the root of the divergent economic performances of the colonies, Figure 16 shows the reversal among the British colonies (with population density in 1500 on the horizontal axis). Just as in Figure 6, there is a strong negative relationship between population density in 1500 and income per capita today.

With respect to the role of Europeans, Singapore and Hong Kong are now two of the richest countries in the world, despite having negligible numbers of Europeans. Moreover, Argentina and Uruguay have higher proportions of people of European descent than the United States and Canada, but are much less rich. To further document this, Figure 17 shows a similar reversal of fortune for countries where the fraction of those with European descent in 1975 is less than 5 percent of the population.

Overall, the evidence is not consistent with a major role of geography, religion or culture transmitted by the identity of the colonizer or the presence of Europeans. Instead, differences in economic institutions appear to be the robust causal factor underlying the differences in income per capita across countries. Institutions are therefore the fundamental cause of income differences and long-run growth.

5 Why Do Institutions Differ?

We saw that economic institutions matter, indeed are central in determining relative prosperity. In terms of the different fundamental theories that we discussed, there is overwhelming support for the emphasis of North and Thomas on institutions, as opposed to alternative candidate explanations which emphasize geography or culture. Yet, as we discussed in the introduction, finding that differences in economic institutions can account for the preponderance of differences in per-capita income between countries creates as many questions as it answers. For example, why do countries have different economic institutions? If poor countries are poor because they have bad economic institutions why do they not change them to better institutions? In short, to explain the evidence presented in the last two sections we need a theory of economic institutions. The theory will help to explain the equilibrium set of economic institutions in a particular country and the comparative statics of this theory will help to explain why economic institutions differ across countries.

In the Introduction (section 1.2), we began to develop such a theory based on social conflict over economic institutions. We have now substantiated the first point we made there, that economic institutions determine prosperity. We must now move to substantiate our second point, that economic institutions must be treated as endogenous and what which economic institutions emerge depends on the distribution of political power in society. This is a key step towards our theory of economic institutions. In the process of substantiating this point however it is useful to step back and discuss other alternative approaches to developing a theory of economic institutions. Broadly speaking, there are four main approaches to the question of why institutions differ across countries, one of which coincides with the approach we are proposing, the social conflict view. We next discuss each of these separately and our assessment as to whether they provide a satisfactory framework for thinking about differences in economic institutions (see Acemoglu, 2003a, and Robinson, 1998, for related surveys of some of these approaches). We shall conclude that the approach we sketched in section 1.2 is by far the most promising one.

5.1 The Efficient Institutions View—The Political Coase Theorem

According to this view, societies will choose the economic institutions that are socially efficient. How this surplus will be distributed among different groups or agents does not affect the choice of economic institutions. We stress here that the concept of efficiency is stronger than simply Pareto Optimality; it is associated with surplus, wealth or output maximization.

The underlying reasoning of this view comes from the Coase Theorem. Coase (1960) argued that when different economic parties could negotiate costlessly, they will be able to bargain to internalize potential externalities. A farmer, who suffers from the pollution created by a nearby factory, can pay the factory owner to reduce pollution. Similarly, if the current economic institutions benefit a certain group while creating a disproportionate cost for another, these two groups can negotiate to change the institutions. By doing so they will increase the size of the total surplus that they can divide between themselves, and they can then bargain over the distribution of this additional surplus.

Many different versions of the efficient economic institutions view have been proposed. Indeed, assuming that existing economic institutions are efficient is a standard methodological approach of economists, i.e., observing an institution, one tries to understand what are the circumstances that lead it to be efficient. Demsetz (1967) argued that private property emerged from common property when land became sufficiently scarce and valuable that it was efficient to privatize it. More recently, Williamson's (1985) research, as well as Coase's (1936) earlier work and the more formal analysis by Grossman and Hart (1986), argues that the governance of firms or markets is such as to guarantee efficiency (given the underlying informational and contractual constraints). Williamson argued that firms emerged as an efficient response to contractual problems that plague markets, particularly the fact that there may be ex-post opportunism when individuals make relationship specific investments. Another famous application of the efficient institutions view is due to North and Thomas (1973) who argued that feudal economic institutions, such as serfdom, were an efficient contract between serfs and lords. The lords provided a public good, protection, in exchange for the labor of the serfs on their lands. In this view, without a modern fiscal system this was an efficient way to organize this exchange. (See Townsend, 1993, for a recent version of the idea that other economic institutions of Medieval Europe, such as the open field system, were efficient).

Williamson and North and Thomas do not specify how different parties will reach agreement to achieve efficient economic institutions, and this may be problematical in

the sense that many economic institutions relevant for development are collective choices not individual bargains. There may therefore be free riding problems inherent in the creation of efficient economic institutions. Nevertheless, the underlying idea, articulated by Becker (1960) and Wittman (1989), is that, at least in democracies, competition among pressure groups and political parties will lead to efficient policies and collective choices. In their view, an inefficient economic institution cannot be stable because a political entrepreneur has an incentive to propose a better economic institution and with the extra surplus generated will be able to make himself more attractive to voters. The efficient institutions view regards the structure of political institutions or power as irrelevant. This may matter for the distribution of total surplus, but it will not matter for efficiency itself. The 'efficient' set of political institutions is therefore indeterminate.

The notion that a Coasian logic applies in political life as well as in economics is referred to by Acemoglu (2003a) as the Political Coase Theorem. Although the intuition that individuals and groups will strive towards efficient economic outcomes is appealing, there are both theoretical and empirical limits to the Political Coase Theorem. First, as argued by Acemoglu (2003a) and further discussed below, in politics there is an inherent commitment problem, often making the Political Coase Theorem inapplicable.

Second, the Political Coase Theorem does not take us very far in understanding the effect of economic (or indeed political) institutions on economic outcomes – in this view, economic institutions are chosen efficiently, and all societies have the best possible economic institutions given their needs and underlying structures; hence, with the Political Coase Theorem, economic institutions cannot be the fundamental cause of income differences. However, the empirical results we discussed above suggest a major role for such institutional differences.

The only way to understand these patterns is to think of economic institutions varying for reasons other than the underlying needs of societies. In fact, the instrumental variables and natural experiment strategies we exploited above make use precisely of a source of variation unrelated to the underlying needs of societies. For example, South and North Korea did not adopt very different economic systems because they had different needs, but because different systems were imposed on them for other exogenous reasons. In sum, we need a framework for understanding why certain societies consistently end up with economic institutions that are not, from a social point of view, in their best interests. We need a framework other than the Political Coase Theorem.

5.2 The Ideology View

A second view is that economic institutions differ across countries because of ideological differences – because of the similarity between this and the previous view, Acemoglu (2003a) calls this the Modified Political Coase Theorem. According to this view, societies may choose different economic institutions, with very different implications, because they—or their leaders—disagree about what would be good for the society. According to this approach, there is sufficient uncertainty about the right economic institutions that well-meaning political actors differ about what's good for their own people. Societies where the leaders or the electorate turn out to be right ex post are those that prosper. The important point is that, just as with the efficient institutions view, there are strong forces preventing the implementation of policies that are *known* to be bad for the society at large.

Several theoretical models have developed related ideas. For example, Piketty (1995) examined a model where different people have different beliefs about how much effort is rewarded in society. If effort is not rewarded then taxation generates few distortions and agents with such beliefs prefer a high tax rate. On the other hand if one believes that effort is rewarded then low taxes are preferable. Piketty showed that dispersion of beliefs could create dispersion of preferences over tax rates, even if all agents had the same objective. Moreover, incorrect beliefs could be self-fulfilling and persist over time because different beliefs tend to generate information consistent with those beliefs. Romer (2003) also presents a model where voters have different beliefs and showed that if mistakes are correlated, then society can choose a socially inefficient outcome. These models show that if different societies have different beliefs about what is socially efficient they can rationally choose different economic institutions.

Belief differences clearly do play a role in shaping policies and institutions. Several interesting examples of this come from the early experience of independence in former British colonies. For example, it is difficult to explain Julius Nyerere's policies in Tanzania without some reference to his and other leading politicians' beliefs about the desirability of a socialist society. It also appears true that in India the Fabian socialist beliefs of Jawaharlal Nehru were important in governing the initial direction that Indian economic policies took.

Nevertheless, the scope of a theory of institutional divergence and comparative development based on ideology seems highly limited. Can we interpret the differences in institutional development across the European colonies or the divergence in the eco-

nomic institutions and policies between the North and South of Korea as resulting from differences in beliefs? For example, could it be the case that while Rhee, Park, and other South Korean leaders believed in the superiority of capitalist institutions and private property rights enforcement, Kim Il Sung and Communist Party members in the North believed that communist policies would be better for the country?

In the case of South versus North Korea, this is certainly a possibility. However, even if differences in beliefs could explain the divergence in economic institutions in the immediate aftermath of separation, by the 1980s it was clear that the communist economic policies in the North were not working. The continued effort of the leadership to cling to these policies, and to power, can only be explained by leaders looking after their own interests at the expense of the population at large. Most likely, North Korean leaders, the Communist Party, and bureaucratic elites are prolonging the current system, which gives them greater economic and political returns than the alternative, even though they fully understand the costs that the system imposes on the North Korean people.

Differences in colonial policies are even harder to explain on the basis of differences in ideology. British colonists established different economic institutions in very different parts of the world: in the Caribbean they set up plantation societies based on slavery, supported by highly oppressive economic institutions. In contrast, the economic institutions that developed in areas where the British settled, and where there was no large population of indigenous to be captured and put to work, and where slavery could not be profitably used, such as northeastern United States, Canada, Australia and New Zealand, were very different. Moreover, differences in the incentives of the colonists in various colonies are easy to understand: when they did not settle, they were choosing economic institutions simply to extract resources from the native population. When they settled in large numbers, economic institutions and policies emerged in order to protect them in the future and encourage investment and prosperity.

These considerations make us tend towards a view which emphasizes the actions of key economic and political agents that are taken rationally and in recognition of their consequences, not simply differences in beliefs. We do not deny that belief differences and ideology often play important roles but we do not believe that a satisfactory theory of institutional differences can be founded on differences in ideology.

5.3 The Incidental Institutions View

The efficient institutions view is explicitly based on economic reasoning: the social costs and benefits of different economic institutions are weighed against each other to deter-

mine which economic institutions should prevail. Efficiency arises because individuals ultimately calculate according to social costs and benefits. Institutions are therefore choices. A different approach, popular among many political scientists and sociologists, but also some economists, is to downplay choices and to think of institutions, both economic and political, as the by-product or unintended consequence of other social interactions or historical accidents. In other words, historical accidents at critical junctures determine institutions, and these institutions persist for a long time, with significant consequences.

Here, we discuss two such theories. The first is the theory of political institutions developed by Moore (1966) in his *Social Origins of Dictatorship and Democracy*, the second is the recent emphasis in the economics literature on legal origins, for example as in the work of Shleifer and his co-authors (La Porta, Lopez-de-Silanes, Shleifer and Vishny, 1998, 1999, Djankov, LaPorta, Lopez-de-Silanes and Shleifer, 2002, 2003, Glaeser and Shleifer, 2002).

Moore attempted to explain the different paths of political development in Britain, Germany and Russia. In particular, he investigated why Britain evolved into a democracy, while Germany succumbed to fascism and Russia had a communist revolution. Moore stressed the extent of commercialization of agriculture and resulting labor relations in the countryside, the strength of the 'bourgeoisie,' and the nature of class coalitions. In his theory, democracy emerged when there was a strong, politically assertive, commercial middle class, and when agriculture had commercialized so that there were no feudal labor relations in the countryside. Fascism arose when the middle classes were weak and entered into a political coalition with landowners. Finally, a communist revolution resulted when the middle classes were non-existent, agriculture was not commercialized, and rural labor was repressed through feudal regulations. In Moore's theory, therefore, class coalitions and the way agriculture is organized determine which political institutions will emerge. However, the organization of agriculture is not chosen with an eye to its effects on political institutions, so these institutions are an unintended consequence. Although Moore was not explicitly concerned with economic development, it is a direct implication of his analysis that societies may end up with institutions that do not maximize income or growth, for example, when they take the path to communist revolution.

Beginning with the work on shareholder rights (La Porta, Lopez-de-Silanes, Shleifer and Vishny, 1998), continuing to the efficiency of government (La Porta, Lopez-de-Silanes, Shleifer and Vishny, 1999) and more recently the efficiency of the legal system

(Djankov, La Porta, Lopez-de-Silanes and Shleifer, 2003), Shleifer and his co-authors have argued that a central source of variation in many critical economic institutions is the origin of the legal system. For example, "Civil laws give investors weaker legal rights than common laws do, independent of the level of per-capita income. Common-law countries give both shareholders and creditors—relatively speaking—the strongest, and French-civil-law countries the weakest, protection. " (La Porta et al., 1998, p. 1116)

These differences have important implications for resource allocation. For example, when shareholders have poor protection of their rights, ownership of shares tends to be more highly concentrated. Djankov et al. (2003) collected a cross-national dataset on how different countries legal systems dealt with the issue of evicting a tenant for nonpayment of rent and collecting on a bounced check. They used these data to construct an index of procedural formalism of dispute resolution for each country and showed that such formalism was systematically greater in civil than in common law countries, and is associated with higher expected duration of judicial proceedings, less consistency, less honesty, less fairness in judicial decisions, and more corruption. Legal origins therefore seems to matter for important institutional outcomes.

Where do legal origins come from? The main argument is that they are historical accidents, mostly related to the incidence of European colonialism. For example, Latin American countries adopted the Napoleonic codes in the nineteenth century because these were more compatible with their Spanish legal heritage. Importantly, the fact that Latin American countries therefore have 'French legal origin' is due to a historical accident and can be treated as exogenous with respect to current institutional outcomes. What about the difference between common law and civil law? Glaeser and Shleifer (2002) argue that the divergence between these systems stems from the medieval period and reflects the balance of power between the lords and the king in England and France. Once these systems established, they persisted long after the initial rationale vanished.

Although we believe that historical accidents and persistence are important, in reality the aspect of choice over institutions seems too important to be denied. Even if institutions have a tendency to persist, their persistence is still a choice, in the sense that if the agents decided to change institutions, change would be possible. There are important examples from history of countries radically changing their legal systems such as in Japan after the Meiji restoration, Russia after the Crimean War, and Turkey under Mustafa Kemal in the 1920's. Another example might be central planning of the economy. Though many countries adopted this way or organizing the economy some abandoned it while others, such as North Korea and Cuba, still maintain it. The point

here is that though institutions may in some circumstances be the incidental outcome of history, at some point people will start to ask why society has the institutions that it does and to consider other alternatives. At this point we are back in the realm of choice.

5.4 The Social Conflict View

According to this view, economic (and political) institutions are not always chosen by the whole society (and not for the benefit of the whole society), but by the groups that control political power at the time (perhaps as a result of conflict with other groups). These groups will choose the economic institutions that maximize their own rents, and the economic institutions that result may not coincide with those that maximize total surplus, wealth or income. For example, economic institutions that enforce property rights by restricting state predation may not be in the interest of a ruler who wants to appropriate assets in the future. By establishing property rights, this ruler would be reducing his own future rents, so may well prefer economic institutions other than enforced private property. Therefore, equilibrium economic institutions will not be those that maximize the size of the overall pie, but the slice of the pie taken by the powerful groups.

The first systematic development of this point of view in the economics literature is North (1981), who argued in the chapter on "A Neoclassical Theory of the State" that agents who controlled the state should be modeled as self-interested. He then argued that the set of property rights that they would choose for society would be those that maximized their payoff and because of 'transactions costs,' these would not necessarily be the set that maximized social welfare. One problem with North's analysis is that he does not clarify what the transactions costs creating a divergence between the interests of the state and the citizens are. Here, we will argue that commitment problems are at the root of this divergence.

The notion that elites, i.e., the politically powerful, may opt for economic institutions which increase their incomes, often at the expense of society, is of course also present in much of the Marxist and dependency theory literature. For example, Dobb (1948), Brenner (1976, 1982) and Hilton (1981) saw feudalism, contrary to North and Thomas's (1973) model, as a set of institutions designed to extract rents from the peasants at the expense of social welfare.[9] Dependency theorists such as Williams (1944), Wallerstein (1974-1982), Rodney (1972), Frank (1978) and Cardoso and Faletto (1979) argued that

[9]Postan (1966, pp. 603-604) famously estimated that lords extracted about 50% of the entire production of peasants.

the international trading system was designed to extract rents from developing countries to the benefit of developed countries.

The social conflict view includes situations where economic institutions may initially be efficient for a set of circumstances but are no longer efficient once the environment changes. For example, Acemoglu, Aghion and Zilibotti (2001) show that though certain sorts of organizations may be useful for countries a long way from the technological frontier, it may be socially efficient to change them subsequently. This may not happen however because it is not privately rational. An interesting example may be the large business enterprises (the *chaebol*) of South Korea. In the context of political institutions, one might then develop a similar thesis. Certain sets of institutions are efficient for very poor countries but they continue to apply even after they cease to be the efficient institutional arrangement.

In stark contrast to the efficient institutions view, political institutions play a crucial role in the social conflict view. Which economic institutions arise depends on who has political power to create or block different economic institutions. Since political institutions play a central role in the allocation of such power they will be an intimate part of a social conflict theory of economic institutions.

What distinguishes the social conflict view from the ideological view is that social conflict can lead to choices of economic institutions which cause underdevelopment even when all agents have common knowledge that this is so. What distinguishes it from the incidental view is that it emphasizes that institutional choices which cause underdevelopment are conscious choices, rather than the result of some historical accident. The aspect that distinguishes the social conflict view from the efficient institutions view is that it does not assume that institutions are always efficient. This is one possible outcome but it is not the only one or indeed the most likely. Why is this? Why cannot efficiency be separated from distribution? We discuss this issue in the next section.

6 Sources of Inefficiencies

Having motivated our first two assertions in section 1.2, we are now in a position to discuss the third, related to the importance of commitment problems. The inability to commit to how political power will be used in the future means that the impact of economic institutions on efficiency cannot be separated from their effects on distribution.[10]

In any market situation where economic exchange takes place, and the quid is sepa-

[10]An alternative approach would be to stress informational asymmetries (Farrell, 1987).

rated from the pro quo, issues of commitment will arise. That these issues are of crucial importance has been recognized in the literatures on incomplete contracts and renegotiation (e.g., Hart, 1995). Nevertheless, if the legal system functions properly, there is an array of enforceable contracts that owners can sign with managers, workers with employers, borrowers with lenders etc. These contracts can be enforced because there is an authority, a third party, with the power to enforce contracts. Although the authority that is delegated to enforce contracts and to resolve disputes varies depending on the exact situation, all such power ultimately emanates from the state, which, in modern society, has a near-monopoly on the use of legitimate coercion. An owner and manager can write a contract because they believe that the state, and its agents the courts, would be impartial enforcers of the contract.

In contrast, if, for example, a manager believed that the state would be aligned with the interests of the owner and refuse to punish the owner if and when he failed to make a payment stipulated by the contract, then the contract would have little value. Therefore, the presence of an impartial enforcer is important for contracting. The problem when it comes to institutional choices is that there is no such impartial third party that can be trusted to enforce contracts. This is the origin of the commitment problem in politics.

To elaborate on this point, let us consider a situation where society can be governed as a dictatorship or as a democracy. Imagine that the dictator does not relinquish his power, but instead he promises that he will obey the rules of democracy, so that individuals can undertake the same investments as they would in democracy. This promise would not necessarily be credible. As long as the political system remains a dictatorship, there is no higher authority to make the dictator stick to his promise. There is no equivalent of a contract that can be enforced by an impartial third-party. After all, the dictator has the monopoly of military and political power, so he is the final arbiter of conflicting interests. There is no other authority to force the dictator to abide by his promises.

A similar problem plagues the reverse solution, whereby the dictator agrees to a voluntary transition to democracy in return for some transfers in the future to compensate him for the lost income and privileges. Those who will benefit from a transition to democracy would be willing to make such promises, but once the dictator relinquishes his political power, there is no guarantee that citizens would agree to tax themselves in order to make payments to this former dictator. Promises of compensation to a former dictator are typically not credible.

The essence of the problem is commitment. Neither party can commit to compensate the other nor can they commit to take actions that would not be in their interests ex

post. The reason why commitment problems are severe in these examples is because we are dealing with political power. Different institutions are associated with different distributions of political power, and there is no outside impartial party with the will and the power to enforce agreements. In some cases, there may be self-enforcing promises that maintain an agreement. Acemoglu (2003a) discusses such possibilities, but in general, there are limits to such self-enforcing agreements, because they require the participants to be sufficiently patient, and when it comes to matters of political power, the future is uncertain enough that no party would behave in a highly patient manner.

Based on this reasoning, we can now discuss three different channels via which the presence of commitment problems will lead to the choice and persistence of inefficient institutions.

6.1 Holdup

Imagine a situation in which an individual or a group holds unconstrained political power. Also suppose that productive investments can be undertaken by a group of citizens or producers that are distinct from the "political elites", i.e., the current power holders. The producers will only undertake the productive investments if they expect to receive the benefits from their investments. Therefore, a set of economic institutions protecting their property rights are necessary for investment. Can the society opt for a set of economic institutions ensuring such secure property rights? The answer is often no (even assuming that "society" wants to do so).

The problem is that the political elites—those in control of political power—cannot commit to respect the property rights of the producers once the investment are undertaken. Naturally, ex ante, before investments are undertaken, they would like to promise secure property rights. But the fact that the monopoly of political power in their hands implies that they cannot commit to not hold-up producers once the investments are sunk.

This is an obvious parallel to the hold-up problem in the theory of the firm, where once one of the parties in a relationship has undertaken investments specific to the relationship, other parties can hold her up, and capture some of the returns from her investments. As in the theory of the firm, the prospect of hold-up discourages investment. But now the problem is much more severe, since it is not only investments that are specific to a relationship that are subject to hold-up, but all investments.

This is therefore an example of how inefficient economic institutions arise because of a monopoly of political power. Those with political power cannot commit not to use their

political power ex post, and this translates directly into a set of economic institutions that do not provide secure property rights to groups without political power. The consequence is clear: without such protection, productive investments are not undertaken, and opportunities for economic growth go unexploited.

The reason why these inefficient economic institutions persist (or may be the equilibrium institutions of the society) is related to commitment problems. Parallel to our above example of inducing the dictator to relinquish power, there are two ways to introduce secure property rights. First, in principle, political elites could promise to respect property rights. However, mere promises would not be credible, unless backed up by the political elites relinquishing power, and this would mean relinquishing their rents and privileges. Second, political elites can be bought off by the beneficiaries of a system of more secure property rights. This would typically be achieved by a promise of future payments. For example, after investments are undertaken and output is produced, a share can be given to the political elites. But, as pointed out above, there is another, reverse commitment problem here; the beneficiaries of the new regime cannot commit to making the promised payments to the previous political elites.

Many real world examples illustrate the commitment problems involved in limiting the use of political power. In practice, although buying off dictators and persuading them to leave power is difficult, there have been many attempts to do so, usually by trying to guarantee that they will not be persecuted subsequently. One way of doing this is to give them asylum in another country. Nevertheless, such attempts rarely succeed, most likely again because of commitment problems (the new regime cannot commit to abide by its promises). An illustrative example of this is the attempts by the Reagan administration to persuade Jean-Claude ('Baby Doc') Duvalier to relinquish power in Haiti in 1986. In the face of a popular uprising and rising social and economic chaos, the Reagan administration, via the intermediation of the Jamaican Prime Minster Edward Seaga, tried to persuade Duvalier to go into exile. He at first agreed and the White House announced his departure on January 30th, but the next day he changed his mind, unsure that he would really be protected, and stayed in Haiti. One month later he was forced into exile in France by the military.

A more common, and in many ways more interesting strategy to induce dictators to relinquish power is to try to structure political institutions so as to guarantee that they will not be punished. Such institutional changes are sometimes important in transitions to democracy. For example, President Pinochet was willing to abide by the results of the 1989 plebiscite he lost in Chile because as a senator the Constitution protected him

from prosecution. It was only when he left the country that he was vulnerable.

Although Pinochet's experience illustrates an example of structuring political institutions to achieve commitment, to create durable institutions constraining future use of political power is difficult in practise. These difficulties are well illustrated by the transition from white rule in Rhodesia to majority rule in Zimbabwe. Facing an unwinable guerilla war, the white elite in Rhodesia sought to negotiate a transition of majority rule, but with enough institutional safeguards that their rents would be protected. These safeguards included the electoral system they wanted, which was used for the first post-independence elections, and massive over-representation in parliament (Reynolds 1999, p. 163). Whites were guaranteed 20% of the seats in the legislature for seven years despite making up only 2-3% of the population and were guaranteed 10 seats of the 40 seat senate. Clauses of the 1980 Constitution were also aimed at directly guaranteeing the property rights of the whites. In particular land reform was outlawed for 10 years after which it could only take place if compensated.

The white negotiators at the Lancaster House talks in 1979 that produced these agreements understood that any promises made by the black majority negotiators about what would happen after independence could not be believed. They sought therefore to find a set of rules that would get around this problem (Herbst, 1990, pp. 13-36). Nevertheless, these guarantees were not enough to protect the property rights (and rents) of the whites in anything other than the short run. The Mugabe regime quickly absorbed the other factions from among the African guerilla opposition, and more moderate relatively pro-white groups, such as Abel Muzorewa's United African National Council, crumbled. In 1985 the Mugabe regime switched back to the electoral system it preferred (Reynolds, 1999, p. 164) and in 1987, at the first possible opportunity, it removed the guaranteed representation for whites. Though in 1987 Mugabe nominated white candidates for these seats (Horowitz, 1991, pp. 135-136), this did not last for long. In 1990 the senate was abolished. Finally, in 1990 the Constitution was amended to allow for the redistribution of land. Since this time the Mugabe government has begun a sustained policy of land redistribution away from whites through legal and extra-legal means.

6.2 Political losers

Another related source of inefficient economic institutions arises from the desire of political elites to protect their political power. Political power is the source of the incomes, rents, and privileges of the elite. If their political power were eroded, their rents would decline. Consequently, the political elite should evaluate every potential economic change

not only according to its economic consequences, such as its effects on economic growth and income distribution, but also according to its political consequences. Any economic change that will erode the elites' political power is likely to reduce their economic rents in the long run.

As an example, imagine a change in economic institutions that will increase economic growth, but in doing so, will also enrich groups that could potentially contest political power in the future. Everything else equal, greater economic growth is good for those holding political power. It will create greater returns on the assets that they possess, and also greater incomes that they can tax or expropriate. However, if their potential enemies are enriched, this also means greater threats against their power in the future. Fearing these potential threats to their political power, the elites may oppose changes in economic institutions that would stimulate economic growth.

That the threat of becoming a political loser impedes the adoption of better institutions is again due to a commitment problem. If those who gained political power from institutional change could promise to compensate those who lost power then there would be no incentive to block better institutions.

There are many historical examples illustrating how the fear of losing political power has led various groups of political and economic elites to oppose institutional change and also introduction of new technologies. Perhaps the best documented examples come from the attitude of the elites to industrialization during the nineteenth century (see Acemoglu and Robinson, 2000b, 2002). There were large differences between the rates at which countries caught up with British industrialization with many countries completely failing to take advantage of the new technologies and opportunities. In most of these cases, the attitudes of political elites towards industrialization, new technology and institutional change appear to have been the decisive factor, and these attitudes were driven by their fears of becoming political losers. These issues are best illustrated by the experiences of Russia and Austria-Hungary.

In both Russia and Austria-Hungary, absolutist monarchies feared that promoting industrialization would undermine their political power. In Russia, during the reign of Nikolai I between 1825 and 1855 only one railway line was built in Russia, and this was simply to allow the court to travel between Moscow and St. Petersburg. Economic growth and the set of institutions that would have facilitated it were opposed since, as Mosse (1992) puts it "it was understood that industrial development might lead to social and political change." In a similar vein, Gregory (1991) argues: "Prior to the about face in the 1850's, the Russian state feared that industrialization and modernization would

concentrate revolution minded workers in cities, railways would give them mobility, and education would create opposition to the monarchy."

It was only after the defeat in the Crimean War that Nikolai's successor, Alexsandr II, initiated a large scale project of railway building and an attempt to modernize the economy by introducing a western legal system, decentralizing government, and ending feudalism by freeing the serfs. This period of industrialization witnessed heightened political tensions, consistent with the fears of the elites that times of rapid change would destabilize the political status quo and strengthen their opposition (McDaniel, 1988, gives a detailed account of these events, see also Mosse, 1958).

The consensus view amongst historians also appears to be that the main explanation for the slow growth of Austria-Hungary in the nineteenth century was lack of technology adoption and institutional change, again driven by the opposition of the state to economic change. This view was proposed by Gerschenkron who argued that the state not only failed to promote industrialization, but rather, "economic progress began to be viewed with great suspicion and the railroads came to be regarded, not as welcome carriers of goods and persons, but as carriers of the dreaded revolution. Then the state clearly became an obstacle to the economic development of the country" (1970, p. 89). See also Gross (1973).

The analysis of Fruedenberger (1967, pp. 498-499) is similar. As with the Tsar, the Hapsburg emperors opposed the building of railways and infrastructure and there was no attempt to develop an effective educational system. Blum (1943) pointed to the pre-modern institutional inheritance as the major blockage to industrialization arguing (p. 26) that

> "these living forces of the traditional economic system were the greatest barrier to development. Their chief supporter was ... Emperor Francis. He knew that the advances in the techniques of production threatened the life of the old order of which he was so determined a protector. Because of his unique position as final arbiter of all proposals for change he could stem the flood for a time. Thus when plans for the construction of a steam railroad were put before him, he refused to give consent to their execution 'lest revolution might come into the country'."

6.3 Economic losers

A distinct but related source of inefficiency stems from the basic supposition of the social conflict view that different economic institutions imply different distributions of incomes. This implies that a move from a bad to a better set of economic institutions will make some people or groups worse off (and will not be Pareto improving). This in turn implies that such groups will have an incentive to block or impede such institutional changes even if they benefit the whole of society in some aggregate sense.

The idea that economic losers impede the choice of efficient economic institutions and economic policies is widespread in economics and was seen earliest in the literature on international trade. Even though free trade may be socially desirable, individuals invested in sectors in which an economy does not enjoy comparative advantage will lose economically from free trade. Since at least the work of Schattshneider (1935) the role of economic losers has been central in understanding why free trade is not adopted. In the context of development economics, this idea was first discussed by Kuznets (1968), developed at length by Olson (1982, 2000) and Mokyr (1990), and formalized by Krusell and Rios-Rull (1996) and Parente and Prescott (1999). Most of the examples discussed in the development literature on economic losers are about technological change—people with specific investments in obsolete technology try to block the introduction of better technology. The most celebrated example is the case of the Luddites, skilled weavers in early nineteenth century England who smashed new mechanized looms which threatened to lead to massive cuts in their wages (see Thomis, 1970, Randall, 1991). Scott (2000, p. 200) relates a similar example from modern Malaysia, "When, in 1976, combine harvesters began to make serious inroads into the wages of poor villagers, the entire region experienced a rash of machine-breaking and sabotage reminiscent of the 1830's in England."

That better economic institutions are blocked by individuals whose incomes are threatened by such change is again due to a problem of commitment. If those whose incomes rose when economic institutions changed could promise to compensate those whose incomes fell then there would be no incentive to block better economic institutions. Nevertheless, it is difficult to commit to such transfers. To consider again the example of the Luddites, the factory owners could have promised to pay the weavers high wages in the future even though their skills were redundant. Once the new technology was in place however, owners would have a clear incentive to fire the weavers and hire

much cheaper unskilled workers.[11]

Although the problem of economic losers is appealing at first sight, has received some attention in the economics literature, and fits into our framework by emphasizing the importance of commitment problems, we view it both theoretically and empirically less important than the holdup and the political loser problems. First, as pointed out in Acemoglu and Robinson (2000b), in theories emphasizing issues of economic losers, there are implicit assumptions about politics, which, when spelled out, imply that political concerns must be important whenever issues of economic losers are present. The idea of economic losers is that certain groups, fearing that they will lose their economic rents, prevent adoption of beneficial economic institutions or technologies. The assumption in this scenario is that these groups have the political power to block socially beneficial changes. But then, if they have the political power to block change, why wouldn't they allow the change to take place and then use their political power to redistribute some of the gains to themselves? The implicit assumption must therefore be that groups losing economically also experience a reduction in their political power, making it impossible for them to redistribute the gains to themselves after to change takes place. This reasoning therefore suggests that whether certain groups will lose economically or not is not as essential to their attitudes towards change as *whether their political power will be eroded*. Problems of political losers therefore seem much more important than problems of economic losers.

Possibly for this reason, advocates of the economic losers view have been unable to come up with any well documented examples where the economic losers hypothesis can actually explain first-order patterns of development. For instance, while it is true that the Luddites tried to break machines, they singularly failed to halt the progress of agricultural technology in nineteenth century Britain. The same is true for Malaysia in the 1970s, one of the fastest growing economies in the world at that time. Neither set of workers had sufficient political power to stop change. Indeed, when political powerful groups became economic losers, such as landowners in nineteenth century England who saw land prices and agricultural rents fall rapidly after 1870, they did nothing to block change because their political power allowed them to benefit from efficient economic institutions (Acemoglu and Robinson, 2002).

[11] One possible way round this problem would be for the owners, if they could afford it, to compensate the weavers in advance for their lower future wages. But this would raise the reverse commitment problem: the weavers would have an incentive to take the money and still break the machines – i.e., they could not commit to not blocking the innovations that would reduce their wages even after they had taken the money.

Perhaps the most interesting failure of economic losers to halt progress in English economic history comes from the impact of the enclosure of common lands. Land has not always been privately owned as property. In much of Africa land is still owned communally, rather than individually, and this was true in Medieval Britain. Starting around 1550 however an 'enclosure movement' gathered pace where 'common land' was divided between cultivators and privatized. By 1850 this process of enclosures had made practically all of Britain private property.

Enclosure was a heterogenous process (Overton 1996, p. 147) and it also took place at different times in different places. Nevertheless, most of it was in two waves, the so called 'Tudor enclosures' between 1550 and 1700 and the 'parliamentary enclosures' in the century after 1750.

> "From the mid-eighteenth century the most usual way in which common rights were removed was through a specific act of parliament for the enclosure of a particular locality. Such acts ... made the process easier because enclosure could be secured provided the owners of a majority (four-fifths) of the land, the lord of the manor, and the owner of the tithe agreed it should take place. Thus the law of parliament (statue law) only took account of the wishes of those *owning* land as opposed to the common law which took account of all those who had both ownership rights and *use* rights to land. Moreover ... in some parishes the ... majority could be held by a single landowner ... parliamentary enclosure often resulted in a minority of owners imposing their will on the majority of farmers." Overton (1996, p. 158, italics in original)

The historical evidence is unanimous that the incentive to enclose was because "enclosed land was worth more than open common field land ... the general consensus has been that rents doubled" Overton 1996, p. 162). More controversial is the source of this increase in rent. Overton continues (pp. 162-163) "The proportion of profits taken as rents from tenants by landlords is the outcome of a power struggle between the two groups, and the increase in rent with enclosure may simply reflect an increase in landlord power." Allen (1982, 1992) showed, in his seminal study of the enclosure movement in the South Midlands, that the main impact was a large increase in agricultural rents and a redistribution of income away from those cultivators who had previously used the commons.

The enclosure of common land thus led to a huge increase in inequality in early modern England. Many peasants and rural dwellers had their traditional property rights expropriated. In protest, groups of citizens dispossessed by enclosure attempted to oppose it through collective action and riots—attempting to influence the exercise of political power. These groups were no match for the British state, however. Kett's rebellion of 1549, the Oxfordshire rebellion of 1596, the Midland Revolt of 1607, and others up to the Swing Riots of 1830-1831 were all defeated (see Charlesworth, 1983). The presence of economic losers did not prevent this huge change in economic institutions and income distribution.

6.4 The Inseparability of Efficiency and Distribution

Commitment problems in the use and the allocation of political power therefore introduce a basic trade-off between efficiency and distribution. For example, when lack of commitment causes hold-ups, those who hold political power know that people will not have the right incentives to invest so growth will be low. In response to this, they might voluntarily give away their power or try to create political institutions that restricted their power. Such a change in political institutions would create better investment incentives. Though this situation is hypothetically possible and has formed the basis for some theories of institutional change (e.g. Barzel, 2001) it appears to be insignificant in reality. Even faced with severe underinvestment, political elites are reluctant to give away their power because of its *distributional* implications, i.e., because this would reduce their ability to extract rents from the rest of society. Thus poor economic institutions, here lack of property rights and hold-up, persist in equilibrium because to solve the problem, holders of political power have to voluntarily constrain their power or give it away. This may increase the security of property in society and increase incentives to invest, but it also undermines the ability of rulers to extract rents. They may be better off with a large slice of a small pie.

Similar phenomena are at work when there are either political or economic losers. In the first case, namely a situation where political power holders anticipate being political losers, promoting good institutions directly reduces the political power and rents of incumbents and a similar trade-off emerges. Adopting efficient economic institutions will stimulate growth, but when the political status quo is simultaneously eroded the amount of rent accruing to the initially powerful may fall. In the second case, the incomes of those with political power to determine economic institutions falls directly when better economic institutions are introduced. In the absence of credible commitments to side-

payments, those whose incomes fall when better economic institutions are introduced have an incentive to block such institutions.

Because commitment problems seem so endemic in collective choice and politics, it seems natural to believe that institutional change has significant distributional consequences and as a result there will be conflict over the set of institutions in society.

6.5 Comparative Statics

Our analysis so far has made some progress towards our theory of differences in economic institutions. Although our full theory is yet to be developed in the later sections, the different mechanisms discussed in this section already point out the major comparative static implications of our approach regarding when economic institutions protecting the property rights of a broad cross-section of society are likely to be adopted, and when they are likely to be opposed and blocked. We now briefly discuss these comparative statics.

Hold-up, political loser and economic loser considerations lead to some interesting comparative static results which can be derived by considering the political institutions that lie behind these phenomena.

1. First, the perspective of hold-ups immediately suggests that situations in which there are constraints on the use of political power, for example, because there is a balance of political power in society or a form of separation of powers between different power-holders, are more likely to engender an environment protecting the property rights of a broad cross-section of society. When political elites cannot use their political power to expropriate the incomes and assets of others, even groups outside the elite may have relatively secure property rights. Therefore, constraints and checks on the use of political power by the elite are typically conducive to the emergence of better economic institutions

2. Second, a similar reasoning implies that economic institutions protecting the rights of a broad cross-section are more likely to arise when political power is in the hands of a relatively broad group containing those with access to the most important investment opportunities. When groups holding political power are narrower, they may protect their own property rights, and this might encourage their own investments, but the groups outside the political elites are less likely to receive adequate protection for their investments (see Acemoglu, 2003b).

3. Third, good economic institutions are more likely to arise and persist when there are only limited rents that power holders can extract from the rest of society, since such rents would encourage them to opt for a set of economic institutions that make the expropriation of others possible.

4. Finally, considerations related to issues of political losers suggest that institutional reforms that do not threaten the power of incumbents are more likely to succeed. Therefore, institutional changes that do not strengthen strong opposition groups or destabilize the political situation are more likely to be adopted.

6.6 The Colonial Experience in Light of the Comparative Statics

We now briefly return to the colonial experience, and discuss how the comparative statics discussed here shed light on the differences in economic institutions across the former colonies and the institutional reversal.

The second comparative static result above suggests a reason why better economic institutions developed in places where Europeans settled. In these societies, a relatively broad-based group of Europeans came to dominate political power, and they opted for a set of economic institutions protecting their own property rights. In contrast, in places where Europeans did not settle, especially where they were a small minority relative to a large indigenous population, they did not have the incentives to develop good economic institutions because such institutions would have made it considerably more difficult for them to extract resources from the rest of society.

The third comparative static suggests an important reason why in places with more wealth, resources and also a high density of indigenous population to be exploited, Europeans were more likely to opt for worse institutions, without any protection for the majority of the population, again because such institutions facilitated the extraction of resources by the Europeans.

The first comparative static result, in turn, is related to the persistence of the different types of economic institutions that Europeans established, or maintained, in different colonies. In colonies where Europeans settled in large numbers, they also developed political institutions placing effective checks on economic and political elites. In contrast, the political institutions in colonies with high population density, extractive systems of production, and few Europeans, concentrated power in the hands of the elite, and built a state apparatus designed to use coercion against the majority of the population. These different political institutions naturally implied different constraints on political and

economic elites. In the former set of colonies, there were constraints on the development of economic institutions that would favor a few at the expense of the majority. Such constraints were entirely absent in the latter set of colonies.

Finally, the fourth comparative static is useful in thinking about why many colonies did not attempt to change their economic institutions during the nineteenth century when new economic opportunities made their previous system based on forced labor, slavery, or tribute-taking much less beneficial relative to one encouraging investment in industry and commerce. Part of the answer appears to lie in the fact that the political power of the elites, for example of the plantation owners in the Caribbean, was intimately linked to the existing economic system. A change in the economic system would turn them into political losers, an outcome they very much wanted to avoid.

6.7 Reassessment of the Social Conflict View

So far we have shown that the econometric evidence is convincing that differences in economic institutions are the root cause of differences in prosperity. We then argued that although there are different approaches which can account for variation in economic institutions, the most plausible approach is the social conflict view. Though we believe that there are clear instances where history and ideology matter for the institutional structure of society, and clearly institutions are highly persistent, the most promising approach to understanding why different countries have different institutions is to focus on choices and their subsequent consequences. The social conflict view emphasizes the distributional implication of economic institutions and how commitment problems imply that efficiency and distribution cannot be separated. Hence the fundamental conflict within society over the nature of economic institutions has important implications for economic performance. Some economic institutions will promote growth, but they will not necessarily benefit all groups in society. Alternative economic institutions may induce economic stagnation, but may nevertheless enrich some groups. Which set of institutions results and whether or not a society prospers will be determined by which of these groups has the political power to get the institutions that differentially benefit them. At this point we have therefore substantiated the first three points we made in the introduction. To develop our theory of economic institutions further we need to be more specific about political power—where it comes from and why some people have it and not others. We undertake this task in section 8. Before doing this however the next section discusses three important historical examples of the evolution of economic institutions. We use these examples to show the explanatory power of the social conflict

view and to begin to illustrate in concrete settings how political power works.

7 The Social Conflict View in Action

We now discuss three important examples to bring out the fact that conflict over economic institutions is critical to the functioning of the economy and that this conflict stems, not from differences in beliefs, ideology or historical accidents, but from the impact of economic institutions on distribution. The examples also show that those with political power have a disproportionate effect on economic institutions and they show how the distribution of political power is influenced by different factors. These factors include the allocation of de jure political power through the structure of political institutions and the ability of groups to solve the collective action problem, or exercise what we called de facto political power. With these examples in mind in section 8 we move to discuss in more detail the nature and sources of political power.

7.1 Labor Markets

A market—an opportunity for individuals to exchange a commodity or service—is obviously a fundamental economic institution relevant for development. As Adam Smith (1776) argued, markets allow individuals to take advantage of the benefits of specialization and the division of labor, and scholars such as Pirenne (1937) and Hicks (1969) argued that the expansion of markets was perhaps *the* driving forces in long-run development.

In the history of Europe a key transformation was from feudal labor market institutions towards modern notions of a free labor market where individuals were able to decide who to work for and where to live. This process of institutional change was intimately connected to the transition from a whole set of feudal economic institutions to the economic institutions we think of as 'capitalist.' Most historians see this as key to the economic take-off that began in the nineteenth century. It was the countries which had made the transition away from feudalism most completely, such as England, the Netherlands and France, thanks to the revolution of 1789, which developed most rapidly. It was those where feudalism was still in operation, such as Russia and Austria-Hungary, which lagged far behind.

What can account for this differential evolution of feudalism? Scholars beginning with Postan (1937) saw the demographic collapse caused by the black death in the 1340's as demolishing feudalism in Western Europe. By dramatically altering the land/labor

ratio as approximately 40% of the population of Europe died (e.g., Cantor, 2001), the Black Death greatly increased the bargaining power of peasants and allowed them to negotiate a free status ending feudal obligations, particularly with respect to labor. Therefore, Postan's demographic theory implicitly emphasizes the role of political power in the decline of feudalism: this set of economic institutions started to disappear when the political power of the peasants increased and that of lords declined.

In fact, the distribution of power may be even more important in the whole story than Postan's theory suggests. As first pointed out by Brenner (1976), the demographic theory of the decline feudalism is not consistent with the comparative evidence. Although demographic trends were similar all over Europe and

> "it is true that ... in most of Western Europe serfdom was dead by the early sixteenth century. On the other hand, in Eastern Europe, in particular Pomerania, Brandenburg, East Prussia and Poland, decline in population from the late fourteenth century was accompanied by an ultimately successful movement towards imposing extra-economic controls, that is serfdom, over what had been, until then, one of Europe's freest peasantries. By 1500 the same Europe-wide trends had gone a long way towards establishing one of the great divides in European history, the emergence of an almost totally free peasant population in Western Europe, the debasement of the peasantry to unfreedom in Eastern Europe." (Brenner, 1976, p. 41).

What can explain these divergent outcomes? Brenner notes (p. 51): "It was the logic of the peasant to try to use his apparently improved bargaining position to get his freedom. It was the logic of the landlord to protect his position by reducing the peasants' freedom." The outcome "obviously came down to a question of power" (p. 51); whether the peasants or the lords had more political power determined whether serfdom declined or became stronger.

Although we are far from an understanding of the determinants of the relative structure of political power in different parts of Europe, Brenner suggests that an important element was the "patterns of the development of the contending agrarian classes and their relative strength in the different European societies: their relative levels of internal solidarity, their self-consciousness and organization, and their general political resources—especially their relationships to the non-agricultural classes (in particular, potential urban class allies) and to the state" (p. 52). To substantiate this view, Brenner studies how villages tended to be organized differently in Eastern Europe, there was

"more of a tendency to individualistic farming; less developed organization of collaborative agricultural practices at the level of the village or between villages; and little of the tradition of the 'struggle for commons rights' against the lords which was so characteristic of western development" (p. 57). This differential organization was due to the process of initial occupation of these Eastern lands.

Although many parts of Brenner's analysis remain controversial, there is general agreement that the decline of feudalism and the transformation of European labor markets were intimately related to the political power of the key groups with opposing interests, the peasants and the lords (see, for example, Aston and Philpin, 1985, on reactions to Brenner's interpretation). Feudal institutions, by restricting labor mobility and by removing the role of the labor market in allocating labor to jobs, undermined incentives and resulted in underdevelopment. But these same economic institutions created large rents for the aristocracy. As a consequence, aristocracies all over Europe attempted to maintain them. It was when their political power weakened that the process of transformation got underway.

7.2 Financial Markets

Much recent work on growth and development has focused on capital markets. Growth requires investment, so poor agents without access to financial markets will not have the resources to invest. Empirically many scholars have found correlations between the depth of financial markets and growth (see Levine, 2004) and absence of financial markets is at the heart of ambitious theories of comparative development by Banerjee and Newman (1993) and Galor and Zeira (1993).

If the stress on financial markets and financial intermediation is correct, a central issue is to understand why financial systems differ. For example, studies of the development of banking in the United States in the nineteenth century demonstrate a rapid expansion of financial intermediation which most scholars see as a crucial facilitator of the rapid growth and industrialization that the economy experienced. In his recent study Haber (2001, p. 9) found that in the United States, "In 1818 there were 338 banks in operation, with a total capital of $160 million-roughly three times as many banks and bank capital as in 1810. Circa 1860, the United States had 1,579 banks, with a total capital of $422.5 million. Circa 1914 there were 27,864 banks in the United States. Total bank assets totaled $27.3 billion."

One might see this rapid expansion of banking and financial services as a natural feature. Yet Haber (2001) shows that the situation was very different in Mexico (p. 24).

"Mexico had a series of segmented monopolies that were awarded to a group of insiders. The outcome, circa 1910 could not have been more different: the United States had roughly 25,000 banks and a highly competitive market structure; Mexico had 42 banks, two of which controlled 60 percent of total banking assets, and virtually none of which actually competed with another bank."

The explanation for this huge difference is not obvious. The relevant technology was certainly readily available everywhere and it is difficult to see why the various types of moral hazards or adverse selection issues connected with financial intermediation should have limited the expansion of banks in Mexico but not the United States. Haber then shows that (p. 9), "at the time that the U.S. Constitution was put into effect in 1789, ... [U.S. banking] was characterized by a series of segmented monopolies that shared rents with state governments via taxes or state ownership of bank stock. In some cases, banks also shared rents directly with the legislators who regulated them."

This structure, which looked remarkably like that which arose subsequently in Mexico, emerged because state governments had been stripped of revenues by the Constitution. In response, states started banks as a way to generate tax revenues. State governments restricted entry "in order to maximize the amount of rent earned by banks, rent which would then be shared with the state government in the form of dividends, stock distributions, or taxes of various types."

Thus in the early nineteenth century, U.S. banks evolved as monopolies with regulations aimed at maximizing revenues for the state governments. Yet this system did not last because states began competing among themselves for investment and migrants.

> "The pressure to hold population and business in the state was reinforced by a second, related, factor: the broadening of the suffrage. By the 1840s, most states had dropped all property and literacy requirements, and by 1850 virtually all states (with some minor exceptions) had done so. The broadening of the suffrage, however, served to undermine the political coalitions that supported restrictions on the number of bank charters. That is, it created a second source of political competition-competition within states over who would hold office and the policies they would enact."

The situation was very different in Mexico. After 50 years of endemic political instability the country unified under the highly centralized 40 year dictatorship of Porfirio Diaz until the Revolution in 1910.

In Haber's argument political institutions in the United States allocated political power to people who wanted access to credit and loans. As a result they forced state governments to allow free competitive entry into banking. In Mexico political institutions were very different. There were no competing federal states and the suffrage was highly restrictive. As a result the central government granted monopoly rights to banks who restricted credit to maximize profits. The granting of monopolies turned out to be a rational way for the government to raise revenue and redistribute rents to political supporters (see North, 1981, Chapter 3).

A priori, it is possible that the sort of market regulation Haber found in Mexico might have been socially desirable. Markets never function in a vacuum, but rather within sets of rules and regulations which help them to function. Yet it is hard to believe that this argument applies to Mexico (see also Maurer, 2002). Haber (2001) documents that market regulation was aimed not at solving market failures and it is precisely during this period that the huge economic gap between the United States and Mexico opened up (on which see Coatsworth, 1993, Engerman and Sokoloff, 1997). Indeed, Haber and Maurer (2004) examined in detail how the structure of banking influenced the Mexican textile industry between 1880 and 1913. They showed that only firms with personal contacts with banks were able to get loans. They conclude (p. 5):

> "Our analysis demonstrates that textile mills that were related to banks were less profitable and less technically efficient than their competitors. Nevertheless, access to bank credit allowed them to grow faster, become larger, and survive longer than their more productive competitors. The implication for growth is clear: relatively productive firms lost market share to relatively unproductive (but bank-related) competitors."

Despite the fact that economic efficiency was hurt by regulations, those with the political power were able to sustain these regulations.

7.3 Regulation of Prices

As our final example we turn to the regulation of prices in agricultural markets (which is intimately related to the set of agricultural policies adopted by governments). The seminal study of agricultural price regulation in Africa and Latin America is by Bates (1981, 1989, 1997). Bates (1981) demonstrated that poor agricultural performance in Ghana, Nigeria and Zambia was due to government controlled marketing boards systematically paying farmers prices for their crops much below world levels.

> "Most African states possess publicly sanctioned monopsonies for the purchase and export of agricultural goods ... These agencies, bequeathed to the governments of the independent states by their colonial predecessors, purchase cash crops for export at administratively determined domestic prices, and then sell them at the prevailing world market prices. By using their market power to keep the price paid to the farmer below the price set by the world market, they accumulate funds from the agricultural sector" Bates (1981, p. 12).

The marketing boards made surpluses which were given to the government as a form of taxation. Bates (1981, p. 15) notes

> "A major test of the intentions of the newly independent governments occurred ... [when] between 1959-1960 and 1961-62, the world price of cocoa fell approximately £50 a ton. If the resources generated by the marketing agencies were to be used to stabilize prices, then surely this was the time to use the funds for that purpose. Instead ... the governments of both Ghana and Nigeria passed on the full burden of the drop in price to the producers."

Bates continues "Using the price setting power of the monopsonistic marketing agencies, the states have therefore made the producers of cash crops a significant part of their tax base, and have taken resources from them without compensation in the form of interest payments or of goods and services returned." (pp. 181-9). As a result of this pernicious taxation, reaching up to 70% of the value of the crop in Ghana in the 1970's, investment in agriculture collapsed as did output of cocoa and other crops. In poor countries with comparative advantage in agriculture such a situation mapped into negative rates of economic growth.

Why were resources extracted in this way? Though part of the motivation was to promote industrialization, the main one is to generate resources that could be either expropriated or redistributed to maintain power

> "governments face a dilemma: urban unrest, which they cannot successfully eradicate through co-optation or repression, poses a serious challenge to their interests ... Their response has been to try to appease urban interests not by offering higher money wages but by advocating policies aimed at reducing the cost of living, and in particular the cost of food. Agricultural

policy thus becomes a by-product of political relations between governments and urban constituents" (1981, p. 33)

In contrast to the situation in Ghana, Zambia and Nigeria, Bates (1981, 1989, 1997) showed that agricultural policy in Kenya and Colombia over this period was much more pro-farmer. The difference was due to who controlled the marketing board. In Kenya, farmers were not smallholders, as they were in Ghana, Nigeria and Zambia, and concentrated landownership made it much easier to solve the collective action problem. Moreover, farming was important in the Kikuyu areas, an ethnic group closely related to the ruling political party, KANU, under Jomo Kenyatta (Bates, 1981, p. 122). Farmers in Kenya therefore formed a powerful lobby and were able to guarantee themselves high prices. Even though the government of Kenya engaged in land reform after independence

> "80% of the former white highlands were left intact and ... the government took elaborate measures to preserve the integrity of the large-scale farms ... [which] readily combine in defense of their interests. One of the most important collective efforts is the Kenya National Farmer's Union (KNFU) ... The organization ... is dominated by the large-scale farmers .. [but] it can be argued that the KNFU helps to create a framework of public policies that provides an economic environment favorable to all farmers" Bates (1981, pp. 93-94).

Bates concludes (p. 95) that in Kenya

> "large farmers ... have secured public policies that are highly favorable by comparison to those in other nations. Elsewhere the agrarian sector is better blessed by the relative absence of inequality. But is also deprived of the collective benefits which inequality, ironically, can bring."

In Colombia, farmers were favored because of competition for their votes from the two main political parties. Bates (1997, p. 54) notes

> "Being numerous and small, Colombia's coffee producers, like peasants elsewhere, encountered formidable costs of collective action. In most similar instances such difficulties have rendered smallholders politically powerless. And yet ... Colombia's peasants elicited favorable policies from politicians,

who at key moments themselves bore the costs of collective action, provisioning the coffee sector with economic institutions and delegating public power to coffee interests."

How could the coffee growers gain such leverage over national policy?

> "A major reason they could do so ... is because the structure of political institutions, and in particular the structure of party competition, rendered them pivotal, giving them the power over the political fortunes of those with ambition for office and enabling them to make or break governments. They thereby gained the power to defeat government officials who sought to orchestrate or constrain their behavior." Bates (1997, p.51, 54)

A telling piece of evidence in favor of this thesis is that during the 1950's when a civil war broke out between the two parties, there was five years of military rule and policy turned decisively again the coffee growers, only to switch back again with the peaceful resumption of democracy in 1958.

7.4 Political Power and Economic Institutions

These three examples of the creation of economic institutions have certain features in common. All these institutions, labor market regulation/feudalism, the rules governing financial market development, and agricultural price regulation, clearly reflect the outcome of conscious choices. Feudalism did not end in England for incidental or ideological reasons, but because those who were controlled and impoverished by feudal regulations struggled to abolish them. In Eastern Europe the same struggle took place but with a different outcome. Similarly, Mexico did not end up with different financial institutions than the United States by accident, because of different beliefs about what an efficient banking system looked like, or because of some historical factor independent of the outcome. The same is true for differences in economic policies in Kenya and Ghana. Moreover, different sets of economic institutions arising in different places cannot be argued to be efficient adaptations to different environments. Most historians believe that the persistence of feudal institutions in Eastern Europe well into the nineteenth century explains why it lagged far behind Western Europe in economic development. The difference between the financial institutions of Mexico and the United States also plausibly played a role in explaining why they diverged economically in the nineteenth century. The same holds with respect to agricultural price regulation.

The driving force behind all three examples is that economic institutions are chosen for their distributional consequences. Which specific economic institutions emerge depends on who is able to get their way—who has political power. In England, peasant communities had developed relatively strong local political institutions and were able to consolidate on the shock of the Black Death to put an end to feudal regulations. In Eastern Europe it was the lords who had relatively more power and they were able to intensify feudalism in the face of the same demographic shock (as Domar, 1970, pointed out, the Black Death actually made serfdom more attractive to the lords even if at the same time it increased the bargaining power of the peasants). In the case of banking in the nineteenth century, Haber's research shows while the authoritarian regime in Mexico had the political power to freely create monopolies and create rents in the banking industry, the United States was different because it was federal and much more democratic. The political institutions of the United States prevented politicians from appropriating the rents that could flow from the creation of monopolies. Finally, in Bates's analysis, distortionary price regulations arose in Ghana and Zambia, but not in Kenya and Colombia, because in the latter countries agricultural producers had more political power and so could prevent the distortionary policies that would harm their interests.

It is also useful to consider in the context of these examples the mechanisms we discussed in section 6 which underlie the adoption of inefficient economic institutions. Why couldn't the peasants and lords of feudal Europe negotiate and allow the introduction of a set of economic institutions that would have given peasants incentives to innovate and would have allowed for the efficient allocation of labor? Why couldn't either the lords have promised not to expropriate any benefits that accrued from innovation, or alternatively the peasants agreed to compensate the lords if feudal labor institutions were abolished? Though it is difficult to find direct evidence on such counterfactuals from the Medieval period, the most plausible explanation is that such 'deals' were impossible to make credible. The political power of the lords was intimately connected to feudal institutions and thus dismantling these would not only have increased peasant incentives to innovate, but would also have dramatically altered the balance of political power and the distribution of rents in society. Moreover, under feudal regulations peasants were tied to the land. The introduction of free labor mobility would have given workers an exit option, thus increasing their bargaining power with the lords over the division of output. Thus lords might anticipate being both political and economic losers from the ending of feudalism, even if total output would have increased.

In the case of agricultural price regulation, similar arguments are plausible. Cocoa farmers in Ghana would not have believed promises by governments that they would not expropriate the fruits of higher investment, and the governments themselves would not have believed promises by the farmers to compensate them if they left office. Moreover, efficient sets of economic institutions in Ghana or Nigeria would have strengthened the economic base of the rural sector at the expense of the political power of the then dominant urban sector. Indeed, for Ghana in the 1960's, we have direct evidence from the urban economy that the threat of being a political loser led to inefficient economic institutions. This emerges in the analysis of Killick (1978, p. 37) of the attempt by the government of Kwame Nkrumah to promote industrialization. Killick notes:

> "Even had there been the possibility [of creating an indigenous entrepreneurial class] it is doubtful that Nkrumah would have wanted to create such a class, for reasons of ideology and political power. He was very explicit about this saying 'we would be hampering our advance to socialism if we were to encourage the growth of Ghanian private capitalism in our midst.' There is evidence that he also feared the threat that a wealthy class of Ghanaian businessmen might pose to his own political power."

Further evidence on the importance of political loser considerations comes from E. Ayeh-Kumi one of Nkrumah's main economic advisers who noted after the coup that Nkrumah (Killick, 1978, p. 60): "informed me that if he permitted African business to grow, it will grow to becoming a rival power to his and the party's prestige, and he would do everything to stop it, which he actually did."

In this context, it is interesting that Nkrumah's solution to consolidate his power was to limit the size of businesses that Ghanaians could own. This caused problems for his industrialization policy which he got round by allowing foreign businessmen to enter Ghana. Though this was inconsistent with his aggressively nationalistic and anti-imperialistic rhetoric, these businessmen did not pose a domestic political threat. Killick (p. 37) notes "Given Nkrumah's desire to keep Ghanaian private businesses small, his argument that 'Capital investment must be sought from abroad since there is no bourgeois class amongst us to carry on the necessary investment' was disingenuous. He goes on to add that, (p. 40) Nkrumah "had no love of foreign capitalists but he preferred to encourage them rather than local entrepreneurs, whom he wished to restrict".

All these examples show that the distribution of political power in society is crucial for explaining when economic institutions are good and when they are bad. But where

does political power come from and who has political power? In addressing these questions we will develop our theory of economic institutions. In a theory based on social conflict where economic institutions are endogenous, it will be to differences in political institutions and the distribution of political power that we must look to explain variation in economic institutions.

8 A Theory of Institutions

8.1 Sources of Political Power

Who has political power and where does it come from? As we noted in the Introduction (section 1.2, point 4), political power comes from two sources. First, an individual or group can be allocated *de jure* power by *political institutions*. But institutions are not the only source of power. A second type of political power accrues to individuals or groups if they can solve the collective action problem, create riots, revolts, or demonstrations, own guns, etc.. We call this type of power *de facto* political power (see Acemoglu and Robinson, 2003, chapter 5).

Actual political power is the composition, the joint outcome, of de jure and de facto power. To see how this works out in practice, consider the situation in Chile in the early 1970's. Salvador Allende was elected President with a majority of the popular vote. The formal political institutions of democracy in Chile allocated power to him to propose legislation, issue decrees, etc. Consequently, even though he did not have an absolute majority in congress, Allende had a great deal of de jure political power. Political power is not just de jure however; it does not simply stem from political institutions. Allende, despite being empowered under the Chilean Constitution, was overthrown by a military coup in 1973. Here, the military under the leadership of General Pinochet, were able to use brute force and guns to over-ride the formal political institutions. The ability to use force is one example of de facto political power.

As we suggested in the introduction, the relationship between political power and economic and political institutions is complex and dynamic. Consider the example we discussed in section 7.2, the research by Haber on the comparative financial evolution of Mexico and the United States in the nineteenth century. Haber traced the different evolution of economic institutions to differences in initial political institutions. These political institutions led to different distributions of power and this was critical for the emergence of good financial institutions in the United States, whereby those who benefitted from a competitive banking industry were able to force politicians to provide the

rules which would guarantee it. But where did these differences in political institutions come from? These differences were partly a result of political events in the nineteenth century, and partially a result of different colonial political institutions. In the United States, during the initial phase of colonization in the early seventeenth century. Very low population density and lack of easily exploitable resources forced colonizing companies and the British state to make both economic and political concessions; they granted the settlers access to land and accepted the formation of representative democratic institutions (Morgan, 1975). Consequently, even at independence the United States had relatively democratic political institutions (Keyssar, 2000). Moreover, the initial egalitarian distribution of assets and the high degree of social mobility made for a situation where, at least in the northern states, the distribution of economic resources, and thus de facto power, was relatively equal. The relatively representative political institutions therefore persisted and were supported by the balance of de facto power in society.

In Mexico there were very different initial conditions during the colonial period with a large indigenous population and rich silver mines to exploit. This led to a much more hierarchical and authoritarian balance of political power and very different colonial economic institutions (see Engerman and Sokoloff, 1997, Acemoglu, Johnson and Robinson, 2004). These conditions fed into the different institutional structures at independence, the United States with its constitution, checks and balances and federalism, Mexico with its much more centralized, unchecked, unbalanced and absolutist state. These different political institutions then led to very different economic institutions and economic outcomes after independence. Thus, in some ultimate sense, the source of different political institutions were different initial conditions during the colonial period.

Consider now the evidence presented by Bates. Agricultural policies were better in Kenya because large farmers could solve the collective action problem and exercise de facto political power. But the main reason for the existence of large farms was that British settlers expropriated the land from Africans during the expansion of colonialism (see Berman and Lonsdale, 1992). Thus previous combinations of formal political institutions (colonial institutions) and de facto power (the military might of the British Empire) determined economic institutions, feeding into the future distribution of de facto power even after the nature of de jure power changed dramatically with independence.

We can now see that these examples substantiate the dynamic model that we sketched in section 1.2. There we showed that at any date, political power is shaped by political institutions, which determine de jure power, and the inherited distribution of resources, which affect the balance of de facto power. Political power then determines economic

institutions and economic performance. It also influences the future evolution of political power and prosperity. Economic institutions determine the distribution of resources at that point, which, in turn, influences the distribution of de facto power in the future. Similarly, the distribution of power at any point determines not just the economic institutions then, but also the future political institutions. Thus the allocation of political power at one date, because of the way it influences the distribution of resources and future political institutions, has a crucial effect on the future allocation of both de facto and de jure political power.

Both the comparison Haber made between Mexico and the United States, and that which Bates made between Ghana, Zambia, Kenya and Colombia illustrate this diagram in action. They show how political institutions and de facto power combine to generate different set of economic institutions, how these institutions determine both the distribution of resources and the growth rate of the economy, and how power and institutions evolve over time, often in ways that tend to reinforce particular initial conditions.

8.2 Political Power and Political Institutions

The examples we discussed above showed how political power depends on political institutions and de facto power, and how this determines economic institutions. Moreover, we saw that at any time the pre-existing economic institutions will be an important determinant of the distribution of de facto power. The final element to emphasize is how political institutions evolve over time and how they influence the distribution of political power.

To see why political institutions are so important as a source of political power think of a situation where a group, say the Chilean army in the early 1970's, has a great deal of de facto power. Indeed, it has so much de facto power that it can overrule the Chilean Constitution, making the political institutions largely irrelevant. In fact in Chile the de facto power of the military was able to overthrow the legitimate government and completely reverse the economic policies and economic institutions chosen by the Allende government (including land reform and mass nationalization of industry). Not only did the military reverse the economic institutions preferred by Allende and the groups who elected him, they then implemented their own preferred set of economic institutions, in particularly deregulating the trade regime and the economy. Yet the Pinochet regime was heavily concerned with formal political institutions, and in 1980 Pinochet re-wrote the constitution.

If de facto power was decisive in Chile what is the role for political institutions? If

the constitution can be overthrown, why bother to re-write it? The secret to this lies in the intrinsically transitory nature of de facto power.[12] Yes, the military were able to organize a coup in 1973 but this was only because times were uniquely propitious. There was a world-wide economic crisis, and factions of the military that opposed the coup could be marginalized. Moreover, the United States government at the time was happy to encourage and endorse the overthrow of a socialist government, even if it had been democratically elected. The coming together of such circumstances could not be expected to happen continually, hence once Chilean society re-democratized, as it did after 1990, the military would not be able to continually threaten a coup. In response to this Pinochet changed the political institutions in order to attempt to lock in the power of the military, and thus the economic institutions that he/they preferred. Therefore, the important role for political institutions is that they influence the future allocation of political power. This dynamic role is crucial because it explains the major desire of agents to change political institutions when they get the chance—this is how they can attempt to enduringly alter the balance of political power in their favor (see Acemoglu and Robinson, 2003).

8.3 A Theory of Political Institutions

We now have in place the outlines of our theory of institutions. There are seven points to emphasize, paralleling the discussion in section 1.2 and our diagrammatic exposition there. First, individuals have preferences over economic institutions because of the allocation of resources that these institutions induce.

Second, peoples' preferences typically do not agree because efficiency and distribution cannot be separated. Different economic institutions will benefit different groups, and this will determine the preferences of these individuals and groups with respect to economic institutions.

Third, the problem of commitment explains why efficiency and distribution are inseparable. Economic institutions are collective choices, and they are chosen and sustained

[12]The empirical literature on the collective action problem has recognized that the difficulty of solving the collective action problems lead collective action to typically be transitory. Lichbach (1995, p. 17) notes "collective action, if undertaken on a short-term basis, may indeed occur; collective action that requires long periods to time does not ... Given that most people's commitments to particular causes face inevitable decline, most dissident groups are ephemeral, most dissident campaigns brief." This transitory nature of collective action is echoed by Tarrow (1991, p. 15) who notes "the exhaustion of mass political involvement," while Ross and Gurr (1989, p. 414) discuss political "burnout." Similarly, Hardin (1995, p. 18) argues that "the extensive political participation of civil society receives enthusiastic expression only in moments of state collapse or great crisis. It cannot be maintained at a perpetually high level."

by the state. Since there is no third party to enforce the decisions of the state, problems of commitment are particularly severe in the political realm.

Fourth, the equilibrium structure of economic institutions will therefore be determined by who has the power to get their way, i.e., who can create and sustain economic institutions that benefit themselves. The distribution of political power thus determines economic institutions, the allocation of resources and the rate of economic growth.

Fifth, political power has two forms: de jure power determined by the political institutions, such as the constitution and the electoral rules, and de facto power, which stems from the ability to solve the collective action problem, mobilize weapons etc.. De facto power can influence political outcomes independently of the political institutions, and its distribution often critically determines how a given set of institutions works in practice and whether or not they are actually obeyed.

Sixth, the distribution of de facto political power at any date is influenced to a large degree by the distribution of resources in society, since those with greater resources can command more power both through legitimate and intimate means, and perhaps can also solve the collective action problem more efficiently. Naturally, the distribution of resources at this point is influenced by economic institutions and economic outcomes in the past.

Finally, political institutions are also endogenous; the current balance of political power, incorporating both de jure and de facto elements, also determines future political institutions. Political institutions are important because they allocate, at least within the limits defined by the exercise of future de facto power, the allocation of future de jure political power. Since de facto power, because of the nature of the collective action problem, is intrinsically transitory and difficult to wield, political institutions are often crucial in creating a source of durable political power. This makes it very attractive for groups to use their de facto political power to change political institutions so as to modify the distribution of future political power in their favor.

9 The Theory in Action

We now consider two examples that demonstrate our theory of institutions in action. Like the examples discussed in section 7, these examples contain all the elements of our theory laid out in a skeletal way in section 1.2. They show the role of political power in determining economic institutions, they demonstrate the different factors, both de facto and de jure, that determine political power, and they illustrate how de facto political power is often used to change political institutions in order to influenced the future

distribution of de jure political power.

9.1 Rise of Constitutional Monarchy and Economic Growth in Early Modern Europe

Our first example is the rise of constitutional monarchy in Europe. In the medieval period most European nations were governed by hereditary monarchies. However, as the feudal world changed, various groups struggled to gain political rights and reduce the autocratic powers of monarchies. In England, this process began as early as 1215 when King John was forced by his barons to sign the Magna Carta, a document which increased the powers of the barons, introduced the concept of equality before the law, and forced subsequent kings to consult with them. Many other European nations also developed 'parliaments' which kings could summon to discuss taxation or warfare (see Graves, 2001, Ertman, 1997). Nevertheless, the movement towards limited, constitutional monarchy was not linear or simple. Indeed, in France, certainly from the beginning of Louis XIV's reign in 1638, a more powerful absolutist monarchy appeared with very few controls. Indeed the feudal French parliaments, the Estates General, were not summoned between 1614 and 1788, just before the Revolution.

In England, the Tudor monarchs, particularly Henry VIII and then Elizabeth I, followed by the first Stuart kings, James I and Charles I, also attempted to build an absolutist monarchy. They failed, however, mostly because of Parliament, which blocked attempts to concentrate power. The constitutional outcome in England was settled by the Civil War from 1642-1651 and the Glorious Revolution in 1688. In the first of these conflicts the forces of Parliament defeated those loyal to Charles I and the king was beheaded. In 1660 the monarchy was restored when Charles II became king, but his brother James II was deposed in 1688 and Parliament invited William of Orange to become king.

Other places in Europe, particularly the Netherlands, saw similar developments to those in England. Under the Dukes of Burgundy, the Netherlands had won a considerable amount of political and economic freedom, particularly under the Grand Privilege of 1477 which gave the States General of the Burgundian Netherlands the right to gather on their own initiative and curbed the right of the ruler to raise taxes. However, the Netherlands were inherited by the Hapsburgs through marriage, and by 1493 Maximilian of Hapsburg had reversed the Grand Privilege. After 1552, war with France increased the Hapsburgs' fiscal needs and led them to impose a large tax burden on the Netherlands, already a prosperous agricultural and mercantile area. Growing fiscal and religious

resentment in 1572 led to a series of uprisings against the Hapsburgs, mostly orchestrated by commercial interests. These culminated in the War of Independence which was finally won in 1648.

While England and the Netherlands were developing limited constitutional governments, Spain and Portugal were moving in the same direction as France, towards greater absolutism. Davis (1973a, p. 66) notes [in Castille] "the king ruled subject only to weak constitutional restraints. In the first decades of the sixteenth century the crown had reduced the pretensions of the Castillian nobility and towns, so that the representative body, the Cortes, could obstruct but not in the last resort prevent royal tax raising."

These differential institutional trajectories were of enormous consequence. Netherlands and England moved ahead economically of the rest of Europe precisely because they developed limited, constitutional government. This form of government led to secure property rights, a favorable investment climate and had rapid multiplier effects on other economic institutions, particularly financial markets (see, e.g., North and Weingast, 1989, de Vries and van der Woude, 1997). While the Netherlands and Britain prospered, France was convulsed by the French Revolution, and by the nineteenth century Spain and Portugal were impoverished backward nations. How can we account for these diverging paths in the early modern period? Why did England and the Netherlands develop limited constitutional rule, while France, Spain and Portugal did not?

We proposed an explanation in Acemoglu, Johnson and Robinson (2002b) related to the differential responses of these countries to the opportunities of 'Atlantic trade', that is, overseas trade and colonial activity unleashed by the discovery of the New World and the rounding of the Cape of Good Hope at the end of the fifteenth century. All five nations engaged in Atlantic trade, but they did so in different ways, with very different implications for the organization of society, political institutions and subsequent economic growth.

In England "most trade was carried on by individuals and small partnerships, and not by the Company of Merchant Adventurers, the Levant Company ... or others of their kind" (Davis, 1973b, p. 41). At least by 1600 there was quite free entry into the English merchant class. The same was true in the Netherlands. In contrast, Cameron (1993, p. 127) describes the Portuguese situation as follows: "The spice trade in the East Indies of the Portuguese Empire was a crown monopoly; the Portuguese navy doubled as a merchant fleet, and all spices had to be sold through the *Casa da India* (India House) in Lisbon ... no commerce existed between Portugal and the East except that organized and controlled by the state." In Spain, similarly, colonial trade was a monopoly of the Crown

of Castille, which they delegated to the *Casa de Contratación* (House of Trade) in Seville. This merchants guild was closely monitored by the government (Parry, 1966, Ch 2). The main aim of these regulations was to make sure that all of the gold and silver from the Americas flowed back to Spain, creating a source of direct tax revenues for the crown. As a result, Latin American colonies were forbidden to buy manufactured goods from anywhere other than Spain, and all exports and imports had to pass through controlled channels. For example, until the Bourbon reforms of the mid eighteenth century, nothing could be exported directly from Buenos Aires, and if somebody produced anything for export on the Pampas, it had to be carried over the Andes and exported from Lima in Peru!

The source of the differences in the organization of trade, in turn, reflected the different political institutions of these countries. At the time, the granting of trade monopolies was a key fiscal instrument to raise revenues; the more powerful monarchs could increase their revenues by granting trade monopolies or by directly controlling overseas trade, while weaker monarchs could not. At the turn of the fifteenth century, the crown was much stronger in France, Spain and Portugal than in Britain and the Netherlands, and this was the most important factor in the differences in the organization of overseas trade. In fact, when both Tudor and Stuart monarchs attempted to create monopolies similar to those in Spain and Portugal, this was successfully blocked by the English Parliament (see, for example, Hill, 1969). Consequently, as world trade expanded in the sixteenth and early seventeenth centuries, it enriched merchants engaged in overseas trade in England and the Netherlands, but the crown and groups allied with it in France, Spain and Portugal. In England and the Netherlands, but not in France, Spain and Portugal, a new class of merchants (and gentry in England) arose with interests directly opposed to those of the Stuarts and the Hapsburgs, and this group was to play a central part in subsequent political changes.

In the case of the Netherlands, de Vries and van der Woude (1997) argue that "urban economic interests ultimately believed it advantageous to escape the Hapsburg imperial framework" (p. 369), and that it was "the traditional pillars of the maritime economy ... that supported and strengthened the young Republic in its hour of need" (p. 366). Moreover, in the case of Amsterdam, "[Hapsburgs'] opponents included most of the city's international merchants ... [I]n 1578 a new Amsterdam city council threw the city's lot in with the Prince of Orange ... among the merchants returning from ... exile were [those whose families] and several generations of their descendents would long dominate the city" (1997, p. 365). The expansion of world trade enriched and

expanded precisely those groups within Dutch society most opposed to Hapsburg rule. Israel (1995, pp. 241-242) writes: "From 1590, there was a dramatic improvement in the Republic's economic circumstances. Commerce and shipping expanded enormously, as did the towns. As a result, the financial power of the states rapidly grew, and it was possible to improve the army vastly, both qualitatively, and quantitatively, within a short space of time. The army increased from 20,000 men in 1588 to 32,000 by 1595, and its artillery, methods of transportation, and training were transformed" (see also Israel, 1989, Chapter 3). By 1629, the Dutch were able to field an army of 77,000 men, 50% larger than the Spanish army of Flanders (Israel, 1995, p. 507). As a consequence of the Dutch revolt, the Netherlands developed a republican form of government closely attuned to mercantile interests. De Vries and van der Woude (1997, p. 587) describe the new political elite following the Dutch Revolt as: "6 to 8% of urban households with incomes in excess of 1,000 guilders per year. This was the *grote burgerij* from whom was drawn the political and commercial leadership of the country. Here we find, first and foremost, the merchants," and point out how merchants dominated the governments of Leiden, Rotterdam and the cities in two largest states, Zeeland and Holland.

In England, the Civil War and Glorious Revolution coincided with the great expansion of English mercantile groups into the Atlantic. The East India Company was founded in 1600 as the culmination of a series of efforts to develop trade routes with Asia. The 1620s saw the great expansion of tobacco cultivation in Virginia. This was shortly followed by the development of the highly profitable English sugar colonies in the Caribbean. Finally, in the 1650s the English began to take over the Atlantic slave trade. Both the Civil War and the Glorious Revolution were at root battles over the rights and prerogatives of the monarchy. In both cases new merchant interests predominantly sided with those in the gentry demanding restrictions on the powers of the monarchy in order to protect their property and commerce.

The majority of merchants trading with the Americas and in Asia supported the Parliament during the Civil War. Brunton and Pennington (1954, p. 62) also note "in the country as a whole there was probably a preponderance of Parliamentarian feeling among merchants." Detailed analyses of the initial members of the Long Parliament in 1640 show that a significant majority of merchants supported the Parliamentarian cause (see Brenner, 1973, 1993, Keeler, 1954, and Brunton and Pennington, 1954). Members of the Commons from the City of London (the main center of mercantile activity), as well as many non-London commercial constituencies, such as Southampton, Newcastle and Liverpool, supported the Parliament against the King. These men included both

professional merchants and aristocrats who invested in colonizing the Americas. These new merchants also provided the financial support needed by the Parliament in the difficult early days of the war. They became the customs farmers for the new regime and therefore advanced tens of thousands of pounds that were essential in building up the army (Brenner, 1973, p. 82).

Pincus (1998, 2001, 2002) further documents the critical role of mercantile interests in the Glorious Revolution. He concludes (2002, p. 34) "England's merchant community actively supported William's plan for invasion, and provided a key financial prop to the regime in the critical early months." He notes that James II favored the East India Company and granted various monopoly privileges, alienating the merchant class. Thus, "no wonder the merchant community poured money into William of Orange's coffers in 1688." (Pincus, 2002, pp. 32-33).

The changes in the distribution of political power, political institutions and thus economic institutions that took place in England and the Netherlands had no counterparts in countries with relatively absolutist institutions, like Spain and Portugal, where the crown was able to closely control the expansion of trade. In these countries it was the monarchy and groups allied with it that were the main beneficiaries of the early profits from Atlantic trade, and groups favoring political and economic change did not become strong enough to induce such change. As a result, only in the Netherlands and England did constitutional rule emerge, and only in these two countries were property rights secure. As a result it was these same two countries that prospered.

Why could the monarchies of Spain and Portugal not negotiate a more efficient set of institutions? Alternatively why did the Stuart monarchs in England have to be beheaded or forced from power before better economic institutions could emerge?

It seems quite clear that a change to a more efficient set of institutions in Spain and Portugal would not have been possible under the auspices of the absolutist state, and a reduction in the power of the state was certainly inimical to the interest of the crown. In the case of England, Hill (1961a) argues directly that the reason that the Tudor and Stuart monarchs were not in favor of efficient economic institutions is because they feared that this would undermine their political power. He notes:

> "in general the official attitude to industrial advance was hostile, or at best indifferent. It was suspicious of social change and social mobility, the rapid enrichment of capitalists, afraid of the fluctuations of the market and of unemployment, of vagabondage, and social unrest ... the Elizabethan codes aimed at stabilizing the existing class structure, the location of industry and

the flow of labor supply by granting privileges and by putting hindrances in the way of the mobility and the freedom of contract."

The account so far explains why a change in the balance of (de facto) political power in England and the Netherlands led to a set of economic institutions favoring the interests of merchants. But in fact much more happened during the seventeenth century; an entirely new set of political institutions, constitutional regimes, restricting the power of the monarchy, were introduced. The reason why the merchants and the gentry in England (and the merchants in the Netherlands) used their newfound powers for political reform illustrates the dynamics of political power emphasized by our theoretical framework.

For example in the case of England, although in 1688 the Parliament might have been strong, it could not be sure that this power would endure. Indeed, the ability to solve the collective action problem and wield de facto power is intrinsically transitory. For instance, the Parliament vanquished James II with the help of a Dutch army, after which they invited William of Orange to take the throne. But how could they anticipate whether or not William would try to assert the absolutist prerogatives that James II had demanded?

The way to make transitory power permanent is to embody it into the rules of the game which is exactly what the English Parliament did after 1688. The changes in institutions after 1688 had large and important effects. For instance, in the eighteenth century the English monarchy was able to borrow huge amounts of money because the fiscal control of Parliament guaranteed that it would not default (see Brewer, 1988, Stasavage, 2003). This borrowing has been seen as crucial to the success of the English war machine. Moreover, with the Parliament in control of fiscal policy, the crown was never able to raise money through arbitrary taxation and not able any more to grant monopoly rights in exchange for money—an issue which had previously been a constant source of friction between the English crown and Parliament. Similarly, after 1688, the greater security of property rights in England led to a huge expansion of financial institutions and markets (Neal, 1990), which, North and Weingast (1989) argue, laid the institutional foundations for the Industrial Revolution.

Of course the English crown was not without some residual power and might have attempted to mount a coup against the Parliament to change political institutions back in its favor. This certainly happened in some places, such as in France after 1849 when Louis Napoleon mounted a successful coup to restore absolutist privileges lost in 1848. Nevertheless, changes in political institutions altered the nature of the status quo in

significant ways, and therefore, influenced the future distribution of de jure political power. Political institutions are not cast stone, and they can change, but they still create a source of political power more durable than mere de facto power.

9.2 Summary

The emergence of constitutional rule in some societies of early modern Europe therefore provides a nice example of how economic institutions, which shape economic outcomes, are determined by political power, which is in turn determined by political institutions and the distribution of resources in society. The Netherlands and England prospered in this period because they had good economic institutions, particularly secure property rights and well developed financial markets. They had these economic institutions because their governments were controlled by groups with a strong vested interest in such economic institutions. These groups wielded political power because of the structure of political institutions, i.e., they received de jure power in the Netherlands after the Dutch Revolt and in England after the Civil War and Glorious Revolution.

Moving one step back, we see that political institutions allocated more de jure political power to commercial interests in England and the Netherlands than in France, Spain and Portugal because of major changes in political institutions during the 1600s. These changes took place because commercial interests in England and the Netherlands acquired significant de facto political power as a result of their improving economic fortunes, itself a consequence of the interaction of Atlantic trade and the organization of overseas trade in these countries. Crucially for our framework, these commercial interests used their de facto power to reform (or revolutionize) political institutions so as to acquire de jure political power and solidify their gains.

These events, therefore, illustrate the various elements of our theoretical framework. In particular, they show how it is useful to think of political institutions and the distribution of economic resources as the state variables of the dynamic system, which determine the distribution of political power, and via this channel, economic institutions and economic outcomes. Political institutions and the distribution of economic resources are, themselves, endogenous, determined by political power and economic institutions, as exemplified by the fact that the distribution of economic resources changed significantly during the sixteenth century as a result of the new economic opportunities presented by the rise of Atlantic trade, and these changes were crucially influenced by the existing economic institutions (the organization of overseas trade). Furthermore, the change in the balance of political power led to the changes in political institutions through the

English Civil War, the Glorious Revolution and the Dutch Revolt.

9.3 Rise of Electoral Democracy in Britain

Our second example, based on Acemoglu and Robinson (2000a, 2001, 2003), is the rise of mass democracy. In the early nineteenth century, European countries were run by small elites. Most had elected legislatures, often descendents of medieval parliaments, but the franchise was highly restricted to males with relatively large amounts of assets, incomes or wealth. However, as the century and the Industrial Revolution progressed, this political monopoly was challenged by the disenfranchised who engaged in collective action to force political change.

In response to these developments, the elites responded in three ways. First by using the military to repress the opposition, as in the responses to the revolutions of 1848. Second, by making concessions to buy off opposition—this is the standard explanation for the beginnings of the welfare state in Germany under Bismarck. Finally, if neither repression nor concessions were attractive or effective, elites expanded the franchise and gave political power to the previously disenfranchised—they created the precedents of modern democracy.

The history of the rise of democracy in Britain is in many ways representative of the experiences of many other European countries. The first important move towards democracy in Britain came with the First Reform Act of 1832. This act removed many of the worst inequities under the old electoral system, in particular the 'rotten boroughs' where several members of parliament were elected by very few voters. The 1832 reform also established the right to vote based uniformly on the basis of property and income. The reform was passed in the context of rising popular discontent at the existing political status quo in Britain.

By the 1820s the Industrial Revolution was well under way and the decade prior to 1832 saw continual rioting and popular unrest. Notable were the Luddite Riots from 1811-1816, the Spa Fields Riots of 1816, the Peterloo Massacre in 1819, and the Swing Riots of 1830 (see Stevenson, 1979, for an overview). Another catalyst for the reforms was the July revolution of 1830 in Paris. Much of this was led and orchestrated by the new middle-class groups who were being created by the spread of industry and the rapid expansion of the British economy. For example, under the pre-1832 system neither Manchester nor Sheffield had any members of the House of Commons.

There is little dissent amongst historians that the motive for the 1832 Reform was to avoid social disturbances (e.g., Lang, 1999, p. 36). The 1832 Reform Act increased

the total electorate from 492,700 to 806,000, which represented about 14.5% of the adult male population. Yet, the majority of British people (the remaining 23 million) could not vote, and the elite still had considerable scope for patronage, since 123 constituencies still contained less than 1,000 voters. There is also evidence of continued corruption and intimidation of voters until the Ballot Act of 1872 and the Corrupt and Illegal Practices Act of 1883. The Reform Act therefore did not create mass democracy, but rather was designed as a strategic concession. In presenting his electoral reform to the British Parliament in 1831, the Prime Minister Earl Grey was well aware that this was a measure necessary to prevent a likely revolution. He argued:

> "The Principal of my reform is to prevent the necessity for revolution ... reforming to preserve and not to overthrow." (quoted in Evans, 1983, p. 212).

Unsurprisingly therefore, the issue of parliamentary reform was still very much alive after 1832, and it was taken up centrally by the Chartist movement. But as Lee (1994, p. 137) notes "The House of Commons was largely hostile to reform because, at this stage, it saw no need for it." This had changed by 1867, largely due to a juxtaposition of factors, including the sharp business cycle downturn that caused significant economic hardship and the increased threat of violence. Also significant was the founding of the National Reform Union in 1864 and the Reform League in 1865, and the Hyde Park riots of July 1866 provided the most immediate catalyst.

Lang (1999, p. 75) sums up his discussion by saying "The Hyde Park affair, coupled with other violent outbursts, helped to underscore the idea that it would be better to keep the goodwill of the respectable workers than to alienate them." Reform was initially proposed by the Liberal Prime Minister Russell in 1866 but was defeated by the Conservatives and dissident MP's. As a result Russell's government fell, and the Conservatives formed a minority administration with Lord Derby as their leader in the House of Lords, and Disraeli in charge of the House of Commons. It was Disraeli who then constructed a coalition to pass the Second Reform Act in 1867. As a result of these reforms, the total electorate was expanded from 1.36 million to 2.48 million, and working class voters became the majority in all urban constituencies. The electorate was doubled again by the Third Reform Act of 1884, which extended the same voting regulations that already existed in the boroughs (urban constituencies) to the counties (electoral constituencies in the rural areas). The Redistribution Act of 1885 removed many remaining inequalities in the distribution of seats and from this point on Britain

only had single member electoral constituencies (previously many constituencies had elected two members—the two candidates who gained the most votes). After 1884 about 60% of adult males were enfranchised. Once again social disorder appears to have been an important factor behind the 1884 act.

In Britain, the Reform Acts of 1867-1884 were a turning point in the history of the British state. Economic institutions also began to change. In 1871 Gladstone reformed the civil service, opening it to public examination, making it meritocratic. Liberal and Conservative governments introduced a considerable amount of labor market legislation, fundamentally changing the nature of industrial relations in favor of workers. During 1906-1914, the Liberal Party, under the leadership of Asquith and Lloyd George, introduced the modern redistributive state into Britain, including health and unemployment insurance, government financed pensions, minimum wages, and a commitment to redistributive taxation. As a result of the fiscal changes, taxes as a proportion of National Product more than doubled in the 30 years following 1870, and then doubled again. In the meantime, the progressivity of the tax system also increased (Lindert, 2004). Finally, there is also a consensus amongst economic historians that inequality in Britain fell after the 1870's (see Lindert, 2000, 2004)

Meanwhile, the education system, which was either primarily for the elite or run by religious denominations during most of the nineteenth century, was opened up to the masses; the Education Act of 1870 committed the government to the systematic provision of universal education for the first time, and this was made free in 1891. The school leaving age was set at 11 in 1893, then in 1899, it increased to 12 and special provisions for the children of needy families were introduced (Mitch, 1993). As a result of these changes, the proportion of 10-year olds enrolled in school that stood at 40 percent in 1870 increased to 100 percent in 1900 (Ringer, 1979, p. 207). Finally, a further act in 1902 led to a large expansion in the resources for schools and introduced the grammar schools which subsequently became the foundation of secondary education in Britain.

Following the Great War, the Representation of the People Act of 1918 gave the vote to all adult males over the age of 21, and women over the wage of 30 who were ratepayers or married to ratepayers. Ultimately, all women received the vote on the same terms as men in 1928. The measures of 1918 were negotiated during the war and may reflect to some extent a quid pro quo between the government and the working classes who were needed to fight and produce munitions. Nevertheless, Garrard (2002, p. 69) notes "most assumed that, if the system was to survive and 'contentment and stability prevail', universal citizenship could not be denied men, perceived to have suffered so

much and to have noticed Russia's Revolution."

Overall, the picture which emerges from British political history is clear. Beginning in 1832, when Britain was governed by the relatively rich, primarily rural aristocracy, a series of strategic concessions were made over an 86 year period to adult men. These concessions were aimed at incorporating the previously disenfranchised into politics since the alternative was seen to be social unrest, chaos and possibly revolution. The concessions were gradual because in 1832, social peace could be purchased by buying off the middle classes. Moreover, the effect of the concessions was diluted by the specific details of political institutions, particularly the continuing unrepresentative nature of the House of Lords. Although challenged during the 1832 reforms, the House of Lords provided an important bulwark for the wealthy against the potential of radical reforms emanating from a democratized House of Commons. Later, as the working classes reorganized through the Chartist movement and later through trade unions, further concessions had to be made. The Great War and the fallout from it sealed the final offer of full democracy. Though the pressure of the disenfranchised played less of a role in some reforms than others, and other factors undoubtedly played a role, the threat of social disorder was the main driving force behind the creation of democracy in Britain.

The story of the rise of mass democracy that emerges from the British evidence is one where economic and social changes connected with industrialization (for example, rising inequality) and urbanization increased the de facto power of the disenfranchised. In response, they demanded political rights, in particular changes in the political institutions which would allocate future political power to them. These changes in political institutions were, in many ways, the direct cause of the changes in economic institutions, in particular, in the labor market, in government policy, in the educational system, with major distributional implications, including the fall in inequality.

Why did elites in Britain create a democracy? Our discussion makes it clear that democracy did not emerge from the voluntary acts of an enlightened elite. Democracy was, in many ways, forced on the elite, because of the threat of revolution. Nevertheless, democratization was not the only potential outcome in the face of pressure from disenfranchised, or even in the face of the threat of revolution. Many other countries faced the same pressures and political elites decided to repress the disenfranchised rather than make concessions to them. This happened with regularity in Europe in the nineteenth century, though by the turn of the twentieth century most had accepted that democracy was inevitable. Repression lasted much longer as the favorite response of elites in Latin America, and it is still the preferred option for current political elites in China or Burma.

The problem with repression is that it is costly. Faced with demands for democracy political elites face a trade-off. If they grant democracy, then they lose power over policy and face the prospect of, possibly radical, redistribution. On the other hand, repression risks destroying assets and wealth. In the urbanized environment of nineteenth century Europe (Britain was 70% urbanized at the time of the Second Reform Act), the disenfranchised masses were relatively well organized and therefore difficult to repress. Moreover, industrialization had led to an economy based on physical, and increasing human, capital. Such assets are easily destroyed by repression and conflict, making repression an increasingly costly option for elites. In contrast, in predominantly agrarian societies like many parts of Latin America earlier in the century or current-day Burma, physical and human are relatively unimportant and repression is easier and cheaper. Moreover, not only is repression cheaper in such environments, democracy is potentially much worse for the elites because of the prospect of radical land reform. Since physical capital is much harder to redistribute, elites in Western Europe found the prospect of democracy much less threatening.

Faced with the threat of revolt and social chaos, political elites may also attempt to avoid giving away their political power by making concessions, such as income redistribution or other pro-poor policies. The problem with concessions however is their credibility, particularly when de facto power is transitory. For example, if a crisis, such as a harvest failure or business cycle recession creates a window of opportunity to solve the collective action problem and challenge the existing regime, the elites would like to respond with the promise of concessions. Yet windows of opportunity disappear and it is difficult to sustain collective action which entails people protesting in the streets and being away from their families and jobs. Thus collective action quickly dissipates and once it does so, the government has an incentive to renege on its promise of concessions. The promise of concessions, which people know to be non-credible is unlikely to defuse collective action. Hence, Acemoglu and Robinson (2000a, 2001, 2003) argue that democratization occurred as a way of making credible commitments to the disenfranchised. Democratization was a credible commitment to future redistribution, because it reallocated de jure political power away from the elites to the masses. In democracy, the poorer segments of the society would be more powerful and could vote, in other words, could use their de jure political power, to implement economic institutions and policies consistent with their interests. Therefore, democratization was a way of transforming the transitory de facto power of the disenfranchised poor into more durable de jure political power.

9.4 Summary

The emergence of mass democracy is another example illustrating our theory of institutions. Into the nineteenth century, economic institutions, particularly in the labor market, disadvantaged the poor. For example, trade unions were illegal and as late as the 1850 in Britain workers trying to organize a union could be shipped to the penal colony in Tasmania, Australia. The poor could not alter economic institutions in their favor because, being disenfranchised, they had little de jure political power and also limited de facto power,the because they were often unable to solve their collective action problems.

However, changes in the structure of society and the economy during the early nineteenth century altered the balance of political power, in particular making the exercise of de facto power by the politically disenfranchised much easier (Tilly, 1995, and Tarrow, 1998, document the changing qualitative nature of collective action over this period). The rise in the de facto political power of the poor necessitated a change in political institutions in their favor to defuse the threat of revolution. This was to tilt the future allocation of de jure political power, and consequently to ensure future economic institutions and policies consistent with their interests.

Whether or not increases in de facto power translated into democracy depended on a number of factors, in particular how difficult and costly it was for elites to use repression to counter the increase in the power of the masses, and how costly the prospect of democracy was. The changes in political institutions that occurred with democracy had profound implications for economic institutions. In the case of Britain, the period after the Second Reform Act of 1867 led the British state to commit itself to providing universal education for the first time and it also led to radical changes in labor market institutions allowing trade unions to form legally for the first time and increasing the bargaining power of labor. Hence economic institutions changed radically in favor of those newly endowed with de jure political power, mostly the relatively poor. This is in fact a relatively general result of democratization. Democracy enfranchises the poor, and the poor are able to use democracy to tilt economic institutions and the distribution of income in society in their favor (Li, Squire and Zou, 1998, Rodrik, 1999).

The emergence of democracy in the nineteenth-century Europe therefore also illustrates the workings of our theoretical framework. In particular, it shows how political institutions determine economic institutions and policies, and thus the distribution of resources, and it shows how political institutions change, especially in response to an im-

balance of de facto political power, as a credible way of influencing the future allocation of de jure political power.

10 Future Avenues

In this chapter we have proposed a framework for thinking about why some countries grow faster and are richer than others. We emphasized, following North and Thomas (1973), that most economic growth theory focuses only on proximate determinants. Although this body of work has been useful in helping us understand the mechanics of growth, it fails to provide a satisfactory account of why some countries grow while others do not. A major research goal must now be to get beyond the neoclassical growth model and its extensions, and search for the deeper causes, i.e., the fundamental determinants of growth.

We argued that the available evidence is consistent with the view that whether or not a society grows depends on how its economy is organized—on its economic institutions. We then proposed the outlines of a theory of institutions and illustrated it through a series of historical examples. We emphasized that a theory of why different countries have different economic institutions must be based on politics, on the structure of political power, and the nature of political institutions. Much remains to be done. First, the framework we outlined was largely verbal rather than mathematical, and thus, by its very nature, not fully specified. Constructing formal models incorporating and extending these ideas is the most important task ahead. Although some of our past work (e.g., Acemoglu and Robinson, 2000a, 2001, Acemoglu 2003b) formalizes parts of this framework, the full model has not been developed yet.

There are also many important issues left out of our framework, which appear to offer fruitful areas for future research. First, though we know that institutions, both economic and political, persist for long periods of time, often centuries (and sometimes millennia), we do not as yet have a satisfactory understanding of the mechanisms through which institutions persist.

Second, and closely related, although institutions do generally persist, sometimes they change. We have important examples of societies which have radically changed their political and economic institutions. Some do so for internal reasons, such as France after the Revolution of 1789, and some do because of external pressures such as Japan after the Meiji restoration or Russia after the Crimean War.

The important point here is that both institutional persistence and institutional change are equilibrium outcomes. Approaches positing institutional persistence as a

matter of fact, and then thinking of institutional changes as unusual events will not be satisfactory. Both phenomena have to be analyzed as part of the same dynamic equilibrium framework.

One type of institutional change, consistent with the examples we discussed in this chapter, takes place when those who benefit from the existing set of institutions are forced to accept change, either because they are the losers in a process of fighting or because of the threat of internal revolution (another possibility is that they might accept change because of the threat of external invasion). However, institutional change can also take place because the set of economic institutions that is optimal for a particular group with political power may vary over time as the state variables in the system and economic opportunities evolve. One example may be the end of slavery in the British Empire and another may be the economic and political changes introduced by Mikhail Gorbachev in the Soviet Union in the 1980s. We need more research on the dynamic mechanisms at work.

Finally, it is important to understand the role of policy and interventions in changing the institutional equilibrium. Though social science research is of intrinsic interest, one would hope that a convincing fundamental theory of comparative growth based on institutions would lead to policy conclusions that would help us improve the institutions and thus the lives and welfare of people in poor countries. It should be obvious that, at the moment, we are a long way from being in a position to draw such conclusions. In a world where political choices are made rationally and are endogenous to the structure of institutions, which are themselves ultimately endogenous, giving policy advice is a conceptually complex issue (see Acemoglu, Johnson, Robinson and Thaicharoen, 2003, for reflections on this issue). Recognizing our current ignorance on this topic in no way diminishes its importance, and its role as the Holy Grail of political economy research, however. And we believe that better and empirically more realistic theoretical frameworks in the future will take us closer to this Holy Grail.

Growth Theory Through the Lens of Development Economics

Abhijit V. Banerjee and Esther Duflo *

March 2004

1 Introduction: Neo-classical Growth Theory

The premise of neo-classical growth theory is that it is possible to do a reasonable job of explaining the broad patterns of economic change across countries, by looking at it through the lens of an aggregate production function. The aggregate production function relates the total output of an economy (a country, for example) to the aggregate amounts of labor, human capital and physical capital in the economy, and some simple measure of the level of technology in the economy as a whole. It is formally represented as $\mathcal{F}(A, \overline{K}_P \overline{K}_H, \overline{L})$ where $\overline{K}_P$ and $\overline{K}_H$ are the total amounts of physical and human capital invested, $\overline{L}$ is the total labor endowment of the economy and A is a technology parameter.

The aggregate production function is not meant to be something that physically exists. Rather, it is a convenient construct. Growth theorists, like everyone else, have in mind a world where production functions are associated with people. To see how they proceed, let us start with a model where everyone has the option of starting a firm, and when they do, they have access to an individual production function

$$Y = F(K_P, K_H, L, \theta), \tag{1}$$

where K_P and K_H are the amounts of physical and human capital invested in the firm and L is the amount of labor. θ is a productivity parameter which may vary over time, but at any point of time is a characteristic of the firm's owner. Assume that F is increasing in all its inputs. To make life simpler, assume that there is only one final good in this economy and physical capital is made from it. Also assume that the population of the economy is described by a distribution function $G_t(W, \theta)$, the joint distribution

*MIT, Department of Economics, 50 Memorial Drive, Cambridge, MA 02142. banerjee@mit.edu, eduflo@mit.edu. of W and θ, where W is the wealth of a particular individual and θ is his productivity parameter. Let $\widetilde{G}(\theta)$ be the corresponding partial distribution on θ.

The lives of people, as often is the case in economic models, is rather dreary: In each period, each person, given his wealth, his θ and the prices of the inputs, decides whether to set up a firm, and if so how to invest in physical and human capital. At the end of the period, once he gets returns from the investment and possibly other incomes, he consumes and the period ends. The consumption decision is based on maximizing the following utility function:

$$\sum_{t=0}^{\infty} \delta^t U(C_t, \theta), 0 < \delta < 1. \tag{2}$$

1.1 The Aggregate Production Function

The key assumption behind the construction of the aggregate production function is that all factor markets are perfect, in the sense that individuals can buy or sell as much as they want at a given price. With perfect factor markets (and no risk) the market must allocate the available supply of inputs to maximize total output. Assuming that the distribution of productivities does not vary across countries, we can therefore define $\mathcal{F}(\overline{K}_P, \overline{K}_H, \overline{L})$ to be:

$$\begin{aligned} & \max_{\{K_P(\theta), K_H(\theta), L(\theta)\}} \{\int_\theta F(K_P(\theta), K_H(\theta), L(\theta), \theta) d\widetilde{G}(\theta)\} \\ \text{subject to} \int_\theta K_P(\theta) d\theta &= \overline{K}_P, \int_\theta K_H(\theta) d\theta = \overline{K}_H, and \int_\theta L(\theta) d\theta = \overline{L}. \end{aligned}$$

This is the aggregate production function. It is notable that the distribution of wealth does not enter anywhere in this calculation. This reflects the fact that with perfect factor markets, there is no necessary link between what someone owns and what gets used in the firm that he owns. The fact that $\widetilde{G}(\theta)$ does not enter as an argument of $\mathcal{F}(\overline{K}_P, \overline{K}_H, \overline{L})$ reflects our assumption that the distribution of productivities does not vary across countries.

It should be clear from the construction that there is no reason to expect a close relation between the "shape" of the individual production function and the shape of the aggregate function. Indeed it is well known that aggregation tends to convexify the production set: In other words, the aggregate production function may be concave even if the individual production functions are not. In this environment where there are a continuum of firms, the (weak) concavity of the aggregate production function is guaranteed as long as the average product of the inputs in the individual production functions is bounded in the sense that there is a λ such that $F(\lambda K_P, \lambda K_H, \lambda L, \theta) \leq \lambda \|(K_P, K_H, L, \theta)\|$ for all K_P, K_H, L and θ. It follows that the concavity of the individual functions is sufficient for the concavity of the aggregate but by no means necessary: The aggregate production would also be concave if the individual production functions

were S-shaped (convex to start out and then becoming concave). Alternately, the individual production function being bounded is enough to guarantee concavity of the aggregate production function. Moreover, the aggregate production function will typically be differentiable almost everywhere.

It is a corollary of this result that the easiest way to generate an aggregate production function with increasing returns is to base the increasing returns not on the shape of the individual production function, but rather on the possibility of externalities across firms. If there are sufficiently strong positive externalities between investment in one firm and investment in another, increasing the total capital stock in all of them together will increase aggregate output by more (in proportional terms) than the same increase in a single firm would raise the firm's output, which could easily make the aggregate production function convex. This is the reason why externalities have been intimately connected, in the growth literature, with the possibility of increasing returns.

The assumption of perfect factor markets is therefore at the heart of neo-classical growth theory. It buys us two key properties: The fact that the ownership of factors does not matter, i.e., that an aggregate production function exists; and that it is concave. The next sub-section shows how powerful these two assumptions can be.

1.2 The Logic of Convergence

Assume for simplicity that production only requires physical capital and labor and that the aggregate production function, $\mathcal{F}(\overline{K_p}, \overline{L})$ defined as above, exhibits constant returns and is concave, increasing, almost everywhere differentiable and eventually strictly concave, in the sense that $\mathcal{F}'' < \varepsilon < 0$, for any $\overline{K}_p > \widetilde{\overline{K_p}}$. As noted above, this does not require the individual production functions to have this shape, though it does impose some constraints on what the individual functions can be like. It does however require that the distribution of firm-level productivities is the same everywhere.

Under our assumption that capital markets are perfect, in the sense that people can borrow and lend as much as they want at the common going rate, r_t, the marginal returns to capital must be the same for everybody in the economy. This, combined with the fact that the preferences as represented by (2), has the immediate consequence that for everybody in the economy:

$$U'(C_t, \theta) = \delta r_t U''(C_{t+1}, \theta).$$

It follows that everybody's consumption in the economy must grow as long as $\delta r_t > 1$ and shrink if $\delta r_t < 1$. And since consumption must increase with wealth, it follows that everyone must be getting richer if and only if $\delta r_t > 1$, and consequently the aggregate wealth of the economy must be growing as long as $\delta r_t > 1$. In a closed economy, the total wealth must be equal to the total capital stock, and therefore the capital stock must also be increasing under the same conditions.

Credit market equilibrium, under perfect capital markets, implies that $\mathcal{F}'(\overline{K}_{Pt}, L) = r_t$. The fact that F is eventually strictly concave implies that as the aggregate capital stock grows, its marginal product must eventually start falling, at a rate bounded away from 0. This process can only stop when $\delta\mathcal{F}'(\overline{K}_{Pt}, L) = 1$. As long as the production function is the same everywhere, all countries must end up equally wealthy

The logic of convergence starts with the fact that in poor countries, capital is scarce, which combined with the concavity of the aggregate production function implies that the return on the capital stock should be high. Even with the same fraction of these higher returns being reinvested, the growth rate in the poorer countries would be higher. Moreover, the high returns should encourage a higher reinvestment rate, unless the income effect on consumption is strong enough to dominate. Together, they should make the poorer countries grow faster and catch up with the rich ones.

Yet poorer countries do not grow faster. According to Mankiw, Romer and Weil (1992), the correlation between the growth rate and the initial level of Gross Domestic Product is small, and if anything, positive (the coefficient of the log of the GDP in 1960 on growth rate between 1960 and 1992 is 0.0943). Somewhere along the way, the logic seems to have broken down.

Understanding the failure of convergence has been one of the key endeavors of the economics of growth. What we try to do in this chapter is to argue that the failure of this approach is intimately tied to the failure of the assumptions that underlie the construction of the aggregate production function and to suggest an alternative approach to growth theory that abandons the aggregate production.

We start by discussing, in section 2, the two implications of the neo-classical model that are at the root of the convergence result: Both rates of returns and investment rates should be higher in poor countries. We show that, in fact, neither rates of returns nor investment are, on average, much higher in poor countries. Moreover, contrary to what the aggregate production approach implies, there are large variations in rate of returns within countries, and large variation in the extent to which profitable investment opportunities are taken advantage of.

In section 3, we ask whether the puzzle (of low convergence) can be solved, while maintaining the aggregate production function, by theories that focus on reasons for technological backwardness in poor countries. We argue that this class of explanations is not consistent with the empirical evidence, which suggests that many firms in poor countries do use the latest technologies, while others in the same country use obsolete modes of production. In other words, what we need to explain is less the overall technological backwardness and more why some firms do not adopt profitable technologies that are available to them (though perhaps not affordable).

In section 4, we attempt to suggest some answers to the question of why firms and people in developing countries do not always avail themselves of the best opportunities afforded to them. We review

various possible sources of the inefficient use of resources: government failures, credit constraints, insurance failure, externalities, family dynamics, and behavioral issues. We argue that each of these market imperfections can explain why investment may not always take place where the rates of returns are the highest, and therefore why resources may be misallocated within countries. This misallocation, in turn, drives down returns and this may lower the overall investment rate. In section 5, we calibrate plausible magnitudes for the aggregate static impact of misallocation of capital within countries We show that, combined with individual production functions characterized by fixed costs, the misallocation of capital implied by the variation of the returns to capital observed within countries can explain the main aggregate puzzles: the low aggregate productivity of capital, and the low Total Factor Productivity in developing countries, relative to rich countries. Non-aggregative growth models thus seem to have the potential to explain why poor countries remain poor.

The last section provides an introduction to an alternative growth theory that does not require the existence of an aggregate production function, and therefore can accommodate the misallocation of resources. We then review the attempts to empirically test these models. We argue that the failure to take seriously the implications of non-aggregative models have led to results that are very hard to interpret. To end, we discuss an alternative empirical approach illustrated by some recent calibration exercises based on growth models that take the misallocation of resources seriously.

2 Rates of Return and Investment Rates in Poor Countries

In this section, we examine whether the two main implications of the neo-classical model are verified in the data: Are returns and investment rates higher in poor countries?

2.1 Are returns higher in poor countries?

2.1.1 Physical Capital

• Indirect Estimates

One way to look at this question is to look at the interest rates people are willing to pay. Unless people have absolutely no assets that they can currently sell, the marginal product of whatever they are doing with the marginal unit of capital should be no less than the interest rate: If this were not true, they could simply divert the last unit of capital toward whatever they are borrowing the money for and be better off.

There is a long line of papers that describe the workings of credit markets in poor countries (Banerjee (2003a) summarizes this evidence). The evidence suggests that a substantial fraction of borrowing takes

place at very high interest rates.

A first source of evidence is the "Summary Report on Informal Credit Markets in India" (Dasgupta (1989)), which reports results from a number of case studies that were commissioned by the Asian Development Bank and carried out under the aegis of the National Institute of Public Finance and Policy. For the rural sector, the data is based on surveys of six villages in Kerala and Tamil Nadu, carried out by the Centre for Development Studies. The average annual interest rate charged by professional moneylenders (who provide 45.6% of the credit) in these surveys is about 52%. For the urban sector, the data is based on various case surveys of specific classes of informal lenders, many of whom lend mostly to trade or industry. For finance corporations, they report that the minimum lending rate on loans of less than one year is 48%. For hire-purchase companies in Delhi, the lending rate was between 28% and 41%. For auto financiers in Namakkal, the lending rate was 40%. For handloom financiers in Bangalore and Karur, the lending rate varied between 44% and 68%.

Several other studies reach similar conclusions. A study by Timberg and Aiyar (1984) reports data on indigenous-style bankers in India, based on surveys they carried out: The rates for Shikarpuri financiers varied between 21% and 37% on loans to members of local Shikarpuri associations and between 21% and 120% on loans to non-members (25% of the loans were to non-members). Aleem (1990) reports data from a study of professional moneylenders that he carried out in a semi-urban setting in Pakistan in 1980-1981. The average interest rate charged by these lenders is 78.5%. Ghate (1992) reports on a number of case studies from all over Asia: The case study from Thailand found that interest rates were 5-7% per month in the north and northeast (5% per month is 80% per year and 7% per month is 125%). Murshid (1992) studies Dhaner Upore (cash for kind) loans in Bangladesh (you get some amount in rice now and repay some amount in rice later) and reports that the interest rate is 40% for a 3-5 month loan period. The Fafchamps (2000) study of informal trade credit in Kenya and Zimbabwe reports an average monthly interest rate of 2.5% (corresponding to an annualized rate of 34%) but also notes that this is the rate for the dominant trading group (Indians in Kenya, whites in Zimbabwe), while the blacks pay 5% per month in both places.

The fact that interest rates are so high could reflect the high risk of default. However, this does not appear to be the case, since several of studies mentioned above give the default rates that go with these high interest rates. The study by Dasgupta (1989) attempts to decompose the observed interest rates into their various components,[1] and finds that the default costs explain 7 per cent (not 7 percentage points!) of the total interest costs for auto financiers in Namakkal and handloom financiers in Bangalore and Karur, 4% for finance companies and 3% for hire-purchase companies. The same study reports that in four case studies of moneylenders in rural India they found default rates explained about 23% of the

[1] In the tradition of Bottomley (1963).

observed interest rate. Timberg and Aiyar (1984), whose study is also mentioned above, report that average default losses for the informal lenders they studied ranges between 0.5% and 1.5% of working funds. The study by Aleem gives default rates for each individual lender. The median default rate is between 1.5 and 2%, and the maximum is 10%.

Finally, it does not seem to be the case that these high rates are only paid by those who have absolutely no assets left. The "Summary Report on Informal Credit Markets in India" (Dasgupta (1989)) reports that several of the categories of lenders that have already been mentioned, such as handloom financiers and finance corporations, focus almost exclusively on financing trade and industry while Timberg and Aiyar (1984) report that for Shikarpuri bankers at least 75% of the money goes to finance trade and, to lesser extent, industry. In other words, they only lend to established firms. It is hard to imagine, though not impossible, that all the firms have literally no assets that they can sell. Ghate (1992) also concludes that the bulk of informal credit goes to finance trade and production, and Murshid (1992), also mentioned above, argues that most loans in his sample are production loans despite the fact that the interest rate is 40% for a 3-5 month loan period.

Udry (2003) obtains similar indirect estimates by restricting himself to a sector where loans are used for productive purpose, the market for spare taxi parts in Accra, Ghana. He collected 40 pairs of observations on price and expected life for a particular used car part sold by a particular dealer (e.g., alternator, steering rack, drive shaft). Solving for the discount rate which makes the expected discounted cost of two similar parts equal gives a lower bound to the returns to capital. He obtains an estimate of 77% for the median discount rate.

Together, these studies thus suggest that people are willing to pay high interest rates for loans used for productive purpose, which suggests that the rates of return to capital are indeed high in developing countries, at least for some people.

• Direct Estimates

Some studies have tried to come up with more direct estimates of the rates of returns to capital. The "standard" way to estimate returns to capital is to posit a production function (translog and Cobb-Douglas, generally) and to estimate its parameters using OLS regression, or instrumenting capital with its price. Using this methodology, Bigsten (2000) estimate returns to physical and human capital in five African countries. They estimate rates of returns ranging from 10% to 32%. McKenzie and Woodruff (2003) estimate parametric and non-parametric relationships between firm earnings and firm capital. Their estimates suggest huge returns to capital for these small firms: For firms with less than $200 invested, the rate of returns reaches 15% per *month*, well above the informal interest rates available in pawn shops or through micro-credit programs (on the order of 3% per month). Estimated rates of return

decline with investment, but remain high (7% to 10% for firms with investment between $200 and $500, 5% for firms with investment between $500 and $1,000).

Such studies present serious methodological issues, however. First, the investment levels are likely to be correlated with omitted variables. For example, in a world without credit constraints, investment will be positively correlated with the expected returns to investment, generating a positive "ability bias" (Olley and Pakes (1996)). McKenzie and Woodruff attempt to control for managerial ability by including the firm owner's wage in previous employment, but this may go only part of the way if individuals choose to enter self-employment precisely because their expected productivity in self-employment is much larger than their productivity in an employed job. Conversely, there could be a negative ability bias, if capital is allocated to firms in order to avoid their failure.

Banerjee and Duflo (2003a) take advantage of a change in the definition of the so-called "priority sector" in India to circumvent these difficulties. All banks in India are required to lend at least 40% of their net credit to the "priority sector", which includes small-scale industry, at an interest rate that is required to be no more than 4% above their prime lending rate. In January, 1998, the limit on total investment in plants and machinery for a firm to be eligible for inclusion in the small-scale industry category was raised from Rs. 6.5 million to Rs. 30 million. Banerjee and Duflo (2003a) first show that, after the reforms, newly eligible firms (those with investment between 6.5 million and 30 million) received on average larger increments in their working capital limit than smaller firms. They then show that the sales and profits increased faster for these firms during the same period. Putting these two facts together, they use the variation in the eligibility rule over time to construct instrumental variable estimates of the impact of working capital on sales and profits. After computing a non-subsidized cost of capital, they estimate that the returns to capital in these firms must be at least 94%.

There is also direct evidence of very high rates of returns on productive investment in agriculture. Goldstein and Udry (1999) estimate the rates of returns to the production of pineapple in Ghana. The rate of returns associated with switching from the traditional maize and Cassava intercrops to pineapple is estimated to be in excess of 1,200%! Few people grow pineapple, however, and this figure may hide some heterogeneity between those who have switched to pineapple and those who have not.

Evidence from experimental farms also suggests that, in Africa, the rate of returns to using chemical fertilizer (for maize) would also be high. However, this evidence may not be realistic, if the ideal conditions of an experimental farm cannot be reproduced on actual farms. Foster and Rosenzweig (1995) show, for example, that the returns to switching to high yielding varieties were actually low in the early years of the green revolution in India, and even negative for farmers without an education. This is despite the fact that these varieties had precisely been selected for having high yields, in proper conditions. But they required complementary inputs in the correct quantities and timing. If farmers were not able or did not

know how to supply those, the rates of returns were actually low.

Chemical fertilizer, however, is not a new technology, and the proper way to use it is well understood. To estimate the rates of returns to using fertilizer in actual farms in Kenya, Duflo and Robinson (2003), in collaboration with a small NGO, set up small scale randomized trials on people's farms: Each farmer in the trials delimited two small plots. On one randomly selected plot, a field officer from the NGO helped the farmer apply fertilizer. Other than that, the farmers continued to farm as usual. They find that the rates of returns from using a small amount of fertilizer varied from 169% to 500% depending on the year, although of returns decline fast with the quantity used on a plot of a given size.

The direct estimates thus tend to confirm the indirect estimates: While there are some settings where investment is not productive, there seems to be investment opportunities which yield substantial rates of returns.

• How high is the marginal product on average?

The fact that the marginal product in some firms is 50% or 100% or even more does not imply that the average of the marginal products across all firms is nearly as high. Of course, if capital always went to its best use, the notion of the average of the marginal products does not make sense. The presumption here is that there may be an equilibrium where the marginal products are not equalized across firms.

One way to get at the average of the marginal products is to look at the Incremental Capital Output Ratio (ICOR) for the country as a whole. The ICOR measures the increase in output predicted by a one unit increase in capital stock. It is calculated by extrapolating from the past experience of the country and assumes that the next unit of capital will be used exactly as efficiently (or inefficiently) as the last one. The inverse of the ICOR therefore gives an upper bound for the average marginal product for the economy—it is an upper bound because the calculation of the ICOR does not control for the effect of the increases in the other factors of production which also contributes to the increase in output.[2] For the late 1990s, the IMF estimates that the ICOR is over 4.5 for India and 3.7 for Uganda. The implied upper bound on the average marginal product is 22% for India and 27% in Uganda.

• Variations in the marginal products across firms.

To reconcile the high direct and indirect estimates of the marginal returns we just discussed and an average marginal product of 22% in India, it would have to be that there is substantial variation in the marginal product of capital within the country. Given that the inefficiency of the Indian public sector is legendary, this may just be explained by the investment in the public sector. However, since the ICOR

[2]The implicit assumption that the other factors of production are growing is probably reasonable for most developing countries, except perhaps in Africa.

is from the late 1990s, when there was little new investment (or even disinvestment) in the public sector, there must also be many firms in the private sector with marginal returns substantially below 22%. The micro evidence reported in Banerjee (2003b), which shows that there is very substantial variation in the interest rate within the same sub-economy, certainly goes in this direction. The Timberg and Aiyar (1984) study mentioned above, is one source of this evidence: It reports that the Shikarpuri lenders charged rates that were as low as 21% and as high as 120%, and some established traders on the Calcutta and Bombay commodity markets could raise funds for as little as 9%. The study by Aleem (1990), also mentioned above, reports that the standard deviation of the interest rate was 38.14%. Given that the average lending rate was 78.5%, this tells us that an interest rate of 2% and an interest rate of 150% were both within two standard deviations of the mean. Unfortunately, we cannot quite assume from this that there are some borrowers whose marginal product is 9% or less: The interest rate may not be the marginal product if the borrowers who have access to these rates are credit constrained. Nevertheless, given that these are typically very established traders, this is less likely than it would be otherwise.

Ideally we would settle this issue on the basis of direct evidence on the misallocation of capital, by providing direct evidence on variations in rates of return across groups of firms. Unfortunately such evidence is not easy to come by, since it is difficult to consistently measure the marginal product of capital. However, there is some rather suggestive evidence from the knitted garment industry in the Southern Indian town of Tirupur (Banerjee and Munshi (2004); Banerjee and Munshi (2003)). Two groups of people operate in Tirupur: the Gounders, who issue from a small, wealthy, agricultural community from the area around Tirupur, who have moved into the ready-made garment industry because there was not much investment opportunity in agriculture. Outsiders from various regions and communities started joining the city in the 1990s. The Gounders have, unsurprisingly, much stronger ties in the local community, and thus better access to local finance, but may be expected to have less natural abilities for garment manufacturing than the outsiders, who came to Tirupur precisely because of its reputation as a center for garment export. The Gounders own about twice as much capital as the outsiders on average. They maintain a higher capital-output ratio than the outsiders at all levels of experience, though the gap narrows over time. The data also suggest that they make less good use of their capital than the outsiders: While the outsiders start with lower production and exports than the Gounders, their experience profile is much steeper, and they eventually overtake the Gounders at high levels of experience, even though they have lower capital stock throughout. This data therefore suggests that capital does not flow where the rates of return are highest: The outsiders are clearly more able than the Gounders, but they nevertheless invest less.[3]

[3]This is not because capital and talent happen to be substitutes. In this data, as it is generally assumed, capital and ability appear to be complements.

To summarize, the evidence on returns to physical capital in developing countries suggests that there are instances with high rates of return, while the average of the marginal rates of return across firms does not appear to be that high. This suggests a coexistence of very high and very low rates of return in the same economy.

2.1.2 Human Capital

• Education

The standard source of data on the rate of return to education is Psacharopoulos (1973; 1985; 1994; 2002)) who compiles average Mincerian returns to education (the coefficient of years of schooling in a regression of log(wages) on years of schooling) as well as what he call "full returns" to education by level of schooling. Compared to Mincerian returns, full returns take into account the variation in the cost of schooling according to year of schooling: The opportunity cost of attending primary school is low, because 6 to 12 year old children do not earn the same wage as adults; and the direct costs of education increase with the level of schooling.

On the basis of this data, Psacharopoulos argues that returns to education are substantial, and that they are larger in poor countries than in rich countries. We re-examine the claim that returns to education are larger in poor countries, using data on traditional Mincerian returns, which have the advantage of being directly comparable. We start with the latest compilation of rates of returns, available in Psacharopoulos (2002) and on the World Bank web site. We update it as much as possible, using studies that seem to have been overlooked by Psacharopoulos, or that have appeared since then (the updated data set and the references are presented in the appendix).[4] We flag the observations that Bennell (1996) rated as being of "poor" or "very poor" quality. We complete this updated database by adding data on years of schooling for the year of the study when it was not reported by Psacharopoulos.

Using the preferred data, the Mincerian rates of returns seem to vary little across countries: The mean rate of returns is 8.96, with a standard deviation of 2.2. The maximum rate of returns to education (Pakistan) is 15.4%, and the minimum is 2.7% (Italy). Averaging within continents, the average returns are highest in Latin America (11.05) and lowest in the Europe and the U.S. (7%), with Africa and Asia in the middle.

If we run an OLS regression of the rates of returns to education on the average educational attainment (number of years of education), using the preferred data (updated database without the low quality data), the coefficient is -0.26, and is significant at 10% level (table 1, column 3). The returns to education

[4]The bulk of the update is for African countries, where Bennell (1996) had systematically investigated the Psacharoupoulos data, and found that many of the underlying studies were unreliable.

predicted from this regression ranges from 6.91 for the country with the lowest education level to 10.09 for the country with the highest education level. This is a small range (smaller than the variation in the estimates of the returns to education of a single country, or even in different specifications in a single paper!): There is therefore no *prima facie* evidence that returns to education are much higher when education is lower, although the relationship is indeed negative. Columns 1 and 2 in the same table show that the data construction matters: When the countries with "poor" quality are included, the coefficient of years of education increases to -0.45. When only the 38 countries in the latest Psacharopoulos update are included (most countries are dropped because the database does not report years of education, even for countries where it is clearly available–Austria for example), the coefficient more than doubles, to -0.71. On the whole, this strong negative number does appear to be an artifact of data quality.

In column (4), we directly regress the Mincerian returns to education on GDP, and we find a small and significant negative relationship. However, this is counteracted by the fact that teacher salary grows less fast than GDP, and the cost of education is thus not proportional to GDP: In column (5) we regress the log of the teacher salary on the log of GDP per capita.[5] The coefficient is significantly less than one, suggesting that teachers are relatively more expensive in poor countries. This is to some extent attenuated by the fact that class sizes are larger in poor countries (which tends to make education cheaper). We then compute the returns to educating a child for one year as the ratio of the lifetime benefit of one year of education (assuming a life span of 30 years, a discount rate of 5%, a share of wage in GDP of 60%, and no growth), to the direct cost of education (assuming that teacher salary is 85% of the cost of education). In column (6), we regress this ratio on GDP: There is no relationship between this measure of returns and GDP.[6] If we factor in indirect costs (as a fraction of GDP) (in column 7), the relationship becomes slightly more negative, but still insignificant. On balance, the returns to one more year of education are therefore no higher in poor countries.

• Health

Education is not the only dimension of human capital. In developing countries, investment in nutrition and health has been hypothesized to have potentially high returns at moderate levels of investment. The report of the Commission for Macroeconomics and Health (on Macroeconomics and Health (2001)), for example, estimated returns to investing in health to be on the order of 500%, mostly on the basis of cross-country growth regressions. Several excellent recent surveys by John Strauss and Duncan Thomas (Strauss and Thomas (1995); Strauss and Thomas (1998)), Thomas (2001) and Thomas and Frankenberg (2002) summarize the existing literature on the impact of different measures of health on fitness and

[5]The teacher salary data is obtained from the "Occupational Wages Around the World" database (Freeman and Oostendorp (2001)).

[6]Note that by assuming that the lifespan is the same in poor and rich countries, we are biasing upwards the returns in poor countries.

productivity, and lead to a much more nuanced conclusion.

There is substantial experimental evidence that supplementation in iron and vitamin A increases productivity at relatively low cost. Unfortunately, not all studies report explicit rates of returns calculations. The few numbers that are available suggest that some basic health intervention can have high of returns: Basta and Scrimshaw (1979) studies an iron supplementation experiment conducted among rubber tree tappers in Indonesia. Baseline health measures indicated that 45% of the study population was anemic. The intervention combined an iron supplement and an incentive (given to both treatment and control groups) to take the pill on time. Work productivity in the treatment group increased by 20% (or $132 per year), at a cost per worker-year of $0.50. Even taking into account the cost of the incentive ($11 per year), the intervention suggests extremely high rates of returns. Duncan Thomas and Al (2003) obtain lower, but still high, estimates in a larger experiment, also conducted in Indonesia: They found that iron supplementation experiments in Indonesia reduced anemia, increased the probably of participating in the labor market, and increased earnings of self-employed workers. They estimate that, for self-employed males, the benefits of iron supplementation amount to $40 per year, at a cost of $6 per year.[7] The cost benefit analysis of a de-worming program (Basta and Scrimshaw (1979)) in Kenya reports estimates of a similar order of magnitude: Taking into account externalities (due to the contagious nature of worms), the program led to an average increase in school participation of 0.14 years. Using a reasonable figure for the returns to a year of education, this additional schooling will lead to a benefit of $30 over the life of the child, at a cost of $0.49 per child per year. Not all interventions have the same rates of return however: A study of Chinese cotton mill workers (Li and Hautvast (1994)) led to a significant increase in fitness, but no corresponding increase in productivity. Likewise, the intervention analyzed by Duncan Thomas and Al (2003) had no effect on earnings or labor force participation of women.

In summary, while there is not much debate on the impact of fighting anemia (through iron supplementation or de-worming) on work capacity, there is more heterogeneity amongst estimates of economic rates of return of these interventions. The heterogeneity is even larger when we consider other forms of health interventions, reviewed, for example, in Strauss and Thomas (1995), or when one compares various human capital interventions. As in the case of physical capital, there are instances of high returns, and substantial heterogeneity in returns.

[7]This number takes into account the fact that only 20% of the Indonesian population is iron deficient: The private returns of iron supplementation for someone who knew they were iron deficient–which they can find out using a simple finger prick–would be $200).

2.1.3 Taking Stock: Returns on Capital

The marginal product of physical and human capital in developing countries seems very high in some instances, but not necessarily uniformly. The average of the marginal products of physical capital in India may well be less than 22%, though even reasonably large firms often have marginal products of 60%, or even 100%.

The question is whether we should think of 22% as a high number or a low number. One way to think about it is that it is only 2.5 times the 9% or so that a marginal dollar earns in the U.S. (the average stock market real return), but is variation by a factor of 2.5 as much we might ever expect?

A more structured way to answer this question is to follow Lucas (1990), and to ask whether, in the neo-classical model, the marginal product of capital is high enough in India to be compatible with the observed difference in output-per-worker. According to the Penn World Tables (Heston and Aten (2002)), in 1990, output-per-worker in India at Purchasing Power Parity was 1/11th of what it was in the U.S. To obtain a productivity gap per effective use of labor, we need to adjust this ratio by the differences in education between the two countries. Based on the work of Krueger (1967), Lucas (1990) argues that "one American worker is equal to five Indian workers" in terms of human capital. In our case, since we are comparing productivity in 1990, and Krueger's estimates of human capital are from the late 1960s, we presumably adjust the correction factor. Between 1965 and 1990, years of schooling among those 25 years or older went from 1.90 years to 3.68 years in India and from 9.25 years to 12 years in the United States, i.e., from approximately 20% of the U.S. level, which fits with the 5:1 gap in productivity that Krueger suggested, to about 30%.[8]

To show what this implies, Lucas starts with the assumption that *net* output is produced using a production function $Y = AL^{1-\alpha}K^{\alpha}$, where K is investment and L is the number of worker.[9]

From this, it follows that ouput per worker is $y = Ak^{\alpha}$, where k is investment per worker in equipment. Assuming that firms can borrow as much as they want at the rate r, profit maximization requires that $\alpha Ak^{\alpha-1} = r$, from which it follows that

$$\frac{y_U}{y_I} = \left(\frac{r_I}{r_U}\right)^{\frac{\alpha}{1-\alpha}} \left(\frac{A_U}{A_I}\right)^{\frac{1}{1-\alpha}}. \tag{3}$$

If we assume that the only difference between the TFP levels in the two countries is due to the

[8]These numbers are based on Barro and Lee (2000). Another angle from which this can be looked at is that health improved also during the period: Over a slightly different period, (1970-75 to 1995-2000), according to the Human Development Report (United Nations Development Program (2001)), life expectancy at birth went from 50.3 to 62.3 years in India and from 71.5 years to 76.5 years in the U.S., reducing the gap between India and the U.S. by about 40%.

[9]Lucas actually computes the ratio of output per effective unit of labor, which, with our parameters, is equal to $11 * \frac{3}{10} \approx 3$. Reassuringly, this is also the ratio that Lucas started with, albeit based on the average numbers for the 1965-1990 period rather than the 1990 numbers.

productivity per worker, the fact that Indian workers are only 30% as productive as the US workers and the share of capital is assumed to be 40% implies that:

$$\frac{A_U}{A_I} = (0.3)^{0.6} \approx 2. \tag{4}$$

With these parameters, the 11-fold difference between y_U and y_I would imply that $r_I = (3)^{5/3} r_U \approx 5r_U$. r is naturally thought of as the marginal product of capital. Given the difference in output-per-worker even after adjusting for the difference in workers' productivity, the marginal product of capital in India should therefore be 5 times, rather than 2.5 times, what it is in the US. In other words, if we take 9% for the marginal product of capital in the U.S., this would imply a 45% rate for India, rather than the 22% we observe in the data.

Lucas saw this as an obvious reason to reject the assumption that the TFP levels in the two countries are the same on the grounds that if the rates were indeed that different, capital would flow from the U.S. to India. Hence, Lucas argued, the rate of returns cannot possibly be that high in India. This seems to be rather a leap of faith: As we have already seen, there are indeed many investment opportunities in India that yield 45% or more, and capital flows from within or without have not yet eliminated them.

On the other hand, it is clear that if the average marginal rate in India is really 22% or less (which is our best guess about it), then Lucas was right in insisting that the actual rates of returns are much lower than what we would expect if the model were correct. Likewise, while there are some types of investment in human capital in developing countries that yield high rates of return, the average investment in human capital does not appear to be particularly lucrative.

The data thus contradicts the predictions of the aggregate production approach from two different directions: First, rates of return are very far from being equalized. Second, the average of these returns is lower in poor countries than an aggregate production function would predict, under the assumption of equal TFP. We now turn to other implications of the neo-classical model: Investment rates should be higher in poor countries and, within countries, capital should be flowing to investments that yield the highest return.

2.2 Investment Rates in Poor Countries

2.2.1 Is investment higher in poor countries?

Prima facie, it does not seem to be the case that investment rates are higher in poor countries. On the contrary, there is a robust positive correlation between investment rates in physical capital and income per capita, when both are expressed in terms of purchasing power parity. In fact, Levine and Renelt (1992) and Sala-I-Martin (1997) identified investment per capita as the only robust correlate of income.

For example, Hsieh and Klenow (2003) estimate that in 1985, the correlation between PPP investment rate and PPP income per capita for the 115 countries present in the Penn World Tables was 0.60. The coefficients they estimate suggest that an increase in one log point in income per capita is associated with about a 5 percentage point higher PPP investment rate (the mean investment rate is 14.5%). The same positive correlation obtains with investment in plant and machinery. The relationship between investment rate and income per capita is much less strong when both of them are expressed in nominal terms rather than in PPP terms (Eaton and Kortum (2001); Restuccia and Urrutia (2001) and Hsieh and Klenow (2003)). The coefficient drops by a third when all investments are considered, and becomes insignificant when the measure of investment includes only plant and machinery. According to Hsieh and Klenow (2003), the fact that poor countries have a lower investment-to-GDP ratio, when expressed in PPP, is explained by the low relative price of consumption, relative to investment: While there is no correlation between investment prices and GDP, there is a strong positive correlation between consumption prices and GDP. It is not clear, however, that knowing this helps us explain why there is not *more* investment in poor countries. First, because the high rates that we found in some firms in developing countries and the lower, but still high, rates that we found on average are there despite the high price of capital goods. Moreover, even if we measure everything in nominal terms, there is no strong negative correlation between investment and GDP.

There are, of course, examples of poor countries with large investment to GDP ratios. Young (1995) shows that a substantial fraction of the rapid growth of the East-Asian economies in the post-WWII period can be accounted for by rapid factor accumulation (including increase in the size of the labor force, factor reallocation, and high investment rates). In particular, according to the national accounts, between 1960 and 1985, the capital stock in Singapore, Korea, and Taiwan grew at more than 12% a year (in Hong Kong, it grew only at 7.7% a year). Between 1966 and 1999, the capital-output ratio has increased at an average rate of 3.4% a year in Korea, and 2.8% in Singapore. In Singapore, for example, the constant investment-to-GDP ratio increased from 10% in 1960 to 47% in 1984. In Singapore, Korea, and Taiwan, this increase in the stock of capital alone is responsible for about 1% out of the average yearly 3.4% to 4% of the "naive" Solow residual. Based on these results, Alwyn Young (Young (1995)) concluded that the East-Asian economies are perfect examples of transitional dynamics in the neo-classical model. However, in subsequent research, Hsieh (1999) questioned the validity of the national account data for investment for Singapore. He observes that if the capital-to-GDP ratio had grown at that speed, one would have observed a commensurate reduction in the rental price of capital. In practice, there was indeed a steady fall in the rental price of capital (both the interest rates and the relative price of capital fell) in Korea, Taiwan and Hong Kong. The drop is particularly large in Korea, where the national account statistics also suggest a large increase in the capital stock. However, in Singapore, there is no

evidence that the rental rate declined over the period. If any thing, it seems to have *increased*.

As for investment in physical capital, there is no *prima facie* evidence that poor countries invest more in education. The data is poor and extremely partial, since it is difficult to estimate private expenditure on education. What we can measure easily, government expenditure on education as a fraction of GDP, however, is not higher in poor countries, though there is significant variation across countries. In 1996, according to the country level data disseminated by the World Bank "edstat" department, government investment on education was 4.8% in Africa, 4% in Asia, 4.1% in Latin America, 4.8% in North America and 5.6% in Europe. The correlation between the log of government expenditure on education as a fraction of GDP and GDP-per-capita is strong (in current prices): The coefficient of the log of GDP was 0.18 in 1990, and 0.08 in 1996, larger than the comparable estimate for rate of investment in physical capital.

As we noted earlier, the fact that teachers are relatively more expensive in developing countries may imply that true returns to education may be much lower than the Mincerian returns. Can this explain why there is not greater investment in education in poor countries? Within the neo-classical model, the answer is no: Banerjee (2003b) shows that in the neo-classical world the same forces that raise the relative price of teachers in poor countries (or in countries with low education levels) also raise the wages paid to educated people, and on net the rate of return has to be higher rather than lower. And, in any case, it is not true that public investment in education is higher when returns are higher: We found no correlation between government expenditure on education as a fraction of GDP and rate of returns to education (the coefficient of the rates of return to education on government expenditure in education in 1996 is -0.008, with a standard error of 0.013).

In summary, while there are isolated cases of high investment rates in relatively poor countries (Taiwan and Korea), this by no means seems to be a general phenomenon. We have already suggested one reason why this might be the case–it does not look like returns are especially high. It may also be that investment is not particularly responsive with respect to returns. This is the issue we turn to next.

2.2.2 Does investment respond to rates of return?

There is little doubt that people do take up many investment opportunities with high potential returns. Investment flowed into Bangalore when it became a hub for the software industry in India. When, in the 1990s, Tirupur, a smallish town in South India, became known in the U.S. as a good place to contract large orders of knitted garments, the industry in the city grew at more than 50% per year, due to substantial investments of both the local community (diversifying out of agriculture) and outsiders attracted to Tirupur (Banerjee and Munshi (2004)). Or, to take a last example from India, new hybrid seeds and fertilizers spread rapidly during the "green revolution", leading to very rapid yield growth

(yields were multiplied by 3 in Karnataka and 2.5 in Punjab (Foster and Rosenzweig (1996))).

However, there are many instances where investments options with very high rates of returns do not seem to be taken advantage of. For example, Goldstein and Udry (1999) find that, despite the high rates of returns to growing pineapple compared to other crops, only 18% of the land is used for pineapple farming. Similarly, Duflo and Robinson (2003) find that only less than 15% of maize farmers in the area where they conducted field trials on the profitability of fertilizer report having used fertilizer in the previous season, despite estimated rates of return in excess of 100%.

From a more macro perspective, Bils and Klenow (2000) argue that the observed high correlation between educational attainment and subsequent growth observed in cross-sectional data (one year of additional schooling attainment is associated with 0.30 percent faster annual growth over the period 1960-1990) must be due, at least in part, to the fact that higher expected growth rates increase the returns to schooling, and therefore the demand for schooling. As we noted earlier, the correlation between education and subsequent growth (found in many studies, e.g., Barro (1991), Benhabib and Spiegel (1994), and Barro and Sala-I-Martin (1995)) appears to be too high to be entirely explained by the causal effect of transitional differences in human capital growth rates on growth rates. Bils and Klenow (2000) calibrate a simple neo-classical growth model, which requires that the impact of schooling on individual productivity has to be consistent with the average coefficient obtained from Mincer regressions. Their calibration suggest that the high level of education in 1960 can only explain up to a third of the correlation between education and growth. Moreover, as we discussed above, this correlation cannot be explained by high human capital externalities. They therefore calibrate an alternative model, where they construct the optimal schooling predicted by a country's expected economic growth. The calibration, once again, requires that the impact of education on human capital be consistent with the micro-estimates of the Mincerian returns, so that there remains a large fraction of the correlation between education and growth to explain. Higher expected growth induces more schooling by lowering the effective discount rate. They assume that a country's expected growth is a weighted average of its real *ex post* growth and the growth of the rest of the world. They estimate that, starting at 6.2 years of schooling, a 1 percent increase in growth induces 1.4 to 2.5 more years of schooling, depending on the values chosen for the parameters that are imposed. A 1 percentage point higher Mincerian return to schooling increases education by 1.1 to 1.9 years.

The aggregate data is thus consistent with a strong response of schooling to growth. However, it is also consistent with the presence of an omitted variable explaining both education and growth: In fact, Bils and Klenow acknowledge that their estimates suggests an elasticity of schooling demand to returns to schooling that is higher than what is implied by existing micro-studies (reviewed by Freeman (1986)). This problem cannot really be adequately addressed in the macroeconomic data, since there it is difficult

to find a plausible instrument for growth, and the impact of expected growth on schooling must essentially be estimated as a residual impact (what remains to be explained from the correlation between growth and schooling after a plausible estimate for the impact of education on growth has been removed).

Foster and Rosenzweig, in a series of papers, use the green revolution in India as a source of partly exogenous increase in rate of returns to human capital to estimate the impact of expected growth and increases in returns to education on schooling and, more generally, investment in human capital. Foster and Rosenzweig (1996) find that returns to education increased faster in regions where the green revolution induced faster technological change: Their estimates imply that in 1971, before the start of the green revolution, the profits in households where the head had completed primary education were 11% higher than the profits in households were he had not. By 1982, the profits were 46% higher for districts where the growth rate was one standard deviation above average. They then turn to estimating whether educational choices were also sensitive to the higher yield growth. After instrumenting for yield growth, they find that the impact of technological change on education is indeed substantial: In areas with recent growth in yields of one standard deviation above the mean, the enrollment rates of children from farm households are an additional 16 percentage points (53%) higher, compared to average-growth areas. Foster and Rosenzweig (2000) find that technological growth also affected the provision of schools, benefiting landless households. However, on balance, technological growth seems to lead to lower educational investment by landless households, perhaps because returns to education increase less for them (since they are engaged in more menial tasks) and because the fact that the withdrawal of children of landed households from the labor market increases children's wages, and thus the opportunity cost of school attendance.

Foster and Rosenzweig (1999) consider another measure of investment in children's human capital, namely child survival. They argue that technological growth in the village increases the returns from investing in boys' health, while technological growth outside the village, but in the potential "marriage market", increases the returns to investing in girls (because better educated and healthier women will fetch a higher prices in regions with higher technological progress). Their results indeed suggest that the gap in boys/girls mortality rates increases with technological change in the village, but decreases with technological change in the labor market.

Other evidence that girls' survival is affected by the expected returns to having girls include Rosenzweig and Schultz (1982), who show that the boys/girls mortality gap is negatively correlated to women's wage, and Qian (2003), who uses the liberalization of tea prices in China as a natural experiment in female productivity. She shows that, in regions suitable to tea production, the ratio of boys to girls diminished considerably after tea production and tea prices were liberalized: She interprets this as evidence that prospects for higher productivity for girls (women are particularly suited to tea picking) encourage parents to invest in their girls.

While these facts taken together do suggest that individuals do respond to returns when making human capital investment decisions, there are possible alternative explanations for these facts. The results from Rosenzweig and Schultz (1982) and Qian (2003) cannot easily be distinguished from a women's bargaining power effect: If mothers tend to prefer girls, and their bargaining power increases as a result of the increase of their productivity, then the outcomes will improve for girls, even if households' decisions do not respond to returns. The results in Foster and Rosenzweig (1996, 2000) could in part be attributed to wealth effects (expected growth makes the households richer, and if education has any consumption value, one would expect growth to respond to it), although Foster and Rosenzweig (1996) estimate the wealth effect directly, and argue that it is not important. But it remains possible that the instrumented expected increase in yield captures real increases in expected wealth better than any other measure (they show that land prices do adjust to the future expected yield increases, for example). Moreover, there is also direct evidence that investment in human capital does not always respond to returns: Munshi and Rosenzweig (2004) show that the rapid increase in the returns to English education in India in the 1990s (the returns increased from 15% to 24% in 10 years for boys, and 0% to 27% for girls) led to a convergence in the choice of English as a medium of instruction between the low and high castes amongst girls, but not amongst boys: Boys from the lower castes seem so far not to have taken full advantage of the new opportunities offered by English medium education.

Another angle for approaching this question is the sensitivity of human capital investment to the direct or indirect costs of these investments. Several recent studies do suggest that the elasticity of school participation with respect to user fees is high: Kremer and Namunyu (2003) conducted a randomized trial in rural Kenya in which an NGO provided uniforms, textbooks, and classroom construction to seven schools randomly selected from a pool of 14 schools. Dropouts fell considerably in the schools that received the program, relative to the other schools (after five years, pupils initially enrolled in the treatment schools had completed 15% more schooling than those enrolled in the comparison schools). They argue that the financial benefits of the free uniforms were the main reason for this increase in participation. Several programs go beyond reducing the school fees to actually pay for attendance. The PROGRESA program in Mexico provided grants to poor families, conditional on continued school participation and participation in health care. The program was initially launched as a randomized experiment, with 506 communities randomly assigned to either the treatment or control group. Schultz (2001) finds a 3.4% increase in enrollment in all children. The largest increase was in the transition between primary and secondary school, especially for girls. Gertler and Boyce (2002) report a similar effect on health. In this case as well, it is difficult to distinguish the pure price effect from the income effect.[10] School meals, which is another way to pay children to attend school, have been shown to be associated with increased school

[10]Moreover, there could be a bargaining power effect, since the grants were distributed through women.

participation in several observational studies (Jacoby (2002); Long (1991); Powell and Elston (1983); Powell and Grantham-McGregor (1998) and Dreze and Kingdon (1999)) and one experimental trial conducted among pre-school children in Kenya (Vermeersch (2002)). The available evidence, therefore, points toward a robust elasticity of schooling decisions with respect to the cost of schooling.

While this could be indicative of households being extremely sensitive to net returns, the magnitude of these effects are hard to reconcile with this explanation. For example, using an estimate of 7% Mincerian returns per year of education, Miguel and Kremer (2004) estimate that the benefit of one year of primary schooling is in excess of $200 over the lifetime of a child. Yet, the provision of a uniform valued at $6 induced an average increase of 0.5 years in the time a child spent in school (time spent in schools increased from 4.8 years in the comparison schools on average, to 5.3 years in the treatment schools). To be consistent with a model where the only reason where the provision of uniforms increase school attendance is the increase in the rate of returns that it leads to, these numbers would mean that a large fraction of children (or their parents) were exactly indifferent between attending school or not, before the uniform is provided.

While this is certainly possible, other evidence suggests that human capital investment does not always respond to rates of returns. For example, the take-up of the de-worming program studied by Miguel and Kremer (2004) was only 57%, despite the fact that the program was *free*, and that the only investment required was to sign an informed consent form (and some disutility for the child). Further, when a nominal fee was introduced in a randomly selected set of schools in the year after the initial experiment, the take-up fell by 80%, relative to free treatment (Kremer and Miguel (2003)). While this could be due to the fact that the private benefits are perceived to be low by the parents, it is worth noting that the hike in user fees happened after one year of free treatment, so that parents would have had time to observe the change in the child's health and attendance at school. Moreover, Kremer and Miguel (2003) also observe that, as long as the price was positive, there was no impact from the actual price on the take-up of the drug. This strong non-linearity between a price of zero and any positive price (which is also consistent with the evidence from school uniforms) appears to be inconsistent with a response to uniforms.

To sum up, the evidence suggests that, while investment seems to respond in part to the cost and the benefits of these investments, it appears to do so in ways that suggest that it does not only respond to returns as we are measuring them.

2.2.3 Taking Stock: Investment Rates

Investment rates, both in physical and human capital, are typically no higher in poorer countries than in rich countries. In part, at least, this probably reflects the fact that investment in poor countries does

not always respond to the availability of high returns.

3 Understanding Rates of Return and Investment Rates in Poor Countries: Aggregative Approaches

The aggregative approach does not aspire to explain why the marginal product varies so much within the same economy. From the point of view of this approach, the main puzzle, put forward for example in the Lucas calculation, is why the average rates of returns on investment in a poor country such as India are not higher compared to what they are in the U.S. Given that the differences in the rates of returns are relatively small, the lack of a bigger difference in investment rates is perhaps less of a mystery.

Though Lucas does not mention it, there is another, equally puzzling, observation lurking in the macro numbers. Given the existing capital stock, output-per-worker in India should be higher than what it is. To see this, recall from equation 4 that assuming that workers are only 30% as productive is equivalent to assuming that TFP in India should be approximately 50% of what it is in the U.S. This, combined with the fact that, according to the Penn World Tables, the U.S. has 18 times more capital-per-worker than India implies that the marginal product of capital ought to be $\frac{1}{2}(18)^{0.6} = 2.8$ times higher in India, which tells us that the marginal product in India ought to be about 25%, which is about what it is. However, using equation 3 in section 2.1.3, we calculated that the difference in output-per-worker between India and the U.S. implied that the rate of return to capital should be 45% in India.

The discrepancy between this number and the 25% we are now getting points to a second puzzle: It tells us that the differences in capital-per-worker that would be implied by the difference in output-per-worker is larger than the observed difference in capital-per-worker. Another way to see this is to substitute the numbers for capital-per-worker into the production function:

$$\frac{y_u}{y_i} = 2(\frac{k_u}{k_i})^{0.4} = 2 * (18)^{0.4} = 6.35. \tag{5}$$

This is obviously not nearly as large as the observed gap of 11:1. In other words, the second puzzle is to explain why output-per-worker in India is so low, given everything else, and in particular given the amount of capital in India.[11]

In the rest of this section we explore three different views of why one economy may lag behind another in terms of productivity. What they have in common is they operate entirely at the level of the economy, and do not directly suggest a theory of why there is so much inefficiency within a given economy.

[11]Note that this puzzle is *different* from the one Lucas started with, as we described earlier: The Lucas puzzle is simply the observation that, given the ratio in output-per-worker, the marginal product of capital is too low in India. Unlike the second puzzle, it makes no mention of the level of capital in India.

3.1 Access to Technology

One obvious answer to both puzzles is that TFP is not the same in India and the U.S. If TFP is lower, both productivity and the marginal product will be lower, for any given level of capital-per-worker.

One standard answer, within growth theory, of why TFP should be lower in poorer countries comes down to technology. There is a now a large literature—due to Aghion and Howitt (1992), Grossman and Helpman (1991) and others—that, emphasizes technological differences as the source of this TFP gap. It is easy to think of reasons why there may be a persistent technology gap between rich and poor countries. Essentially, it is too costly for the poor country to jump to the technological frontier because the frontier technologies belong to firms in the rich countries (who are the ones who have the biggest stake in keeping the technological frontier moving) and they charge monopolistic prices for access to these technologies.[12] Moreover, there is the issue of appropriate technology: The latest technology may not be suitable for use in a country with little human capital or poor infrastructure.

By itself, this explanation focuses on investment in technology and cannot directly account for the lack of investment in human capital in LDCs or why the returns there often seem so low. However, if there is strong complementarity between human capital investment and investments in new technology,[13] then the slow growth of TFP could explain the relative absence of investment in human capital in LDCs, assuming that we accept the rather mixed evidence, reviewed above, on the responsiveness of investment in human capital to the expected returns.

If the productivity gap between the U.S. and India has to be fully accounted for by technological differences in an aggregative model (i.e., if we rule out any differences in the interest rates), then TFP in the U.S. would have to be about twice that in India. How plausible is a TFP gap of 1:2 in a world of efficiently functioning markets? One way to look at this is to observe that U.S. TFP growth rates seem to be on the order of 1-1.5% a year. Even at 1.5%, TFP takes about 45 years to go up by 200%.[14] Therefore in 2000, Indians would have been using machines discarded by the U.S. in the 1950s.

This is also clearly very far from being true of the better Indian firms in most sectors. The McKinsey Global Institute's (McKinsey Global Institute (2001)) recent report on India, reports on a set of studies of the main sources of inefficiency in a range of industries in India in 1999, including apparel, dairy processing, automotive assembly, wheat milling, banking, steel, retail, etc. In a number of these cases

[12]The dominance of rich countries in the latest technologies is reinforced by the fact that the rich countries may have an actual advantage in R&D, because of their larger market size or their superior human capital endowments.

[13]As suggested, for example, in the work by Foster and Rosenzweig (1995) on the green revolution, which we discussed above.

[14]The effective rate of technological improvement will be larger, for example, if new technology needs to be embodied in machines and machines are more expensive (or savings rates are lower) in the poorer country (see Jovanovic and Rob (1997)).

(dairy processing, steel, software) they explicitly say that the better firms were using more or less the global best practice technologies wherever they were economically viable. The latest (or if not the latest, the relatively recent) technologies were thus both available in India and profitable (at least for some firms).

However, most firms do not make use of these technologies. And, according to the same McKinsey report, it is not because these technologies are not economically viable in this sector: The report on the apparel industry tells us that in the apparel industry:

> "Although machines such as the spreading machine provide major benefits to the production process and are viable even at current labor costs, they are extremely rare in domestic (i.e., non-exporting) factories." (McKinsey Global Institute (2001))

Despite this, technological backwardness is not one of the main sources of inefficiency that is highlighted in their report on the apparel industry. They focus, instead, on the fact that the scale of production is frequently too small, and in particular, on the fact that the median producer is a tailor who makes made-to-measure clothes at a very small scale, rather than a firm that mass produces clothes. TFP is low, not because the tailors are using the wrong technology, but because tailoring firms are too small to benefit from the best technologies and therefore should not exist.

Reports from a number of other industries show a similar pattern. Certain specific types of technological backwardness is mentioned as a source of inefficiency in both the dairy processing industry and the telecommunications industry, but in both cases it is argued that all firms should find it profitable to upgrade along these dimensions (McKinsey Global Institute (2001)).

In these two cases, however, there is also a reference to the gains (in terms of productive efficiency) from what the report calls "non-viable automation". This is automation that would raise labor productivity but lower profits. One reason why automation may be non-viable in this sense is that the technology may be under patent and therefore expensive, along the lines suggested by Aghion and Howitt (1992), Grossman and Helpman (1991) and others, or it may demand skills that the country does not have. Or, it could also be something entirely neo-classical: Labor-saving devices are less useful in labor-abundant countries. Since we have no way of determining why the technology is non-viable, we looked at the total labor productivity gain promised by this category of innovation. In both the dairy processing industry and the telecom case, this number is 15% or less, and in the automotive industry it is no larger (McKinsey Global Institute (2001)). This is clearly not large enough to explain the entire TFP gap.

On other hand, it is clearly true that there are many firms that, for some reason, have opted not to adopt the best practice despite the fact that others within the same economy find it profitable to do so and, at least according to McKinsey, they too would benefit from moving in this direction. If the

technological piece of the TFP gap turns out to be large, our presumption would be that it is driven by this second, more microeconomic, source of technological stickiness: Indeed, in their more recent work, Aghion and Mayer-Foulkes (2003) also emphasize the importance of the fact that firms may not have access to enough capital to implement the technologies that they would like to adopt.

3.2 Human Capital Externalities

Another source of difference between TFP that has been proposed (starting with Lucas), is the increasing returns stemming from human capital externalities: Human capital is valuable, not only in the firm that employs the worker, but for all firms.

This could explain a puzzle we did not discuss until now, pointed out by Acemoglu and Angrist (2001) and Bils and Klenow (2000): The high correlation between human capital and income that is observed in the cross-country data (e.g., Mankiw et al. (1992)) is hard to reconcile with the micro evidence we have reviewed earlier, which suggested relatively low returns to education. To see this, note that the difference in average schooling between the top and bottom deciles of the world education distribution in 1985 was less than 8 years. With a Mincerian returns to schooling of about 10%, the top decile countries should thus produce about twice as much per worker as the countries in the bottom decile. In fact, the output-per-worker gap is about 15. One possibility is that the Mincerian rate of return *understates* the true rate of returns to education, because it does not take into account positive externalities generated by educated workers. More specifically, the human capital externalities on the order of 20-25% (more than twice the private return) would be necessary to explain the cross-country relationship between education and income, which sounds implausible. Early evidence (e.g., Rauch (1993)) suggested that externalities were positive, but not of that order of magnitude. Using variation in education across U.S. cities, Rauch (1993) estimated that the human capital externalities may be on the order of 3% to 5%. Moreover, even this evidence is to be taken with caution, as cities where workers are more educated vary in many other respects. Using variation in average education generated by the passage of compulsory schooling laws, Acemoglu and Angrist (2001) find no evidence of average education on individual wages, after controlling for individual education.

In Indonesia, Duflo (2003) actually finds evidence that there may be *negative pecuniary* externalities across people who invest in education. She studies the impact of an education policy change that differentially affected different cohorts and different regions of Indonesia. Between 1973 and 1979, oil proceeds were used to construct over 61,000 primary schools throughout the country. Duflo (2001) shows that the program resulted in an increase of 0.3 years of education for the cohorts exposed to the program. Duflo (2003) takes advantage of the fact that individuals who were 12 or older when the program started did not benefit from the program, but worked in the same labor markets as those who did. As the

newly educated workers entered the labor force, starting in the 1980s, the fraction of educated workers in the labor force increased. Since migration flows in Indonesia remained relatively modest, the increase in the fraction of workers with primary education between 1986 and 1999 was faster in regions which received more INPRES schools. Using the interaction of year and region as instruments for the fraction of educated workers, she estimates that an increase of 10 percentage points in the fraction of educated workers in the labor force resulted in a *decrease* in the wages of the older workers (both educated and uneducated) by 4% to 10%. This suggests that, on balance, there are strongly diminishing aggregate returns at the local level: Any positive externality is more than compensated by these declining returns. The Mincerian returns could then actually *overestimate* the aggregate returns of increasing education, because by comparing individuals within a labor market, they do not take into account the diminishing returns that affect everybody in the labor market. In any case, at this point, there is no evidence that there are strongly increasing returns to human capital.

3.3 Coordination Failure

Another source of lower aggregate productivity is the possibility of coordination failures, which reduces aggregate productivity through a demand effect. There is a long line of work, starting with Rosenstein-Rodan (1943), that has emphasized the role of coordination failure in explaining why certain countries successfully industrialize, while others remain poor and non-industrialized. Murphy and Vishny (1989) explore models where industrialization in a sector creates demand for the products of another sector (through higher wages for the workers), and which leads to multiple equilibria. A coordinated "big push", where all industries start together, can place the country on a permanently higher level of investment and income. Developing countries may have low investments and low returns to capital because such a "big push" has not happened. A large literature explores different forms of strategic complementarities. Since the argument involves an entire economy's coordination, it is difficult to use micro-evidence to provide much direct evidence about these aggregate externalities.[15] However, while these theories certainly have some relevance, it is not entirely clear whether aggregate demand effects can be so powerful as to generate the necessary gap in TFP between, say, India and the U.S., given the existence of international trade. Further, this aggregate approach cannot explain the fact, reviewed earlier, of why some firms seem to adopt the latest technologies, while others do not, and why the marginal product of capital varies so much.

[15] Below, we will review the evidence on more local externalities.

3.4 Taking Stock

While the evidence is somewhat impressionistic, it seems unlikely that the aggregative theories discussed above can explain the entire TFP gap. Of course, if we were prepared to give up the idea that the entire problem comes from a lower aggregate productivity, for example by accepting that the marginal product is higher in India, the problem of fitting the data would be easier. For example, if the TFP gap were 1.5 times higher in the U.S. (on top of what is predicted by the difference in the productivity of labor), the fact that the U.S. has 18 times more capital-per-worker would imply that output-per-worker would be $(1.5)(2)(18)^{0.4} = 9.5$ times higher in the U.S., and the marginal product of capital would be $\frac{(18)^{0.6}}{2(1.5)} = 1.9$ times higher in India. These are both clearly in the ballpark, although the output gap between the U.S. and India predicted by this model is still too low (the output gap is about 11:1 in the data) and the ratio of the marginal product of capital between India and the U.S., which was too high in a model with identical TFP, is now too low (the ratio in the data is about 2.5).

It is worth noting that in order to get closer to the 11:1 ratio in the data, the TFP ratio would need to be higher than 1.5, which is perhaps already too big. Moreover, this would further reduce the predicted ratio between the marginal product of capital in India and in the U.S., which was already too low when the TFP gap was 1.5. In other words, we are facing a new problem: Given the existing capital stock, if a difference in TFP were the reason why the output-per-worker is so low in India, the marginal product of capital should be even lower in India than what it is. Indeed, there is no way to adjust the TFP ratio to improve the fit along both dimensions—we can increase the gap in output-per-worker by raising the TFP ratio, but only at the cost of making the ratio of marginal product even smaller. The problem is quite basic: With a Cobb-Douglas production function, the average product of capital is proportional to its marginal product. But then output-per-worker must be proportional to the product of the marginal product of capital and capital-per-worker. If the marginal product in India is 2.5 times that of the U.S., but capital-per-worker is 18 times greater in the U.S., output-per-worker has to be $\frac{18}{2.5} = 7.2$ times larger in the U.S. and not 11 times larger, *irrespective of what we assume about the ratio of TFP in the two countries.* In other words, the only way we can hope to really fit what we see in the data is by abandoning the standard Cobb-Douglas formulation. This is useful to keep in mind when, in later sections, we discuss ways to improve the fit between the theory and the data.

To sum up, Lucas' question about why capital does not flow from the U.S. to India was, in some sense, where it all started, but from the vantage point of what we know today, this is in some ways the lesser problem. We know now that there are differences in the marginal product of capital within the same economy that dwarf the gap that Lucas calculated from comparison of India and the U.S., and found so implausibly large that he set out to rewrite all of growth theory. The harder question is why capital flows do not eliminate these differences.

Lucas' resolution of the puzzle was to give up the key neo-classical postulate of equal TFP across countries. Based on the McKinsey report, this seems to be the obvious step, but the problem is less that people in developing countries do not find it profitable to adopt the latest (and best) technologies and more that many firms do not adopt technologies that are available and would be profitable if adopted. The key question, once again, is why the market allows this to be the case.

The premise of the aggregative approach to growth was that markets function well enough within countries that we can largely ignore the fact that there is inefficiency and unequal access to resources within an economy when we are interested in dynamics at the country level. The evidence suggests that this is not true: The cross-country differences in marginal products or technology that we want to explain are of the same order of magnitude as the differences we observe within each economy. Development economists are therefore more interested in theories of cross-country differences that also help us understand why rates of returns vary so much within each country. This is what we turn to next: In section 4, we first review the various reasons that have been proposed. In section 5, we will then calibrate their impact to evaluate whether they can form the basis of an explanation for the puzzles we observed.

4 Understanding Rates of Return and Investment Rates in Poor Countries: Non- Aggregative Approaches

In this section, we review various possible reasons why individuals do not always make the best possible use of resources available to them.

4.1 Government Failure

One reason why firms may not choose the latest technologies or make the right investments is because they do not have the proper incentives to do so. A line of work has developed the hypothesis that governments are largely responsible for this situation, either by not protecting investors well enough or by protecting some of them excessively. The firms that are ill-protected underinvest and have high marginal returns, while the over-protected firms overinvest and show low marginal returns. The net effect on investment may be negative, because even those who are currently favored may fear a future falling out and a corresponding loss of protection. Overall productivity may also go down, since the right people may not always end up in the right business, since connections rather than skills will dominate the choice of professions.[16]

One approach to investigating this hypothesis has been to try to document variations in the quality

[16] See Murphy and Vishny (1995).

of institutions, and to try to evaluate their impact. La Porta and Vishny (1998) document important variations in the degree to which the law protects investors (creditors and shareholders) across countries, part of which seem to be explained by the origin of these countries' legal codes (the French civil law has much less legal protection for investors than Anglo-Saxon common law). Djankov and Shleifer (2002) document wide variation in the ability of someone to start a new firm in 85 countries. They argue that the costs of entry are high in most countries (on average, they sum up to 47% of a country's GDP per capita), and can be very high indeed: While it take 3 procedures and 3 days to obtain the permit to start company in New Zealand, it takes 19 procedures, 149 business days and 111.5 percent of GDP per capita in Mozambique. The procedure is shorter, and generally less expensive in terms of GDP per capita, in rich countries than in poor or middle-income countries. Djankov and Shleifer (2003) document the time it takes in court to evict a tenant or collect a bounced check, as well as the degree of formalism of the legal procedures. They find, once again, wide variation: In particular, these procedures take a much shorter time in countries with common law legal origins. Similarly, many studies argue that, in cross-country regressions, there is a strong association between aggregate investment and measures of bad institutions or corruption (e.g., Knack and Keefer (1995), Mauro (1995), Svensson (1998)).

These papers also argue that low investor protections, legal barriers to entry, and long legal procedures have implications for welfare and efficiency. There are indeed suggestive associations in the data (for example, ownership is more concentrated when investor protection is worst), but there is always the possibility that the correlation between the quality of the institutions and the real outcomes they consider is due to a third factor. Acemoglu and Robinson (2001) try to address this issue by finding exogenous variations in the quality of institutions. They argue that there is a persistence of institutions, so that countries which accessed independence with extractive institutions (e.g., Congo) have tended to keep these bad institutions. They then argue that colonial powers were more likely to set up extractive institutions, with an unrestrained executive power, in places where they did not intend to settle. Finally, they were less likely to settle in places where the environment was hostile: In particular, the mortality of early settlers predicted the number of people of European descent who settled in these countries, the quality of institutions at the turn of the 20th century, and the quality of institutions in 1995 (measured as the risk of expropriation perceived by investors). In turn, it also is associated with lower GDP in 1995. The authors then use early settler mortality as an instrument for institutions in a regression of the impact of institutions on inequality, and find a strong positive coefficient.

This evidence suggests that government matters, and that bad government will lower returns and discourage new investments. There is a literature that tries to investigate the exact mechanisms through which the government affects the allocation of resources. One version of the story blames excessive intervention, while another talks about the lack of appropriate regulations. We now discuss these two

explanations in turn, and try to assess how far they can help us fit the evidence.

4.1.1 Excessive Intervention

There is a line of work, following Parente and Prescott (1994, 2000), which argues that the productivity gap results from the way the heavy hand of the government operates. The government makes rules that discourage innovation and protects the inept, and thereby slows the economy's progress towards the ideal state where only the most productive firms survive.

There is clearly something to this vision. Gelos and Werner (2002) show that financial de-regulation in Mexico (which started in 1988 and eliminated the interest rate ceiling, high reserve requirements which channeled 72% of commercial bank lending to the government, and priority lending) increased the ability of small firms to access the credit market, and reduced the excess cash flow sensitivity of investment *for small firms only*. Until recently in India, a large number of sectors were reserved for firms below a certain size (the small-scale sector) and/or firms in the cooperative sector. Small firms also benefited from tax exemptions and priority sector credits. This clearly limited the ability to take advantage of economies of scale and restricted the market share of the most efficient players.

Nonetheless, this is probably only a part of the story. As we noted in the context of the discussion of Banerjee and Duflo (2003a), even medium-sized firms that were well above the cut-off for being included in the small-scale sector seem to be operating well below their optimal scale. In other words, notwithstanding the politically protected presence of the small-scale firms that is presumably driving down profits in the sector, these medium-sized firms were clearly still at the point where further investment would be extremely profitable. There has to be something other than a policy-induced lack of profitability that was holding them back.

The same point is made in a different style in the paper by Banerjee and Munshi (2004), mentioned above. This paper studies investment and productivity differences among firms in the knitted-garment industry in Tirupur, India. The firms owned by the Gounders, tend to be much larger than the firms owned by all other participants in the industry: The gap among firms that had just started is on the order of three to one. Yet these Gounder firms produce much less per unit of capital, and Gounder firms that have been in business for more than five years actually produce less *in absolute terms* than the smaller firms of the same vintage owned by non-Gounders. In other words, it is the bigger firms that are less productive, in an environment where the government discriminates, if at all, in favor of the smaller firms.

To sum up, while there are certainly instances of excessive intervention, it seems that there are many inefficiencies that cannot be blamed on the government.

4.1.2 Lack of Appropriate Regulations: Property Rights and Legal Enforcement

Effective rates of return and investment rates can be low because the responsibilities and/or the benefits of the investments are shared, or the investors are worried about being expropriated: The investor is therefore not capturing the full marginal returns of its investment. Imperfect property rights will thus lead to low investments. Poorly enforced property rights also make it difficult to provide collateral, which exacerbates the problems of the credit market. For example, the study of the Mexican financial deregulation discussed above (Gelos and Werner (2002)) showed that after the deregulation, small firms' access to credit became more linked to the value of the real estate assets they could use as collateral: The role of the government does not end with not interfering, it may also be to provide secure property rights.

In addition to the macro-economic evidence mentioned above, there is some micro-economic evidence that property rights matter for investment, although the findings are more mixed. Goldstein and Udry (2002) show that, in Ghana, individuals are less likely to leave their land fallow (which is an investment in long run land productivity) if they do not hold a position of power within the family of the village hierarchy which ensures that their land is not taken away from them when it is fallow. However, Besley (1995) finds that, also in Ghana, investment (tree planting) is not significantly larger when individuals have more secure rights to their land. Johnson and Woodruff (2002) find that, in five post-Soviet countries, firms that are run by entrepreneurs who perceive that their property rights are more secure invest more than those who do not. The effect is as strong for firms who rely mostly on internal finances as for those who have access to external finance. Entrepreneurs who believe that they have strong property rights invest 56% of their profits in their firms (against 32% for those who do not). Do and Iyer (2003) find that a land reform which gave farmers the right to sell, transfer or inherit their land usage rights also increased agricultural investment, in particular the planting of multi-year crops (such as coffee).

Even when property rights themselves are legally well defined and protected, there are institutions which reduce the private incentives to invest. Sharecropping is one environment where both the landlord and the tenants have low incentive to invest in the inputs that they are responsible for providing (Eswaran and Kotwal (1985)). Binswanger and Rosenzweig (1986) and Shaban (1987) both show that, controlling for farmer's fixed effect (that is, comparing the productivity of owner-cultivated and farmed land for farmers who cultivate both their own land and that of others) and for land characteristics, productivity is 30% lower in sharecropped plots. Shaban (1987) shows that all the inputs are lower on sharecropped land, including short-term investments (fertilizer and seeds). He also finds systematic differences in land quality (owner-cultivated has a higher price per hectare), which could in part reflect long-term investment. Banerjee and Ghatak (2002) study a tenancy reform which increased the tenants' bargaining power and security of tenure. They found that the land reform resulted in a substantial increase in the productivity

of the land (62%). Since the reform took place at the same time as the green revolution, this increase in productivity is probably in part due to an increased willingness to switch to the new seeds after the registration program.[17]

The example of sharecropping suggests that bad governments are not the only cause for the emergence of bad institutions. If sharecropping is inefficient, why does it arise? In particular, why do the landlord and the tenant not agree on a fixed rent, which will ensure that the tenant is the full beneficiary of his effort at the margin? Explanations of the persistence of sharecropping involve risk aversion (Stiglitz (1974)) or limited liability (Banerjee and Ghatak (2002)). This suggests that while the proximate explanation for inefficient investment may well be based in a specific institution, the more basic cause may be lying elsewhere, in the way various asset markets function. This is what we turn to next.

4.2 Credit Constraints

• Why would credit markets function poorly in poor countries?

The fact that the capital market does not function well in poor countries is a result of a number of factors. First, information systems, including property records, are often underdeveloped, making it hard to enforce contracts. This, in turn, partly reflects the fact that people may not know how to read or write and partly the fact that there has not been enough institutional investment.[18] Second, the fact that potential borrowers are poor and under extreme economic pressure, might make them all too willing to try to cheat the lender. Third, there are political pressures to protect borrowers from lenders in most LDCs.

• Consequence of poorly functioning credit market.

Given the problems in enforcing the credit contract, what a lender will be prepared to offer a particular borrower will depend on the quality of the borrower's collateral, his reputation in the market, the ease of keeping an eye on him and a host of other characteristics of the borrower. This has the obvious implication that two firms facing the exact same technological options may end up choosing very different methods of production. In particular, one person may start a large or more technologically advanced firm because he has money and another may start a small and backward one because he does not. As a result, neither interest rates, nor TFP, nor the marginal product need be equalized across borrowers.

This would also explain why investment responds so unpredictably to returns: Sometimes the oppor-

[17]This interpretation is reinforced by the fact that their estimates are higher than Shaban's and that of a study by Laffont and Matoussi (1995) who use data from Tunisia to show that a shift from sharecropping to fixed-rent tenancy or owner cultivation raised output by 33 percent, and moving from a short-term tenancy contract to a longer-term contract increased output by 27.5 percent.

[18]For example, Djankov and Shleifer (2002) document the time it takes the recover a bounced check across countries. It takes longer in poorer countries.

tunities become available when there is large group of people who are looking to invest and have the wherewithal to do it. At other times, the returns may be there but most of those who have money may be heavily involved in promoting something else.

A second set of implications of imperfect contracting in the credit market is that the supply curve of capital to the individual borrower slopes up—a borrower who is more leveraged will need more monitoring and the lender will charge him more to do the extra monitoring. And eventually, the extra monitoring may be too costly to be worth it, and the borrower will face an absolute limit on how much he can borrow.

An immediate consequence of an upward-sloping supply curve is that the marginal product of capital will be higher than what the borrower pays the lender. Indeed, the gap between the two may quite substantial, since the fact that borrowers are constrained in borrowing also implies that the lenders are constrained in how much they can lend at rewarding rates. This drives the interests rates down, as lenders compete for the best borrowers. Moreover, since the rates the lenders charge include the cost of the monitoring that they have to do, the rates the lenders charge could be much higher than the opportunity cost of capital. In the case of a financial intermediary, such as a bank, this implies that the rates they charge their borrowers may be much higher than the rates they pay their depositors.

This implies, for example, that the American investor who gets 9% on his stock market investment could not just put the money in a bank in India and earn the 22.5% average marginal product. Indeed, he may not earn much more than 9% if he were to put it in an Indian bank. However, he could set up a business in India and earn those returns, and presumably if enough people did that, the returns would be equalized; below we will try to say something about why this does not happen.

It also implies that the incentive to save may be low in countries where the marginal product is high, except for those who are planning to invest directly. This might help to explain the low equilibrium investment rate, though it is theoretically possible that the negative effect on the savers would be swamped by the positive effect on investors if the fraction of investors is large enough.

• Evidence

We have already mentioned some evidence from South Asia showing that the interest rate varies enormously across borrowers within the same local capital market and that the extent of variation is too large to be explained by the observed differences in default rates. Banerjee (2003a) lists a number of studies that make it clear that this is also true in developing countries outside South Asia. This is suggestive, albeit indirect, evidence of credit constraints.

If the marginal product of capital in the firm is greater than the market interest rate, credit constraints naturally mean that a firm would want to borrow more than what is available. It is, however, not clear how one should go about estimating the marginal product of capital. The most obvious approach, which relies on using shocks to the market supply curve of capital to estimate the demand curve, is only valid under

the assumption that the supply is always equal to demand, i.e., if the firm is never credit constrained.

The literature has therefore taken a less direct route: The idea is to study the effects of access to what are taken to be close substitutes for credit—current cash flow, parental wealth, community wealth—on investment. If there are no credit constraints, greater access to a substitute for credit would be irrelevant for the investment decision. While this literature has typically found that these credit substitutes do affect investment,[19] suggesting that firms are indeed credit constrained, the interpretation of this evidence is not uncontroversial. The problem is that access to these other resources is unlikely to be entirely uncorrelated with other characteristics of the firm (such as productivity) that may influence how much it wants to invest. To take an obvious example, a shock to cash-flow potentially contains information about the firm's future performance.

The estimation of the effects of credit constraints on farmers is significantly more straightforward since variation in the weather provides a powerful source of exogenous short-term variation in cash flow. Rosenzweig and Wolpin (1993) use this strategy to study the effect of credit constraints on investment in bullocks in rural India.

The paper by Banerjee and Duflo (2003a) that we discussed above makes use of an exogenous policy change that affected the flow of directed credit to an identifiable subset of firms in India. Since the credit was subsidized, an increase in sales and investment as a response to the increase in funds available needs to mean that firms are credit constrained, since it may have decreased the marginal cost of capital faced by the firm. However, they argue that if a firm is not credit constrained then an increase in the supply of subsidized directed credit to the firm must lead it to substitute directed credit for credit from the market. Second, while investment, and therefore total production, may go up even if the firm is not credit constrained, it will only go up if the firm has already fully substituted market credit with directed credit. They showed that bank lending and firm revenues went up for the newly targeted firms in the year of the reform. They find no evidence that this was accompanied by substitution of bank credit for borrowing from the market and no evidence that revenue growth was confined to firms that had fully substituted bank credit for market borrowing. As already argued, the last two observations are inconsistent with the firms being unconstrained in their market borrowing.

The logic of credit constraints applies as much or more to human capital investments. Hart and Moore (1994), among others, have used human capital as the archetype of investment that cannot be collateralized, and therefore is hard to borrow against. This is made even more difficult by the fact that children would need to borrow for their education, or parents would need to borrow on their behalf. We

[19]The literature on the effects of cash-flow on investment is enormous. Fazzari and Petersen (1988) provide a useful introduction to this literature. The effects of family wealth on investment have also been extensively studied (see Blanchflower and Oswald (1998) for an interesting example). There is also a growing literature on the effects of community ties on investment (see, for example, Banerjee and Munshi (2004)).

return to this evidence below. The high responsiveness to user fees that we reviewed in section 2, and the evidence that investment in education are sensitive to parental income,[20] are both consistent with credit constraints. However, because human capital investments may involve direct utility or disutility (for example, a parent may like to see his child being educated), it is more difficult to come up with evidence that systematically nails the role of credit constraints for human capital investment. Edmonds (2004) is an interesting attempt to try to isolate the effect of credit constraints using household's response to an *anticipated* income shock. He studies the effect on child labor and education of a large old age pension program, introduced in South Africa at the end of the Apartheid. Many children live with older family members (often their grandparents). Women become eligible at age 60 and men become eligible at age 65. Since at the time he studies the program, the program was well in place and therefore fully anticipated, he argues that if more children start attending school as soon as their grandfather or grandmother crosses the age threshold and becomes eligible (rather than continuously, as they come closer to eligibility), this must be an indication of credit constraint. Indeed, he finds that child labor declines, and school enrollment increases, discretely when a household member becomes eligible.

• Summary

Credit constraints seem to be pervasive in developing countries. Of course, we are interested in whether the fact that access to capital varies across people helps us understand the productivity gap. If people invest different amounts because of differential access to capital, our intuitive presumption would be that capital is being misallocated, because there is no reason why richer people are always better at making use of the capital. This misallocation could be a source of difference in productivity. We will return to this question in section 5.

4.3 Insurance Market Failures

Even if credit markets function well, and there is no limited liability, individuals may be reluctant to invest in any risky activity, for fear of losing their investment, if they are not properly insured against fluctuations in their incomes. Risk aversion leads to inefficient investment, and efficiency would improve with insurance (this idea is explored theoretically in Stiglitz (1969), Kanbur (1979), Kihlstrom and Laffont (1979), Banerjee and Newman (1991), Newman (1995) and Banerjee (2001)).

• Insurance in developing countries.

A considerable literature has investigated the extent of insurance in rural areas in developing countries (see Bardhan and Udry (1999) for a survey). Townsend (1994) used the ICRISAT data, a very detailed panel data set covering agricultural households in four villages in rural India to test for perfect insurance. The main idea behind this test is that with perfect insurance at the village level only aggregate

[20] See Strauss and Thomas (1995) for several studies along these lines.

(village-level) income fluctuation, and not idiosyncratic income fluctuations, should translate into fluctuation in individual consumption. He was unable to reject the hypothesis that the villagers insure each other to a considerable extent: Individual consumption seems to appear to be much less volatile than individual income, and to be uncorrelated with variations in income. This exercise had limits, however (see Ravallion and Chaudhuri (1997) for a comment on the original paper), and subsequent analyses, notably by Townsend himself, have shown the picture to be considerably more nuanced. Deaton (1997) shows that there is no evidence of insurance in Cote d'Ivoire. Townsend (1995) finds the same results across different areas in Thailand. Fafchamps and Lund (2003) find that, in the Philippines, households are much better insured against some shocks than against others. In particular, they seem to be poorly insured against health risk, a finding corroborated by Gertler and Gruber (2002) in Indonesia. Most interestingly, Townsend (1995) describes in detail how insurance arrangements differ across villages. While in one village there is a web of well-functioning risk-sharing institutions, the situations in other villages are different: In one village, the institutions exist but are dysfunctional; in another village, they are non-existent; finally, in a third village, close to the roads, there seems to be no risk-sharing whatsoever, even within family.

This last fact is attributed to the proximity to the city, which makes the village a less close-knit community, where enforcement of informal insurance contracts is more difficult. Coate and Ravallion (1993) was the first paper to build a theoretical model of insurance with limited commitment, and to show that, when the only incentive to contribute to the insurance scheme in good times is the fear of being cut away from the insurance in future periods, insurance will be limited. It will also be optimal to make payment contingent on past history, which will lead to a blur between credit and insurance (Ray (1998)). Udry (1990) presents evidence from Nigeria that is consistent with this model. The villages he studies are characterized by a dense network of loan exchange: Over the course of one year, 75% of the households had made loans, 65% had borrowed money, and 50% had been both borrowers and lenders. Ninety-seven percent of these loans took place between neighbors and relatives. Most importantly, the loans are "state-contingent": Both the repayment schedule and the amount repaid are affected by the lender's state *and* the borrower's state. This is evidence that credit is to some extent used as an insurance device. The resulting system is a mix of credit and insurance close to what the model of limited commitment would predict. However, and still consistent with this prediction, there is not enough of this "security" to fully insure households against income fluctuations: A shock to a particular borrower has a negative impact on the sum of the transfers received by his lender, which means that the lender did not fully diversify risk.

Despite this evidence, we do not fully understand the reasons for the lack of insurance among households. It is unlikely that either limited commitment or the more traditional explanations in terms of

moral hazard or adverse selection can explain why the level of insurance seems to vary from one village to the next, or why there is no more insurance against rainfall, for example.

• Consequences for investment.

Irrespective of the ultimate reason for the lack of insurance, it may lead households to use productive assets as buffer stocks and consumption smoothing devices, which would be a cause for inefficient investment. Rosenzweig and Wolpin (1993) argue that bullocks (which are an essential productive asset in agriculture) serve this purpose in rural India. Using the ICRISAT data, covering three villages in semi-arid areas in India, they show that bullocks, which constitute a large part of the households' liquid wealth (50% for the poorest farmers), are bought and sold quite frequently (86% of households had either bought or sold a bullock in the previous year, and a third of the household-year observations are characterized by a purchase or sale), and that sales tend to take place when profit realizations are high, while purchases take place when profit realizations are low. Since there is very little transaction in land, this suggests that bullocks are used for consumption smoothing. Because everybody needs bullocks around the same time, and bullocks are hard to rent out, Rosenzweig and Wolpin estimate that, in order to maximize production efficiency, each household should own exactly two bullocks at any given point in time. The data suggest that, for poor or mid-size farmers there is considerable underinvestment in bullocks, presumably because of the borrowing constraints and the inability to borrow and accumulate financial assets to smooth consumption: Almost half the households in any given year hold no bullock (most of the others own exactly two).[21] Using the estimates derived from a structural model where household use bullocks as a consumption smoothing device in an environment where bullocks cannot be rented and there is no financial asset available to smooth consumption, they simulate a policy in which the farmers are given a certain non-farm income of 500 rupees (which represents 20% of the mean household food consumption) every period. This policy would raise the average bullock holding to 1.56, and considerably reduce its variability, due to two effects: The income is less variable, and by increasing the income, it makes "prudent" farmers (farmers with declining absolute risk aversion) more willing to bear the agricultural risk.

Moreover, we observe only insurance against the risks that people have chosen to bear; the inability to smooth consumption against variation in income may lead households to choose technologies that are less efficient, but also less risky. Banerjee and Newman (1991) argue, for example, that the availability of insurance in one location (the village), while its unavailability in another (the city), may lead to inefficient migration decisions, since some individuals with high potential in the city may prefer to stay in the village

[21] The fact that there is under-investment on average, and not only a set of people with too many bullocks and a set of people with too few, is probably due to the fact that bullocks are a lumpy investment, and owning more than two is very inefficient for production–there is no small adjustment possible at the margin.

to remain insured.

There is empirical evidence that households' investment is affected by the lack of *ex post* insurance. Rosenzweig and Binswanger (1993) estimate profit functions for the ICRISAT villages, and look at how input choices are affected by variability in rainfall. They show that more variable rainfall affects input choices, and in particular, poor farmers make less efficient input choices in a risky environment. Specifically, a one standard deviation increase in the coefficient of variation of rainfall leads to a 35% reduction in the profit of poor farmers, 15% reduction in the profit of median farmers, and no reduction in the profit of rich farmers. Morduch (1993) specifically investigates how the anticipation of credit constraint affects the decision to invest in HYV seeds. Using a methodology inspired by Zeldes (1989), he splits the sample into two groups, one group of landholders who are expected to have the ability to smooth their consumption, and one group that owns little land, whom we expect *a priori* to be constrained. He finds that the more constrained group uses significantly less HYV seeds.

It is worth noting that the estimated impact of lack of insurance on investment is likely to be a serious underestimate. It is not clear how one could evaluate how much the lack of insurance affects investment. While we might observe certain options considered by the investor, there is no obvious way for knowing what other, even more lucrative choices, he chose not to even think about.

4.4 Local externalities

As we discussed in section 4, there is a line of work that focuses on coordination failures at the level of the economy: However, Durlauf (1993) shows that externalities do not have to be aggregated for the economy to exhibit multiple equilibria: Local complementarities (where adoption of a particular technology lowers production costs in a few "neighboring" sectors) can build up over time to affect aggregate behavior and generate lower aggregate growth.

An example of strategic complementarity of this kind arises when agents are learning from each other. Banerjee (1992) shows how, when people try to infer the truth from other people's actions, this leads them to under-utilize their own information, and leads to "herd behavior". While this behavior is rational from the point of view of the individual, the resulting equilibrium is inefficient, and can lead to underinvestment, overinvestment, or investment in the wrong technology whatsoever.[22]

The impact of learning on technology adoption in agriculture has been studied particularly extensively. Besley and Case (1994) show that in India, adoption of HYV seeds by an individual is correlated with adoption among their neighbors. While this could be due to social learning, it could also be the case that common unobservable variables affect adoption of both the neighbors.[23] To partially address this problem,

[22]For a related model, see Bikhchandani, Hirshleifer and Welch (1992).

[23]See Manski (1993) for a discussion of the identification problem in social learning problems.

Foster and Rosenzweig (1995) focus on profitability. As we mentioned previously, during the early years of the green revolution, returns to HYV were uncertain and dependent on adequate use of fertilizer. In this context, the paper shows that profitability of HYV seeds increased with past experimentation, by either the farmers or others in the village. Farmers do not fully take this externality into account, and there is therefore underinvestment. In this environment, the diffusion of a new technology will be slow if one neighbors' outcomes are not informative about an individual's own conditions.[24] Indeed, Munshi (2003) shows that in India, HYV rice, which is characterized by much more varied conditions, displayed much less social learning than HYV wheat.

All of these results could still be biased in the presence of spatially correlated profitability shocks. Using detailed information about social interactions Conley and Udry (2003) distinguish geographical neighbors from "information neighbors", the set of individuals from whom an individual neighbor may learn about agriculture. They show that pineapple farmers in Ghana imitate the choices (of fertilizer quantity) of their information neighbors when these neighbors have a good shock, and move further away from these decisions when they have a bad shock. Conley and Udry try to rule out that this pattern is due to correlated shocks by observing that the choices made on an established crop (maize-cassava intercropping), for which there should be no learning, do not exhibit the same pattern.

The ideal experiment to identify social learning is to exogenously affect the choice of technology of a group of farmers and to follow subsequent adoption by themselves and their neighbors, or agricultural contacts. Duflo and Robinson (2003) performed such an experiment in Western Kenya, where less than 15% of the farmers use fertilizer on their maize crop (the main staple) in any given year despite the official recommendation (based on results from trials in experimental farms), as well as the high returns (in excess of 100%) that they estimated. They randomly selected a group of farmers and provided fertilizer and hybrid seeds sufficient for small demonstration plots in these farmers' fields. Field officers from an NGO working in the area guided the farmers throughout the trial, which was concluded by a debriefing session. In the next season, the adoption of fertilizer by these farmers increased by 17%, compared to the adoption of the comparison group. However, there is no evidence of any diffusion: People named by the treatment farmers as people they talk to about agriculture did not adopt fertilizer any more than the contacts of the comparison group. The neighbors of the treatment group actually tended to adopt fertilizer *less* often, relative to the neighbors of the comparison group. This is not because only experimentation in one's own field changes someone's priors: When randomly selected friends were invited to attend the harvest, the debriefing session, and other key periods of the trials, they were as likely to adopt fertilizer as the farmers who participated in the experiment. Rather, it suggests that, spontaneously, information

[24] Ellison and Fudenberg (1993) describe "rule of thumb" learning rules where individuals learn from others only if they are similar.

about agriculture is not shared. This points towards another type of externality and source of multiple equilibria: When there is very little innovation in a sector, there is no news to exchange, and people do not discuss agriculture. As a result, innovation dies out before spreading, and no innovation survives.

Depending on the priors of the individuals, social learning can either decrease or increase investment. In Kenya, Miguel and Kremer show that random variation in the number of friends of a child who was given the deworming medicine had a *negative* impact of the propensity of a child to take the medicine. They attribute this to the fact that parents may have initially over-estimated the benefits of the deworming drug.

In addition to social learning, there are many other sources of local interactions. First, people imitate each other even when they are not trying to learn, because of fashion or social pressure. Social norms may prevent the adoption of new technologies, because coordinating on a new equilibrium may require many people to change their practices at the same time.[25] Second, there are several sources of positive spillovers between industries located close to each other. Silicon Valley-style geographic agglomerations occur in the developing world as well, such as the software industry in Bangalore. Ellison and Glaeser (1997) show that, in the U.S., most industries are indeed more concentrated than they would be if firms decided to place their plants randomly. Only about half of this concentration is explained by the fact that some locations have natural advantages for (Ellison and Glaeser (1999)) specific industries.

In addition to the traditional arguments for positive spillovers, such as transport costs (fast telecommunication lines that were installed for the software industry in Bangalore greatly reduced the cost of setting up call centers, for example), intellectual spillovers or labor market pooling, a powerful reason for geographical agglomeration in developing countries is the role of a town's reputation in the world market. For example, outsiders who want to start working in garment manufacturing come to Tirupur, the small town studied in Banerjee and Munshi (2004), despite their difficulty of finding credit there, because this is the place where large American stores come to place orders. There is a sense in which the town has a good reputation, for quality and timeliness of the delivery, and everybody who works there benefits from it. Tirole (1996) models "collective reputation": If many people in a group are known to deliver good quality products, buyers will have high expectations and be willing to trust the sellers to produce more elaborate products, where quality matters. In turn, this will encourage sellers to produce high quality products to avoid being outcast from the group, which will sustain a "high quality-high trust equilibrium". But if buyers are expected to only ask for basic products in the future, building a reputation for high quality is not useful, and opportunistic sellers will produce low quality in the first period. Knowing this, sellers indeed have the incentive to ask for simple products, and the bad equilibrium persists. In this world, history matters. A collective reputation for low quality is very difficult to

[25] See Munshi and Myaux (2002) for an example on the spread of family planning in Bangladesh.

reverse, and a collective reputation for high quality is valuable. We should therefore expect groups to try to set up institutions to develop a good collective reputation. There is certainly some indication that this is happening. For example, the association of Indian software firms (NASSCOM) tries to help the firms access quality certifications such as ISO 9001, SEI, or others. Much more work on whether collective reputation matters in practice is, however, clearly needed before we can assess the empirical relevance of these sources of externality.

To summarize, externalities can explain very large variations in productivity and investment rates across otherwise similar environments.

4.5 The Family: Incomplete Contracts Within and Across Generations

Investment in human capital often pays in the long term, and in many crucial instances must be done by parents on behalf of the child. In this context, the way the decisions are made in the family has a direct impact on investment decisions. In the benchmark neo-classical model (Barro (1974); Becker (1981)), parents value the utility of their children, perhaps at some discounted rate. This world tends to be observationally equivalent to one where an individual maximizes his long run income, and has the same strong convergence properties. However, if parents are not perfectly altruistic, the ability to constrain the repayment of future generations influences investment decisions. Banerjee (2003b) studies the short and long run implications of different ways to model the family decision-making process. He shows that incomplete contracting between generations generates potentially large deviations from the very strong convergence property of the Barro-Becker model. Deviations also occur if parents value human capital investment for its own sake (for example, because people like to see their children happy).[26]

In particular, even with perfect credit markets, parental wealth will determine how much is invested in human capital. There can be more than one steady state, and there can be inequality in equilibrium. In this world, increases in returns to human capital may not lead to an increase in human capital, if the production of human capital is skill-intensive (the increase in the price of teachers may dominate the added incentives to invest in education).

Many studies have shown that human capital investment is correlated with family income (see Strauss and Thomas (1995) for references for developing countries). In general, however, it is difficult to separate out the pure income effect from the effect of an increase in the returns to investing in human capital,

[26]Part of the reason why investment in human capital may appear like a preference factor is that individuals want their offspring to thrive and survive. In the U.S., Case and Paxson (2001) and Case and McLanahan (2000) find that investment in children is lower when they do not live with their birth mother. Using data from several African countries, Case and Ableidinger (2002) find that the gap between the probably of being enrolled in school for orphans and non-orphans can be in part accounted for by the fact that they are less likely to live with at least one parent, and more likely to live with non-relatives.

differences in the opportunity cost or the direct cost of schooling, and different discount rates. For example, in the Barro-Becker model, families with a lower discount rate will tend to be richer and more likely to invest in education. To avoid this problem, a few studies have focused on exogenous changes in government transfers. For example, Carvalho (2000) shows that an increase in pension income in Brazil led to a decrease in child labor and an increase in school enrollment. Duflo (2003) shows that, in South Africa, girls (though not boys) have better nutritional status (they are taller and heavier) in households where a grandmother is the recipient of a generous old age pension program.

This paper also touches on another set of issues. Different members of the family may have different preferences. If education and health were pure investment, and if the members of the household bargained efficiently (as in Lundberg and Pollack (1994, 1996) or the papers reviewed in Bourguignon and Chiappori (1992)), this would not have any impact on education or health decisions. However, if either assumption is violated, it means that not only the size of the income effects, but who gets the income, will affect investment decisions. In the case of the South African pensions, this was clearly the case: Pensions received by men had no impact on the nutritional status of children of either gender. This may come from the fact that women and men value child health differently, or from the fact that the household is not efficient, and a specific individual is more likely to invest in children if the returns are more likely to directly accrue to her.

If the household does not bargain efficiently, the consequences extend beyond investment in human capital to all investment decisions. In a Pareto efficient household, production and consumption decisions are separable: The household should choose inputs and investment levels to maximize production, and then bargain over the division of the surplus. This property will be violated if individuals make investment decisions with an eye toward maximizing the share of income that directly accrues to them. Udry (1996) shows that, in Burkina Faso, after controlling for various measures of the productivity of the field (soil quality, exposure, slope, etc.), crop, year, and household fixed effects, yields on plots controlled by women are 20% smaller than yields on men's plots.[27] This does not seem to be due to the fact that women and men have different production functions. Instead, this difference is largely attributed to differences in input intensity: In particular, much less male labor and fertilizer is used on plots controlled by women than on plots controlled by males. The fertilizer result is particularly striking, since there is ample evidence that it has sharply decreasing returns to scale. Udry estimates that the households could increase production by 6% just by reallocating factors of production within the household.

Udry explains underinvestment on women's plots by their fear of being expropriated by their husband if he provides too much labor and inputs. Another reason for inefficient investment may be the fear

[27] In Burkina Faso, as in many other African countries, agricultural production is carried out simultaneously on different plots controlled by different members of the household.

of being fully taxed by family members once the investment bears fruit. Again, an efficient household would first maximize production. However, the specific claims that a household member (or a neighbor, or a member of the extended family) can make on someone's income stream may lead to inefficient investment. Consider, for example, a situation where individuals have the right to make emergency claims on the income or savings of others in their group (for example, if someone is sick and has no money to pay for the doctors, others in his extended family have an obligation to pay the doctor). Consider a savings opportunity that will increase income by a large amount in the future (for example, saving money after harvest to be able to buy fertilizer at the time of planting). If everybody could commit not to exercise their claim during the period where the income needs to be saved, the money should be saved, and the proceeds eventually distributed to those who have a claim on it, and everybody would be better off. However, if no such commitment is possible, the individual who earned the income knows that it is likely that, should he choose to save enough for fertilizer, a claim will be exercised in the period during which the money needs to be held. He is then better off spending the money right away: Even if individuals are rational and have a low discount rate, as a group they will behave as "hyperbolic discounters", who discount the immediate future relative to today more than future periods relative to each other (Laibson (1991)). The level of investment will be low in the absence of savings opportunities offering some commitment to household members.

The fact that investments are often decided within a family, rather than by a single individual, or that the proceeds of the investment will be shared among a set of people who have not necessarily supported the cost of the investment therefore greatly complicates the incentive to invest. This may, once again, explain why some potential investments with high marginal product are not taken advantage of. It is worth noting that the lack of credit and insurance in poor countries makes these problems particularly acute there. For example, the lack of credit markets means that investment decisions are taken within the families–e.g., women cannot borrow to get the optimal amount of fertilizer on their plot–and the lack of insurance plays an important role in justifying the norms on family solidarity that seem to be hindering productive investment.

4.6 Behavioral Issues

Individuals in the developing world appear not only to be credit constrained, but also to be savings constrained. Aportela (1998) shows that when the Mexican Savings Institution "Pahnal" (Patronoto del Ahorro Nacional) expanded its number of branches through post offices in poor areas and introduced new savings instruments in the 1990s, household's savings rates increased by 3% to 5% in areas where the expansion took place. The largest increase occurred for low income households.

When an individual (or his household) has time-inconsistent preferences, formal savings instruments

may increase savings rates even when they offer very low returns (even compared to holding onto cash), because they offer a commitment mechanism. Micro-credit programs may also be understood as programs helping individuals to commit to regular reimbursements. This is particularly clear for programs, like the FINCA program in Latin America, which require that their clients maintain a positive savings balance even when they borrow.[28]

Duflo and Robinson (2003) provide direct evidence that there is an unmet demand for commitment savings opportunities among Kenyan farmers, and that investment in fertilizer increases when households have access to this opportunity. In several successive seasons, they offered farmers the option to purchase a voucher for fertilizer right after harvest (when farmers are relatively well off). The vouchers could be redeemed for fertilizer at the time when it is necessary to plant it. The take up of this program was quite high: 15% of the farmers took up the program the first time it was tried with farmers who had never encountered the NGO before. Net adoption of fertilizer increased in this group. The program was then offered to some of the farmers who had participated in the pilot program mentioned above (and thus had the opportunity to test the fertilizer for themselves, and trusted the NGO), and in this group, the take up was 80%. There is also direct evidence of the difficulty for farmers to hold on to cash: In other experiments, when farmers were given a few days before they could purchase the voucher, the take up fell by more than 50%. When they were offered the option of having the fertilizer delivered at home at the time they actually needed it (and to pay for it then), none of the farmers who had initially signed up for the program had the money to pay for the fertilizer when it was delivered. Farmers were also more likely to take up the scheme when they had cash available (for example, because the researchers had purchased their maize as part of the evaluation) than when they had maize available (even though they were offered the option to sell maize). This suggests that they are more eager to commit cash than to commit maize: Maize may be easier to save than cash.

This area of research is quite recent, and wide open. Many questions need answering, and the area of applicability is wide. For example, what is the best way to increase parents' willingness to invest in deworming drugs? Why don't all parents sign the authorization form which will grant free access to deworming to their children (Miguel and Kremer (2003))? Is it a rational decision or is it procrastination? Why does the take up of the deworming drug fall so rapidly when a small cost-sharing fee is introduced (Miguel and Kremer (2003))? Understanding the psychological factors that constrain investment decisions, and the role that social norms play in disciplining individuals, but also potentially in limiting their options, is an important area for future research. Several randomized evaluations are

[28]Karlan (2003) argues that simultaneous borrowing and savings by many clients in these institutions can be explained by the value to the small business owner of the fixed repayment schedule as a discipline device. Gugerty (2000) and Anderson and Baland (2002) interpret rotating credit and savings (ROSCAs) institutions in this light.

trying to make progress in this area. They are addressing questions as diverse as: What is the role of marketing factors in the access of poor people to loans in South Africa? Do poor people take advantage of savings products with commitment options in the Philippines? What prevents people from doing a small action that would lead them to a high return? What factors (deadline, framing, etc.) make it more likely they will do it?

A defining characteristic of these projects is that they do not involve laboratory experiments: Like the research on fertilizer in Kenya, they set up real programmes which are likely to increase poor people's investment and improve welfare if they indeed deviate from perfect rationality in the way the psychological literature suggests. In order to be fruitful, this agenda will need to avoid simply transplanting to developing countries some of the insights developed by observing behaviors in rich countries. Being poor almost certainly affects the *way* people think and decide. Decisions, after all, are based not on actual returns but on what people perceive the returns to be, and these perceptions may very well be colored by their life experience. Also, when choices involve the subsistence of one's family, trade-offs are distorted in different ways than when the question is how much money one will enjoy at retirement. Pressure by extended family members or neighbors is also stronger when they are at risk of starvation. It is also plausible that decision-making is influenced by stress. What is needed is a theory of how poverty influences decision making, not only by affecting the constraints, but by changing the decision making process itself.[29] That theory can then guide a new round of empirical research, both observational and experimental.

5 Can these micro distortions explain the macroeconomic gaps?

In this long list of potentially distorting factors there are some, like government failures or credit market failures, that most people find *a priori* plausible, and others, such as intra-family inefficiencies or learning externalities, that are more contentious, and yet others, like the behavioral factors, that have not yet been widely studied. However, even where the *prima facie* evidence is the strongest, we cannot automatically conclude that the particular distortion has resulted in a *significant* loss in productivity.

To get a sense of the potential productivity loss, we return to the Indo-U.S. comparison. Taking as given the stock of capital in India and the U.S. today, *any of the multiple distortions listed above* could have affected productivity in two different ways: First, there may be across-the-board inefficiency, because everyone could have chosen the wrong technology or the wrong product mix. Second, capital may be misallocated across firms: There may be differences in productivity across firms, either because of differences in scale, or because of differences in technology or because some entrepreneurs are more

[29] See Ray (2003) for a very nice attempt to start in this direction.

skilled than others, and the distribution of capital across these firms may be sub-optimal, in the sense that the most productive firms are too small.

Here we have chosen to emphasize this latter source of inefficiency, motivated in part by the evidence, discussed above, that tells us that there are enormous differences in productivity across firms. *We take no stance on how such an inefficient allocation of capital came about, nor on why the firms do not make the right choices, either of scale or of technologies.* Lack of access to credit is, of course, a potential explanation for both, but it could be equally explained by lack of insurance, the fear of confiscation by the government, or the gap between real and perceived returns.

The goal of this section is to set up and calibrate a simple model to investigate whether the misallocation of capital across firms within a country can explain the aggregate puzzles we started from: The low output-per-worker in developing countries, given the level of capital, and the low marginal product of capital, given the output-per-worker.

We begin with a model where the misallocation only affects the scale of production, because all the firms share the same technology. Scale obviously does not matter where there are constant returns to scale, so we need to turn to a model where there are diminishing returns at the firm level.[30] We will show that, with realistic assumptions about the relative firm sizes in India and the U.S., this model cannot go very far in explaining the aggregate facts. We then turn to a model where a better technology can be purchased for a fixed cost. We show that this model, coupled with the misallocation of capital, will help generate the aggregate facts, with realistic assumptions about the distribution of firm sizes.

5.1 A Model with Diminishing Returns

• Model setup

Consider a model where there is a single technology that exhibits diminishing returns at the firm level, say, $Y = AL^{\gamma}K^{\alpha}$, with $\gamma < 1 - \alpha$. Also, we will assume that the economy has a fixed number of firms: Without that assumption, everyone will set up multiple minuscule firms, thereby eliminating the diminishing returns effect. To justify this, we make the standard assumption that the economy has a fixed number of entrepreneurs and each firm needs an entrepreneur.

Under these assumptions, every firm would invest the same amount when markets function perfectly, but when different firms are of different sizes, the marginal product would vary across the firms and efficiency would suffer. The question is whether these effects are large enough to help us explain what we see in the data.

[30]The obvious alternative—increasing returns at the firm level—will clearly not fit the basic fact that there is more than one firm in the U.S., or that the marginal product of capital is higher in India than in the U.S.

To look at this, assume that there is a population of firms indexed by i, and that firms face a limit on how much they can borrow, so that for firm i, $K \leq K(i)$. The demand for labor from a firm that invests $K(i)$, is given by $\left[\frac{A\gamma K(i)^{\alpha}}{w}\right]^{\frac{1}{1-\gamma}}$. We assume a perfect labor market, so that given the level of capital, labor is efficiently allocated across firms. Labor market clearing then requires that

$$w = A\gamma \left[\frac{\int [K(i)^{\alpha}]^{\frac{1}{1-\gamma}} dG(i)}{\overline{L}}\right]^{1-\gamma},$$

where $G(i)$ represents the distribution of i and $\overline{L}$ is labor supply per firm. Since wages are a fraction γ of output-per-worker, it follows that output-per-worker will be

$$A \left[\frac{\int [K(i)^{\alpha}]^{\frac{1}{1-\gamma}} dG(i)}{\overline{L}}\right]^{1-\gamma}.$$

Consider an economy where, for any of the reasons we outlined above, some firms have access to more capital than others. In particular, assume that in equilibrium a fraction λ of firms get to invest an amount K^1 and the rest get to invest $K^2 > K^1$.[31] This would clearly explain why the marginal product of capital varies within the same economy. We would also expect that this inefficiency in the allocation of capital would lower productivity relative to the case where capital was optimally allocated. To get at the magnitude of the efficiency loss, note that output-per-worker in this economy will be:

$$A[\frac{\lambda(K^1)^{\alpha/(1-\gamma)} + (1-\lambda)(K^2)^{\alpha/(1-\gamma)}}{\overline{L}}]^{1-\gamma}.$$

We compare this economy with another which has a TFP of A', a labor force $\overline{L}'$ and a capital stock $\overline{K}'$, which is, in contrast with the other economy, allocated optimally across firms. To say something about productivity we also need to say how many firms there are in this economy. Let us start by assuming that the number of firms is the same. Then the ratio of output-per-worker in our first economy to that in the second is:

$$(A/A')(\frac{\overline{K}}{\overline{L}}/\frac{\overline{K}'}{\overline{L}'})^{\alpha}(\overline{L}'/\overline{L})^{1-\alpha-\gamma}[(\lambda(K^1/\overline{K})^{\alpha/(1-\gamma)} + (1-\lambda)(K^2/\overline{K})^{\alpha/(1-\gamma)}]^{1-\gamma}. \quad (6)$$

We already noted that for the India-U.S. comparison, the ratio $\frac{\overline{K}}{\overline{L}}/\frac{\overline{K}'}{\overline{L}'}$ is about 1:18. The same source (the Penn World Tables) tells us that $\overline{L}/\overline{L}'$ is about 2.7. What are reasonable values of α and γ? For $1-\alpha-\gamma$, which is the share of pure profits in the economy, we assume 20%, which is what Jovanovic and Rousseau (2003) find for the U.S. This is presumably counted as capital income, so we keep $\gamma = 0.6$ and set $\alpha = 0.2$.

First consider the case where $\lambda = 1$, so that capital is efficiently allocated in both countries. Then the productivity ratio ought to be $(A/A')(\frac{\overline{K}}{\overline{L}}/\frac{\overline{K}'}{\overline{L}'})^{\alpha}(\overline{L}'/\overline{L})^{1-\alpha-\gamma}$: Assuming that $2A = A'$, as before, because

[31] Since all firms face the same technology and there are diminishing returns to scale, this would not happen in the absence of these imperfections (all the firms should invest the same amount, $\lambda K^1 + (1-\lambda)K^2 = \overline{K}$).

of the human capital differences across these economies, the ratio works out to be $\frac{1}{2}\left(\frac{1}{18}\right)^{0.2}(\frac{1}{2.7})^{0.2} = 23\%$. Recall from equation 5 that the model with constant returns predicted that output should be 6.35 times higher in the U.S., or, equivalently that output-per-capita in India should be 15.7% the U.S. level. The 23% predicted by the current model is, of course, even further from the 9% we find in the data. The reason why this model does worse is because the production function is more concave: The concavity penalizes the U.S., which has more capital relative to India.

• Misallocation of capital: Effects on the average marginal product of capital

To bring in the effects of misallocating capital, we need to determine the size of the gap between K^2 and K^1 that we can reasonably assume. One way to calibrate these numbers is to make use of the estimate from Banerjee and Duflo (2003a) that in India there are firms where the marginal product of capital seems to be close to 100%. On the other hand, some seem to have access to capital at 9% or so, and therefore may well have a marginal product reasonably close to 9% (Timberg and Aiyar (1984)). From the production function, we know that if we assume K^1 corresponds to the firm with a marginal product of 100%, while K^2 is the firm with the marginal product of 9%, then $(K^2/K^1)^{\frac{\alpha}{1-\gamma}-1} = \frac{9}{100}$ or $K^2/K^1 = (\frac{100}{9})^2 = 123$. We can now evaluate the ratio of output-per-worker in the two economies for any given value of λ, the fraction for firms with capital stock K^1. To pin down λ, we use the fact that the average of the marginal product in India seems to be somewhere in the range of 22%. In our model, under the assumption that the marginal dollar is allocated between small firms and large firms in the same proportion as the average dollar, the average marginal product of capital is given by:

$$\frac{\lambda}{\lambda + 123(1-\lambda)}100 + \frac{(1-\lambda)123}{\lambda + 123(1-\lambda)}9.$$

Since this is equal to 22% we have that $\lambda = 0.95$. We can now compute the extent of productivity loss due to the misallocation. From equation 6, this is given by the expression $[(\lambda(K^1/\overline{K})^{\alpha/(1-\gamma)} + (1-\lambda)(K^2/\overline{K})^{\alpha/(1-\gamma)}]^{1-\gamma}$. Under the assumed values, it is approximately 0.8. In other words, the misallocation brings the productivity ratio we expect to see between India and the U.S. down from 23% to about 18%.

Relative to the neo-classical model we started from (which generates an output-per-worker in India of 15.7% of the U.S. level), moving to this model therefore does not help close the productivity gap between India and the U.S. The problem is, once again, that the additional productivity gap that the misallocation generates is more than compensated for by the effect of making the production function concave while keeping the number of firms fixed.

What does this model predict for the marginal product of capital in the U.S? Since $K^2 = 123K^1$, $\overline{K_I} = [0.955 + 123(0.045)]K^1 = 6.5K^1$. Therefore, $K^2 \approx 19\overline{K_I}$. Now since $\left(\frac{\overline{K}}{\overline{L}}\right)_I / \left(\frac{\overline{K}}{\overline{L}}\right)_U$ is about 1/18

and $\overline{L}_I/\overline{L}_U$ is about 2.7, $\overline{K}_I/\overline{K}_U = 0.15$. Therefore $K^2/\overline{K}_U = 2.85$. The ratio of the marginal product of capital in the large Indian firms to that in the average U.S. firm under the assumption that TFP is twice as high in the U.S. (because workers in India are about 30% as productive as workers in the U.S.), is given by the expression

$$\begin{aligned}(\frac{A^I}{A^U})^{\frac{1}{1-\gamma}}(K^2/\overline{K}_U)^{\frac{\alpha}{1-\gamma}-1}(w_U/w_I)^{\frac{\gamma}{1-\gamma}} &= (\frac{A^I}{A^U})^{\frac{1}{1-\gamma}}(K^2/\overline{K}_U)^{\frac{\alpha}{1-\gamma}-1}(y_U/y_I)^{\frac{\gamma}{1-\gamma}} \\ &= (\frac{1}{2})^{\frac{5}{2}}(2.85)^{-1/2}(11)^{3/2} \approx 3.8.\end{aligned}$$

This predicts return on capital in the U.S. to be a quarter of the 9% return we assumed for the large firms in India, which is clearly much too low (the U.S. rate is usually estimated to be 9%).

One way to resolve both these problems is to give up the assumption that the two economies have same number of firms. Suppose the U.S. had $\lambda > 1$ times as many firms as India: Then the labor productivity ratio computed above would have to be divided by $\lambda^{1-\alpha-\gamma}$. If λ were equal to 32, the ratio of labor productivity in India to that in the U.S. would be 9%, which is what we find in the data.

Of course, increasing the number of firms in the U.S. will tend to make the average firm in the U.S. smaller: Even with the same number of firms in the two countries, the fact that the biggest firms in India have about 18 times the average capital stock means that they are about 3 times the size of U.S. firms, which seems implausible. If there are 32 times as many firms in the U.S., the average U.S. firm would be about a 1/100th of the biggest Indian firm, close to 25% in the Indian size distribution. This seems entirely counterfactual.

• Predictions on the distribution of marginal product of capital within countries

We see another problem with this model when we focus on the comparison of marginal products within countries—this is not something that can be fixed by manipulating the number of firms. Table 1 lists, for nine of the largest industries in India (where industry is defined at 3 digit level) outside of agriculture, known for having a substantial presence of small enterprises, some measures of variation in firm sizes (where size is measured by the net fixed capital in year 2000). We see that the ratio of the 95th percentile firm to the 5th percentile firm in the median industry is approximately 1,600:1.[32] Given the production function, we know that the marginal return on capital in the two firms should differ by a factor of $1600^{1/2} = 40 : 1$. Since the biggest firms pay about 9% for their capital, the smaller firms must have a marginal product that exceeds 360%, which seems implausible.

Finally, this particular parameterization of the model assumes an industry structure that is rather extreme. In the industry described by our model, the large firm in our model is 123 times the size of the small firm. In the ASI data, even the 95th percentile firm in the median industry is no more than 72

[32]The median industry is the Textile Garment Manufacturing industry.

Table 1: Distribution of firm size (Annual Survey of Industry, 2000)

	95-5 ratio	median-5 ratio	mean-5 ratio	5th percentile
Manufacture of Pasteurized Milk	1007	95	216	61466
Flour milling	786	150	285	29899
Rice milling	1392	90	620	5681
Cotton Spinning	22300	440	5423	12870
Cotton Weaving	3093	31	1292	14159
Textile garment manufacture	1581	104	410	22461
Curing raw hides and skins	235	10	53	37075
Manufacture of footwear	2639	122	683	21825
Manufacture of car parts	1700	29	504	84103

times the 25th percentile firm. The firm that is $\frac{1}{123}$ times the 95th percentile firm in the median industry is around the 20th percentile in the size distribution. More than 50% of the capital stock in the Indian economy is in firms that are bigger than the "small" firm and smaller than the "large" firm as we defined them here. If we tried to use a more realistic distribution of firm sizes, it would make it even harder to explain the productivity gap between India and the U.S.: Moving weight closer to the mean would dampen the effect of concavity that is at the heart of our theory.

• Taking Stock

To sum up, moving to this more sophisticated model does not help us fit the macro facts better. It obviously does suggest a simple theory of the cross-sectional variation in returns to capital, which is entirely absent from the model with constant returns, at the cost of predicting an implausibly high degree of variation in firm sizes. Moreover, it only helps to explain the productivity gap between India and the U.S. if we assume that the biggest firms in India are almost six times the average U.S. firms in the same sector.

The next section introduces an alternative model where firms differ both in scale and in technology, but still retains the assumption that there is no inherent difference between these alternative investors.

5.2 A Model with Fixed Costs

• Model Setup

Consider a world where setting up requires a fixed start-up cost in addition to an entrepreneur, but once these are in place, capital and labor get combined as in a standard Cobb-Douglas with diminishing

returns. This fixed cost could come from many sources: Machines come in certain discrete sizes and even the smallest machine may be expensive from someone's point of view. Buildings, likewise, are somewhat indivisible, at least by the time we come down to a single room or less. Marketing and building a reputation may also require an indivisible up-front investment—Banerjee and Duflo (2000) describe the costs that a new firm in the customized software industry has to pay in terms of harsh contractual terms, until it has a secured reputation. Turning to investment in human capital, it also appears that the first five years or so of education may have much lower returns than the next few years, which in effect makes the first few years of education a fixed cost.[33] Finally, as emphasized by Banerjee (2003a) the fixed cost may be in the financial contracting that the firm has to go through—starting loans are often expensive because the lender cannot trust the borrower with a big loan and when the loan is small, the fixed costs of setting up the contract loom large.

Formally, we assume a production function $y = A(K - \underline{K})^{\alpha} L^{\gamma}$. Since we continue to assume that the firm can buy as much labor as it wants, the production function can be rewritten as:

$$A^{\frac{1}{1-\gamma}} \left[\frac{\gamma}{w}\right]^{\frac{\gamma}{1-\gamma}} [K - \underline{K}]^{\frac{\alpha}{1-\gamma}}. \tag{7}$$

We continue to assume that $\gamma + \alpha < 1$, so that there are diminishing returns. The average cost function in this world has the classic Marshallian shape: Average costs go down first as the fixed costs get amortized over more and more output and then start to rise again. The optimal scale of production is given by the equality of the marginal and average product of capital, which reduces to:

$$K = \underline{K} \frac{1-\gamma}{1-\gamma-\alpha}.$$

We allow firms the option of choosing between alternative technologies. Assume that there are three alternative technologies available, characterized by three different levels of the fixed cost, $\underline{K}_1$, $\underline{K}_2$ and $\underline{K}_3$, three differing levels of labor and capital intensity, $\{(\alpha_1, \gamma_1), (\alpha_2, \gamma_2), (\alpha_3, \gamma_3)\}$ and three correspondingly different levels of productivity, A_1, A_2 and A_3. We make the usual assumption that a higher cost buys a higher levels of TFP, i.e., that $\underline{K}_1 \leq \underline{K}_2 \leq \underline{K}_3$ and $A_1 \leq A_2 \leq A_3$.

Compared to a Cobb-Douglas model with diminishing returns, this formulation has a number of advantages. First, it allows firms to have large differences in size without necessarily large differences in the marginal product of capital, since they could be using different technologies. The fact that there are firms in the same industry operating at very different scales posed a problem for the model with diminishing returns because the implied variation in the marginal product of capital seems implausibly large. Second, the fact that production requires a fixed cost helps explain why, despite the diminishing

[33] All the estimates (14) we could find of Mincerian returns at different levels of education suggest that in developing countries the marginal benefits of a year of education increase with the level of education (in the U.S., it appears to be very flat). Schultz (2001) finds the same result in his study of six African countries.

returns from technology, we do not see people setting up a very large number of very small firms, thereby completely eliminating the diminishing returns effect. In this case, we can let the number of firms be determined by what people are willing to invest, in combination with what we know about the fixed costs (actually as noted below, we cheat slightly on this point, but only because it simplifies the calculations). Third, because we allow the number of firms to be determined endogenously, there are fewer overall diminishing returns when we compare the U.S. and India, which helps explain why the productivity gap is so large and why interest rates are not lower in the U.S. Fourth, as noted above, this model generates a unique optimal scale of production, which would provide a reason why the most productive Indian and U.S. firms would look relatively similar. Finally, making this assumption alters the nature of the link between the marginal product of capital and its average product. With a Cobb-Douglas, the ratio of the average product is always proportional to the marginal product. Here, the average product starts lower than the marginal product but grows faster and eventually becomes larger than the marginal product. In other words, as firm size goes up the ratio of the marginal product of capital to its average product goes down, at least initially. This would suggest that the ratio of the average products of capital in India and the U.S. should be less than the ratio of the marginal products, and indeed we find that while output-per-worker is 11 times larger in the U.S., capital-per-worker is 18 times as large, implying an average product ratio of about 1.6:1, as against the 2.5:1 ratio of marginal product delivered by the standard Cobb-Douglas model. This is clearly an *a priori* advantage of this formulation, since, as we noted in section 3, the proportionality between the average product and the marginal product prevents any model based on a Cobb-Douglas production function to fit these facts.

In order to impose restrictions on the parameters of the model, we make use of the industry data described in table 1. We describe the representative Indian industry by a 3-point distribution of firm sizes, with fractions λ_1, λ_2, and λ_3 at K_1, K_2 and K_3. The first group of firms is made up from the bottom 10% of the distribution of firms, and we assigned to them the size of the firm at the 5th percentile of the actual size distribution in the data. Likewise, we assume that the top 10% of all firms are in the group of "large firm", and that their size is that of the firm at the 95th percentile of the firm size distribution.[34] The rest we assign to the middle category, whose size we set at the mean for the distribution. We assume that the largest firm is 1,600 times as big as the smallest firm, which is roughly the median value of these ratios across these nine industries in our data.

These parameter values imply that the mean firm size in the industry will be 800 times as large as the 5th percentile firm, which is higher than the mean in the median industry in our data (500 times), but well within the existing range in the data. Once again we are interested in the within-economy variation

[34] We pick the 5th and the 95th percentile to make the difference in the returns to capital between the biggest and smallest firms as large as possible.

in returns to capital. We therefore assume, as before, that the small firms have a marginal product of 100% while the medium-sized firms have a marginal product of just 9%.

The more unorthodox assumption is that the large firms also have a marginal product of 100%. While clearly somewhat artificial, this is meant to capture the idea that the best technology is expensive and only the biggest firms in India can afford to be at the cutting edge, an idea that is very much in the spirit of the McKinsey Global Institute's study of a number of specific Indian industries. However, they are still relatively small and therefore the marginal returns on an extra dollar of investment are very high. The rest of the firms use cheaper (i.e., lower $\underline{K}$) but less effective technologies. In particular, the small firms are simply too small (which explains their high marginal product), and the middle category consists of firms that have exhausted the potential of the mediocre technology that they can afford but are too small to make use of the ideal technology.

How plausible is our assumption about industry structure? The average capital stock of the 95th percentile firms in the median industry was Rs. 36 million, which puts them at a size just above the category of firms that are the focus of Banerjee and Duflo (2003a). The point of that paper was that a subset of these firms (the firms that attracted the extra credit after the policy change) had marginal returns on capital of 100% or more. Therefore, it is not absurd to assume that the large firms in our model economy have very high returns. Once we accept the idea that some large firms are very productive, given that the average marginal product is probably close to 22%, it is obviously very likely that there are many smaller firms that have a *lower* marginal product than the largest firms. Indeed, when we calculate the average marginal product based on our assumptions, under the premise that the marginal dollar is distributed across the three size categories in the ratio of their share in the capital stock, the average marginal product turns out to be about 27%.

Even with this long list of assumptions, we do not have enough information to compute output per worker in our model economy—there are several remaining degrees of freedom. First, we need to choose units: Our assumption, which simplifies calculations, is that capital is measured in multiples of the small firm. Finally, we assume that $\underline{K}_1 = 0$, $\underline{K}_2 = 100$, and $\underline{K}_3 = 800$. The assumption that $\underline{K}_3 = 800$, implies that the biggest Indian firms (which have 1,600 units of capital) are operating at the bottom of the average cost curve—given by $\underline{K}\frac{1-\gamma}{1-\gamma-\alpha}$.[35]

• Results: Output-per-worker and average marginal product of capital

Under these assumptions, we can use the assumed marginal products to solve for A_1, A_2 and A_3.

[35]This is where we cheat, since with decreasing returns to scale, there could again be an infinity of very small firms, so that all the firms should be in the small group. We can prevent this if we assume that the smallest feasible firm size is actually ϵ greater than zero, and only a certain number of entrepreneurs are able (or willing) to invest at least ϵ.

According to these calculations, TFP in the medium firms is about 1.4 times bigger than that in the small firms, and that in the large firms is about 2.7 times that in the medium firms. Nevertheless, given the assumed limits on how much they can invest, each category of firms is optimizing by choosing its current technology. However, large gains in productivity are obviously possible if the economy can reallocate its capital so that all the firms adopt the most productive technology.

To see how large this gain may be, we do another India-U.S. comparison. Once again we assume that the U.S. takes full advantage of the available technology. In other words, every firm in the U.S. operates the best technology at the optimal scale, i.e., each of these firms operates technology 3 and has 1,600 units of capital. The distribution of firm sizes in India, by contrast, includes a large fraction of firms that neither use the best technology nor operate at the optimal scale. The implicit assumption is that in the U.S. there are enough people who are able and willing to invest 1,600 units if there is any money to be made, but this is not true in India because of borrowing constraints or other reasons.

A series of straightforward calculations gives the expression for the ratio of output-per-worker, which is also the ratio of wages in the two economies:

$$
\begin{aligned}
& (\frac{y_I}{y_U})^{\frac{1}{1-\gamma}} = (\frac{w_I}{w_U})^{\frac{1}{1-\gamma}} \\
= \quad & \frac{N_I}{N_U}\frac{L_U}{L_I} \times \\
& \frac{[\lambda_1(A_I)^{\frac{1}{1-\gamma}}(K_1-\underline{K_1})^{\frac{\alpha}{1-\gamma}} + \lambda_2(A_IA_2/A_1)^{\frac{1}{1-\gamma}}(K_2-\underline{K_2})^{\frac{\alpha}{1-\gamma}} + \lambda_3(A_IA_3/A_1)^{\frac{1}{1-\gamma}}(K_3-\underline{K_3})^{\frac{\alpha}{1-\gamma}}]}{(A_UA_3/A_1)^{\frac{1}{1-\gamma}}(K_3-\underline{K_3})^{\frac{\alpha}{1-\gamma}}},
\end{aligned}
$$

where N_I and N_U are the numbers of firms in India and the U.S., and A_I and A_U represent the base levels of TFP. The only reason that $A_I \neq A_U$ is, as before, that the human capital levels vary. We continue to assume that $A_U = 2A_I$. N_I/N_U can be computed from the fact that the total demand for capital from these firms must exhaust the supply of capital: i.e.,

$$\frac{K_I}{K_U} = \frac{N_I[\lambda_1K_1 + \lambda_2K_2 + \lambda_3K_3]}{N_UK_3},$$

which, given the assumed parameter values, implies that $N_I/N_U = 0.3$, which can then be used to calculate $\frac{y_I}{y_U}$, which turns out to be almost exactly 1/10, not too far from the 1/11 that we found in the data.

We can also derive, as before, what this model tells us about the marginal product of capital in the U.S. Using the expression derived in the previous sub-section, it is easily shown that the ratio of the marginal product of capital in the U.S. to that in the biggest and best Indian firms will be given by $(\frac{A^I}{A^U})^{\frac{1}{1-\gamma}}(w_U/w_I)^{\frac{\gamma}{1-\gamma}}$,[36] which turns out to be 6.45. Given that the biggest Indian firms have a marginal

[36]The fact that the biggest firms in India are the same size as any U.S. firm obviously simplifies the calculation.

product of 100%, the average U.S. firms should have a marginal product of 100/6.45=15.5%. This is obviously higher than the average stock market return, but hardly beyond the reasonable range.

• Distribution of firm sizes

The most obvious advantage of the fixed cost approach is that we do not obtain the unreasonably large gap in the marginal products of capital between small and large firms within the same economy, which came out of the previous model. This underscores the importance of using evidence on cross-sectional differences within an economy to assess the validity of alternative models.

Finally, the success of this model in explaining the productivity gap depends, as in the case of the previous model, heavily on the assumption that the U.S. has many more firms than India. However, while in that model we needed the U.S. to have 32 times as many firms as in India to fit the observed productivity gap, here we are doing very well with the U.S. having $3\frac{1}{3}$ times as many.

How reasonable is the assumption that the U.S. has more firms than India? This is not an easy question to answer, mainly because we have no clear sense of what should count as a firm: Both economies have enormous numbers of tiny firms that reflect what people do on the side. In India these "firms" are concentrated in a few sectors, such as retailing or the collection of leaves, wood or waste products, which require little or no skills and can be done on part-time basis. In the U.S., the equivalent would be the numerous ways in which you end up owning a small business for tax purposes, such as part-time consulting, renting out part of your home, part-time telemarketing, etc. It is not clear which of these should count as legitimate firms from the point of view of our model and which of these should not.

A way to restate the same point is that by focusing on the median industry in the ASI data we have effectively ignored the industries (like the ones listed above) which attract all those in India who have nowhere better to go. While there are only a few such industries, they are enormous, and quite unlike the rest of the industries: Among the industries listed in the table above, cotton spinning is probably most like what one of these industries looks like, and it is apparent that it is quite different from the rest—there are many more tiny firms.

Adopting a model of the industry structure in India that has more small and inefficient firms, and therefore less large and efficient firms, is in many ways very much like assuming that there are fewer firms in India. It is easy to show that if we re-parameterize the model in this section to reduce the fraction of large firms (firms with 1,600 units of capital) to 3% (from 10%), but assume that the two economies have the same number of firms, output-per-worker in India would once again be 10% of what it is in the U.S.

• Why doesn't capital flow to India?

Finally we subject this model to an additional test: The fact that in our model there are firms in India

with returns in the neighborhood of 100% would suggest that there are many unexploited opportunities. We have already argued that there are many reasons why a U.S. bank could not just lend to an Indian firm, and thereby benefit from these opportunities. Nor is it easy for an American to borrow money in the U.S. and set up a firm in India: Once he is in India he may be beyond the reach of U.S. law and for that reason alone, lenders will shy away from him. What is much more plausible, however, is that a U.S. entrepreneur moves to India to invest his money in these opportunities. The question is why this does not happen more often.

There are some obvious answers to this question: If the reason why these opportunities have not already been taken advantage of is the lack of secure property rights in India, there is no reason why foreigners would be particularly keen to invest in India. On the other hand, if the problem is that Indians do not have the capital or that they fear the risk exposure or that they are simply unaware of the opportunity, to take some plausible alternatives, a well-diversified wealthy U.S. investor may well be attracted to move to India and start a firm.

How much money would such an investor make? To answer this we start by observing from (7) that the production function in the largest Indian firms can be written as $C(K-800)^{1/2}$, where $C = A_3^{\frac{1}{1-\gamma}} \left[\frac{\gamma}{w}\right]^{\frac{\gamma}{1-\gamma}}$. Of this, a fraction 3/5 goes to wages. Profits are therefore given by $\frac{2}{5}C(K-800)^{1/2}$. Since this firm has 1,600 units of capital, and the marginal product of capital in this firm was assumed to be 100%, it follows that

$$\frac{1}{5}C(800)^{-1/2} = 1,$$

or

$$C = 141.42.$$

The opportunity cost of capital for a U.S. investor is 9%. The optimal investment in this Indian firm for a U.S. investor who can invest as much as he wants will be given by the solution to

$$(141.42)(0.2)(K-800)^{-1/2} = 0.09.$$

This tell us that the optimal investment is $K = 99564$. The total after-wage income generated by the firm is $(0.4)(141.42)(99564-800)^{1/2} = 17777$. This is in units of the smallest firm. We know that the biggest firms in our model are 1,600 times as large as the smallest firms and from the table above, such firms have Rs. 36 million worth of capital in the median industry. The smallest firm therefore has Rs.22,500 worth of capital, which implies that the U.S. investor will earn 17777(22500)=Rs. 400 million on his investment of (99564)(22500)=Rs. 2.24 billion. This is a net gain of about Rs. 200 million, or about 4 million dollars.

Is this a large enough gain to tempt someone to leave his home and family and settle in India? For

someone with an average income, obviously. But no one with an average income has 50 million dollars of his own that he is willing to put into a single project in India. Anyone who is willing to do it has to be very rich indeed—he must have $50 million several times over. How many people are so wealthy that they are willing to give up their life in the U.S. for an extra $4 million per year?

In other words, while the model developed in this section generates very large productivity losses, it does not offer any one person the possibility of arbitraging these unexploited opportunities to become enormously rich. This is because diminishing returns set in quite fast.

5.2.1 Taking Stock

We started by describing some of the major puzzles left unanswered by the neo-classical model, and in particular the productivity gap between rich and poor countries. The coexistence of high and low returns to investment opportunities, together with the low average marginal product of capital, suggested that some of the answer might lie in the misallocation of capital. The microeconomic evidence indeed suggests that there are some sources of misallocation of capital, including credit constraints, institutional failures, and others. In this section, we have seen that, combined with multiple technological options and a fixed cost of upgrading to better technologies, a model based on misallocation of capital does quite well in terms of explaining the productivity gap. The value of the marginal productivity of capital in the U.S. predicted by this model is only marginally too high, and the degree of variation in the marginal product of capital within a single economy that the model requires is not implausibly large.

Of course the model does make unrealistic assumptions—there is, for example, surely some amount of inefficiency in the U.S., and some U.S. firms are surely more productive than others. On the other hand, we have also ignored many reasons why Indian firms may be less efficient than they are in our model. For example, our current model assumes that only 10% of the firms, who use less than 1% of the capital stock and produce less than 1% of the output, use the least efficient technology whereas the MGI report on the apparel sector tells us that almost 55% of the output of the sector is produced by tailors who still use primitive technology. We also assumed that 10% of Indian firms are as productive as the best U.S. firms. Clearly that fraction could be smaller.

We also assumed that everyone is equally competent. In the real world, imperfect credit markets, for example, drives down the opportunity cost of capital and this encourages incompetent producers to stay in business. In the model, we assume that all large firms earn high returns but in reality there are probably some large firms that have much lower productivity (anywhere down to 9% per year would be consistent with our model). This too will drive down productivity. In a recent paper, Caselli and Gennaioli (2002) try to calibrate the impact of this factor in the context of a dynamic model with credit constraints. They show that in steady state this can generate productivity losses of 20% or so. We will

argue in the next section that this severely understates the potential productivity gap starting from an arbitrary allocation of capital.

6 Towards a Non-aggregative Growth Theory

6.1 An Illustration

The presumption of neo-classical growth theory was that being a citizen of a poor country gives one access to many exciting investment opportunities, which eventually lead on to convergence. The point of the previous section was to argue that most citizens of poor countries are not in a position to enjoy most of these opportunities, either because markets do not do what they ought to or the government does what it ought not to, or because people find it psychologically difficult to do what is expected of them.

What can we say about the long-run evolution of an economy where there are rewarding opportunities that are not necessarily exploited? In this section we will explore this question under the assumption that the only source of inefficiency in this economy comes from limited access to credit. The goal is to illustrate what non-aggregative growth theory might look like, rather than to suggest an alternative canonical model.

The model we have in mind is as follows: There are individual production functions associated with every participant in this economy that are assumed to be identical and a function of capital alone ($F(K)$) but otherwise quite general. In particular, we do assume that they are concave. Individuals maximize an intertemporal utility function of the form:

$$\begin{aligned} \sum_{t=0}^{\infty} \delta^t U(C_t), 0 &< \delta < 1 \\ U(C_t) &= \frac{c^{1-\phi}}{1-\phi}, \phi > 0. \end{aligned}$$

People are forward-looking and at each point of time they choose consumption and savings to maximize lifetime utility. However, the maximum amount they can borrow is linear and increasing in their wealth and decreasing in the current interest rate: An individual with wealth w can borrow up to $\lambda(r_t)w$. Credit comes from other members of the same economy and the interest rate clears the credit market. We do not assume that everyone starts with the same wealth, but rather that at each point of time there is a distribution of wealth that evolves over time.

This model is a straightforward generalization of the standard growth model. What it tells us about the evolution of the income distribution and efficiency depends, not surprisingly, on the shape of the production function.

The simplest case is that of constant returns in production. In this case, inequality remains unchanged over time, and production and investment is always efficient.

With diminishing returns, greater inequality can lead to less investment and less growth, because the production function is concave. However, inequality falls over time and in the long run no one is credit constrained, although we do not necessarily get full wealth convergence. The long run interest rate converges to its first best level, and hence investment is efficient. To see why this must be the case, note first that because of diminishing returns the poor always have more to gain from borrowing and investing than the rich. In other words, the rich must be lending to the poor. As long as the poor are credit constrained, they will earn higher returns on the marginal dollar than their lenders, i.e., the rich (that is what it means to be credit constrained). As a result, they will accumulate wealth faster than the rich and we will see convergence. This process will only stop when the poor are no longer credit constrained, i.e., they are rich enough to be able to invest as much as they want.

With increasing returns, inequality increases over time; we converge to a Gini coefficient of 1. Wealth becomes more and more concentrated with only the richest borrowing and investing. Because there are increasing returns, this is also the first best outcome. The logic of this result is very similar to the previous one: Now it is the rich who will be borrowing and the poor who will be lending, with the implication that the rich are the ones who are credit constrained and the ones earning high marginal returns. Therefore, they will accumulate wealth faster and wealth becomes increasingly concentrated.

Finally we consider the case of "S-shaped" production functions, which are production functions that are initially convex and then concave. The Cobb-Douglas with an initial set-up cost discussed at length in section 5.2 is a special case of this kind of technology.

What happens in the long run in this model depends on the initial distribution of income. When the distribution is such that most people in the economy can afford to invest in the concave part of the production function, the economy converges to a situation that is isomorphic to the diminishing returns case, with the entire population "escaping" the convex region of the production function.

The more unusual case is the one where some people start too poor to invest in the concave region of the production function. The poorer among such people will earn very low returns if they were to invest and therefore will prefer to be lenders. Now, as long as the interest rate on savings is less than $1/\delta$, they will decumulate capital (since the interest is less than the discount factor) and eventually their wealth will go to zero. On the other hand, anyone in this economy who started rich enough to want to borrow will stay rich, even though they are also dissaving, in part because at the same time they benefit from the low interest rates. The economy will converge to a steady state where the interest rate is $1/\delta$, those who started rich continue to be rich and those who started poor remain poor (in fact have zero wealth).

This is classic poverty trap: Moreover, since no one escapes from poverty, nor falls into it, there is a

continuum of such poverty traps in this model. This kind of multiplicity is, however, fragile with respect to the introduction of random shocks that allow some of the poor to escape poverty and impoverish some of the rich.

Even in a world with such shocks there can be more than one steady state: The reason is that the presence of lots of poor people drives down interest rates, and low interest rates make it harder for the poor to save up to escape poverty even with the help of a positive shock. As a result, in an economy that starts with lots of poor people, a greater fraction of people may remain poor.

The key to this multiplicity is the endogeneity of the interest rate. It is the pecuniary externality that the poor inflict on other poor people that sustains it. This is why such poverty traps are sometimes called *collective poverty traps*, in contrast to the *individual poverty traps* described above.

The investigation of the evolution of income distribution in models with credit constraints and endogenous interest rates goes back to Aghion and Bolton (1997). Matsuyama (2000, 2003) and Piketty (1997) emphasize the potential for collective poverty traps in a variant of this model, without the forward-looking savings decisions.

This class of models is a part of a broader group of models which study the simultaneous evolution of the occupational structure, factor prices and the wealth distribution in a model with credit constraints. Loury (1981) studied this class of models and showed that in the long run the neo-classical predictions tend to hold as long as the production function is concave. Dasgupta and Ray (1986) and Galor and Zeira (1993) provide examples of individual poverty traps in the presence of credit constraints and S-shaped production functions. Banerjee and Newman (1993) show the possibility of a collective poverty trap in a model with a S-shaped production function which is driven by the endogeneity of the wage–essentially high wages allow workers to become entrepreneurs easily, which keeps the demand for labor, and hence wages, high. Recent work by Buera (2003) shows that the multiplicity results in Banerjee and Newman survive in an environment where savings is based on expectations of future returns.[37] Ghatak, Morelli and Sjostrom (2001, 2002) and Mookerjee and Ray (2002, 2003) explore related but slightly different sources of individual and collective poverty traps.

6.2 Can we take this model to the data?

Models like the one we just developed (as well as political economy models that we do not discuss here[38]) have been invoked as motivation for a large empirical literature on the relationship between inequality

[37] On the possibility of collective poverty traps, see also Lloyd-Ellis and Bernhardt (2000), and Mookerjee and Ray (2002, 2003).

[38] See Alesina and Rodrik (1994), Persson and Tabellini (1991) and Benhabib and Rustichini (1998). For a contrarian point of view, arguing that the premise of the political economy model argument does not hold true in the data, see Benabou (1996).

and growth in cross-country data. In 1996, Benabou cited 16 studies on the question, and the number has been growing rapidly since then, in part due to the availability of more complete data sets, due to the effort of Deininger and Squire (see Deininger and Squire (1996)), expanded by the World Institute for Development Economics Research (WIDER). However, it is not clear that if we were to take this class of models seriously, they would justify estimating relationships like the ones that are in the literature: First because the exact form of the predicted relationship between inequality and growth depends on the shape of the production function. Imposing the assumption that there are diminishing returns helps in this respect, but with this assumption functional form issues loom large. Finally, it is not clear how, given the model's structure, we can avoid running into serious identification problems.

In this section, we evaluate whether, given these concerns, estimating the relationship between inequality and growth in a cross-country data set remains useful. Having concluded that it has, at best, very limited use, we discuss an alternative approach based on calibrating non-aggregative models using micro data.

6.2.1 What are the empirical implications of the above model?

Functional Form Issues With constant returns to scale, distribution is irrelevant for growth. With diminishing returns, an exogenous mean-preserving spread in the wealth distribution in this economy will reduce future wealth and, by implication, the growth rate. However, the impact depends on the level of wealth in the economy: Once the economy is rich enough that everyone can afford the optimal level of investment, inequality should not matter. The estimated relationship between inequality and growth should therefore allow for an interaction term between inequality and mean income. Moreover, an economy closer to the steady state has both lower inequality and lower growth. This has two implications for the estimation of the inequality growth relationship. First, the fact that the economy becomes more equal as it grows tends to generate a spurious positive relation between growth and inequality, both in the cross-section as well as in time-series. As a result, both the cross-sectional and the first differenced (or fixed effects) estimates of the effect of inequality on growth run the risk of being biased upwards, compared to the true negative relation that we might have found if we had compared economies at the same mean wealth levels. Moreover, consider a variant of the model where there are occasional shocks that increase inequality. Since the natural tendency of the economy is towards convergence, we should expect to see two types of changes in inequality: Exogenous shocks that increase inequality and therefore reduce growth and endogenous reductions in inequality that are also associated with a fall in the growth rate. In other words, measured changes in inequality in either direction will be associated with a fall in growth.

Controlling properly for the effect of mean wealth (or mean income), is therefore vital for getting

meaningful results. The usual procedure is to control linearly (as in most other growth regressions) for the mean income level at the beginning of the period. It is, however, not clear that there is any good reason why the true effect should be linear. Moreover, it seems plausible that different economies will typically have different λs, and therefore will converge at different rates.

The model also tells us that while initial distribution matters for the growth rate, it only matters in the short run. Over a long enough period, two economies starting at the same mean wealth level will exhibit the same average growth rate. In other words, the length of the time period over which growth is measured will affect the strength of the relationship between inequality and growth.

The preceding discussion assumed that the interest rates converged. As we noted, that does not need to be the case. If we do not assume it, variants of the simple concave economy may no longer converge, even in the weaker sense of the long-run mean wealth being independent of the initial distribution of wealth. Intuitively, poor economies will tend to have high interest rates, and this in turn will make capital accumulation difficult (note that $\lambda' < 0$) and tend to keep the economy poor.[39] This effect reinforces the claim made above that inequality matters most in the poorest economies.[40] This economy can have a number of distinct steady states that are each locally isolated. This means that small changes in inequality can cause the economy to move towards a different and further away steady state, making it more likely that the relationship will be non-linear.

With increasing returns, growth rates increase with a mean preserving spread in income. As the economy grows, it also becomes more unequal. Interpreting the relationship between inequality and growth is difficult even after controlling for convergence.

In the S-shaped returns case, the relationship between inequality and growth can be negative or positive depending on the initial distribution, and the size of the increase. For example, if everybody is very poor (on the left of the convex zone), a small increase in inequality will reduce growth, but increasing inequality enough may push more people to the point where they are able to take advantage of the more efficient technology, and increases in inequality will increase growth. The relation between inequality and growth delivered by this model is clearly non-monotonic. Moreover, the strong convergence property does not hold in general. In other words, the growth rate of wealth may *jump up* once the economy is rich enough, with the obvious implication that economies with higher mean wealth will not necessarily grow more slowly. In other words, the effect of mean wealth, that is the so-called convergence effect, may not be monotonic in this economy. Linearly controlling for mean wealth therefore does not guarantee that

[39] See Piketty (1997). For a more general discussion of the issue of convergence in this class of models, see Banerjee and Newman (1993).

[40] There is, however, a counteracting effect: Poorer economies with high levels of inequality may actually have low interest rates because a few people may own more wealth than they can invest in their own firms, and the rest may be too poor to borrow. For a model where this effect plays an important role, see Aghion and Bolton (1997).

we will get the correct estimate of the effect of inequality. It is worth noting that this economy will have a connected continuum of steady states. This means that after a shock the economy will not typically return to the same steady state. However, since it does converge to a nearby steady state, this is not an additional source of non-linearity.

Identification Issues Even if we could agree on a specification that is worth estimating, it is not clear how we can use cross-country data to estimate it. Countries, like individuals, are different from each other. Even in a world of perfect capital markets, countries can have very different distributions of wealth because, for example, they have different distributions of ability. There is no causal effect of inequality on growth in this case, but they could be correlated for other reasons. For example, cultural structures (such as a caste system) may restrict occupational choices and therefore may not allow individuals to make proper use of their talents, causing both higher inequality and lower growth. Conversely, if countries use technologies that are differently intensive in skilled labor, those countries using the more skill intensive technology can have both more inequality and faster growth.

As we discussed in detail above, countries have different kinds of financial institutions, implying differences in the λ's in our model. Our basic model would predict that the country with the better capital markets is likely both to be more equal and to grow faster (at least once we control for the mean level of income). The correlation between inequality and growth will therefore be a downwards-biased estimate of the causal parameter, if the quality of financial institutions differs across countries.[41]

If these country specific effects were additive, one could control for them by including a country fixed-effect in the estimated relationship (or by estimating the model in first difference). This strategy will be valid only under the assumption that changes in inequality are unrelated to unobservable country characteristics that are correlated with changes in the growth rate. While this is a convenient assumption, it has no reason to hold in general. For example, skill-biased technological progress will lead both to a change in inequality and a change in growth rates, causing a spurious positive correlation between the two. To make matters worse, we have to recognize the fact that λ itself (and therefore the effect of inequality on growth at a given point in time) may be varying over time as a result of monetary policies or financial development, and may itself be endogenous to the growth process.[42]

The more general point that comes out of the discussion above is that unless we assume capital

[41] Allowing λ to vary also implies that the causal effects of inequality will vary with financial development (which is how Barro (2000) explains his results). The OLS coefficient is therefore a weighted average of different parameters, where the weights are the country-specific contributions to the overall variance in inequality (Krueger and Lindahl (1999)). It is not at all clear that we are particularly interested in this set of weights.

[42] See Acemoglu and Zilibotti (1994), and Greenwood and Jovanovic (1999), for theories of growth with endogenous financial development.

markets are extremely efficient (which, in any case, removes one of the important sources of the effect of inequality), changes in inequality will be partly endogenous and related to country characteristics which are themselves related to changes in the growth rate. Identifying the effect of inequality by including a country fixed-effect would not necessarily solve all the endogeneity problems. Moreover, as we discussed above, the theory suggests that the specification should allow for non-linear functional forms, and interaction effects, which will be difficult to accommodate with a fixed effect specification.

6.2.2 Empirical Evidence

The preceding discussion suggests that empirical exercises using aggregate, cross-country data to estimate the impact of inequality and growth will be extremely difficult to interpret. The results are also likely to be sensitive to the choice of specification. This may explain the variety of results present in the literature. A long literature (see Benabou (1996) for a survey) estimated a long run equation, with growth between 1990 and 1960 (say) regressed on income in 1960, a set of control variables, and inequality in 1960. Estimating these equations tended to generate negative coefficients for inequality. As the discussion in the previous subsection suggests, there are many reasons to think that this relationship may be biased upward or downwards. To address this problem, Li and Zou (1998) and Forbes (2000) used the Deininger and Squire data set to focus on the impact of inequality on short run (5 years) growth, and introduced a linear fixed effect.[43] The results change rather dramatically: The coefficient of inequality in this specification is positive, and significant. Finally, Barro (2000) used the same short frequency data (he is focusing on ten-year intervals), but does not introduce a fixed effect. He finds that inequality is negatively associated with growth in the poorer countries, and positively in rich countries.

Banerjee and Duflo (2003b) investigate whether there is any reason to worry about the non-linearities that the theory suggests should be present. They find that when growth (or changes in growth) are regressed non-parametrically on changes in inequality, the relationship is an inverted U-shape. There is also a non-linear relationship between past inequality and the magnitudes of changes in inequality. Finally, there seems to be a negative relationship between growth rates and inequality lagged one period. These facts taken together, and in particular the non-linearities in these relationships (rather than the variation in samples or control variables), account for the different results obtained by different authors using different specifications.

[43] Forbes (2000) also corrects for the bias introduced by introducing a lagged variable in a fixed effect specification by using the GMM estimator developed by Arellano and Bond (1991).

6.3 Where do we go from here?

The discussion on functional form and identification, coupled with the empirical evidence of non-linearities even in very simple exercises, suggests that cross-country regressions are unlikely to be able to shed any meaningful light on the empirical relevance of models that integrate credit constraints and other imperfections of the credit markets. This is made worse by the poor quality of the aggregate data, despite the considerable efforts to produce consistent and reliable data sets. This contrasts with the increased availability of large, good quality, micro-economic data sets, which allow for testing specific hypotheses and derive credible identifying restrictions from theory and exogenous sources of variation. Throughout this chapter, we quoted many studies using micro-economic data which tested the micro-foundations for the models we discussed in this section.

Even a series of convincing micro-empirical studies will not be enough to give us an overall sense of how, together, they generate aggregate growth, the dynamics of income distribution, and the complex relationships between the two. The lessons of development economics will be lost to growth if they are not brought together in an aggregate context. In other words, it is not enough to use them to loosely motivate cross-sectional growth regression exercises—the discussion in this section is but an example of the misleading conclusions to which this can lead.

An alternative that seems likely to be much more fruitful is to try to build macroeconomic models that incorporate the features we discussed, and to use the results from the microeconomic studies as parameters in calibration exercises. The exercise we performed in section 5 of this chapter is an illustration of the kind of work that we can hope to do. There are a number of recent papers that in some ways go further in this direction than we have gone. In particular, Quadrini (1999) and Cagetti and Nardi (2003), for the U.S., and Paulson and Townsend (2003), for Thailand, try to calibrate a model with credit constraints to understand the correlation between wealth and the probability of becoming an entrepreneur. The paper by Buera (2003) mentioned above, emphasizes the fact that the long run correlation between wealth and entrepreneurship is weaker than the short run correlation, because as noted by Skiba (1978), Deaton (1992), Aiyagari (1994) and Carroll (1997), those who are credit constrained now but want to invest in the future have a very strong incentive to save. This, Buera points out, reduces the ultimate efficiency cost of imperfect credit markets, though in spite of this, the person with the median ability level and the median starting wealth loses about 18% of lifetime welfare because of the credit constraints. Caselli and Gennaioli (2002) offer a slightly different calibration: Like Buera, they are worried about the fact that with credit constraints the biggest firms may not be run by the best entrepreneurs. This can be a source of very large productivity losses in the short run. However, since the best entrepreneurs will make the most money, in the long run their firms would necessarily become the largest, unless they died young. They show that even with this limiting factor, reasonable death rates would imply a 20% loss of

productivity when we compare an economy without credit constraints with one that has them.

The calibrations so far have not attempted to see if the path of wealth distribution that results from calibrating this type of model matches the data. Our exercise above, for example, tries to match the distribution of firm sizes at a point of time, but says nothing about the path, while Buera does not try to match the data. The one exception is the papers by Robert Townsend and his collaborators based on Thai data (Jeong and Townsend (2003); Townsend and Ueda (2003)).

These papers, as well as those mentioned in the previous paragraphs, start from the assumption that every firm has a single, usually strictly concave, production technology. The only fixed cost comes from the fact that the firm needs an entrepreneur. As we saw above, this model does not do very well in terms of explaining the cross-sectional variation in the firm sector or the overall productivity gap, as compared to a model with a small number of alternative technologies and varying fixed costs. More generally, we need both a better empirical understanding of where the most important sources of inefficiency lie and better integration of this understanding when we assess the predictions of growth theory.

And perhaps above all, we need better growth theory: Our exercise at the beginning of this section was intended to advertise the possibility of a growth theory that does not assume aggregation. While we attempted to link the results to some relatively general properties of the production function, our analysis relies heavily on the fact that the inefficiency we assumed was in the credit market and that this took the form of a credit limit that was linear in wealth. One can easily imagine other ways for the credit market to be imperfect and other results from such models. Moreover, while the class of production technologies covered by our model was broader than usual, it does not include the (multiple-fixed-cost) technology that the previous section advocates.

There are, of course, other types of non-aggregative models: There are some examples of non-aggregative growth models that build on the inefficiency that comes from poorly functioning insurance markets.[44] There are also interesting attempts to build growth models that emphasize the fact that some people are favored by the government while others are not, and especially the fact that this changes over time in some predictable way (see Roland Benabou's contribution to this volume). Some interesting recent work has been done on the dynamic interplay between growth and political institutions (see the chapter by Acemoglu and Robinson in this volume) as well as between growth and social institutions (see Oded Galor's contribution to this volume, as well as Cole, Mailath and Postelwaithe (1992, 1998, 2001)). However, even more than in the case of the literature on credit markets and growth, it is not clear how much the insights from these models rely on specific details of how the environment or the imperfection

[44]See Banerjee and Newman (1991) for a theoretical model of non-aggregative growth based on imperfect insurance markets. Deaton and Paxson (1994) investigate some of empirical implications of this type of model using Taiwanese data. Krussel and Smith (1998) and Angeletos and Calvet (2003) are attempts to calibrate the impact of imperfect insurance on welfare and growth.

was modeled and to what extent they can be seen as robust properties of this entire class of models.

There are also areas where growth theory has not really reached: We have no models that, for example, incorporate reputation-building or learning into growth theory. The same can be said about the entire class of behavioral models of underinvestment.

Finally, there is the open question of whether we gain anything by building grand models that incorporate all these different reasons for inefficiency in a single model. To answer this we would need to assess whether the fact that different forms of inefficiency interact with each other has empirically important consequences.

This is an exciting time to think about growth. We are beginning to see the contours of a new vision, both more rooted in evidence and more ambitious in its theorizing.

Growth Econometrics

Steven N. Durlauf, Paul A. Johnson and Jonathan R. W. Temple

Final Draft: October 22, 2004

Durlauf thanks the University of Wisconsin and John D. and Catherine T. MacArthur Foundation for financial support. Johnson thanks the Department of Economics, University of Wisconsin for its hospitality in Fall 2003, during which part of this chapter was written. Temple thanks the Leverhulme Trust for financial support under the Philip Leverhulme Prize Fellowship scheme. Ritesh Banerjee, Ethan Cohen-Cole, Giacomo Rondina and Lisa Wong have provided excellent research assistance. Finally, we thank Gordon Anderson, William Brock and Stephen Bond for useful discussions.

Growth Econometrics

Abstract

This paper provides a survey and synthesis of econometric tools that have been employed to study economic growth. While these tools range across a variety of statistical methods, they are united in the common goals of first, identifying interesting contemporaneous patterns in growth data and second, drawing inferences on long-run economic outcomes from cross-section and temporal variation in growth. We describe the main stylized facts that have motivated the development of growth econometrics, the major statistical tools that have been employed to provide structural explanations for these facts, and the primary statistical issues that arise in the study of growth data. An important aspect of the survey is attention to the limits that exist in drawing conclusions from growth data, limits that reflect model uncertainty and the general weakness of available data relative to the sorts of questions for which they are employed.

The totality of our so-called knowledge or beliefs, from the most causal matters of geography and history to the profoundest laws of atomic physics…is a man-made fabric which impinges on experience only along the edges…total science is like a field of force whose boundary conditions are experience…A conflict with experience on the periphery occasions readjustments in the interior of the field. Reevaluation of some statements entails reevaluation of others, because of their logical interconnections…But the total field is so underdetermined by its boundary conditions, experience, that there is much latitude of choice as to what statements to reevaluate in the light of any single contrary experience.

W. V. O. Quine[1]

I. Introduction

The empirical study of economic growth occupies a position that is notably uneasy. Understanding the wealth of nations is one of the oldest and most important research agendas in the entire discipline. At the same time, it is also one of the areas in which genuine progress seems hardest to achieve. The contributions of individual papers can often appear slender. Even when the study of growth is viewed in terms of a collective endeavor, the various papers cannot easily be distilled into a consensus that would meet standards of evidence routinely applied in other fields of economics.

A traditional defense of empirical growth research would be in terms of expected payoffs. Each time an empirical growth paper is written, the probability of gaining genuine understanding may be low, but the payoff to that understanding is potentially vast. But even this argument relies on being able to discriminate between the status of different pieces of evidence – the good, the bad and the ugly – and this process of discrimination carries many difficulties of its own.

Rodriguez and Rodrik (2001) begin their skeptical critique of evidence on trade policy and growth with an apt quote from Mark Twain: "It isn't what we don't know that kills us. It's what we know that ain't so." This point applies with especial force in the identification of empirically salient growth determinants. As illustrated in Appendix 2 of this chapter, approximately as many growth determinants have been proposed as there are countries for which data are available. It is hard to believe that all these determinants are

[1] "Two Dogmas of Empiricism," *Philosophical Review*, 1951.

central, yet the embarrassment of riches also makes it hard to identify the subset that truly matters.

There are other respects in which it is difficult to reconcile alternative empirical studies, including the functional form posited for the growth process. An important distinction between the neoclassical growth model of Solow (1956) and Swan (1956) and many of the models that have been produced in the endogenous growth theory literature launched by Romer (1986) and Lucas (1988) is that the latter can require the specification of a nonlinear data generating process. But researchers have not yet agreed on the empirical specification of growth nonlinearities, or the methods that should be used to distinguish neoclassical and endogenous growth models empirically.

These and other difficulties inherent in the empirical study of growth have prompted the field to evolve continuously, and to adopt a wide range of methods. We argue that a sufficiently rich set of statistical tools for the study of growth have been developed and applied that they collectively define an area of growth econometrics. This chapter is designed to provide an overview of the current state of this field. The chapter will both survey the body of econometric and statistical methods that have been brought to bear on growth questions and provide some assessments of the value of these tools.

Much of growth econometrics reflects the specialized questions that naturally arise in growth contexts. For example, statistical tools are often used to draw inferences about long-run outcomes from contemporary behaviors. This is most clearly seen in the context of debates over economic convergence; as discussed below, many of the differences between neoclassical and endogenous growth perspectives may be reduced to questions concerning the long-run effects of initial conditions. The available growth data typically span at most 140 years (and many fewer if one wants to work with a data set that nontrivially spans countries outside Western Europe and the United States) and the use of these data to examine hypotheses about long-run behavior can be a difficult undertaking. Such exercises lead to complicated questions concerning how one can identify the steady-state behavior of a stochastic process from observations along its transition path.

As we have already mentioned, another major and difficult set of growth questions involves the identification of empirically salient determinants of growth when

the range of potential factors is large relative to the number of observations. Model uncertainty is in fact a fundamental problem facing growth researchers. Individual researchers, seeking to communicate the extent of support for particular growth determinants, typically emphasize a single model (or small set of models) and then carry out inference as if that model had generated the data. Standard inference procedures based on a single model, and which are conditional on the truth of that model, can grossly overstate the precision of inferences about a given phenomenon. Such procedures ignore the uncertainty that surrounds the validity of the model. Given that there are usually other models that have strong claims on our attention, the standard errors can understate the true degree of uncertainty about the parameters, and the choice of which models to report can appear arbitrary. The need to properly account for model uncertainty naturally leads to Bayesian or pseudo-Bayesian approaches to data analysis.[2]

Yet another set of questions involves the characterization of interesting patterns in a data set comprised of objects as complex and heterogeneous as countries. Assumptions about parameter constancy across units of observation seem particularly unappealing for cross-country data. On the other hand, much of the interest in growth economics stems precisely from the objective of understanding the distribution of outcomes across countries. The search for data patterns has led to a far greater use of classification and pattern recognition methods, for example, than appears in other areas of economics. Here and elsewhere, growth econometrics has imported a range of methods from statistics, rather than simply relying on the tools of mainstream econometrics.

Whichever techniques are applied, the weakness of the available data represents a major constraint on the potential of empirical growth research. Perhaps the main obstacle to understanding growth is the small number of countries in the world. This is a problem for the obvious reason (a fundamental lack of variation or information) but also because it limits the extent to which researchers can address problems such as measurement error and parameter heterogeneity. Sometimes the problem is stark: imagine trying to infer the consequences of democracy for growth in poorer countries. Because the twentieth century provided relatively few examples of stable, multi-party democracies among the

[2]See Draper (1995) for a general discussion of model uncertainty and Brock, Durlauf, and West (2003) for discussion of its implications for growth econometrics.

poorer nations of the world, statistical evidence can make only a limited contribution to this debate, unless one is willing to make exchangeability assumptions about nations that would seem not to be credible.[3]

With a larger group of countries to work with, many of the difficulties that face growth researchers could be addressed in ways that are now standard in the microeconometrics literature. For example, the well known concerns expressed by Harberger (1987), Solow (1994) and many others about assuming a common linear model for a set of very different countries could, in principle, be addressed by estimating more general models that allow for heterogeneity. This can be done using interaction terms, nonlinearities or semiparametric methods, so that the marginal effect of a given explanatory variable can differ across countries or over time. The problem is that these solutions will require large samples if the conclusions are to be robust. Similarly, some methods for addressing other problems, such as measurement error, are only useful in samples larger than those available to growth researchers. This helps to explain the need for new statistical methods for growth contexts, and why growth econometrics has evolved in such a pragmatic and eclectic fashion.

One common response to the lack of cross-country variation has been to draw on variation in growth and other variables over time, primarily using panel data methods. Many empirical growth papers are now based on the estimation of dynamic panel data models with fixed effects. Our survey will discuss not only the relevant technical issues, but also some issues of interpretation that are raised by these studies, and especially their treatment of fixed effects as nuisance parameters. We also discuss the merits of alternatives. These include the before-and-after studies of specific events, such as stock market liberalizations or democratizations, which form an increasingly popular method for examining certain hypotheses. The correspondence between these studies and the microeconometric literature on treatment effects helps to clarify the strengths and limitations of the event-study approach, and of cross-country evidence more generally.

[3]See Temple (2000b) and Brock and Durlauf (2001a) for a conceptual discussion of this issue.

Despite the many difficulties that arise in empirical growth research, we believe some progress has been made. Researchers have uncovered stylized facts that growth theories should endeavor to explain, and developed methods to investigate the links between these stylized facts and substantive economic arguments. We would also argue that an important contribution of growth econometrics has been the clarification of the limits that exist in employing statistical methods to address growth questions. One implication of these limits is that narrative and historical approaches (Landes (1998) and Mokyr (1992) are standard and valuable examples) have a lasting role to play in empirical growth analysis. This is unsurprising given the importance that many authors ascribe to political, social and cultural factors in growth, factors that often do not readily lend themselves to statistical analysis.[4] For these reasons, Willard Quine's classic statement of the underdetermination of theories by data, cited at the beginning of this chapter, seems especially relevant to the study of growth.

The chapter is organized as follows. Section II describes a set of stylized facts concerning economic growth. These facts constitute the objects that formal statistical analysis has attempted to explain. Section III describes the relationship between theoretical growth models and econometric frameworks for growth, with a primary focus on cross-country growth regressions. Section IV discusses the convergence hypothesis. Section V describes methods for identifying growth determinants, and a range of questions concerning model specification and evaluation are addressed. Section VI discusses econometric issues that arise according to whether one is using cross-section, time series or panel data, and also examines the issue of endogeneity in some depth. Section VII evaluates the implications of different data and error properties for growth analysis. Section VIII concludes with some thoughts on the progress made thus far, and possible directions for future research.

[4]Narrative approaches can, of course, be subjected to criticisms every bit as severe as apply to quantitative studies. Similarly, efforts to study qualitative growth ideas using formal tools can go awry; see Durlauf (2002) for criticism of efforts to explain growth and development using the idea of social capital.

II. Stylized facts

In this section we describe some of the major features of cross-country growth data. Our goal is to identify some of the salient cross-section and intertemporal patterns that have motivated the development of growth econometrics. Section II.i makes some general observations on growth in the very long-run. Section II.ii discusses the main data set used to study growth since 1960. Section II.iii describes general facts about differences in output per worker across countries. Section II.iv extends this discussion by focusing on growth miracles and disasters. Basic facts concerning convergence are reported in Section II.v. In Section II.vi we describe the general slowdown in growth over the last two decades. Section II.vii extends this discussion by considering the question of predictability of growth rates over time. Section II.viii identifies growth differences across levels of development and across geographic regions. In Section II.ix, we characterize some aspects of stagnation and volatility. Section II.x draws some general conclusions about the basic growth facts.

i. a long-run view

Taking a long view of economic history, a central fact concerning aggregate economic activity across countries is the massive divergence in living standards that has occurred over the last several centuries. A snapshot of the world in 1700 would show all countries to be poor, if their living standards were assessed in today's terms. Over the course of the 18^{th} and 19^{th} centuries, growth rates increased slightly in the UK and other countries in Western Europe. Annual growth rates appear to have remained low, by modern standards, even in the midst of the Industrial Revolution; but because this growth was sustained over time, GDP per capita steadily rose. The outcome was that the UK, some other countries in Western Europe, and then the USA gradually advanced further ahead of the rest of the world.

What was happening elsewhere? As Pritchett (1997) argues, even in the absence of national accounts data, we can be almost certain that rapid productivity growth was never sustained in the poorer regions of the world. The argument proceeds by

extrapolating backwards from their current levels of GDP per capita, using a fast growth rate. This quickly implies earlier levels of income that would be too low to support human life.

ii. data after 1960

Today's overall inequality across countries is partly the legacy of rapid growth in a small group of Western economies, and its absence elsewhere. But there have been important deviations from this general pattern. Since the 1960s, some developing countries have grown at rates that are unprecedented, at least based on the experiences of the advanced economies of Europe and North America. The tiger economies of East Asia have seen GDP per worker grow at around 5% a year, or even faster, for the best part of forty years. A country that grows at such rates over forty years will see GDP per worker rise more than sevenfold, as in the case of Hong Kong, Singapore, South Korea and Taiwan.

In the rest of this section, we describe these patterns in more detail. As with most of the empirical growth literature, we will focus on the period after 1960, the point at which national accounts data start to become available for a larger group of countries.[5] Our calculations use version 6.1 of the Penn World Table (PWT) due to Heston, Summers, and Aten (2002). They have constructed measures of real GDP that adjust for international differences in price levels, and are therefore more comparable across space than measures based on market exchange rates.[6]

For the purposes of our analysis, the "world" will consist of 102 countries, those with data available in PWT 6.1 and with populations of at least 350,000 in the year 1960. These 102 countries account for a large share of the world's population. The most important missing countries are economies in Eastern Europe that were centrally planned for much of the period. Because of its enormous population, collectivist China is included in the sample, but is a country for which output measurement is especially difficult. In a

[5]Another reason for this starting point is that many colonies did not gain independence until the 1960s.

[6]For more discussion of the PWT data, and further references, see Temple (1999).

small number of cases, data for GDP per worker for 2000 are extrapolated from preceding years using growth rates for the early and mid-1990s. The Appendix gives more details of the sample, and the extrapolation procedure.

Throughout, we use data on GDP per worker. Most formal growth models are based on production functions, and their implications relate more closely to GDP per worker than GDP per capita. Jones (1997) provides another justification for this choice. When there is an unmeasured non-market sector, such as subsistence agriculture, GDP per worker could be a more accurate index of average productivity than GDP per capita.

The paths of GDP per worker and GDP per capita will diverge when there are changes in the ratio of workers to population, which is one form of participation rate. There has been an upwards trend in these participation rates where such rates were originally low, while at the upper end of the distribution participation has been stable.[7] For a sample of 90 countries with available data, the median participation rate rose from 41% to 45% between 1960 and 2000. There was a sharp increase at the 25th percentile (from 33% to 40%) but very little change at the 75th percentile. This pattern suggests that growth in GDP per capita has usually been close to growth in GDP per worker, except for the countries that started with low participation rates.

There is an important point to bear in mind, when interpreting our later tables and graphs, and those found elsewhere in the literature. Our unit of observation is the country. In one sense this is clearly an arbitrary way to divide the world's population, but one that can have systematic effects on perceptions of stylized facts. We can illustrate this with a specific example. Sub-Saharan Africa has many countries that have small populations, while India and China combined account for about 40% of the world's population. In a decade where India and China did relatively well, such as the 1990s, a country-based analysis will understate the overall improvement in living standards. In contrast, in a decade where Africa did relatively well, such as the 1960s, the overall growth record would appear less strong if assessed on a population-weighted basis. The point that countries differ greatly in terms of population size is important when interpreting tables, graphs and regressions that use the country as the unit of observation.

[7]The figures we use for participation rates are those implicit in the Penn World Table, 6.1.

iii. differences in levels of GDP per worker

Initially, we document the international disparities in GDP per worker. We first look at data for countries with large populations. Table 1 lists a set of countries that together account for 4.3 billion people. Of the countries with large populations, the main omissions are Germany, because of the difficulty posed by reunification, and economies that were centrally planned, including Russia.

Table 1: International Disparities in GDP per Worker

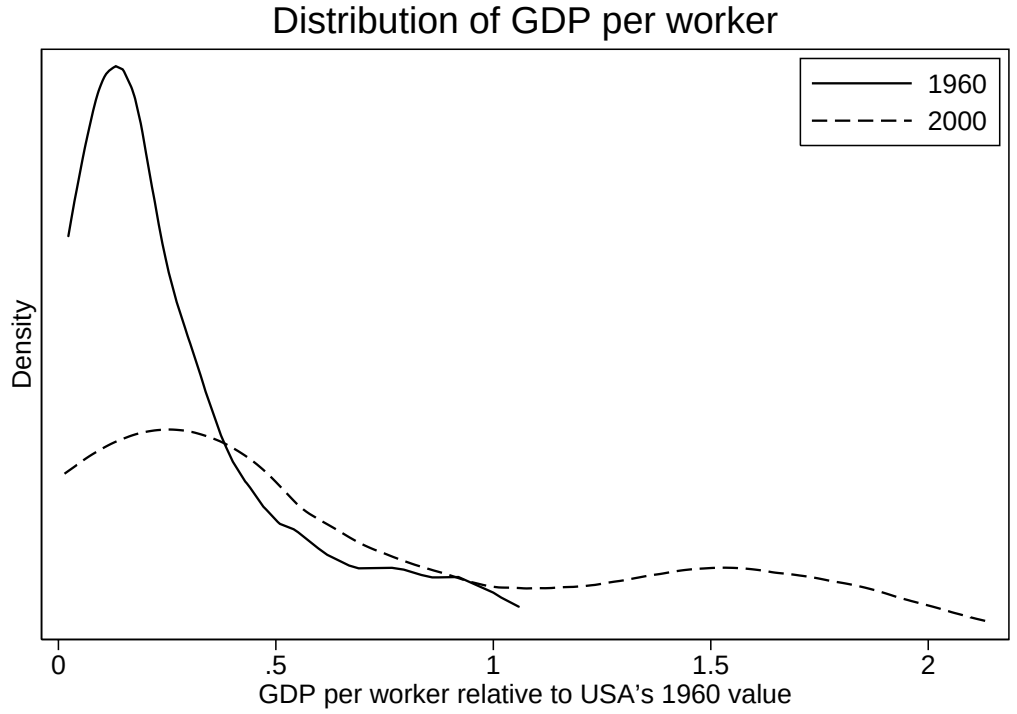
Country	Population(m, 2000)	R1960	R2000
USA	275	1	1
United Kingdom	60	.69	.69
Argentina	37	.62	.40
France	60	.60	.76
Italy	58	.55	.84
South Africa	43	.47	.34
Mexico	97	.44	.38
Spain	40	.40	.68
Iran	64	.30	.30
Colombia	42	.27	.18
Japan	127	.25	.60
Brazil	170	.24	.30
Turkey	67	.17	.24
Philippines	76	.17	.13
Egypt	64	.17	.21
Korea, Republic of	47	.15	.57
Bangladesh	131	.10	.10
Nigeria	127	.08	.02
Indonesia	210	.08	.14
Thailand	61	.07	.20
Pakistan	138	.07	.11
India	1016	.06	.10
China	1259	.04	.10
Ethiopia	64	.04	.02
Mean		.29	.35
Median		.21	.27

Notes:
- R is GDP per worker as a fraction of that in the USA.

The table shows GDP per worker, relative to the USA, for 1960 and 2000. The countries are ranked in descending order in terms of their 1960 position. Some clear patterns emerge: the major economies of Western Europe have maintained their position relative to the USA (as in the case of the UK) or substantially improved it (France, Italy, Spain). Among the poorer nations, there are some countries that have improved their relative position dramatically (Japan, Republic of Korea, Thailand) and others that have performed badly (Argentina, Nigeria). If we look at the mean and median of relative

GDP per worker, there has been a moderate increase, suggesting a slight tendency for reduced dispersion. But these statistics disguise a wide variety of experience, and we will discuss the issue of convergence in more detail below.

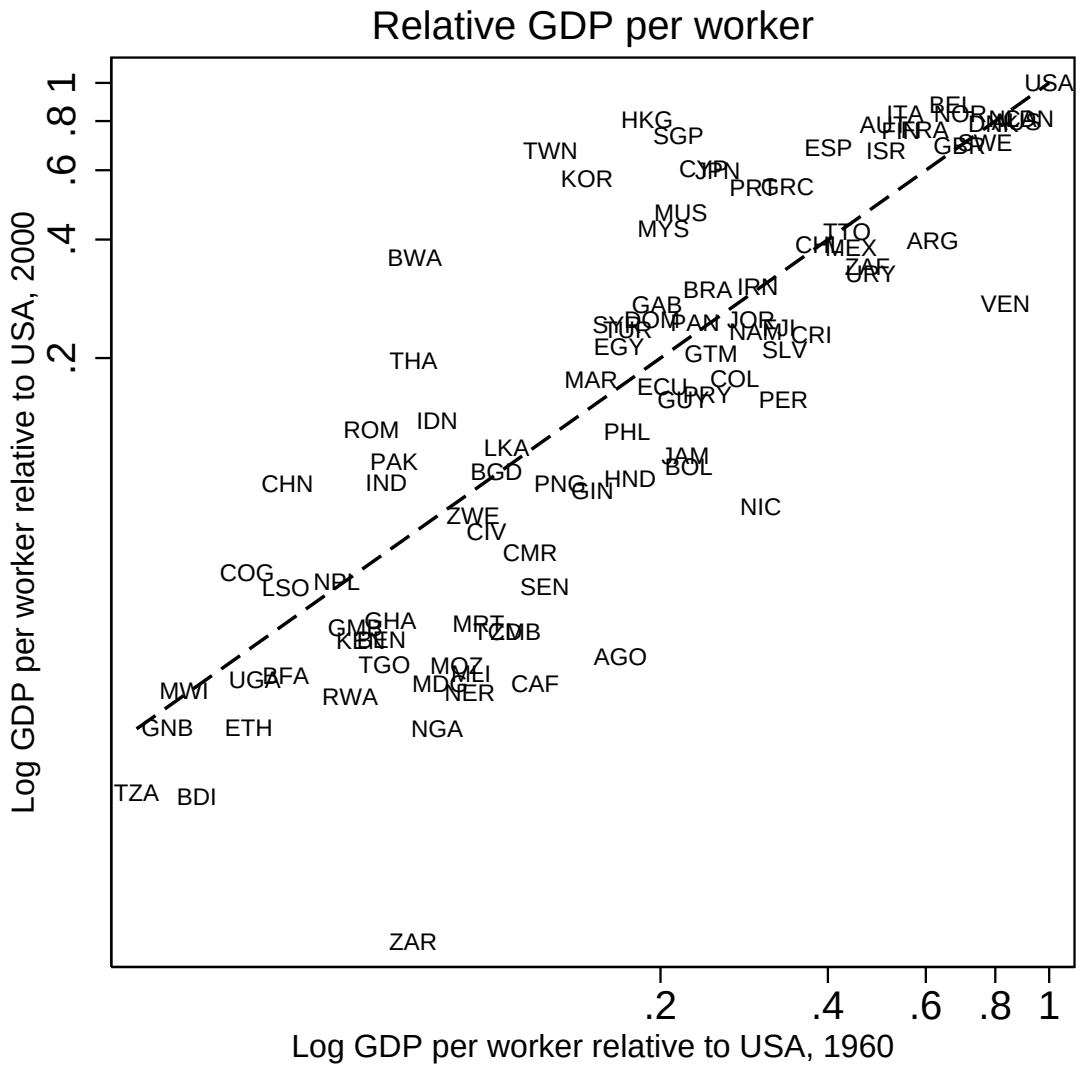
Figure 1: Cross-Country Density of Output per Worker



We now consider the shape of the international distribution of GDP per worker, using the USA's 1960 value as the benchmark. Figure 1 shows a kernel density plot of the distribution of GDP per worker in 1960 and 2000, relative to the benchmark. The rightwards movement reflects the growth that took place over this period. Also noticeable is a thinning in the middle of the distribution, the "Twin Peaks" phenomenon identified in a series of papers by Quah (1993a,b,1996a,b,c,1997).

Is the position in the league table of GDP per worker in 1960 a good predictor of that in 2000? The answer is a qualified yes: the Spearman rank correlation is 0.84. This pattern is shown in more detail in Figure 2, which plots the log of GDP per worker relative to the USA in 2000, against that in 1960. In this and later figures, one or two outlying observations are omitted to facilitate graphing.

Figure 2: Output Per Worker: 1960 versus 2000



The high rank correlation is not a new phenomenon. Easterly et al (1993) report that, for 28 countries for which Maddison (1989) has data, the rank correlation of GDP per capita in 1988 with that in 1870 is 0.82.

iv. growth miracles and disasters

Despite some stability in relative positions, it is easy to pick out countries that have done exceptionally well and others that have done badly. There is an enormous range in observed growth rates, to an extent that has not previously been observed in world history. To show this, we rank the countries by their annual growth rate between 1960 and 2000, and present a list of the fifteen best performers (Table 2) and the fifteen worst (Table 3). To show the dramatic effects of sustaining a high growth rate over forty years, we also show the ratio of GDP per worker in 2000 to that in 1960.

These tables of growth miracles and disasters show a regional pattern that is familiar to anyone who has studied recent economic growth. The best performing countries are mainly located in East Asia and Southeast Asia. These countries have sustained exceptionally high growth rates; for example, GDP per worker has grown by a factor of 11 in the case of Taiwan. If we now turn to the growth disasters, we can see many instances of "negative growth", and these are predominantly countries in sub-Saharan Africa. Later in this section, we will compare Africa's performance with that of other regions in more detail.[8]

[8]Easterly and Levine (1997) and Collier and Gunning (1999a,b) examine various explanations for slow growth in Africa.

Table 2: Fifteen Growth Miracles, 1960-2000

Country	Growth 1960-2000	Factor increase
Taiwan	6.25	11.3
Botswana	6.07	10.6
Hong Kong	5.67	9.09
Korea, Republic of	5.41	8.24
Singapore	5.09	7.29
Thailand	4.50	5.83
Cyprus	4.30	5.39
Japan	4.13	5.04
Ireland	4.10	5.00
China	3.99	4.77
Romania	3.91	4.63
Mauritius	3.88	4.58
Malaysia	3.82	4.48
Portugal	3.48	3.93
Indonesia	3.34	3.72

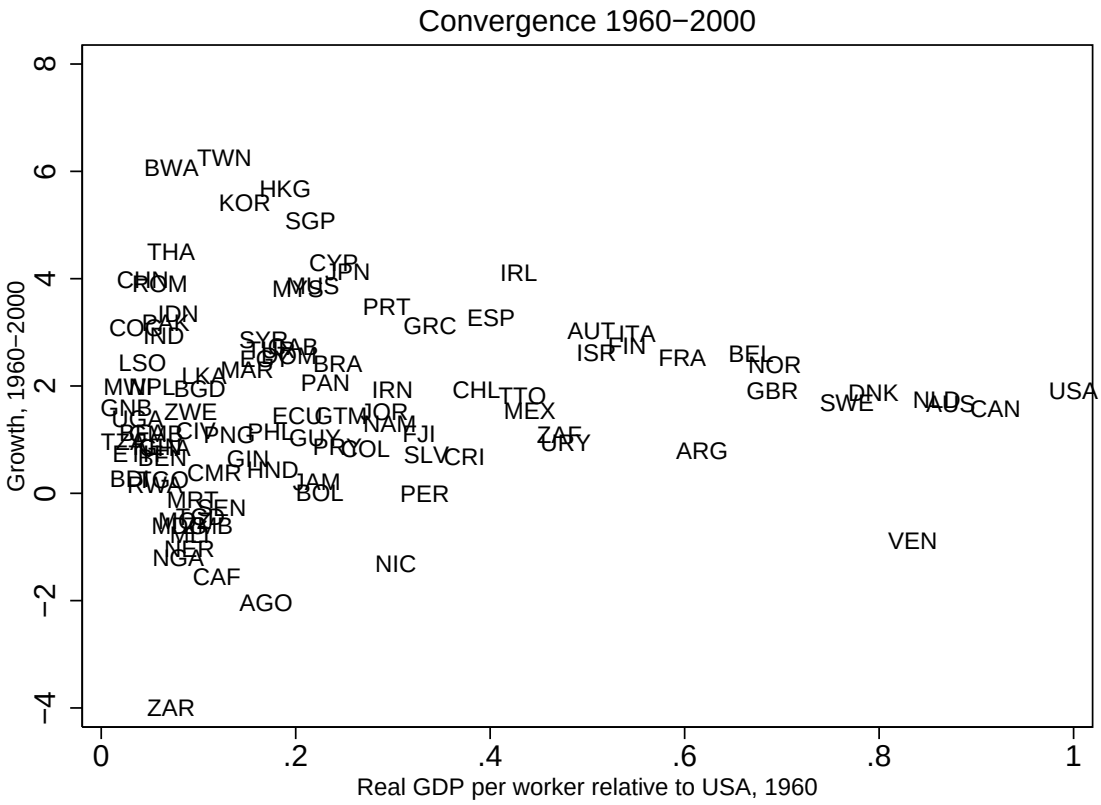
Table 3: Fifteen Growth Disasters, 1960-2000

Country	Growth 1960-2000	Ratio
Peru	0.00	1.00
Mauritania	-0.11	0.96
Senegal	-0.26	0.90
Chad	-0.43	0.84
Mozambique	-0.50	0.82
Madagascar	-0.60	0.79
Zambia	-0.61	0.78
Mali	-0.77	0.74
Venezuela	-0.88	0.70
Niger	-1.03	0.66
Nigeria	-1.21	0.62
Nicaragua	-1.30	0.59
Central African Republic	-1.56	0.53
Angola	-2.04	0.44
Congo, Democratic Rep.	-4.00	0.20

v. convergence?

An alternative way of showing the diversity of experience is to plot the growth rate over 1960-2000 against the 1960 level of real GDP per worker, relative to the USA. This is shown in Figure 3. The most obvious lesson to be drawn from this figure is the diversity of growth rates, especially at low levels of development. The figure does not provide much support for the idea that countries are converging to a common level of income, since that would require evidence of a downward sloping relationship between growth and initial income. Neither does it support the widespread idea that poorer countries have always grown slowly.

Figure 3: Growth Versus Initial Income: 1960-2000



vi. the growth slowdown

Next, we present similar figures for two sub-periods, 1960-1980 and 1980-2000. These plots, shown as Figures 4 and 5, reveal another important pattern. For many developing countries, growth was significantly lower in the second period, with many countries seeing a decline in real GDP per worker after 1980. We can see this more clearly by looking at the international distribution of growth rates for the two sub-periods. Figure 6 shows kernel density estimates, and reveals a clear pattern: the mass of the distribution has shifted leftwards (slower growth) while at the same time the variance has increased (greater dispersion in growth rates).

Figure 4: Growth Versus Initial Income 1960-1980

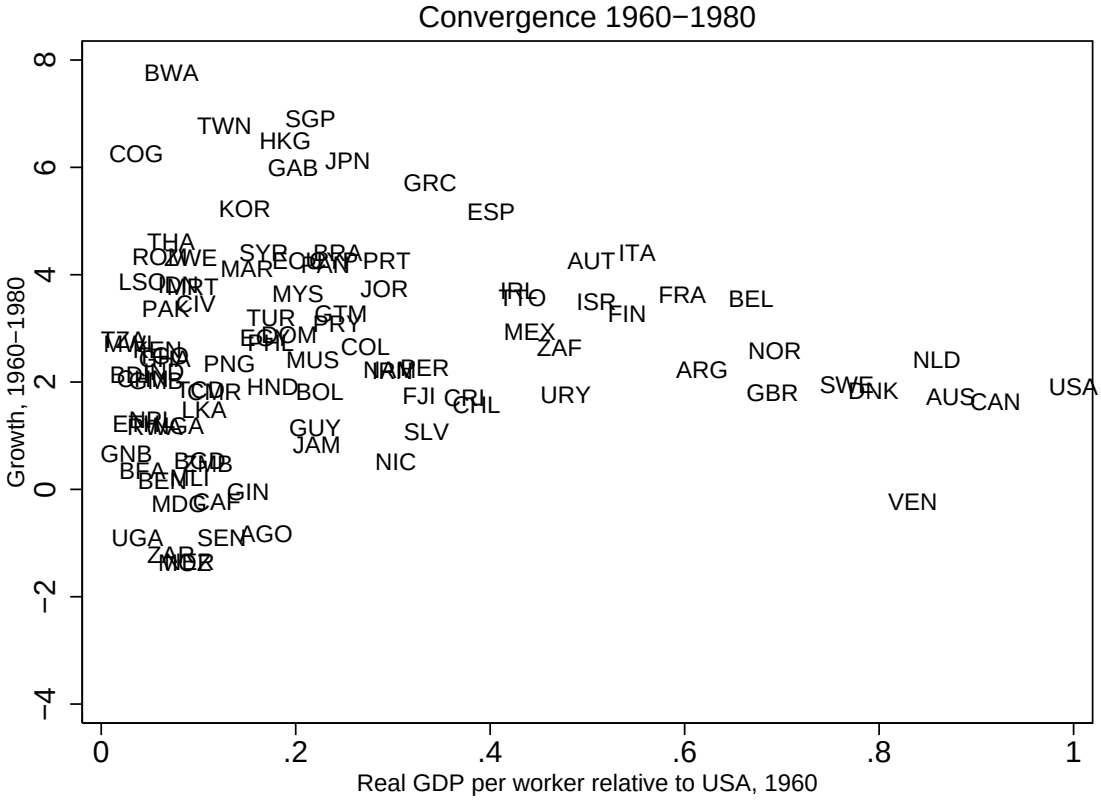


Figure 5: Growth Versus Initial Income: 1980-2000

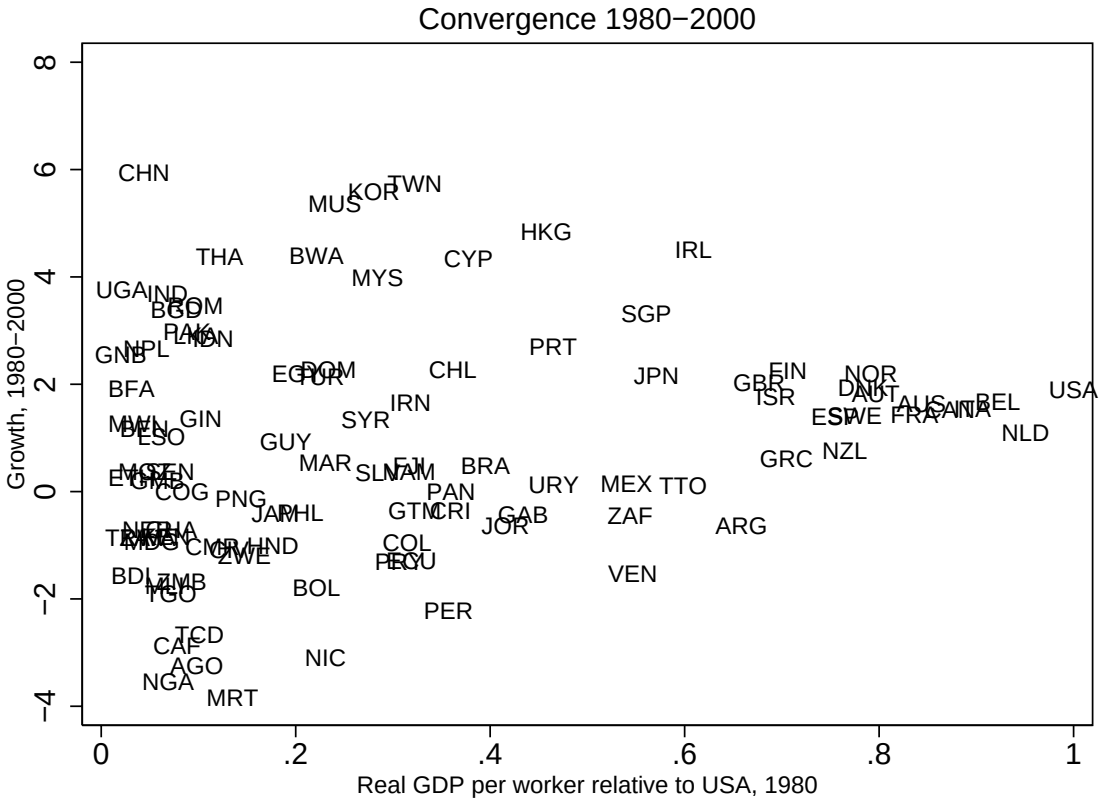

Figure 6: Density of Growth Rates across Countries

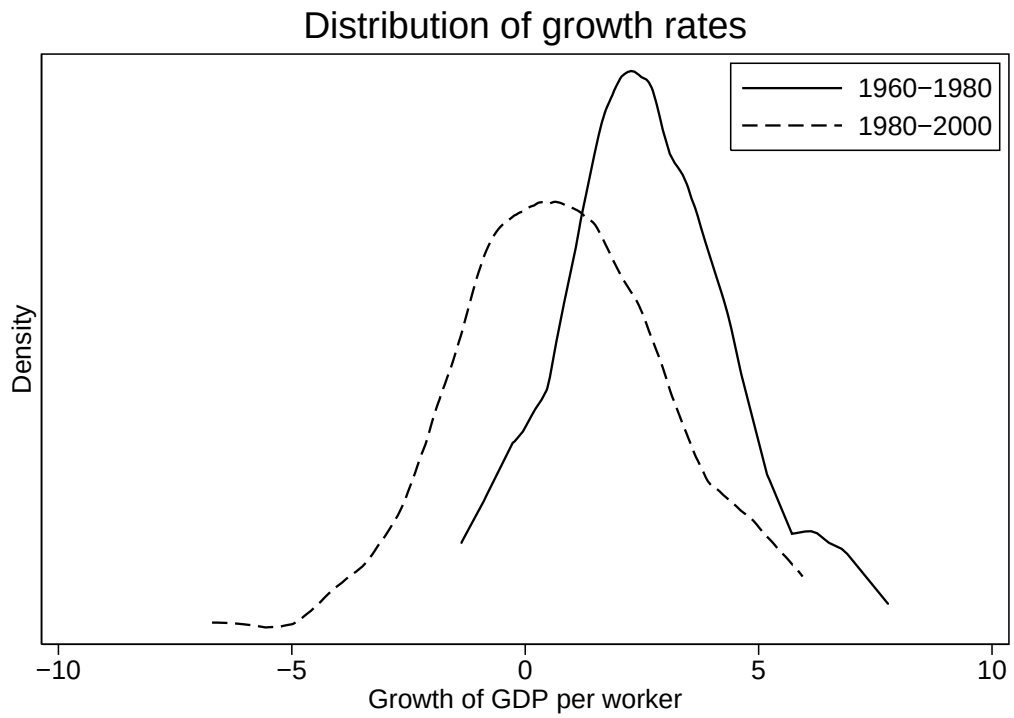

Figure 7: Growth Rates in 1960-1980 versus 1980-2000

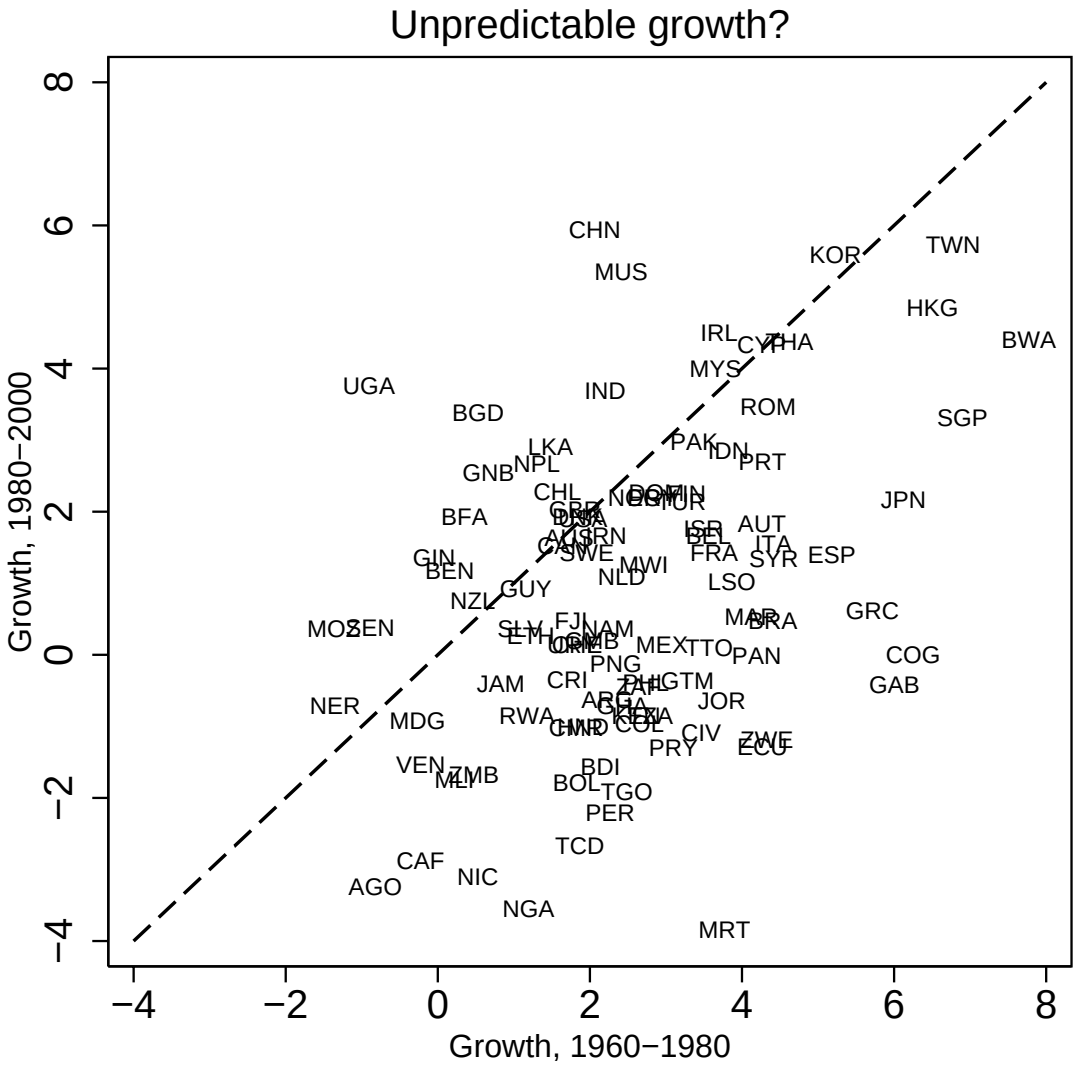


A different way to highlight the growth slowdown is to plot the growth rate in 1980-2000 against that in 1960-1980 as is done in Figure 7, which also includes a 45 degree line. Countries above the line have seen growth increase, whereas countries below have seen growth decline. There are clearly more countries in which growth has declined over time, with the crucial exceptions of China and India, which have seen a dramatic improvement. To reveal the same pattern, Table 4 lists the countries in various categories, classified by growth rates in 1960-80 and in 1980-2000.

Table 4: Growth in 1960-1980 and 1980-2000

	G2≤0	0<G2≤1.5	1.5<G2≤3	G2>3
G1<=0	Angola, Central African Republic, DR Congo, Madagascar, Niger, Venezuela	Guinea, Mozambique, Senegal		Uganda
0<G1≤1.5	Jamaica, Mali, Nicaragua, Nigeria, Rwanda, Zambia	Benin, El Salvador, Ethiopia, Guyana, New Zealand	Burkina Faso, Guinea-Bissau, Nepal, Sri Lanka	Bangladesh
1.5<G1≤3	Argentina, Bolivia, Burundi, Cameroon, Chad, Colombia, Costa Rica, Ghana, Honduras, Kenya, Papua New Guinea, Peru, Philippines, South Africa, Tanzania, Togo	Fiji, Gambia, Malawi, Mexico, Namibia, Netherlands, Sweden, Switzerland, Uruguay	Australia, Canada, Denmark, Chile, Dominican Rep., Egypt, Iran, Norway, UK, USA	China, India, Mauritius
G1>3	Ecuador, Gabon, Guatemala, Ivory Coast, Jordan, Mauritania, Panama, Paraguay, Zimbabwe	Brazil, Rep. Congo, France, Greece, Lesotho, Morocco, Spain, Syria, Trinidad and Tobago	Austria, Belgium, Finland, Indonesia, Israel, Italy, Japan, Pakistan, Portugal, Turkey	Botswana, Cyprus, Hong Kong, Ireland, Korea, Malaysia, Romania, Singapore, Taiwan, Thailand

Notes:

- The above table classifies countries according to their annual growth rates over 1960-80 (G1) and over 1980-2000 (G2).

vii. does past growth predict future growth?

Another lesson to be drawn from Figure 7 and Table 4 is that relative performance has been unstable. The correlation between growth in 1960-1980 and that in 1980-2000 is just 0.40, so past growth is not a particularly useful predictor of future growth.[9] For the whole sample, the correlations across decades are also weak (Table 5). It is less well known that the cross-decade correlation has tended to increase over time, as is clear from Table 5's below diagonal elements for the whole sample. This is tentative evidence that national economies are gradually sorting themselves into a pattern of distinct winners and losers.

Table 5: Growth Rate Correlations Across Decades

	1960-1970	1970-1980	1980-1990	1990-2000
Whole sample				
Growth 1960-1970	1.00			
Growth 1970-1980	0.16	1.00		
Growth 1980-1990	0.28	0.31	1.00	
Growth 1990-2000	0.11	0.33	0.44	1.00
Rich country group				
Growth 1960-1970	1.00			
Growth 1970-1980	0.73	1.00		
Growth 1980-1990	0.06	0.40	1.00	
Growth 1990-2000	-0.07	0.37	0.61	1.00

Notes:
- Whole sample is 102 countries. Rich country group is 19 countries.

[9]Easterly et al (1993) emphasized this point, and suggested that the lack of persistence in growth rates indicates the importance of good luck.

viii. Growth differences by development level and geographic region

Can we say anything more about the characteristics of the winners and losers? First, we investigate the relationship between growth and initial development levels in more detail. We rank the sample of 102 countries by initial income in 1960, and then look at the distribution of growth rates for subgroups. In Table 6, for various ranges of initial income relative to the USA, we show the growth rate at the 25th percentile, the median, and the 75th percentile. If we take the 22 countries which began somewhere between 5% and 10% of GDP per worker in the USA, the annual growth rate at the 25th percentile is negative, but is 2.9% at the 75th percentile. This diversity of experience extends throughout the distribution of relative incomes, but is less pronounced for the richest group.

Table 6: Growth, 1960-2000, by Initial Relative Income

Percentile	N	25th	Median	75th
All	102	0.7	1.6	2.7
Relative income:				
R≤0.05	10	1.0	1.5	2.4
R>0.05 & R≤0.10	22	-0.5	0.9	2.9
R>0.10 & R≤0.25	33	0.4	1.9	2.7
R>0.25 & R≤0.50	19	0.8	1.5	3.1
R>0.50	18	1.6	1.9	2.6

Notes:
- This table shows the 25th, 50th and 75th percentiles of the distribution of growth rates for countries at various levels of development in 1960.
- "R" is GDP per worker in 1960 relative to the US level.

Table 7: Growth, 1960-2000, by Country Groups

Group	N	25th	Median	75th
Sub-Saharan Africa	36	-0.5	0.7	1.3
South and Central America	21	0.4	0.9	1.5
East and Southeast Asia	10	3.8	4.3	5.4
South Asia	7	1.9	2.2	2.9
Industrialized countries	19	1.7	2.4	3.0

Notes:
- This table shows the 25th, 50th and 75th percentiles of the distribution of growth rates for various groups of countries.

Table 7 shows the quartiles of growth rates for countries in different regions.[10] Once again, sub-Saharan Africa is revealed as a weak performer. Within sub-Saharan Africa, even the country at the 75th percentile shows growth of just 1.3%. Performance is slightly better for South and Central America, but still not strong. Against this background, the record of East and Southeast Asia looks all the more remarkable.

[10]These country groupings are not exhaustive; for example Fiji and Papua New Guinea do not appear in any of these groups. Analysis of the group of industrialized countries is subject to the sample selection issue highlighted by DeLong (1988).

In further work (not shown) we have constructed versions of Tables 6 and 7 for 1960-1980 and 1980-2000. These reinforce the patterns already discussed: dispersion of growth rates at all levels of development, major differences across regional groups, and a collapse in growth rates after 1980. Even for the developed countries, growth rates were noticeably lower after 1980 than before, reflecting the well-known productivity slowdown and the reduced potential for catch-up by previously fast-growing countries, such as France, Italy and Japan.

ix. stagnation and output volatility

Some countries did not record fast growth even in the boom of the 1960s. Some have simply stagnated or declined, never sustaining a high or even moderate growth rate for the length of time needed to raise output appreciably. In our sample, there are nine countries that have never exceeded their 1960 level of GDP per worker by more than 30%. Even more striking, a quarter of the countries (26 of 102) never exceeded their 1960 level by more than 60%. To put this in context, a country that grew at an average rate of 2% a year over a forty-year period would see GDP per worker rise by around 120%. Easterly (1994) drew attention to the international prevalence of stagnation, and the failure of some poorer countries to break out of low levels of development.

There are other ways in which the behavior of the poorer countries looks very different to that of rich countries. As emphasized by Pritchett (2000a), it is not uncommon for output to undergo a major collapse in less developed countries (LDCs). To show this, we calculate the largest percentage drop in output over three years recorded for each country, using data from 1960 to the latest available year. The precise statistic we calculate is:

$$100 * \left(1 - \min \left(\frac{Y_{1963}}{Y_{1960}}, \frac{Y_{1964}}{Y_{1961}}, \ldots, \frac{Y_{2000}}{Y_{1997}} \right) \right)$$

The largest ten output falls are shown in Table 8, which shows how dramatic an output collapse can be. Several of these output collapses are associated with periods of

intense civil war, as in the cases of Rwanda, Angola and the Democratic Republic of the Congo. But the phenomenon of output collapse is a great deal more widespread than may be explained by events of this type. Of the 102 countries in our sample, 50 showed at least one three-year output collapse of 15% or more. 65 countries experienced a three-year output collapse of 10% or more. In contrast, between 1960 and 2000, the largest three-year output collapse in the USA was 5.4%, and in the UK 3.6%, both recorded in 1979-82. A corollary of these patterns is that time series modeling of LDC output, whether on a country-by-country basis or using panel data, has to be approached with care. It is not clear that the dynamics of output in the wake of a major collapse would look anything like the dynamics at other times.

Table 8: Output Collapses

Country	Largest 3-year drop	Dates
Chad	50%	1980-83
Rwanda	47%	1991-94
Angola	46%	1973-76
Romania	37%	1977-80
Dem. Rep. Congo	36%	1992-95
Mauritania	34%	1985-88
Tanzania	34%	1987-90
Mali	34%	1985-88
Cameroon	33%	1987-90
Nigeria	32%	1997-00

Notes:
- This table shows the ten countries with the largest output collapses over a three-year period, using data on GDP per worker between 1960 and the latest available year.

We conclude our consideration of stylized facts by briefly reporting some evidence on long-run output volatility. Table 9 reports figures on the standard deviation of annual growth rates between 1960 and 2000. Industrialized countries are relatively stable, while sub-Saharan Africa is by far the most volatile region, followed by South and Central America. Volatility is not uniformly higher in developing countries, however: using the standard deviation of annual growth rates, South Africa is less volatile than the USA, Sri Lanka less volatile than Canada, and Pakistan less volatile than Switzerland.

Table 9: Volatility, 1960-2000, by Regions

Group	N	25th	Median	75th
Sub-Saharan Africa	36	5.5	7.4	9.3
South and Central America	21	3.9	4.8	5.4
East and Southeast Asia	10	3.8	4.1	4.7
South Asia	7	3.0	3.3	5.2
Industrialized countries	19	2.3	2.9	3.5

Notes:

- This table shows the 25th, 50th and 75th percentiles of the distribution of the standard deviation of annual growth rates, using data from the earliest available year until the latest available, between 1960 and 2000.

x. a summary of the stylized facts

The stylized facts we consider can be summarized as follows:

1. Over the forty-year period as a whole, most countries have grown richer, but vast income disparities remain. For all but the richest group, growth rates have differed to an unprecedented extent, regardless of the initial level of development.

2. Although past growth is a surprisingly weak predictor of future growth, it is slowly becoming more accurate over time, and so distinct winners and losers are beginning to emerge. The strongest performers are located in East and Southeast Asia, which have sustained growth rates at unprecedented levels. The weakest performers are predominantly located in sub-Saharan Africa, where some countries have barely grown at all, or even become poorer. The record in South and Central America is also distinctly mixed. In these regions, output volatility is high, and dramatic output collapses are not uncommon.

3. For many countries, growth rates were lower in 1980-2000 than in 1960-1980, and this growth slowdown is observed throughout most of the income distribution. Moreover, the dispersion of growth rates has increased. A more optimistic reading would also

emphasize the growth take-off that has taken place in China and India, home to two-fifths of the world's population and a greater proportion of the world's poor.

Even this brief overview of the stylized facts reveals that there is much of interest to be investigated and understood. The field of growth econometrics has emerged through efforts to interpret and understand these facts in terms of simple statistical models, and in the light of predictions made by particular theoretical structures. In either case, the complexity of the growth process and the paucity of the available data combine to suggest that scientific standards of proof are unattainable. Perhaps the best this literature can hope for is to constrain what can legitimately be claimed.

Researchers such as Levine and Renelt (1991) and Wacziarg (2002) have argued that, seen in this more modest light, growth econometrics can provide a signpost to interesting patterns and partial correlations, and even rule out some versions of the world that might otherwise seem plausible. Seen in terms of establishing stylized facts, empirical studies help to broaden the demands made of future theories, and can act as a discipline on quantitative investigations using calibrated models. In the remainder of this chapter, we will discuss in more detail the uses and limits of statistical evidence. We first examine how empirical growth studies are related to theoretical models, and then return in more depth to the study of convergence.

III. Cross-country growth regressions: from theory to empirics

The stylized facts of economic growth have led to two major themes in the development of formal econometric analyses of growth. The first theme revolves around the question of convergence: are contemporary differences in aggregate economies transient over sufficiently long time horizons? The second theme concerns the identification of growth determinants: which factors seem to explain observed differences in growth? These questions are closely related in that each requires the specification of a statistical model of cross-country growth differences from which the effects on growth of various factors, including initial conditions, may be identified. In this section, we

describe how statistical models of cross-country growth differences have been derived from theoretical growth models.

Section III.i provides a general theoretical framework for understanding growth dynamics. The framework is explicitly neoclassical and represents the basis for most empirical growth work; even those studies that have attempted to produce evidence in favor of endogenous or other alternative growth theories have generally used the neoclassical model as a baseline from which to explore deviations. Section III.ii examines the relationship between this theoretical model of growth dynamics and the specification of a growth regression. This transition from theory to econometrics produces the canonical cross-country growth regression.

i. growth dynamics: basic ideas

For economy *i* at time *t*, let $Y_{i,t}$ denote output, $L_{i,t}$ the labor force assumed to obey $L_{i,t} = L_{i,0}e^{n_i t}$ where the population growth rate n_i is constant, and $A_{i,t}$ the efficiency level of each worker with $A_{i,t} = A_{i,0}e^{g_i t}$ where g_i is the (constant) rate of (labor augmenting) technological progress. We will work with two main per capita notions: output per efficiency unit of labor input, $y^E_{i,t} = \frac{Y_{i,t}}{A_{i,t}L_{i,t}}$ and output per labor unit $y_{i,t} = \frac{Y_{i,t}}{L_{i,t}}$. As is well known, the generic one-sector growth model, in either its Solow-Swan or Ramsey-Cass-Koopmans variant, implies, to a first-order approximation, that

$$\log y^E_{i,t} = \left(1 - e^{-\lambda_i t}\right) \log y^E_{i,\infty} + e^{-\lambda_i t} \log y^E_{i,0} \qquad (1)$$

where $y^E_{i,\infty}$ is the steady-state value of $y^E_{i,t}$ and $\lim_{t\to\infty} y^E_{i,t} = y^E_{i,\infty}$. The parameter λ_i (which must be positive) measures the rate of convergence of $y^E_{i,t}$ to its steady-state value

and depends on the other parameters of the model. Given $\lambda_i > 0$, the value of $y_{i,\infty}^E$ is independent of $y_{i,0}^E$ so that, in this sense, initial conditions do not matter in the long-run.[11]

Eq. (1) expresses growth dynamics in terms of the unobservable $y_{i,t}^E$. In order to describe dynamics in terms of the observable variable $y_{i,t}$ we can write equation (1) as

$$\log y_{i,t} - g_i t - \log A_{i,0} = \left(1 - e^{-\lambda_i t}\right) \log y_{i,\infty}^E + e^{-\lambda_i t} \left(\log y_{i,0} - \log A_{i,0}\right) \tag{2}$$

so that

$$\log y_{i,t} = g_i t + \left(1 - e^{-\lambda_i t}\right) \log y_{i,\infty}^E + \left(1 - e^{-\lambda_i t}\right) \log A_{i,0} + e^{-\lambda_i t} \log y_{i,0} \tag{3}$$

In parallel to equation (1), one can easily see that

$$\lim_{t \to \infty} \left(y_{i,t} - y_{i,\infty}^E A_{i,0} e^{g_i t}\right) = 0 \tag{4}$$

so that the initial value of output per worker has no implications for its long-run value.

This description of the dynamics of output provides the basis for describing the dynamics of growth. Let

$$\gamma_i = t^{-1} \left(\log y_{i,t} - \log y_{i,0}\right) \tag{5}$$

denote the growth rate of output per worker between 0 and *t*. Subtracting $\log y_{i,0}$ from both sides of (3) and dividing by *t* yields

$$\gamma_i = g_i + \beta_i \left(\log y_{i,0} - \log y_{i,\infty}^E - \log A_{i,0}\right) \tag{6}$$

[11]Implicit in our discussion is the assumption that $y_{i,0}^E > 0$ which eliminates the trivial equilibrium $y_{i,t}^E = 0 \ \forall t$.

where

$$\beta_i = -t^{-1}\left(1 - e^{-\lambda_i t}\right) \tag{7}$$

The β_i parameter will prove to play a key role in empirical growth analysis.

Equation (6) thus decomposes the growth rate in country i into two distinct components. The first component, g_i, measures growth due to technological progress, whereas the second component $\beta_i\left(\log y_{i,0} - \log y^E_{i,\infty} - \log A_{i,0}\right)$ measures growth due to the gap between initial output per worker and the steady-state value, both measured in terms of efficiency units of labor. This second source of growth is what is meant by "catching up" in the literature. As $t \to \infty$ the importance of the catch-up term, which reflects the role of initial conditions, diminishes to zero.

Under the additional assumptions that the rates of technological progress, and the λ_i parameters are constant across countries, i.e. $g_i = g$, and $\lambda_i = \lambda \ \forall i$, (6) may be rewritten as

$$\gamma_i = g - \beta \log y^E_{i,\infty} - \beta \log A_{i,0} + \beta \log y_{i,0} \tag{8}$$

The important empirical implication of equation (8) is that, in a cross-section of countries, we should observe a negative relationship between average rates of growth and initial levels of output over any time period – countries that start out below their balanced growth path must grow relatively quickly if they are to catch up with other countries that have the same levels of steady-state output per effective worker and initial efficiency. This is closely related to the hypothesis of conditional convergence, which is often understood to mean that countries converge to parallel growth paths, the levels of which are assumed to be a function of a small set of variables.[12] Note, however, that a negative coefficient on initial income in a cross-country growth regression does not automatically imply conditional convergence in this sense, because countries might instead simply be moving toward their own different steady-state growth paths.

[12]We provide formal definitions of convergence in Section IV.i.

ii. cross-country growth regressions

Equation (8) provides the motivation for the standard cross-country growth regression that is the foundation of the empirical growth literature. Typically, these regression specifications start with (8) and append a random error term υ_i so that

$$\gamma_i = g - \beta \log y_{i,\infty}^E - \beta \log A_{i,0} + \beta \log y_{i,0} + \upsilon_i \tag{9}$$

Implementation of (9) requires the development of empirical analogs for $\log y_{i,\infty}^E$ and $\log A_{i,0}$. Mankiw, Romer, and Weil (1992) in a pioneering analysis, show how to do this in a way that produces a growth regression model that is linear in observable variables. In their analysis, aggregate output is assumed to obey a three-factor Cobb-Douglas production function

$$Y_{i,t} = K_{i,t}^{\alpha} H_{i,t}^{\phi} \left(A_{i,t} L_{i,t} \right)^{1-\alpha-\phi} \tag{10}$$

where $K_{i,t}$ denotes physical capital and $H_{i,t}$ denotes human capital. Physical and human capital are assumed to follow the continuous time accumulation equations

$$\dot{K}_{i,t} = s_{K,i} Y_{i,t} - \delta K_{i,t} \tag{11}$$

and

$$\dot{H}_{i,t} = s_{H,i} Y_{i,t} - \delta H_{i,t} \tag{12}$$

respectively, where δ denotes the depreciation rate, $s_{K,i}$ is the saving rate for physical capital and $s_{H,i}$ is the saving rate for human capital and dots above variables denote time

derivatives. Note that the saving rates are both assumed to be time invariant. These accumulation equations, combined with the parameter constancy assumptions used to justify eq. (8) imply that the steady-state value of output per effective worker is

$$y_{i,\infty}^{E} = \left(\frac{s_{K,i}^{\alpha} s_{H,i}^{\phi}}{\left(n_i + g + \delta\right)^{\alpha+\phi}} \right)^{\frac{1}{1-\alpha-\phi}} \tag{13}$$

producing a cross-country growth regression of the form

$$\gamma_i = g + \beta \log y_{i,0} + \beta \frac{\alpha+\phi}{1-\alpha-\phi} \log\left(n_i + g + \delta\right) - \beta \frac{\alpha}{1-\alpha-\phi} \log s_{K,i} - \beta \frac{\phi}{1-\alpha-\phi} \log s_{H,i} - \beta \log A_{i,0} + \upsilon_i \tag{14}$$

Mankiw, Romer and Weil assume that $A_{i,0}$ is unobservable and that $g + \delta$ is known. These assumptions mean that (14) is linear in the logs of various observable variables and therefore amenable to standard regression analysis.

Mankiw, Romer, and Weil argue that $A_{i,0}$ should be interpreted as reflecting not just technology, which they assume to be constant across countries, but country-specific influences on growth such as resource endowments, climate and institutions. They assume these differences vary randomly in the sense that

$$\log A_{i,0} = \log A + e_i \tag{15}$$

where e_i is a country-specific shock distributed independently of n_i, $s_{K,i}$, and $s_{H,i}$[13]. Substituting this into (14) and defining $\varepsilon_i = \upsilon_i - \beta e_i$, we have the regression relationship

[13]This independence assumption is justified, in turn, on the basis that 1) n_i, $s_{K,i}$, and $s_{H,i}$ are exogenous in the neoclassical model with isoelastic preferences and 2) the estimated parameter values are consistent with those predicted by the model.

$$\gamma_i = g - \beta \log A + \beta \log y_{i,0} + \beta \frac{\alpha+\phi}{1-\alpha-\phi} \log\left(n_i + g + \delta\right) - \beta \frac{\alpha}{1-\alpha-\phi} \log s_{K,i} - \beta \frac{\phi}{1-\alpha-\phi} \log s_{H,i} + \varepsilon_i \quad (16)$$

Using data from a group of 98 countries over the period 1960 to 1985, Mankiw Romer and Weil produce regression estimates of $\hat{\beta} = -.299$, $\hat{\alpha} = .48$ and $\hat{\phi} = .23$.[14] [15] Mankiw, Romer, and Weil are unable to reject the overidentifying restrictions present in (16). While this result is echoed in studies such as Knight, Loayza, and Villenueva (1993), other authors, Caselli, Equivel, and Lefort (1996), for example, are able to reject the restrictions.

Many cross-country regression studies have attempted to extend Mankiw, Romer and Weil by adding additional control variables Z_i to the regression suggested by (16). Relative to Mankiw, Romer and Weil, such studies may be understood as allowing for predictable heterogeneneity in the steady-state growth term g_i and initial technology term $A_{i,0}$ that are assumed constant across *i* in (16). Formally, the $g_i - \beta \log A_{i,0}$ terms in (6) are replaced with $g - \beta \log A + \pi Z_i - \beta e_i$ rather than with $g - \beta \log A - \beta e_i$ which produced (16). (As far as we know, empirical work universally ignores the fact that $\log\left(n_i + g + \delta\right)$ should also be replaced with $\log\left(n_i + g_i + \delta\right)$.) This produces the cross country growth regression

$$\gamma_i = g - \beta \log A + \beta \log y_{i,0} + \beta \frac{\alpha+\phi}{1-\alpha-\phi} \log\left(n_i + g + \delta\right) - \beta \frac{\alpha}{1-\alpha-\phi} \log s_{K,i} - \beta \frac{\phi}{1-\alpha-\phi} \log s_{H,i} + \pi Z_i + \varepsilon_i \quad (17)$$

[14] Based on data from the US and other economies, Mankiw, Romer, and Weil set $g + \delta = .05$ prior to estimation.

[15] Using $\lambda = -t^{-1} \log\left(1 - t\beta\right)$, the implied estimate of λ is .0142. The relationship $\lambda_i = \left(1-\alpha-\phi\right)\left(n_i + g + \delta\right)$ was not imposed by Mankiw, Romer and Weil, who instead treat λ as a constant to be estimated. Durlauf and Johnson (1995, Table II, note b) show that estimating this model when λ varies with *n* in the way implied by the theory produces only very small changes in parameter estimates.

. The regression described by (17) does not identify whether the controls Z_i are correlated with steady-state growth g_i or the initial technology term $A_{i,0}$. For this reason, a believer in a common steady-state growth rate will not be dissuaded by the finding that particular choices of Z_i help predict growth beyond the Solow regressors. Nevertheless, it seems plausible that the controls Z_i may sometimes function as proxies for predicting differences in efficiency growth g_i rather than in the initial technology $A_{i,0}$. As argued in Temple (1999), even if all countries have the same total factor productivity growth (TFP) in the long run, over a twenty- or thirty-year sample the assumption of equal TFP growth is highly implausible, so the variables in Z_i can explain these differences. That being said, the attribution of the predictive content of Z_i to initial technology versus steady state growth will entirely depend on a researcher's prior beliefs. It is possible that proper accounting of the $\log(n_i + g_i + \delta)$ term would allow for some progress in identifying g_i versus $A_{i,0}$ effects since g_i effects would imply a nonlinear relationship between Z_i and overall growth γ_i; however this nonlinearity may be too subtle to uncover given the relatively small data sets available to growth researchers.

The canonical cross-country growth regression may understood as a version of (17) when the cross-coefficient restrictions embedded in (17) are ignored (which is usually the case in empirical work). A generic representation of the regression is

$$\gamma_i = \beta \log y_{i,0} + \psi X_i + \pi Z_i + \varepsilon_i \tag{18}$$

where X_i contains a constant, $\log(n_i + g + \delta)$, $\log s_{K,i}$ and $\log s_{H,i}$. The variables spanned by $\log y_{i,0}$ and X_i thus represent those growth determinants that are suggested by the Solow growth model whereas Z_i represents those growth determinants that lie outside Solow's original theory.[16] The distinction between the Solow variables and Z_i is

[16]We distinguish $\log y_{i,0}$ from the other Solow variables because of the role it plays in analysis of convergence; see Section IV for detailed discussion.

important in understanding the empirical literature. While the Solow variables usually appear in different empirical studies, reflecting the treatment of the Solow model as a baseline for growth analysis, choices concerning which Z_i variables to include vary greatly.

Equation (18) represents the baseline for much of growth econometrics. These regressions are sometimes known as Barro regressions, given Barro's extensive use of such regressions to study alternative growth determinants starting with Barro (1991). This regression model has been the workhorse of empirical growth research.[17] In modern empirical analyses, the equation has been generalized in a number of dimensions. Some of these extensions reflect the application of (18) to time series and panel data settings. Other generalizations have introduced nonlinearities and parameter heterogeneity. We will discuss these variants below.

iii. interpreting errors in growth regressions

Our development of the relationship between cross-country growth regressions and neoclassical growth theories illustrates the standard practice of adding regression errors in an ad hoc fashion. Put differently, researchers usually derive a deterministic growth relationship and append an error in order to capture whatever aspects of the growth process are omitted from the model that has been developed. One problem with this practice is that some types of errors have important implications for the asymptotics of estimators. Binder and Pesaran (1999) conduct an exhaustive study of this question, one important conclusion of which is that if one generalizes the assumption of a constant rate of technical change so that technical change follows a random walk, this induces nonstationarity in many levels series, raising attendant unit root questions.

[17]Such regressions appear to have been employed earlier by Grier and Tullock (1989) and Kormendi and Meguire (1985). The reason these latter two studies seem to have received less attention than warranted by their originality is, we suspect, due to their appearance before endogenous growth theory emerged as a primary area of macroeconomic research, in turn placing great interest on the empirical evaluation of growth theories. To be clear, Barro's development is original to him and his linking of cross-country growth regressions to alternative growth theories was unique.

Beyond issues of asymptotics, the ad hoc treatment of regression errors leaves unanswered the question of what sorts of implicit substantive economic assumptions are made by a researcher who does this. Brock and Durlauf (2001a) address this issue using the concept of exchangeability. Basically, their argument is that in a regression such as (18), a researcher typically thinks of the errors ε_i as interchangeable across observations: different patterns of realized errors are equally likely to occur if the realizations are permuted across countries. In other words, the information available to a researcher about the countries is not informative about the error terms.

Exchangeability is a mathematical formalization of this idea and is defined as follows. For each observation *i*, there exists an associated information set F_i available to the researcher. In the growth context, F_i may include knowledge of a country's history or culture as well as any "economic" variables that are known. A definition of exchangeability (formally, *F*-conditional exchangeability) is

$$\mu\left(\varepsilon_1 = a_1, ..., \varepsilon_N = a_N \left| F_1 ... F_N \right.\right) = \mu\left(\varepsilon_{\rho(1)} = a_1, ..., \varepsilon_{\rho(N)} = a_N \left| F_1 ... F_N \right.\right) \qquad (19)$$

where $\rho(\ )$ is an operator that permutes the *N* indices.

Many criticisms of growth regressions amount to arguments that exchangeability has been violated. For example, omitted regressors induce exchangeability violations as these regressors are elements of F. Parameter heterogeneity also leads to nonexchangeability. For these cases, the failure of nonexchangeability calls into question the interpretation of the regression. This is not always the case; heteroskedasticity in errors violates exchangeability but does not induce interpretation problems for coefficients.

Brock and Durlauf argue that exchangeability produces a link between substantive social science knowledge and error structure, i.e. this knowledge may be used to evaluate the plausibility of exchangeability. They suggest that a good empirical practice would for researchers to question whether the errors in a model are exchangeable, and if not, determine whether the violation invalidates the purposes for which the regression is being used. This cannot be done in an algorithmic fashion, but as is the case with empirical

work quite generally, requires judgments by the analyst. See Draper et al (1993) for further discussion of the role of exchangeability in empirical work.

IV. The convergence hypothesis

Much of the empirical growth literature has focused on the convergence hypothesis. Although questions of convergence predate them, recent widespread interest in the convergence hypothesis originates from Abramovitz (1986) and Baumol (1986). This interest and the availability of the requisite data for a broad cross-section of countries, due to Summers and Heston (1988,1991), spawned an enormous literature testing the convergence hypothesis in one or more of its various guises.[18]

In this section, we explore the convergence hypothesis. In Section IV.i we consider the specification of notions of convergence as related to the relationship between initial conditions and long-run outcomes. Section IV.ii explores the main technique that has been employed in studying long-run dependence, β-convergence. Section IV.iii considers alternative notions of convergence that focus less on the persistence of initial conditions and instead on whether the cross-section dispersion of incomes is decreasing across time. This section explores both σ-convergence and more general notions and recent methods that fall under the heading of distributional dynamics. It also considers how distibutional notions of convergence may be related to definitions found in Section IV.i. Section IV.iv develops time series approaches to convergence. Section IV.v moves beyond the question of whether convergence is present to consider analyses that have attempted to identify the sources of convergence when it appears to be present.

i. **convergence and initial conditions**

The effect of initial conditions on long-run outcomes arguably represents the primary empirical question that has been explored by growth economists. The claim that

[18]See Durlauf (1996) and the subsequent papers in the July 1996 *Economic Journal*, Durlauf and Quah (1999), Islam (2003) and Barro and Sala-i-Martin (2004) for surveys of aspects of the convergence literature.

the effects of initial conditions eventually disappear is the heuristic basis for what is known as the convergence hypothesis. The goal of this literature is to answer two questions concerning per capita income differences across countries (or other economic units, such as regions). First, are the observed cross-country differences in per capita incomes temporary or permanent? Second, if they are permanent, does that permanence reflect structural heterogeneity or the role of initial conditions in determining long-run outcomes? If the differences in per capita incomes are temporary, unconditional convergence (to a common long-run level) is occurring. If the differences are permanent solely because of cross-country structural heterogeneity, conditional convergence is occurring. If initial conditions determine, in part at least, long-run outcomes, and countries with similar initial conditions exhibit similar long-run outcomes, then one can speak of convergence clubs.[19]

We first consider how to formalize the idea that initial conditions matter. While the discussion focuses on $\log y_{i,t}$, the log level of per capita output in country i at time *t*; these definitions can in principle be applied to other variables such as real wages, life expectancy, etc. Our use of $\log y_{i,t}$ rather than $y_{i,t}$ reflects the general interest in the growth literature in relative versus absolute inequality, i.e. one is usually more interested in whether the ratio of income between two countries exhibits persistence than an absolute difference, particularly since sustained economic growth will imply that a constant levels difference is of asymptotically negligible size when relative income is considered.

We associate with $\log y_{i,t}$ initial conditions, $\rho_{i,0}$. These initial conditions do not matter in the long-run if

$$\lim_{t\to\infty} \mu\left(\log y_{i,t} \middle| \rho_{i,0}\right) \textit{does not depend on } \rho_{\mathrm{i},0} \qquad (20)$$

[19]This taxonomy is due to Galor (1996) who discusses the relationship between it and the theoretical growth literature, giving several examples of models in which initial conditions matter for long-run outcomes.

where $\mu(\cdot)$ is a probability measure. To see how this definition connects with empirical growth work, empirical studies of convergence are often focused on whether long-run per capita output depends on initial stocks of human and physical capital.

Economic interest in convergence stems from the question of whether certain initial conditions lead to persistent differences in per capita output between countries (or other economic units). One can thus use (20) to define convergence between two economies. Let $\| \ \|$ denote a metric for computing the distance between probability measures.[20] Then countries *i* and *j* exhibit convergence if

$$\lim_{t\to\infty} \left\| \mu\left(\log y_{i,t} \left| \rho_{i,0}\right.\right) - \mu\left(\log y_{j,t} \left| \rho_{j,0}\right.\right) \right\| = 0 \tag{21}$$

Growth economists are generally interested in average income levels; eq. (21) implies that countries *i* and *j* exhibit convergence in average income levels in the sense that

$$\lim_{t\to\infty} E\left(\log y_{i,t} - \log y_{j,t} \left| \rho_{i,0}, \rho_{j,0}\right.\right) = 0. \tag{22}$$

To the extent one is interested in whether countries exhibit common steady-state growth rates, one can modify (22) to require that the limiting expected difference between $\log y_{i,t}$ and $\log y_{j,t}$ is bounded. One way of doing this is due to Pesaran (2004a) and is discussed below.

These notions of convergence can be relaxed. Bernard and Durlauf (1996) suggest a form of partial convergence that relates to whether contemporaneous income differences are expected to diminish. If $\log y_{i,0} > \log y_{j,0}$, their definition amounts to asking whether

$$E\left(\log y_{i,t} - \log y_{j.t} \left| \rho_{i,0}, \rho_{j,0}\right.\right) < \log y_{i,0} - \log y_{j,0} \tag{23}$$

[20]There is no unique or single generally agreed upon metric for measuring deviations between probability measures.

A number of modifications of these definitions have been proposed. Hall, Robertson, and Wickens (1997) suggest appending a requirement that the variance of output differences diminish to 0 over time, i.e.

$$\lim_{t\to\infty} E\left(\left(\log y_{i,t} - \log y_{j,t}\right)^2 \left| \rho_{i,0}, \rho_{j,0} \right.\right) = 0 \tag{24}$$

so that convergence requires output for a pair of countries to behave similarly in the long-run. In our view, this is an excessively strong requirement since it does not allow one to regard the output series as stochastic in the long-run. Eq. (24) would imply that convergence does not occur if countries are perpetually subjected to distinct business cycle shocks. However, Hall, Robertson and Wickens (1997) do identify a weakness of definition (22), namely the failure to control for long-run deviations whose current direction is not predictable. To see this, suppose that $\log y_{i,t} - \log y_{j,t}$ is a random walk with current value 0. In this case, definition (22) would be fulfilled, although output deviations between countries *i* and *j* will become arbitrarily large at some future date.

In recent work, Pesaran (2004a) has proposed a convergence definition that focuses specifically on the likelihood of large long-run deviations. Specifically, Pesaran defines convergence as

$$\lim_{t\Rightarrow\infty} \text{Prob}\left(\left(\log y_{i,t} - \log y_{j,t}\right)^2 < C^2 \left| \rho_{i,0}, \rho_{j,0} \right.\right) > \pi \tag{25}$$

where *C* denotes a deviation magnitude and π is a tolerance probability. The idea of this definition is to focus convergence analysis on output deviations that are economically important and to allow for some flexibility with respect to the probability with which they occur.

These convergence definitions do not allow for the distinction between the long-run effects of initial conditions and the long-run effects of structural heterogeneity. From the perspective of growth theory, this is a serious limitation. For example, the distinctions between endogenous and neoclassical growth theories focus on the long-run

effects of cross-country differences initial human and physical capital stocks; in contrast, cross-country differences in preferences can have long-term effects under either theory. Hence, in empirical work, it is important to be able to distinguish between initial conditions $\rho_{i,0}$ and structural characteristics $\theta_{i,0}$. Steady state effects of initial conditions imply the existence of convergence clubs whereas steady-state effects of structural characteristics do not. In order to allow for this, one can modify (21) so that

$$\lim_{t\to\infty} \left\| \mu\left(\log y_{i,t} \left| \rho_{i,0}, \theta_{i,0}\right.\right) - \mu\left(\log y_{j,t} \left| \rho_{j,0}, \theta_{j,0}\right.\right) \right\| = 0 \text{ if } \theta_{i,0} = \theta_{j,0} \tag{26}$$

implies that countries *i* and *j* exhibit convergence. The notions of convergence in expected value (eq. (22)) may be modified in this way as well,

$$\lim_{t\to\infty} E\left(\log y_{i,t} - \log y_{j,t} \left| \rho_{i,0}, \theta_{i,0}, \rho_{j,0}, \theta_{j,0}\right.\right) = 0 \text{ if } \theta_{i,0} = \theta_{j,0} \tag{27}$$

as can partial convergence in expected value (eq. (23)) and the other convergence concepts discussed above.

In practice, the distinction between initial conditions and structural heterogeneity generally amounts to treating stocks of initial human and physical capital as the former and other variables as the latter. As such, both the Solow variables *X* and the control variables *Z* that appear in cross-country growth regression cf. (18) are usually interpreted as capturing structural heteogeneity. This practice may be criticized if these variables are themselves endogenously determined by initial conditions, a point that will arise below.

The translation of these ideas into restrictions on growth regressions has led to a range of statistical definitions of convergence which we now examine. Before doing so, we emphasize that none of these statistical definitions is necessarily of intrinsic interest per se; rather each concept is useful only to the extent it elucidates economically interesting notions of convergence such as eq. (20). The failure to distinguish between convergence as an economic concept and convergence as a statistical concept has led to a good deal of confusion in the growth literature.

ii. β-convergence

Statistical analyses of convergence have largely focused on the properties of β in regressions of the form (18). β-convergence, defined as $\beta < 0$ is easy to evaluate because it relies on the properties of a linear regression coefficient. It is also easy to interpret in the context of the Solow growth model, since the finding is consistent with the dynamics of the model. The economic intuition for this is simple. If two countries have common steady-state determinants and are converging to a common balanced growth path, the country that begins with a relatively low level of initial income per capita has a lower capital-labor ratio and hence a higher marginal product of capital; a given rate of investment then translates into relatively fast growth for the poorer country. In turn, β-convergence is commonly interpreted as evidence against endogenous growth models of the type studied by Romer and Lucas, since a number of these models specifically predict that high initial income countries will grow faster than low initial income countries, once differences in saving rates and population growth rates have been accounted for. However, not all endogenous growth models imply an absence of β-convergence and therefore caution must be exercised in drawing inferences about the nature of the growth process from the results of β-convergence tests.[21]

There now exists a large body of studies of β-convergence, studies that are differentiated by country set, time period and choice of control variables. When controls are absent, $\beta < 0$ is known as unconditional β-convergence: conditional β-convergence is said to hold if $\beta < 0$ when controls are present. Interest in unconditional β-convergence, while not predicted by the Solow growth model except when countries have common steady-state output levels, derives from interest in the hypothesis that all countries are converging to the same growth path, which is critical in understanding the

[21]Jones and Manuelli (1990) and Kelly (1992) are early examples of endogenous growth models compatible with β-convergence. Each model produces steady state growth without exogenous technical change yet each implies relatively fast growth for initially capital poor economies.

extent to which current international inequality will persist into the far future.[22] Typically, the unconditional β-convergence hypothesis is supported when applied to data from relatively homogeneous groups of economic units such as the states of the US, the OECD, or the regions of Europe; in contrast there is generally no correlation between initial income and growth for data taken from more heterogeneous groups such as a broad sample of countries of the world.[23]

Many cross-section studies employing the β-convergence approach find estimated convergence rates of about 2% per year.[24] This result is found in data from such diverse entities as the countries of the world (after the addition of conditioning variables), the OECD countries, the US states, the Swedish counties, the Japanese prefectures, the regions of Europe, the Canadian provinces, and the Australian states, among others; it is also found in data sets that range over time periods from the 1860's though the 1990's.[25] Some writings go so far as to give this value a status analogous to a universal constant in physics.[26] In fact, there is some variation in estimated convergence

---

[22]Formally, $\beta-$convergence is an implication of (9) if $\log y_{i,\infty}^{E}$ is assumed constant across countries in addition to the assumption on $\log A_{i,0}$ made in (15).

[23]See Barro and Sala-i-Martin (2004, chapters 11 and 12) for application of β-convergence tests to a variety of data sets. Homogeneity can reflect self-selection as pointed out by DeLong (1988). He argues that Baumol's (1986) conclusion that unconditional β-convergence occurred over 1870-1979 among a set of affluent (in 1979) countries is spurious for this reason.

[24]Panel studies estimates of convergence rates have typically been substantially higher than cross-section estimates. Examples where this is true for regressions that only control for the Solow variables include Islam (1995) and Lee, Pesaran, and Smith (1998). The panel approach has possible interpretation problems which we discuss in Section VI.

[25]For example, Barro and Sala-i-Martin (1991) present results for US states and regions as well as European regions; Barro and Sala-i-Martin (1992) for US states, a group of 98 countries and the OECD; Mankiw, Romer, and Weil (1992) for several large groups of countries; Sala-i-Martin (1996a,b) for US states, Japanese prefectures, European regions, and Canadian provinces; Cashin (1995) for Australian states and New Zealand; Cashin and Sahay (1996) for Indian regions; Persson (1997) for Swedish counties; and, Shioji (2001a) for Japanese prefectures and other geographic units.

[26]An alternative view is expressed by Quah (1996b) who suggests that the 2% finding may be a statistical artifact that arises for reasons unrelated to convergence *per se*. At the most primitive level, like any endogenous variable, the rate of convergence is determined by preferences, technology, and endowments. Operationally, this means that the rate of convergence will depend on model parameters and exogenous variables. For example, as

rates, but the range is relatively small; estimates generally range between 1% and 3%, as noted by Barro and Sala-i-Martin (1992).[27]

Despite the many confirmations of this result now in the literature, the claim of global conditional β-convergence remains controversial; here we review the primary problems with the β-convergence literature.

a. robustness with respect to choice of control variables

In moving from unconditional to conditional β-convergence, complexities arise in terms of the specification of steady-state income. The reason for this is the dependence of the steady-state on Z. Theory is not always a good guide in the choice of elements of *Z*; differences in formulations of equation (18) have led to a "growth regression industry" as researchers have added plausibly relevant variables to the baseline Solow specification. As a result, one can identify variants of (18) where convergence appears to occur as $\hat{\beta} < 0$ as well as variants where divergence occurs, i.e. $\hat{\beta} > 0$.

We discuss issues of uncertainty in the specification of growth regressions below. Here we note here that one class of efforts to address model uncertainty has led to confirmatory evidence of conditional β-convergence. This approach assigns probabilities to alternative formulations of (18) and uses these probabilities to construct statements about β that average across the different models. Doppelhofer, Miller, and

---

stated above, in the augmented Solow model studied by Mankiw, Romer, and Weil (1992), the relationship between the rate of convergence and the parameters of the model is $\lambda_i = (1-\alpha-\phi)(n_i + g + \delta)$. Barro and Sala-i-Martin (2004, p. 111-113) discuss the relationship for the case of the Ramsey-Cass-Koopmans model with an isoelastic utility function and a Cobb-Douglas production function. Given this dependence, the ubiquity of the estimated 2% rate of convergence, taken at face value, appears to suggest a remarkable uniformity of preferences, technologies, and endowments across the economic units studied.

[27]Barro and Sala-i-Martin argue that this variation reflects unobserved heterogeneity in steady-state values with more variation being associated with slower convergence. However, in as much as it is correlated with variables included in the regression equations, unobserved heterogeneity renders the parameter estimators inconsistent, which renders the estimated convergence parameter hard to interpret.

Sala-i-Martin (2004) conclude the posterior probability that initial income is part of the linear growth model is 1.00 with a posterior expected value for β of -0.013; this leads to a point estimate of a convergence rate of 1.3% per annum, which is somewhat lower than the 2% touted in the literature; Fernandez, Ley, and Steel (2001a) also find that the posterior probability that initial income is part of the linear growth model is 1.00, despite using a different set of potential models and different priors on model parameters.[28] We therefore conclude that the evidence for conditional β-convergence appears to be robust with respect to choice of controls.

b. identification and nonlinearity: β – convergence and economic divergence

A second problem with the β-convergence literature is an absence of attention to the relationship between β-convergence and economic convergence as defined by eq. (20) or variations based upon it. Put differently, in the β-convergence literature there is a general failure to develop tests of the convergence hypothesis that discriminate between convergent economic models and a rich enough set of non-converging alternatives.

While $\beta < 0$ is an implication of the Solow growth model and so is an implication of the baseline convergent growth model in the literature, this does not mean that $\beta < 0$ is inconsistent with economically interesting non-converging alternatives. One such example is the model of threshold externalities and growth developed by Azariadis and Drazen (1990). In this model, there is a discontinuity in the aggregate production function for aggregate economies. This discontinuity means that the steady-state behavior of a given economy depends on whether its initial capital stock is above or below this threshold; specifically, this model may exhibit two distinct steady states. (Of course, there can be any number of such thresholds.) An important feature of the Azariadis-Drazen model is that data generated by economies that are described by it can exhibit statistical convergence even when multiple steady states are present.

To illustrate this, we follow an argument in Bernard and Durlauf (1996) based on a simplified growth regression. Suppose that for every country in the sample, the Solow

[28]Fernandez, Ley, and Steel (2001a) do not report a posterior expected value for β.

variables X_i and additional controls Z_i are identical. Suppose as well that there is no technical change or population growth. Following the standard arguments for deriving a cross-country regression specification, the growth regression implied by the Azariadis-Drazen assumption on the aggregate production function is

$$\gamma_i = k + \beta\left(\log y_{i,0} - \log y^*_{l(i)}\right) + \varepsilon_i \tag{28}$$

where $l(i)$ indicates the steady state with which country i is associated and $y^*_{l(i)}$ denotes output per capita in that steady state; all countries associated with the same steady state thus have the same $\log y^*_{l(i)}$ value.

The threshold externality model clearly does not exhibit economic convergence as defined above so long as there are at least two steady states. Yet the data generated by a cross-section of countries exhibiting multiple steady states may exhibit statistical convergence. To see this, notice that for this stylized case, the cross-country growth regression may be written as

$$\gamma_i = k + \beta \log y_{i,0} + \varepsilon_i \tag{29}$$

Since the data under study are generated by (28), this standard regression is misspecified. What happens when (29) is estimated when (28) is the data generating process? Using population moments, the estimated convergence parameter β_{ols} will equal

$$\beta_{ols} = \beta \frac{\operatorname{cov}\left(\left(\log y_{i,0} - \log y^*_{l(i)}\right), \log y_{i,0}\right)}{\operatorname{var}(\log y_{i,0})} = \beta\left(1 - \frac{\operatorname{cov}\left(\log y^*_{l(i)}, \log y_{i,0}\right)}{\operatorname{var}\left(\log y_{i,0}\right)}\right) \tag{30}$$

From the perspective of tests of the convergence hypothesis, the noteworthy feature of (30) is that one cannot determine the sign of β_{ols} a priori as it depends on

$1-\frac{\text{cov}\left(\log y^{*}_{l(i)},\log y_{i,0}\right)}{\text{var}\left(\log y_{i,0}\right)}$, which is a function of the covariance between the initial and steady-state incomes of the countries in the sample. It is easy to see that it is possible for β_{ols} to be negative even when the sample includes countries associated with different steady states. Roughly speaking, one would expect $\beta_{ols}<0$ if low-income countries tend to initially be below their steady states whereas high-income countries tend to start above their steady states. While we do not claim this is necessarily the case empirically, the example does illustrate how statistical convergence (defined as $\beta<0$) may be consistent with economic nonconvergence. Interestingly, it is even possible for the estimated convergence parameter β_{ols} to be smaller (and hence imply more rapid convergence) than the structural parameter β in (28).

Below, we review evidence of multiple steady states in the growth process. At this stage, we would note two things. First, some studies have produced evidence of multiple regimes in the sense that statistical models consistent with multiple steady states appear to better fit the cross-country data than the linear Solow model, e.g. Durlauf and Johnson (1995). Second, other studies have produced evidence of parameter heterogeneity such that β appears to depend nonlinearly on initial conditions so that it is equal to 0 for some countries; Liu and Stengos (1999) find precisely this when they reject the specification of constant β for all countries in favor of a specification in which β depends on initial income. These types of findings imply the compatibility of observed growth patterns with the existence of permanent income differences between economies with identical population growth and savings rates and access to identical technologies.

c. endogeneity

A third criticism that is sometimes made of the empirical convergence literature is based on the failure to account for the endogeneity of the explanatory regressors in growth regressions. One obvious reason why endogeneity may matter concerns the consistency of the regression estimates. This concern has led some authors to propose instrumental variables approaches to estimating β. Barro and Lee (1994) analyze

growth data in the periods 1965 to 1975 and 1975 to 1985 and use 5-year lagged explanatory variables as instruments. Barro and Lee find that the use of instrumental variables has little effect on coefficient estimates. Caselli, Esquivel, and Lefort (1996) employ a generalized method of moments (GMM) estimator to analyze a panel variant of the standard cross-country growth regression; growth in the panel is measured in 5-year intervals for 1960-1985. Their analysis produces estimates of β on the order of 10%, which is much larger than the 2% typically found.

Endogeneity raises a second identification issue with respect to the relationship between β-convergence and economic convergence: this idea appears in Cohen (1996) and Goetz and Hu (1996). Focusing on the Solow regressors, the value of β can fail to illustrate how initial conditions affect expected future income differences if the population and saving rates are themselves functions of income. Hence, $\beta \geq 0$ may be compatible with at least partial economic convergence, if the physical and human capital savings rates depend, for example, on the level of income. In contrast, $\beta < 0$ may be compatible with economic divergence if the physical and human capital accumulation rates for rich and poor are diverging across time. As such, this critique is probably best understood as a debate over what variables are the relevant initial conditions for evaluating (22) and/or (23). Cohen (1996) argues that the conventional human capital accumulation equation, in which accumulation is proportional to per capita output, is misspecified, failing to account for feedbacks from the stock of human capital to the accumulation process. This feedback means that poor countries with low initial stocks of human capital fail to accumulate human capital as quickly as richer ones. Goetz and Hu (1996) directly focus on the feedback from income to human capital accumulation.

The implications of this form of endogeneity for empirical work on convergence are mixed. Cohen (1996) concludes that a proper accounting for the dependence of human capital accumulation on initial capital stocks reconciles conditional β – convergence with unconditional β – divergence for a broad cross-section. Goetz and Hu (1996), in contrast, find that estimates of the speed of convergence are increased if one accounts for the effect of income on human capital accumulation for counties in the US South. This seems to be an area that warrants much more work.

d. measurement error

As Abramovitz (1986), Baumol (1986), DeLong (1988), Romer (1990), and Temple (1998) point out, measurement errors will tend to bias regression tests towards results consistent with the hypothesis of β-convergence. This occurs because, by construction, $\gamma_{i,t}$ is measured with positive (negative) error when $\log y_{i,0}$ is measured with negative (positive) error so there tends to be a negative correlation between the measured values of the two variables even if there is none between the true values. To see this, we ignore the issue of control variables and consider the case where growth is described by $\gamma_i = k + \beta \log y_{i,0} + \varepsilon_i$ where ε_i is independent across observations. Suppose that log output is measured with error so that the researcher only observes $\varsigma_{i,t} = \log y_{i,t} + e_{i,t}$, $t = 0, T$ where $e_{i,t}$ is a serially uncorrelated random variable with variance σ_e^2 and distributed independently of $\log y_{i,s}$ and ε_i for all *i* and *s*. The regression of observed growth rates will, under these assumptions, obey the equation

$$T^{-1}\left(\varsigma_{i,T} - \varsigma_{i,0}\right) = k + \beta\varsigma_{i,0} + T^{-1}e_{i,T} - \left(\frac{\beta T + 1}{T}\right)e_{i,0} + \varepsilon_i \qquad (31)$$

This is a classic errors in variables problem; the term $\left(\frac{\beta T + 1}{T}\right)e_{i,0}$ is negatively correlated with $\varsigma_{i,0}$ which induces a negative bias in the estimate $\hat{\beta}$. In other words, the regression of observed growth rates on observed initial incomes will tend to produce an estimated coefficient that is consistent with the β-convergence hypothesis even if the hypothesis is not reflected in the actual behavior of growth rates across countries. In practice, as Temple (1998) explains, the direction of the bias is made ambiguous by the possibilities that the $e_{i,t}$ are serially dependent and that other right-hand-side (conditioning) variables are also measured with error. The actual effect of measurement error on results then becomes an empirical matter to be investigated by individual researchers.

In studying the role of the level of human capital in determining the rate of growth, Romer (1990) estimates a growth equation that has among its explanatory variables the level of per capita income at the beginning of the sample period. Consistent with the conditional β-convergence hypothesis, he finds a negative and significant coefficient on this variable when the equation is estimated by ordinary least squares. Wary of the possibility and effects of measurement error in initial income, as well as in the human capital variable – the literacy rate – Romer also estimates the equation using the number of radios per 1000 inhabitants and (the log of) per capita newsprint consumption as instruments for initial income and literacy with the result that the coefficients on both variables become insignificant "suggesting" that the OLS results are "attributable to measurement error" (p. 278).

Temple (1998) uses the measurement error diagnostics developed by Klepper and Leamer (1984), Klepper (1988), and classical method-of-moments adjustments, to investigate the effects of measurement error on the estimated rate of convergence in MRW's augmented Solow model. He finds that allowing for the possibility of small amounts of unreliability in the measurement of initial income implies a lower bound on the estimated convergence rate just above zero – too low to elevate conditional convergence to the status of a stylized fact. Barro and Sala-i-Martin (2004, pp. 472-3) use lagged values of state personal income as instruments for initial income to check for the possible effects of measurement error in their β-convergence tests for the US states. They find little change in the estimated convergence rates and conclude that measurement error is not an important determinant of their results. Barro (1991) follows the same procedure for other data sets and reaches a similar conclusion about the unimportance of measurement error in his results.

Some authors have attempted to address the sources of measurement error. Dowrick and Quiggin (1997) is a notable example in this regard in their consideration of the role of price indices in affecting convergence tests. Specifically, they examine the effect of constant price estimates of GDP on β-convergence calculations and find that when the prices used to construct these measures are based on prices in advanced economies, tendencies towards convergence are understated.

e. effects of linear approximation

There is a body of research that explores the effects of the approximations that are employed to produce the linear regression models used to evaluate β-convergence. As outlined earlier, regression tests of the β-convergence hypothesis rely on a log-linear approximation to the law of motion in a one sector neoclassical growth model. In addition to the possibility that Taylor series approximations in the nonstochastic version of the model are inadequate, Binder and Pesaran (1999) show that the standard practice of adding a random term to the log-linearized solution of a nonstochastic growth model does not necessarily produce the same behavior as associated with the explicit solution of a stochastic model.

Efforts to explore the limits of the linear approximation used in empirical growth studies have generally concluded that the approximation is reasonably accurate. Romer (2001, p. 25 n. 18) claims that the approximation will be "quite reliable" in this context and Dowrick (2004) presents results showing that the approximation to the true transition dynamics is quite good in a Solow model with a single capital good and an elasticity of output with respect to capital of $2/3$. This is larger than the typical physical capital share but it is not an unreasonable number for the sum of the shares of physical and human capital. To test for nonlinearity, Barro (1991) adds the square of initial (1960) income to one of his regressions and finds a positive estimated coefficient implying that the rate of convergence declines as income rises and that it is positive only for incomes below $10800 – a figure that exceeds all of the 1960 income levels in his sample. However, the t-ratio for the estimated coefficient on the square of initial income is just 1.4 which represents weak evidence against the adequacy of the approximation.

How should one interpret such findings? At one level, these studies conclude that the approximation used to derive the equation used in cross-section convergence studies appears to be reasonably accurate. It follows that the previously discussed nonlinearities in the growth process found by researchers investigating the possibility of multiple steady states do not reflect the inadequacy of the linear approximation used in most cross-section studies. Put differently, evidence of nonlinearity appears to reflect deeper factors than simple approximation error from the use of a first order Taylor series expansion.

iii. Distributional approaches to convergence

A second approach to convergence focuses on the behavior of the cross-section distribution of income in levels. Unlike the β-convergnece approach, the focus of this literature has been less on the question of relative locations within the income distribution, i.e. whether one can expect currently poor countries to either equal or exceed currently affluent countries, but rather on the shape of the distribution as a whole. Questions of this type naturally arise in microeconomic analyses of income inequality, in which one may be concerned with whether the gap between rich and poor is diminishing, regardless of whether the relative positions of individuals are fixed over time.

a. σ-convergence

Much of the empirical literature on the cross-country income distribution has focused on the question of the evolution of the cross-section variance of $\log y_{i,t}$. For a set of income levels let $\sigma^2_{\log y,t}$ denote the variance across i of $\log y_{i,t}$. σ-convergence is said to hold between times t and $t+T$ if

$$\sigma^2_{\log y,t} - \sigma^2_{\log y,t+T} > 0 \tag{32}$$

This definition is designed, like β-convergence, to formalize the idea that contemporary income differences are transitory, but does so by asking whether the dispersion of these differences will decline across time.

Recent work has attempted to identify regression specifications from which one can infer σ-convergence. Friedman (1992) and Cannon and Duck (2000) argue that it is possible to produce evidence concerning σ-convergence from regressions of the form

$$\gamma_i = T^{-1}\left(\log y_{i,t+T} - \log y_{i,t}\right) = \alpha + \pi \log y_{i,t+T} + \varepsilon_i \tag{33}$$

To see why this is so, following Cannon and Duck (2000), observe that $\sigma-$ convergence requires that $\sigma_{\log y_{i,t},\log y_{i,t+T}} < \sigma^2_{\log y_{i,t}}$. The regression coefficient in (33) may be written as

$$\pi = T^{-1}\left(1-\frac{\sigma_{\log y_{i,t},\log y_{i,t+T}}}{\sigma^2_{\log y_{i,t+T}}}\right) \tag{34}$$

which means that $\pi < 0$ implies $\sigma_{\log y_{i,t},\log y_{i,t+T}} < \sigma^2_{\log y_{i,t}}$. Postiveness definiteness of the variance/ covariance matrix for $\log y_{i,t}$ and $\log y_{i,t+T}$ requires that $\left(\sigma_{\log y_{i,t},\log y_{i,t+T}}\right)^2 < \sigma^2_{\log y_{i,t}}\sigma^2_{\log y_{i,t}}$ Therefore, if $\pi < 0$, then it must be the case that (32) holds. Hence a test that accepts null hypothesis that $\pi < 0$ by implication accepts the null hypothesis of σ-convergence. But even this type of test has some difficulties. As pointed out by Bliss (1999,2000), it is difficult to interpret tests of σ-convergence since these tests presume that the data generating process is not invariant; an evolving distribution for the data makes it difficult to think about test distributions under a null. Additional issues arise when unit roots are present.

One limitation to this approach is that it is not clear how one can formulate a sensible notion of conditional σ-convergence. A particular problem in this regard is that one would not want to control for initial income in forming residuals, which would render the concept uninteresting as it could be generated by nothing more than time-dependent heteroskedasticity in the residuals. On the other hand, omitting income would render the interpretation of the projection residuals problematic since initial income is almost certain to be correlated with the variables that have been included when the residuals are formed. An economically interesting formulation of conditional σ-convergence would be a useful contribution.

b. evolution of the world income distribution

Work on σ-convergence has helped stimulate the more general study of the evolution of the world income distribution. This work involves examining the cross-

section distribution of country incomes at two or more points in time in order to identify how this cross-section distribution has changed. Of particular interest in such studies is the presence or emergence of multiple modes in the distribution. Bianchi (1997) uses nonparametric methods to estimate the shape of the cross-country income distribution and to test for multiple modes in the estimated density. He finds evidence of two modes in densities estimated for 1970, 1980, and 1989. Moreover, he finds a tendency for the modes to become more pronounced and to move further apart over time. This evidence supports the ideas of a vanishing middle as the distribution becomes increasingly polarized into "rich" and "poor" and of a growing disparity between those two groups. While such polarization might be desirable, were it the case that middle income economies were becoming high income ones, Bianchi's evidence suggests that much of this movement represents a transition from middle income to poor. Further, by "cutting" each of the estimated densities at the anti-mode between the two modes, Bianchi is able to measure mobility within the distribution by counting the crossings of the cut points. These crossings represent countries moving from one basin of attraction to the other. Just 3 of the possible 238 crossings are observed.[29] The implication is that there is very little mobility within the cross-country income distribution. The 20 or so countries in the "rich" basin of attraction in 1970 are still there in 1989 and similarly for the 100 or so countries starting in the "poor" basin.

Paap and van Dijk (1998) model the cross-country distribution of per capita income as the mixture of a Weibull and a truncated normal density. The Weibull portion captures the left-hand mode and right skewness in the data while the truncated normal portion captures the right-hand mode. This combination is selected after testing the goodness of fit of various combinations of the normal density (truncated at zero), gamma, log normal and Weibull distributions; the data set that is employed measures levels of real GDP per capita for 120 countries for the time period 1960 and 1989. They find a bimodal fitted density in each year with "poor" and "rich" components corresponding to the Weibull and truncated normal densities respectively. The computed means of these

[29]Bianchi's data contains 119 countries observed at 3 distinct years, so each country is capable of making two crossings. The only crossings observed are 1) Trinidad and Tobago, which moves down between 1980 and 1989, 2) Venezuela, which moves down between 1970 and 1980, and 3) Hong Kong, which moves up between 1970 and 1980.

components diverge over the sample period and the weight given to the poor component in the mixture jumps in the mid-1970's from about .72 to about .82 implying that the mean gap between rich and poor countries grew and the poor increased in number. The attention to levels rather than log levels makes it hard to evaluate the welfare significance of this increased dispersion.

Recently, analyses of the distributions of income and growth have focused on identifying differences in these distributions across time and across subsets of countries. Anderson (2003) studies changes in the world income distribution by using nonparametric density function estimates combined with stochastic dominance arguments to compare the distributions at different points in time.[30] These methods allow him to construct measures of polarization of the income distribution; polarization is essentially characterized by shifts in probability density mass that increase disparities between relatively rich and relatively poor economies. Anderson finds that between 1970 and 1995 polarization between rich and poor countries increased throughout the time period. Maasoumi, Racine, and Stengos (2003) analyze the evolution of the cross-country distributions of realized, predicted, and residual growth rates; fitted growth rates and residuals are formed from nonparametric growth regressions using the Solow variables. These authors find that the distributions of growth rates for OECD and non-OECD countries are persistently different between 1965 and 1995, with the OECD distribution's variance reducing over time whereas the non-OECD distribution appears to be becoming less concentrated. One finds the same results for fitted growth rates; in contrast it is difficult to identify dimensions along which the distributions of OECD and non-OECD growth rate residuals differ. The major methodological difference between these papers relative to Paap and van Dijk (1998) is that these analyses do not rely on a mixture specification.

Distributional approaches suggest the utility of convergence measures that are based on the complete properties of probability measures characterizing output for different economies. Letting $\mu_i(x)$ and $\mu_j(x)$ denote the probability density functions

[30]Anderson (2004) discusses issues related to the interpretation and econometric implementation of these methods.

for the variable of interest in economies i and j respectively, Anderson and Ge (2004) propose computing the convergence statistic $CI_{i,j}$

$$CI_{i,j} = \int_{-\infty}^{\infty} \min\left(\mu_i(x), \mu_j(x)\right) dx \tag{35}$$

This statistic is bounded between 0 and 1; a value of zero means that the density functions never assign positive probability to any common intervals or values of x whereas a value of 1 means that the densities coincide on all positive probability intervals or values. Anderson and Ge (2004) refer to the case $CI_{i,j} = 1$ as complete convergence. This statistic differs from the convergence measure described by eq. (21) as it evaluates differences between current densities and not asymptotic ones, but they are clearly closely related.

In our view, this approach will likely prove useful in a range of contexts. In particular, if one is interested in comparing income distributions between two economies, the Anderson-Ge statistic is a natural metric. In growth contexts, it is less clear whether the higher moments that distinguish (22) from (35) are of major concern, at least in the context of current debates.

d. distribution dynamics

In a series of papers, Quah (1993a,b,1996a,b,c,1997) has persuasively criticized standard regression approaches to studying convergence issues for being unable to shed light on important issues of mobility, stratification, and polarization in the world income distribution. Rather than studying the average behavior of a representative country, Quah proposes a schema, which he calls "distribution dynamics", for studying the evolution of the entire cross-country income distribution. One way of implementing this approach is to assume that the process describing the evolution of the distribution is time-invariant and first-order Markov. Discretizing the state space then permits representation of cross-country income distribution as a probability mass function, λ_t, with an associated transition matrix, M. Each row of M is a probability mass function describing the

distribution over states of the system after one transition given that the system is currently in the state corresponding to that row. The evolution of the income distribution can then be described by $\lambda_t = M'\lambda_{t-1}$ so that $\lambda_{t+s} = (M^s)'\lambda_t$ is the *s*-step-ahead probability mass function and $\lambda_\infty = M'\lambda_\infty$ defines the long-run (ergodic) mass function (if it exists). Quah (1993b, 1996b) takes this approach and finds that the estimated *M* implies a bimodal ("twin-peaked") ergodic mass function indicating a tendency towards polarization in the evolution of the world income distribution.[31]

Updating Quah's analysis using more recent data, Kremer, Onatski, and Stock (2001) also find evidence of twin-peaks in the long-run distribution of per capita incomes. However, they find the rich (right-hand) peak to be much larger than the poor (left-hand) peak unlike Quah, who found similarly sized peaks at both ends of the distribution. Kremer, Onatski, and Stock's point estimates imply that most countries will ultimately move to the rich state although, during the transition period, which could last hundreds of years, polarization in the income distribution may worsen. They are also unable to reject the hypothesis that there is a single right-hand peak in the long-run distribution. Quah (2001) responds to these claims by arguing that the imprecision in the estimates of the ergodic distributions is such that it is not possible to reject a wide range of null hypotheses including, by construction, that of twin-peakedness. Importantly, as Quah notes his work and that of others, including Kremer, Onatski, and Stock, is consistent with the view that the global poor are many in number and likely to be so for a very long time.

In addition, as Quah (1996c,1997,2001) and Bulli (2001) discuss, the process of discretizing the state space of a continuous variable is necessarily arbitrary and can alter the probabilistic properties of the data. Especially relevant here is the fact that the shape of the ergodic distribution can be altered by changing the discretization scheme. Reichlin (1999) demonstrates that the dynamic behavior inferred from the analysis of Markov transition probabilities, and the apparent long-run implications of that behavior, are

[31]As Quah (1993b, footnote 4) explains, the estimated ergodic distributions "… should *not* be read as forecasts of what will happen in the future…" (his emphasis). Rather, he continues, they "… should be interpreted simply as characterizations of tendencies in the post-War history that actually realized."

sensitive to the discretization scheme employed; this work also shows that the estimated ergodic distribution can be sensitive to small changes in the transition probabilities. Bulli (2001) addresses this critique and shows how to discretize the state space in a way that preserves the probabilistic properties of the data. Applying her method to cross-country income data she finds an estimated ergodic distribution quite different from that found by arbitrary discretization as well as being an accurate approximation to the distribution computed using a continuous state space method.

An alternative formulation of distribution dynamics that avoids discretization problems is proposed by Quah (1996c,1997) and models the cross-country income distribution at time *t* with the density function, $f_t(x)$. If the process describing the evolution of the distribution is again assumed to be time-invariant and first-order Markov, then density at time $t+\tau$, $\tau > 0$, will be $f_{t+\tau}(x) = \int_0^\infty g_\tau(x|z) f_t(z)\, dz$ where $g_\tau(x|z)$ is the τ-period-ahead density of *x* conditional on *z*. The function $g_\tau(x|z)$ is the continuous analog of the transition matrix *M* and, assuming it exists, the ergodic (long-run) density function, $f_\infty(x)$, implied by $g_\tau(x|z)$ is the solution to $f_\infty(x) = \int_0^\infty g_\tau(x|z) f_\infty(z)\, dz$. Using nonparametric methods, Quah (1996c,1997) estimates various $g_\tau(x|z)$ and finds strong evidence of twin-peakedness in the cross-country income distribution. The estimated ergodic densities presented by Bulli (2001) and Johnson (2004) support Quah's conclusions.

Azariadis and Stachurski (2003) derive the form of the $g_\tau(x|z)$ implied by a stochastic version of the model in Azariadis and Drazen (1990). Estimation of the model's parameters enables them to compute forward projections of the sequence of cross-country income distributions, and ultimately the ergodic distribution, implied by the model. Consistent with the work of Quah (1996c, 1997) they find bimodality to be a pervasive feature of the sequence of distributions for about 100 years. Eventually, however, all countries transition to the rich mode so the ergodic distribution is unimodal as found by Kremer, Onatski, and Stock (2001). As Quah (2001) notes, there is "as yet" no theory of inference for this case so reconciliation of this result with the view that the

ergodic distribution is bimodal cannot be done through formal statistical tests. However, while Quah (2001) observes that such a theory is an "obvious next step," he suggests that we may be close to the limits of what can be reasonably inferred from the cross-country income data.

Johnson (2000) offers an interpretation of $g_\tau(x|z)$ which draws an analogy between the median of the conditional distribution and the law of motion of a non-stochastic one-variable dynamic system. The median is the function $m(x)$ such that $\int_0^{m(x)} g_\tau(z|x)dz = .5$ so that a country with income of $m(x)$ at time *t* has an equal chance of having a higher or lower income at time $t+\tau$. Consider a point x_0 such that $m(x_0) = x_0$ and suppose that, in some neighborhood of x_0, $m(x) > x$ for $x < x_0$ and $m(x) < x$ for $x > x_0$ implying $\Pr(x_{t+\tau} > x_t) > .5$ for $x < x_0$ and $\Pr(x_{t+\tau} < x_t) > .5$ for $x > x_0$ so that, in this neighborhood, countries with incomes different from x_0 tend to move toward x_0. In the long run we may expect to find many countries in the vicinity of x_0 creating the tendency for a mode in the ergodic density, $f_\infty(x)$, at x_0. Similarly, in a non-stochastic one-variable dynamic system with the law of motion $x_{t+\tau} = m(x_t)$, the condition on the phase diagram for the local stability of a steady-state at x_0 is that the graph of $m(x)$ intersects the 45° line from above at x_0. In both cases, x_0 is a point of accumulation in the sense that the long-run probability of finding countries in the vicinity of x_0 will tend to be high relative to that elsewhere. Conversely, just as steady states are unstable in the non-stochastic case when $m(x)$ crosses the 45° line from below, analogous points in the stochastic case tend to produce antimodes in the ergodic density.

While Quah's estimated $g_\tau(x|z)$ indicate a strong tendency towards polarization in the world income distribution, they do not reveal much about intra-distribution mobility. Bimodality is arguably of less concern in a normative sense if there is movement between the two modes than it is if there is none. Quah (1996c) studies the mobility within the distribution by computing, (through stochastic simulation) the mean

time for a "growth miracle" which he defines as passage from the 10th to 90th percentile of the distribution. He finds an expected time of 201 years for such a miracle to occur.

Quah's methods have subsequently been applied to a range of contexts. Andres and Lamo (1995) apply these methods to the OECD, Lamo (2000) to the regions of Spain, Johnson (2000) to US states, Bandyopadhyay (2002) to the Indian states, and Andrade, Laurini, Madalozzo, and Valls Pereira (2004) to Brazilian municipalities. These methods have also been extended to broader notions of distributional dynamics. Fiaschi and Lavezzi (2004) develop an analysis of the joint distribution of income levels and growth rates; their findings are compatible with the existence of multiple equilibria in the sense that countries may become trapped in the lower part of the income distribution.

e. relationship between distributional convergence and the persistence of initial conditions

Distributional methods have proven important in establishing stylized facts concerning the world income distribution. At the same time, there has been relatively little formal effort to explore the implications of findings such as twin peaks for the empirical salience of alternative growth theories. Some potential implications of distributional dynamics for evaluating theories are suggested by Quah (1996c), who finds that conditioning on measures of physical and human capital accumulation similar to those used by Mankiw, Romer, and Weil (1992) and a dummy variable for the African continent has little effect on the dynamics of the cross-country income distribution. The polarization and immobility features are similar in both cases and conditioning increases the expected time for a growth miracle to 760 years.[32] These results suggest that the heterogeneity revealed by the distributional approaches is, at least in part, due to the existence of convergence clubs.

[32]Other efforts to find determinants of polarization and immobility have produced mixed results. For the OECD countries, Andres and Lamo (1995) condition on the steady state implied by the Solow model and find little decrease in the tendency to polarization unless country specific effects are permitted. Lamo (2000) finds only a small increase in mobility for Spanish regions after conditioning on interregional migration flows. Bandyopadhyay (2002) shows that infrastructure spending and education measures appear to contribute to polarization between rich and poor states of India.

That being said, in general, it is relatively difficult to interpret properties of the cross-country income distribution in the context of economic convergence in the sense of (22). To see why this is so, it is useful to focus on the absence of a clear relationship between β-convergence, which measures the relative growth of rich versus poor countries and σ-convegence, which focuses explicitly on the distribution of countries. These two convergence notions do not have any necessary implications for one another, i.e. one may hold when the other does not. For our purposes, what is important is that σ-convergence is not an implication of β-convergence and so does not speak directly to the question of the transience of contemporary income differences. The erroneous assertion that β-convergence implies σ-convergence is known as Galton's fallacy and was introduced into the modern economic growth context by Friedman (1992) and Quah (1993a).

To understand the fallacy, suppose that log per capita output in each of *N* countries obeys the AR(1) process

$$\log y_{i,t} = \alpha + \varsigma \log y_{i,t-1} + \varepsilon_{i,t} \tag{36}$$

where $0 < \varsigma < 1$ and the random variables $\varepsilon_{i,t}$ are i.i.d across countries and time. For this model, each country will, by definition (22), exhibit convergence as any contemporaneous difference in output between two countries will disappear over time. Further, it is easy to see, using $\gamma_i = T^{-1}\left(\log y_{i,t+T} - \log y_{i,t}\right)$, that the regression of growth on a constant and initial income will exhibit β-convergence. This is immediate when one considers growth between t and $t+1$ which means that growth obeys

$$\gamma_{i,t} = \alpha + \left(\varsigma - 1\right)\log y_{i,t-1} + \varepsilon_{i,t} \tag{37}$$

where $\varsigma - 1 < 0$ by assumption. In this model, by construction, the unconditional population variance of log output is constant because the reduction in cross-section variance associated with the tendency of high-income countries to grow more slowly than low-income countries is offset by the presence of the random shocks $\varepsilon_{i,t}$. This indicates

why σ-convergence is not a natural implication of long run independence from initial conditions; rather σ-convergence captures the evolution of the cross-section income distribution towards an invariant measure. This suggests that an important next step in the distributional approach to convergence is the development of tools which will allow distribution methods to more directly adjudicate substantive growth questions as they relate to the persistence of initial conditions.

iv. time series approaches to convergence

A final approach to convergence is based on time series methods. This approach is largely statistical in nature, which allows various hypotheses about convergence to be precisely defined, and thereby reveals appropriate strategies for formal testing. A disadvantage of the approach is that it is not explicitly tied to particular growth theories. Bernard and Durlauf (1995,1996), Evans (1998) and Hobijn and Franses (2000) provide a systematic framework for time series convergence tests.

Following Bernard and Durlauf (1995), a set of countries I is said to exhibit convergence if

$$\lim_{T\to\infty} \text{Proj}\left(\log y_{i,t+T} - \log y_{j,t+T} \,|F_t\right) = 0 \;\forall i, j \in I \tag{38}$$

where $\text{Proj}\left(a|b\right)$ denotes the projection of a on b and F_t denotes some information set; operationally, this information set will typically contain various functions of time and current and lagged values of $\log y_{i,t}$ and $\log y_{j,t}$. Relative to our previous discussion, this definition represents a form of unconditional convergence that is closely related to (22). One can modify the definition to apply to the residual of per capita income after it has been projected on control variables such as savings rates in order to produce a definition of conditional convergence, but this has apparently not been done in the empirical literature.

In evaluating (38), researchers have generally focused on whether deterministic or stochastic trends are present in $\log y_{i,t} - \log y_{j,t}$; the presence of such trends immediately

implies a violation of (38). As such, time series tests of convergence have typically been implemented using unit root tests. One reason for this focus is that the presence of unit roots in $\log y_{i,t} - \log y_{j,t}$ allows for an extreme and therefore particularly interesting form of divergence between economies since a unit root implies that the difference $\log y_{i,t} - \log y_{j,t}$ will, with probability 1, become arbitrarily large at some point in the future.

The use of unit root and related time series tests has important implications for the sorts of countries that may be tested. Time series tests presuppose that $y_{i,t}$ may be thought of as generated by an invariant process in either levels or first differences, i.e., either levels or first differences may be modeled as the sum of deterministic terms plus a Wold representation for innovations. Such an assumption has significant economic content. As argued by Bernard and Durlauf (1996) countries that start far from their invariant distributions and are converging towards them, as occurs for countries that are in transition to the steady-state in the Solow-Swan model, will be associated with $\log y_{i,t} - \log y_{j,t}$ series that do not fulfill this requirement. Hence, tests of (38) can produce erroneous results if applied to such economies. To see this intuitively, suppose that for country *i*, $\log y_{i,t} = \log y_{i,t+1}$ for all *t*, so that country has converged to a constant steady-state. Suppose that country *j* has the same steady-state as country *i* and is monotonically converging to this state so that $\log y_{i,t} > \log y_{j,t}$ for all observations. Then $\log y_{i,t} - \log y_{j,t} > 0$ for all *t* in the sample; which means that the series has a nonzero mean and tests that fail to account for the fact that the density of $\log y_{i,t} - \log y_{j,t}$ is changing across time can easily give erroneous inferences. For example one may use a test and conclude $\log y_{i,t} - \log y_{j,t}$ possesses a nonzero mean and erroneously interpret this as evidence against convergence, when the fact that the process does not have a time-invariant mean is ignored. This argument suggests that time series convergence tests are really only appropriate for advanced economies that may plausibly be thought of as characterized by invariant distributions.

Generally, the first generation of these tests rejected convergence for countries as well as other economic units. For example, Bernard and Durlauf (1995), studying 15

advanced industrialized economies between 1900 and 1989 based on data developed in Maddison (1982,1989), find little evidence that convergence is occurring; Hobijn and Franses (2000) similarly find little evidence of convergence across 112 countries taken from the Penn World Table for the period 1960-1989. The findings of nonconvergence in output levels are echoed in recent work by Pesaran (2004a) who employs convergence definitions that explicitly focus on the probability of large deviations, i.e. eq. (25). He finds little evidence of output level convergence using either the Maddison or Penn World Table data.

Relatively little explicit attention has been paid to the question of systematically identifying convergence clubs using time series methods. One exception is Hobijn and Franses (2000) who employ a clustering algorithm to identify groups of converging countries.[33] Their algorithm finds many small clusters in their sample of 112 countries – depending on the particular rule used to determine cluster membership, they find 42 or 63 clusters with most containing just two or three countries. Hobijin and Frances view these clusters as convergence clubs but it is not clear that they represent groups of countries in distinct basins of attraction of the growth process. Absent controls for structural characteristics, these groupings could simply reflect the pattern of differences in those characteristics rather than differences in long-run outcomes due to differences in initial conditions. Moreover, the Bernard and Durlauf (1996) argument about the substantive economic assumptions that underlie time series methods for studying convergence seems applicable here. Given the breadth of the sample used by Hobijn and Franses, it is unlikely that it contains only data generated by countries whose behavior is near their respective steady-states; such an assumption is much more plausible for restricted samples such as the OECD countries. The clusters they find could thus reflect, in many cases at least, transition dynamics rather than convergence clubs. An important extension of this work would be the exploration of how one can distinguish convergence clubs from

[33]Corrado, Martin, and Weeks (2004) extend this approach to allow for time variation in clusters. They conclude that there is substantial evidence of club convergence as opposed to overall convergence for European regions. A nice feature of their analysis is the effort to interpret the clubs that are identified statistically with alternative economic theories, and conclude that geographic proximity and demographic similarity correlate with their observed clusters.

what may be called "transition" clubs, i.e. groups of countries exhibiting similar transition dynamics.

A number of studies of time series convergence have criticized these claims of nonconvergence; these criticisms are based upon inferential issues that have arisen in the general unit roots literature. One of these issues concerns the validity of unit root tests in the presence of structural breaks in $\log y_{i,t} - \log y_{j,t}$; as argued initially by Perron (1989), the failure to allow for structural breaks when testing for unit roots can lead to spurious evidence in support of the null hypothesis that a unit root is present. An initial analysis of this type in cross-country contexts is Greasley and Oxley (1997) who, imposing breaks exogenously, find convergence for Denmark and Sweden whereas the sort of test employed by Bernard and Durlauf (1995) does not. The role of breaks in time series convergence tests is systematically studied in Li and Papell (1999). An important feature of their analysis is that Li and Papell avoid exogenous imposition of trend breaks and in fact find that the dates of these breaks exhibit some heterogeneity, although many of them cluster around World War II. Li and Papell find that the evidence for OECD convergence is more mixed than did Bernard and Durlauf (1995) in the sense that allowing for trend breaks reduces the number of country pairs that fail to exhibit convergence. Related findings are due to Carlino and Mills (1993) who study US regions and reject convergence except under specifications that allow for a trend break in 1946. These conclusions are shown by Loewy and Papell (1996) to hold even if one allows potential trend breaks to be endogenously determined by the data.

While the analysis of trend breaks and convergence tests is valuable because of its implications about the time series structure of output differences between countries, studies of this type suffer from some interpretation problems. The presence of the regime break is presumably suggestive of an absence of convergence in the sense of (22) or (38), since it implies that there is some component of $\log y_{i,t} - \log y_{j,t}$ that will not disappear over a sufficiently long time horizon. The time series definition of convergence is violated by any long-term predictability in output differences. Hence, claims by authors that allowing for data breaks produces evidence of convergence begs the question of what is meant by convergence. That being said, the sort of violation of (22) or (38) implied by a trend break is different from the type implied by a unit root. In particular, a break

associated with the level of output means that the output difference between two countries is always bounded, unlike the unit root case.

A distinct line of criticism of time series convergence tests is due to Michelacci and Zaffaroni (2000) who argue that convergence tests based on the presence of unit roots may perform badly when the true processes exhibit long memory. Let $\gamma(L)u_{i,j.t}$ denote the moving average representation for $\log y_{i,t} - \log y_{j,t}$. Suppose that the k'th coefficient in the representation has the property that

$$\gamma_k \propto k^{d-1},\ 0 < d < 1 \tag{39}$$

In this case, shocks die out at a hyperbolic rather than geometric rate, which is one definition of long memory in a time series process. Michelacci and Zaffaroni (2000) show that if output deviations exhibit long memory, one can reconcile the claim of β-convergence with time series evidence of divergence, i.e. the failure of various tests to reject the presence of a unit root in per capita output deviations. This is a potentially important reconciliation of these two distinct testing strategies.

That being said, the plausibility of a long memory characterization has yet to be established in the economics literature. One problem is that there is an absence of a body of economic theory that predicts the presence of long memory.[34] The existing theoretical justifications of long memory processes derive from aggregation arguments originating with Granger (1980); the conditions under which aggregation produces long memory do not have any particular empirical justification. In addition, there are questions concerning the ability of conventional statistical methods to allow one to distinguish between long memory models and various alternatives. Diebold and Inoue (2001) indicate how long memory may be spuriously inferred for series subject to regime shifts, so the strength of evidence of long memory cited by Michelacci and Zaffaroni (2000)

[34]There are at least two reasons why unit roots stem naturally from exisiting economic theories. First, technology shocks are generally modeled as permanent. Second, Euler equations often produce unit root or near unit root like conditions. The random walk theory of stock prices is one example of this, in which risk neutral agents produce unpredictability of stock price changes as an equilibrium.

may be questioned. Nevertheless, the Michelacci-Zaffaroni argument is important, not least because it focuses attention on the role in growth empirics of size and power issues that arise in all unit root contexts.

Time series approaches to convergence are melded with analysis related to σ-convergence in Evans (1996) who considers the cross-section variance of growth rates at time t,

$$\sigma_t^2 = \frac{1}{N}\sum_i \left(\log y_{i,t} - \overline{\log y}_t\right)^2 \tag{40}$$

where $\overline{\log y}_t = \frac{1}{N}\sum_i \log y_{i,t}$ and N is the cardinality of I. Evans observes that σ_t^2 may be represented as a unit root process with a quadratic time trend when there is no cointegration among the series $\log y_{i,t}$. This leads Evans to suggest a time-series test of convergence based on unit root tests applied to σ_t^2. Employing this test, Evans concludes that there is convergence to a common trend among 13 industrial countries. One interpretation problem with this analysis is that it allows different countries to possess different deterministic trends in per capita output albeit with the same trend growth rate. Such differences are obviously germane with respect to convergence as an economic concept being consistent, for example, with the club and conditional convergence hypotheses but not with the unconditional convergence hypothesis. Evans (1997) provides a time series approach to estimating rates of convergence. He shows that OLS applied to equation (18) yields a consistent estimator of β, and hence the rate of convergence, only if (i) each $\log y_{i,t} - \overline{\log y}_t$ obeys an AR(1) process having the same AR(1) parameter lying strictly between 0 and 1; and, (ii) the control variables, X_i and Z_i, account for all cross-country heterogeneity. He argues that neither condition is likely to hold and offers an alternative method of measuring the rate of convergence based on the supposition that $\log y_{i,t} - \overline{\log y}_t$ follows an AR(q) process with lag polynomial $\Lambda(L)$. Again, this specification allows countries to follow different parallel balanced

growth paths and Evans defines the rate of convergence for economy *i* as the rate at which $\log y_{i,t}$ "is expected to revert toward its balanced growth path far in the future." He shows that, given that it is a real, distinct, positive fraction, the dominant root of the polynomial $z^q \Lambda\left(z^{-1}\right)$ equals one minus this rate. Evans computes estimates of the convergence rates and their 90% confidence intervals for a sample of 48 countries over the period 1950-90 and for the contiguous US states over the period 1929-91. For the states, about a third of the point estimates are negative and about two-thirds of the confidence intervals contain zero, while for the countries, about half of the point estimates are negative and all but two of the confidence intervals contain zero. However, in spite of these positive estimated average convergence rates of 15.5% and 5.9% respectively, Evans' analysis fails to yield persuasive evidence in favor of the conditional convergence hypothesis since, in most cases, the hypothesis of a convergence rate of zero cannot be rejected at the 10% level of significance.

Later sections of the chapter will discuss how growth researchers can draw on time series data in other ways. One popular route has been to use panel data, with repeated observations on each country or region. Another method is to use techniques broadly similar to those of event studies in empirical finance, and trace out the consequences of specific events, such as major political or economic reforms. We will consider these approaches in Section VI.iii below.

v. sources of convergence or divergence

Abramowitz (1986), Baumol (1986), DeLong (1988) and many others, both before and since, view convergence as the process of follower countries "catching up" to leader countries by adopting their technologies. Some more recent contributors, such as Barro (1991) and Mankiw, Romer, and Weil (1992), adopt the view that convergence is driven by diminishing returns to factors of production.[35] In the neoclassical model, if

[35] When an economy is below its steady-state value of capital per efficiency unit of labor, the marginal product of capital is relatively high (and is higher than in the steady state). As a result, a given investment rate translates into relatively high output growth. Capital grows as well but, because of diminishing returns, the capital-output ratio rises and the marginal product of capital declines, causing the growth of output and capital to slow.

each country has access to the same aggregate production function the steady-state is independent of an economy's initial capital and labor stocks and hence initial income. In this model, long-run differences in output reflect differences in the determinants of accumulation, not differences in the technology used to combine inputs to produce output. Mankiw (1995, p. 301), for example, argues that for "understanding international experience, the best assumption may be that all countries have access to the same pool of knowledge, but differ by the degree to which they take advantage of this knowledge by investing in physical and human capital." Even if one relaxes the assumption that countries have access to the same production function, convergence in growth rates can still occur so long as each country's production function is concave in capital per efficiency unit of labor and each country experiences the same rate of labor-augmenting technical change.

Klenow and Rodríguez-Clare (1997a) challenge this "neoclassical revival" with results suggesting that differences in factor accumulation are, at best, no more important than differences in productivity in explaining the cross-country distribution of output per capita. They find that only about half of the cross-country variation in the 1985 level of output per worker is due to variation in human and physical capital inputs while a mere 10% or so of the variation in growth rates from 1960 to 1985 reflects differences in the growth of these inputs. The differences between the results of Mankiw, Romer, and Weil (1992) and the findings of Klenow and Rodríguez-Clare (1997a) in their reexamination of Mankiw, Romer and Weil have two principal origins. First, citing concerns about the endogeneity of the input quantities, Klenow and Rodríguez-Clare (1997a) eschew estimation of the capital shares and choose to impute parameters based on the results of other studies. Second, they modify Mankiw, Romer and Weil's measure of human capital accumulation by supplementing secondary school enrollment rates using data on primary enrollment. This yields a measure of human capital accumulation with less cross-country variation than that used by Mankiw, Romer and Weil. This one modification decreases

---

Eventually, the economy converges to a steady state in which capital and output grow at the same rate and the marginal product of capital is sustained at a constant level by labor-augmenting technical progress. Dowrick and Rogers (2002) find that both diminishing returns and technology transfer are important contributors to the convergence process. See also Bernard and Jones (1996) and Barro and Sala-i-Martin (1997).

the relative contribution of cross-country variation in human and physical capital inputs to variation in the 1985 level of output per worker to 40% from the 78% found by Mankiw, Romer, and Weil. Prescott (1998) and Hall and Jones (1999) confirm the view that differences in inputs are unable to explain observed differences in output and Easterly and Levine (2001, p. 177) state that "[t]he 'residual' (total factor productivity, TFP) rather than factor accumulation accounts for most of the income and growth differences across countries."

Unlike many authors, who estimate TFP as a residual after assuming a common Cobb-Douglas production function, Henderson and Russell (2004) use a non-parametric production frontier approach (data envelopment analysis) to decompose the 1965 to 1990 growth of labor productivity into (i) shifts in the (common, worldwide) production frontier (technological change); (ii) movements toward (or away from) the frontier (technological catch-up); and, (iii) capital accumulation. They find a dominant role for capital accumulation in the growth of the cross-country mean of labor productivity with human and physical capital each accounting for about half of that role.[36] They also observe that the distribution of labor productivity became more dispersed from 1965 to 1990 and their results suggest that physical and human capital accumulation were largely responsible for the increased dispersion.

The results of Henderson and Russell (2004) and those of the previous authors are, however, more consistent than it may seem. Klenow and Rodríguez-Clare (1997a), Hall and Jones (1999) and Barro and Sala-i-Martin (2004) argue that the standard growth accounting decomposition overstates the contribution of capital accumulation to output growth by attributing to capital the effect on output of increases in capital induced by increases in TFP. This effect also applies to Henderson and Russell's approach and adjusting for it provides some reconciliation of their findings with those of Klenow and Rodríguez-Clare (1997a), Prescott (1998) and Hall and Jones (1999). The standard growth accounting formula attributes a fraction (equal to labor's share of output) of the

[36]Note that any misspecification of the production function due to the Cobb-Douglas assumption in other studies will tend to increase the apparent variation in TFP relative to that found by Henderson and Russell (2004) under the weaker assumption of constant returns to scale. In a rare effort to evaluate the Cobb-Douglas specification, Duffy and Papageorgiou (2000) reject it in favor of a more general CES functional form.

growth in output per worker to growth in TFP and a fraction (equal to capital's share of output) to capital accumulation despite the fact that, in the steady-state, growth in output per worker is entirely due to technological progress (Barro and Sala-i-Martin (2004, p. 457-60) and Klenow and Rodríguez-Clare (1997a p. 75, fn. 4)). The total effect of technological progress on output growth can thus be estimated by dividing labor's share into the estimated growth rate of TFP. Interpreting "capital" broadly, labor's share is about $1/3$ suggesting that this effect is about three times the rate of growth of TFP. Henderson and Russell (2004, Table 5, row (a)) find that, on average, about 90% of the increase in output per worker over the 1965 to 1990 period is attributable to the accumulation of human and physical capital with increases in TFP accounting for the remaining 10%. Applying the adjustment discussed above suggests that technological progress accounts for about 30% of the growth in output per worker over this period while capital accumulation, due to transition dynamics, accounts for the remainder.

As well as determining the relative contributions of inputs and TFP to the cross-country variation in output and output growth, some have studied what features of the cross-country output distribution are explained by the cross-country distributions of inputs and TFP. Henderson and Russell (2004) document the emergence of a second mode in the cross-country distribution of output per worker between 1965 and 1990 and find changes in efficiency (the distance from the world technological frontier) to be largely responsible. A primary role for TFP in determining the shape of the long-run distribution of output per capita is found by Feyrer (2003) who uses Markov transition matrices estimated with data from 90 countries over the period 1970 to 1989 to estimate the ergodic distributions of output per capita, the capital-output ratio, human capital per worker, and TFP. He finds that the long-run distributions of both output per capita and TFP are bimodal while those of both the capital-output ratio and human capital per worker are unimodal. This result, Feyrer observes, has potentially important implications for theoretical modelling of development traps. It suggests that models of multiple equilibria that give rise to equilibrium differences in TFP are more promising than

models that emphasize indeterminacy in capital intensity or educational attainment.[37] It is also consistent with Quah's (1996c) finding that conditioning on measures of physical and human capital accumulation (and a dummy variable for the African continent) has little effect on the dynamics of the cross-country income distribution.

As discussed in Section III.iii.d, the shapes of ergodic distributions computed from transition matrices estimated with discretized data are not, in general, robust to changes in the way in which the state space is discretized. To avoid these problems, Johnson (2004) extends Feyrer's analysis using Quah's (1996c,1997) continuous state-space methods and finds evidence of bimodality in the long-run distributions of both the capital-output ratio and TFP in addition to that in the long-run distribution of output per capita. This finding is broadly consistent with data produced by a version of the Solow growth model that includes a threshold externality à la Azariadis and Drazen (1990) but may be partly due to the computation of TFP after supposing a Cobb-Douglas production function across countries. Accordingly, some care must be exercised when drawing conclusions from these results.

More generally, in much of the development accounting literature cited above, TFP is measured as a residual under the assumption of a concave worldwide production function. Durlauf and Johnson (1995) present evidence contrary to that assumption and in support of the implied multiple steady states in the growth process. It seems likely that the imposition of a concave production function in this case will tend to exaggerate the measured differences in TFP and so confound inferences about the importance of TFP variation.[38] While Henderson and Russell (2004)'s approach is nonparametric and free from any assumption of a particular technology *per se*, it estimates the world technology frontier by fitting a convex cone to data on outputs and inputs. The imposed convexity of the production set prevents the method from discovering any nonconvexities that may exist and, in addition to masking the presence of multiple steady states, convexifying

[37]Romer (1993) discusses the intellectual origins of the centrality of capital accumulation in models of economic development and argues that "idea gaps are central to the process of economic development" (p. 548).

[38]Graham and Temple (2003) show that the existence of multiple steady states can increase the variance and accentuate bimodality in the observed cross-country distribution of TFP.

these nonconvexities would tend to overstate the cross-country variation in TFP. The extent to which our current understanding of the relative contributions of variation in inputs and variation in TFP to the observed variation in income levels is influenced by the effects on measured TFP of a misspecified worldwide technology remains an open research question.

Despite these concerns and the differences in the precise estimates found by different researchers, it is clear that cross-country variation in inputs falls short of explaining the observed cross-country variation in output. The result that the TFP residual, a "measure of our ignorance" computed as the ratio of output to some index of inputs, is an important (perhaps the dominant) source of cross-country differences in long-run economic performance is useful but hardly satisfying and the need for a theory of TFP expressed by Prescott (1998) is well founded. Research such as Acemoglu and Zilibotti (2001) and Caselli and Coleman (2003) are promising contributions to that agenda.

V. Statistical models of the growth process

While the convergence hypothesis plays a uniquely prominent role in empirical growth studies, it by no means represents the bulk of empirical growth studies. The primary focus of empirical growth papers may be thought of as a general exploration of potential growth determinants. This work may be divided into three main categories: 1) studies designed to establish that a given variable does or does not help explain cross-country growth differences, 2) efforts to uncover heterogeneity in growth and 3) studies that attempt to uncover nonlinearities in the growth process. While analyses of these types are typically motivated by formal theories, operationally they represent efforts to develop statistical growth models that are consistent with certain types of specification tests.

Section V.i discusses the analysis of how specific determinants affect growth. We describe the range of different variables that have appeared in growth regressions and consider alternative methodologies for analyzing growth models in the presence of

uncertainty about which regressors should be included to define the "true" growth model. Section V.ii addresses issues of parameter heterogeneity. The complexity of the growth process and the plethora of new growth theories suggest that the mapping of a given variable to growth is likely a function of both observed and unobserved factors; for example, the effect of human capital investment on growth may depend on the strength of property rights. We explore methods to account for parameter heterogeneity and consider the evidence that has been adduced in support of its presence. Section V.iii focuses on the analysis of nonlinearities and multiple regimes in the growth process. Endogenous growth theories are often highly nonlinear and can produce multiple steady states in the growth process, both of which have important implications for econometric practice. This subsection explores alternative specifications that have been employed to allow for nonlinearity and multiple regimes and describes some of the main findings that have appeared to date.

i. specifying explanatory variables in growth regressions

In the search for a satisfactory statistical model of growth, the main area of effort has concerned the identification of appropriate variables to include in linear growth regressions, this generally amounts to the specification of Z in equation (18). Appendix 2 provides a survey of different regressors that have been proposed in the growth literature with associated studies that either represent the first use of the variable or a well known use of the variable.[39] The table contains 145 different regressors, the vast majority of which have been found to be statistically significant using conventional standards.[40] One reason why so many alternative growth variables have been identified is due to questions of measurement. For example, a claim that domestic freedom affects growth leaves unanswered how freedom is to be measured. We have therefore organized the body of growth regressors into 43 distinct growth "theories" (by which we mean conceptually

[39]Our choices of which studies to include should not be taken to reflect any stance on any cases where there is disagreement about priority as to who first proposed a variable.
[40]Of course, the high percentage of statistically significant growth variables reflects publication bias as well as data mining.

distinct growth determinants); each of these theories is found to be statistically significant in at least one study.

As Appendix 2 indicates, the number of growth regressors that have been identified approaches the number of countries available in even the broadest samples. And this regressor list does not consider cases where interactions between variables or nonlinear transformations of variables have been included as regressors; both of which are standard ways of introducing nonlinearities into a baseline growth regression. This plethora of potential regressors starkly illustrates one of the fundamental problems with empirical growth research, namely, the absence of any consensus on which growth determinants ought to be included in a growth model. In this section, we discuss efforts to address the question of variable choice in growth models.

To make this discussion concrete, define S_i as the set of regressors which a researcher always retains in a regression and let R_i denote additional controls in the regression, so that

$$\gamma_i = \psi S_i + \pi R_i + \varepsilon_i \tag{41}$$

Notice that the inclusion of a variable in *S* does not mean the researcher is certain that it influences growth, only that that it will be included in all models under consideration. To make this concrete, one can think of an exercise in which one wants to consider the relationship between initial income and growth. A researcher may choose to include initial income and the other Solow growth regressors in every specification of the model, but may in contrast be interested in the effects of different non-Solow growth regressors on inferences about the initial income/growth connection.

If one takes the regressors that comprise *R* as fixed, then statements about elements of ψ are straightforward. A frequentist approach to inference will compute an estimate of the parameter $\hat{\psi}$ with an associated distribution that depends on the data generating process; Bayesian approaches will compute a posterior probability density of ψ given the researcher's prior, the data, and the assumption that the linear model is correctly specified, i.e. the choice of variables in *R* corresponds to the "true" model. Designating

the available data as D and a particular model as m, this posterior may be written as $\mu(\psi|D,m)$.

The basic problem in developing statistical statements either about $\hat{\psi}$ or $\mu(\psi|D,m)$ is that there do not exist good theoretical reasons to specify a particular model m. This is *not* to say that the body of growth theories may not be used to identify candidates for *R*. Rather, the problem is that growth theories are, using a phrase due to Brock and Durlauf (2001a), openended. Theory openendedness means that the growth theories are typically compatible with one another. For example, a theory that institutions matter for economic growth is not logically inconsistent with a theory that emphasizes the role of geography in growth. Hence, if one has a set of K potential growth theories, all of which are logically compatible with one another (and all subsets of theories), there exist $2^K - 1$ potential theoretical specifications of the form (41), each one of which corresponds to a particular combination of theories.

One approach to resolving the problem of model uncertainty is based on identifying variables whose empirical importance is robust across different model specifications. This is the idea behind Levine and Renelt's (1992) use of extreme bounds analysis (Leamer (1983) and Leamer and Leonard (1983)) to assess growth determinants. To see how extreme bounds analysis may be applied to the assessment of robustness of growth determinants, suppose that one has specified a space of possible models M. For model m, the growth process is

$$\gamma_i = \psi_m S_i + \pi_m R_{i,m} + \varepsilon_{i,m} \tag{42}$$

where the subscripts *m* reflect the model specific nature of the parameters and associated residuals. One can compute $\hat{\psi}_m$ for every model in M. Motivated by Leamer (1983), Levine and Renelt employ the rule that there is strong evidence that a given regressor in *S*, call it s_l, robustly affects growth if the sign of the associated regression coefficient $\hat{\psi}_{l,m}$ is constant and the coefficient estimate is statistically significant across all model

specifications in M. In this analysis the S vector is composed of a variable of interest and other variables whose presence is held fixed across specifications.

In the Levine and Renelt (1992) analysis, S includes a constant, the initial income, the investment share of GDP, secondary school enrollment rates, and population growth; these variables proxy for those suggested by the Solow model. Models are distinguished by alternative combinations of 1 to 3 variables taken from a set of 7 variables; these correspond to alternative choices of $R_{i,m}$. Based on the constant sign and statistical significance criteria, Levine and Renelt (1992) conclude that the only robust growth determinants among the elements of S_i are initial inome and the share of investment in GDP. These two findings are confirmed in subsequent work by Kalaitzidakis, Mamuneas, and Stengos (2000) who allow for potential nonlinearities in (41). Specifically, they consider partially linear versions of (41), so that

$$\gamma_i = \psi_m S_i + f_m\left(\pi R_{i,m}\right) + \varepsilon_{i,m} \tag{43}$$

Note that the function $f(\cdot)$ is allowed to vary across specifications of *R*. As in Levine and Renelt (1992), Kalaitzidakis, Mamuneas, and Stengos conclude that initial income and physical capital investment rates are robust determinants of growth. Unlike Levine and Renelt, they also find that inflation volatility and exchange rate distortions are robust; this is interesting as it is an example where the failure to account for nonlinearity in one set of variables masks the importance of another.

From a decision-theoretic perspective, the extreme bounds approach is a problematic methodology. The basic difficulty, discussed in detail in Brock and Durlauf (2001a) and Brock, Durlauf, and West (2003) is that if one is interested in ψ_l because one is considering whether to change $s_{i,l}$, by one unit, i.e. one is advising country *i* on a policy change, the extreme bounds standard corresponds to a very risk averse way of responding to model uncertainty. Specifically, suppose that for a policymaker, $El\left(s_{i,l}, m\right)$ represents the expected loss associated with the current policy level in country *i*. We assume that one is only interested in the case where an increase in the policy raises

growth, which means we will assume that it is necessary for $\hat{\psi}_{l,m} > 0$ in order to conclude that one should make the change. One can approximate the *t*-statistic rule, i.e. requiring that the coefficient estimate for s_l be statistically significant in order to justify a policy as implying that

$$El\left(s_{i,l}+1,m\right)-El\left(s_{i,l},m\right)=\left(\hat{\psi}_{l,m}-2sd\left(\hat{\psi}_{l,m}\right)\right)>0 \tag{44}$$

where $sd\left(\hat{\psi}_{l,m}\right)$ is the estimate of the standard deviation associated with $\hat{\psi}_{l,m}$ and the statistical significance level required for the coefficient is assumed to correspond to a *t*-statistic of 2. This loss function may look odd, but it is in fact the sort of loss function implicitly assumed whenever one relies on *t*-statistics to make policy decisions. Extreme bounds analysis requires that (44) holds for every model in *M*. This requires that $El\left(s_{i,l}\right)$, the expected loss for a policymaker when one conditions only on the policy variable, has the property that

$$El\left(s_{i,l}+1\right)-El\left(s_{i,l}\right)>0 \Rightarrow El\left(s_{i,l}+1,m\right)-El\left(s_{i,l},m\right)>0 \ \forall m \tag{45}$$

This means that the policymaker must have minimax preferences with respect to model uncertainty, i.e. he will make the policy change only if it yields a positive expected payoff under the least favorable model in the model space. While there are reasons to believe that in practice, individuals assess model uncertainty differently than within-model uncertainty[41], the extreme risk aversion embedded in (45) seems hard to justify.

Even when one moves away from decision-theoretic considerations, extreme bounds analysis is somewhat difficult to interpret as a statistical procedure. Hoover and Perez (2004), for example, show that the use of extreme bounds analysis can lead to the conclusion that many growth determinants are fragile even when they are part of the data

[41]See discussion in Brock, Durlauf, and West (2003) of the Ellsberg Paradox.

generating process. They also find that the procedure has poor power properties in the sense that some regressors that do not matter may spuriously appear to be robust.[42]

The concern that extreme bounds analysis represents an excessively conservative approach to evaluating empirical results led Sala-i-Martin (1997a,b) to propose a different way to evaluate the robustness of findings. Within a model, suppose there is an evaluative criterion for $\hat{\psi}_m$ that is used to determine whether the variable s_l matters for the growth process. One example of such a standard is whether or not $\hat{\psi}_{l,m}$ is statistically significant at some level. Sala-i-Martin first proposes averaging the statistical significance levels via

$$\hat{S}_i = \sum_m \hat{\omega}_m \hat{S}_{i,m} \tag{46}$$

where $\hat{S}_{i,m}$ is the statistical significance level associated with $\hat{\psi}_m$ and $\hat{\omega}_m$ is the weight assigned to model *m*, $\sum_m \hat{\omega}_m = 1$. Sala-i-Martin (1997a,b) employs weights determined by the likelihoods of each model as well as employing equal weighting. Second, Sala-i-Martin (1997a,b) proposes examining the percentage of times a variable appears statistically significant with a given sign; a variable whose sign and statistical significance holds across 95% of the different models estimated is regarded as robust. This approach finds that initial income, the investment to GDP ratio and secondary school education are all robust determinants of growth. Sala-i-Martin (1997a,b) extends this analysis to the evaluation of additional variables and finds a number also are robust by his criteria.

While these approaches have the important advantage over extreme bounds analysis of accounting for the informational content of the entire distribution of $\hat{\psi}_m$, the procedures do not have any decision-theoretic or conventional statistical justification. We are unaware of any statistical interpretation to averaged significance levels. Further, little is understood about the statistical properties of these procedures. Hoover and Perez

[42]For further discussion of extreme bounds analysis, see Temple (2000b) and the references therein.

(2004), for example, find that the second Sala-i-Martin procedure has poor size properties, in the sense that "true" growth determinants are still likely to fail to be identified.

Dissatisfaction with extreme bounds analysis and the variants we have described have led some authors to embed the determinants of robust growth regressors in a general model selection context. Hendry and Krolzig (2004) and Hoover and Perez (2004) both employ general-to-specific modeling methodologies generally associated with the research program of David Hendry (cf. Hendry 1995)) to select one version of (41) out of the model space. In both papers, the linear model that is selected out of the space of possible models is one where growth is determined by years an economy is open, the rate of equipment investment, a measure of political instability based on the number of coups and revolutions, a measure of the percentage of the population that is Confucian and a measure of the percentage of the population that is Protestant.

Methodologically, these papers in essence employ algorithms which choose a particular regression model from a space of models through comparisons based on a set of statistical tests. The extent to which one finds this approach appealing is a function of the extent to which one is sympathetic to the general methodological foundations of the Hendry research program; we avoid such an extended evaluation here, but simply note that like other general prescriptions the program remains controversial, especially the extent to which it relies on automatic model selection procedures that do not possess a clear decision-theoretic justification. As such, it is somewhat unclear how to evaluate the output of the procedure in terms of the objectives of a researcher. That being said, the automated procedures Hendry works with have the important virtue that they can facilitate identifying small sets of models that are well supported by available data. Identification of such models is important, for example, in forecasting, where Hendry's procedures appear to have a strong track record.

In our judgment, the most promising current approach to accounting for model uncertainty employs model averaging techniques to construct parameter estimates that formally address the dependence of model-specific estimates on a given model. Examples where model averaging has been applied to cross-country growth data include Brock and Durlauf (2001a), Brock, Durlauf, and West (2003), Doppelhofer, Miller, and

Sala-i-Martin (2004), Fernandez, Ley, and Steel (2001a) and Masanjala and Papageorgiou (2004). The basic idea in this work is to treat the "true" growth model[43] as an unobservable variable. In order to account for this variable, each element *m* in the model space *M* is associated with a posterior model probability $\mu(m|D)$. By Bayes' rule,

$$\mu(m|D) \propto \mu(D|m)\mu(m) \tag{47}$$

where $\mu(D|m)$ is the likelihood of the data given the model and $\mu(m)$ is the prior model probability. These model probabilities are used to eliminate the dependence of parameter analysis on a specific model. For frequentist estimates, averaging is done across the model-specific estimates $\hat{\psi}_m$ to produce an estimate $\hat{\psi}$ via

$$\hat{\psi} = \sum_m \hat{\psi}_m \mu(m|D) \tag{48}$$

whereas for the Bayesian context, the dependence of the posterior probabilility measure of the parameter of interest, $\mu(\psi|D,m)$ on the model choice is eliminated via standard conditional probability arguments, i.e.

$$\mu(\psi|D) = \sum_{m \in M} \mu(\psi|D,m)\mu(m|D) \tag{49}$$

Brock, Durlauf, and West (2003) argue that the strategy of constructing posterior probabilities that are not model-dependent is the appropriate one when the objective of the statistical exercise is to evaluate alternative policy questions such as whether to

[43]In this discussion, we will assume that one of the models in the model space *M* is the correct specification of the growth process. When none of the model specifications is the correct one, this naturally affects the interpretation of the model averaging procedure.

change elements of S_i by one unit. Notice that this approach assumes that the goal of the exercise is to study a parameter, i.e. ψ, not to identify the best growth model.

Model averaging approaches are still quite new in the growth literature, so many questions exist as to how to implement the procedure. One issue concerns the specification of priors on parameters within a model. Brock and Durlauf (2001a), Brock, Durlauf and West (2003), and Doppelhofer, Miller, and Sala-i-Martin (2004) assume a diffuse prior on the model specific coefficients. The advantage of this prior is that, when the errors are normal with known variance, the posterior expected value of ψ, conditional on the data *D* and model m, is the ordinary least squares estimator $\hat{\psi}_m$. The disadvantage of this approach is that since the diffuse prior on the regression parameters is improper, one has to be careful that the posterior model probabilities associated with the prior are interpretable. For this reason, Doppelhofer, Miller, and Sala-i-Martin (2004) eschew reference to their methodology as strictly Bayesian. That being said, so long as the posterior model probabilities include appropriate penalties for model complexity, (and Brock and Durlauf (2001a), Brock, Durlauf, and West (2003), and Doppelhofer, Miller, and Sala-i-Martin (2004) all compute posterior model probabilities using BIC adjusted likelihoods) we do not see any conceptual problem in interpreting this approach as strictly Bayesian. Fernandez, Ley, and Steel (2001a) and Masanjala and Papageorgiou (2004) employ proper priors and therefore avoid such concerns.[44] We are unaware of any evidence that the choice of prior for the within-model regression coefficients is of great importance in terms of empirical inferences for the growth contexts that have been studied; Masanjala and Papageorgiou (2004) in fact compare results using using proper priors with the improper priors we have described and find that the choice of prior is unimportant.

A second unresolved issue concerns the specification of the prior model probabilities $\mu(m)$. In the model averaging literature, the general assumption has been to assign equal prior probabilities to all models in M. This prior may be interpreted as assuming that the prior probability that a given variable appears in the "true" model is .5

[44]Fernandez, Ley, and Steel (2001b) provide a general analysis of proper model specific priors for model averaging exercises.

and that the probability that one variable appears in the model is independent of whether others appear. Doppelhofer, Miller, and Sala-i-Martin (2004) consider modifications of this prior in which the probability that a given variable appears in the true model is $p < .5$; these alternative probabilities are chosen in order to assign greater weight to more parsimonious growth models, i.e. models in which fewer regressors appear.[45]

Brock and Durlauf (2001a) and Brock, Durlauf, and West (2003) argue against the assumption that the probability that one regressor should appear in a growth model is independent of the inclusion of others. The basic problem with priors that assume independence is analogous to the red bus/blue bus problem in discrete choice theory; namely, some regressors are quite similar to others, e.g. alternative measures of trade openness, whereas other regressors are quite disparate, e.g. geography and institutions. Brock, Durlauf, and West (2003) propose a tree structure to organize model uncertainty for linear growth models. First, they argue that growth models suffer from theory uncertainty. Hence, one can identify alternative classes of models based on what growth theories are included. Second, for each specification of a body of theories to be embedded, they argue there is specification uncertainty. A given set of theories requires determining whether the theories interact, whether they are subject to threshold effects or other types of nonlinearity, etc. Third, for each theory and model specification, there is measurement uncertainty. The statement that weather affects growth does not specify the relevant empirical proxies, e.g. the number of sunny days, average temperature, etc. Finally, each choice of theory, specification and measurement is argued to suffer from heterogeneity uncertainty, which means that it is unclear which subsets of countries obey a common linear model. Brock, Durlauf, and West (2003) argue that one should assign priors that account for the interdependences implied by this structure in assigning model probabilities. Appendix 2 follows this approach in organizing growth regressors according to theory.

Doppelhofer, Miller, and Sala-i-Martin (2004) and Fernandez, Ley, and Steel (2001a) employ model averaging methods to identify which growth regressors should be

[45]In our judgment, this presumption is unappealing as our own prior beliefs suggest that the true growth model is likely to contain many distinct factors. One implication of the openendedness of growth theories is that the simultaneous importance of many factors is certainly plausible.

included in linear growth models. These analyses do not distinguish between variables to be included in all regressions and variables whose inclusion determines alternative models; all variables are pooled and all possible combinations are considered. Doppelhofer, Miller, and Sala-i-Martin (2004) working with 31 potential growth determinants, conclude, weighting prior models so that the expected number of included regressors is 7 (this corresponds to a prior probability of variable inclusion of about .25), that four variables have posterior model inclusion probabilities above .9: initial income, fraction of GDP in mining, number of years the economy has been open,[46] and fraction of the population following Confucianism. Working with a universe of 41 potential growth determinants, Fernandez, Ley, and Steel find that, under the assumption that the prior probability that a given variable appears in the correct growth model is .5, four variables have posterior model inclusion probabilities above .9: initial income, fraction of the population following Confucianism, life expectancy, and rate of equipment investment.

Brock and Durlauf (2001a) and Masanjala and Papageorgiou (2004) employ model averaging to study the reason for the poor growth performance of sub-Saharan Africa. Brock and Durlauf (2001a) reexamine Easterly and Levine's (1997a) finding that ethnic heterogeneity helps explain sub-Saharan Africa's growth problems. This reanalysis finds that the Easterly and Levine (1997) claim is robust in the sense that ethnic heterogeneity helps explain why growth in sub-Saharan Africa had stagnated relative to the rest of the world. On the other hand, Brock and Durlauf (2001a) also find that ethnic heterogeneity does not appear to explain growth patterns in the rest of the world. This leads to the unresolved question of why ethnic heterogeneity has uniquely strong growth effects in sub-Sahran Africa. Masanjala and Papageorgiou (2004) conduct a general analysis of the determinants of sub-Saharan African growth versus the world as a whole and conclude that the relevant growth variables for Africa are quite different. In particular, variation in sub-Saharan growth is much more closely associated with the share of the economy made up by primary commodities production. They also find, contrary to Doppelhofer, Miller, and Sala-i-Martin (2004) that the share of mining in the economy is a robust determinant of growth in Africa but not the world as a whole.

[46]Sachs and Warner (1995) use this variable as an index of overall openness of an economy.

Finally, model averaging has been applied by Brock, Durlauf, and West (2003) to analyze the question of how to employ growth regressions to evaluate policy recommendations. Specifically, the paper assesses the question of whether a policymaker should favor a reduction of tariffs for sub-Saharan African countries; the analysis assumes that the policymaker possesses mean/variance preferences with respect to the effects of changes in current policies with a constant tradeoff of mean against standard deviation of 1 to 2. The analysis finds strong support for a tariff reduction in that it concludes that a policymaker with these preferences should support a tariff reduction for any of the countries in sub-Saharan Africa unless the policymaker has a very strong prior that sub-Saharan African countries obey a distinct linear growth process from the rest of the world. In the case where the policymaker has a strong prior that sub-Saharan Africa is "different" from the rest of the world, there is sufficient uncertainty about the relationship between tariffs and growth for these countries that a change in the rates cannot be justified; the strong prior in essence means that the growth experiences of non-African countries have little effect on the precision of estimates of growth behavior that are constructed using data on sub-Saharan African countries in isolation.

ii. parameter heterogeneity

From its earliest stages, the use of linear growth models has generated considerable unease with respect to the statistical foundations of the exercise. Arguably, the data for very different countries cannot be seen as realizations associated with a common data generating process (DGP). For econometricians that have been trained to search for a good approximation to a DGP, the modeling assumptions and procedures of the growth literature can look arbitrary. One expression of this concern is captured in a famous remark in Harberger (1987): "What do Thailand, the Dominican Republic, Zimbabwe, Greece, and Bolivia have in common that merits their being put in the same regression analysis?"

Views differ on the extent to which this objection is fundamental. There is general agreement that, when studying growth, it will be difficult to recover a DGP even if one exists. In particular, the prospects for recovering causal effects are clearly weak. Those

who are only satisfied with the specification and estimation of a structural model, in which parameters are either 'deep' or correspond to precisely defined causal effects within a coherent theoretical framework, will be permanently disappointed.[47] The growth literature must have a less ambitious goal, namely to investigate whether or not particular hypotheses have any support in the data. In practice, growth researchers are looking for patterns and systematic tendencies that can increase our understanding of the growth process, in combination with historical analysis, case studies, and relevant theoretical models. Another key aim of empirical growth research, which is harder than it looks at first sight, is to communicate the degree of support for any patterns identified by the researcher.

The issue of parameter heterogeneity is essentially that raised by Harberger. Why should we expect disparate countries to lie on a common surface? Clearly this criticism could be applied to most empirical work in social science, whether the data points reflect the actions and characteristics of individuals and firms, or the aggregations of their choices that are used in macroeconometrics. What is distinctive about the growth context is not so much the lack of a common surface, as the way in which the sample size limits the scope for addressing the problem. In principle, one response would be to choose a more flexible model that has a stronger chance of being a good approximation to the data. Yet this can be hard, and an inherently fragile procedure, when the sample is rarely greater than 100 observations.

If parameter heterogeneity is present, the consequences are potentially serious, except in a special case. If a slope parameter varies randomly across units, and is distributed independently of the variables in the regression and the disturbances, the coefficient estimate should be an unbiased estimate of the mean of the parameter. The assumption of independence is not one, however, that may be expected in light of the body of growth theories. For example, when estimating the relationship between growth and investment, the marginal effect of investment will almost certainly be correlated with aspects of the economic environment that should also be included in the regression.

[47]Note that this reflects the shortcomings of economic theory as well as those of data and econometric analysis.

The solution to this general problem is to change the specification in a way that allows greater flexibility in estimation. There are many ways of doing this. One approach is to consider more general functional forms than the canonical Solow regression which for comparison purposes we restate as:

$$\gamma_i = k + \beta \log y_{i,0} + \pi_n \log\left(n_i + g + \delta\right) + \pi_K \log s_{K,i} + \pi_H \log s_{H,i} + \varepsilon_i \qquad (50)$$

Liu and Stengos (1999) estimate a semiparametric partially linear version of this model, namely

$$\gamma_i = k + f_\beta\left(\log y_{i,0}\right) + \pi_n \log\left(n_i + g + \delta\right) + \pi_K \log s_{K,i} + f_{\pi_H}\left(\log s_{H,i}\right) + \varepsilon_i \qquad (51)$$

where $f_\beta(\cdot)$ and $f_{\pi_H}(\cdot)$ are arbitrary (except for variance smoothness requirements) functions. One important finding is that the value of $f_\beta\left(\log y_{i,0}\right)$ is only negative when initial per capita income exceeds about \$1800. They also find a threshold effect in secondary school enrollment rates (their empirical proxy for $\log s_{H,i}$) so the variable is only associated with a positive impact on growth if it exceeds about 15%. Banerjee and Duflo (2003) use this same regression strategy to study nonlinearity in the relationship between changes in inequality and growth; their specification estimates a version of (51) where initial income and human capital savings enter linearly (along with some additional non-Solow variables) but with the addition on the right hand side of the function $f_G\left(G_{i,t} - G_{i,t-5}\right)$ where $G_{i,t}$ is the Gini coefficient. Using a panel of 45 countries and 5 year growth averages, their analysis produces an estimate of $f_G(\cdot)$ which has an inverted U shape. One limitation of such studies is that they only allow for nonlinearity for a subset of growth determinants, an assumption that has little theoretical justification and is, from a statistical perspective, ad hoc; of course the approach is more general and less ad hoc then simply assuming linearity as is done in most of the literature.

Durlauf, Kourtellos, and Minkin (2001) extend this approach and estimate a version of the augmented Solow model that allows the parameters for each country to vary as functions of initial income, i.e.

$$\gamma_i = k\left(y_{i,0}\right) + \beta\left(y_{i,0}\right)\log y_{i,0} + \pi_n\left(y_{i,0}\right)\log\left(n_i + \delta + g\right) + \pi_K\left(y_{i,0}\right)\log s_{K,i} + \pi_H\left(y_{i,0}\right)\log s_{H,i} + \varepsilon_i \quad (52)$$

This formulation means that each initial income level defines a distinct Solow regression; as such it shifts the focus away from nonlinearity towards parameter heterogeneity, although the model is of course nonlinear in $y_{i,0}$. This approach reveals considerable parameter heterogeneity especially among the poorer countries. Durlauf, Kourtellos, and Minkin (2001) confirm Liu and Stengos (1999) in finding that $\beta\left(y_{i,0}\right)$ is positive for low $y_{i,0}$ values and negative for higher ones. They also find that $\pi_K\left(y_{i,0}\right)$ fluctuates greatly over the range of $y_{i,0}$ values in their sample. This work is extended in Kourtellos (2003a) who finds parameter dependence on initial literacy and initial life expectancy. The varying coefficient approach is also employed in Mamuneas, Savvides, and Stengos (2004) who analyze annual measures of total factor productivity for 51 countries. They consider a regression model of TFP in which the coefficient on human capital in the regression is allowed to depend on human capital both in isolation and in conjunction with a measure of trade openness (other coefficients are held constant). Constancy of the human capital coefficient is rejected across a range of specifications.

At a minimum, it generally makes sense for empirical researchers to test for neglected parameter heterogeneity, either using interaction terms or by carrying out diagnostic tests. Chesher (1984) showed that White's information matrix test can be used in this context. For the normal linear model with fixed regressors, Hall (1987) showed that, asymptotically, the information matrix test corresponds to a joint test for heteroskedasticity and non-normality. Later in the chapter, we discuss how evidence of heteroskedasticity should sometimes be seen as an indicator of misspecification.

Other authors have attempted to employ panel data to identify parameter heterogeneity without the imposition of a functional relationship between parameters and various observable variables. An important early effort is Canova and Marcet (1995). Defining $s_{i,t}$ as the logarithm of the ratio of a country's per capita income to the time t international aggregate value, Canova and Marcet estimate models of the form

$$s_{i,t} = a_i + \rho_i s_{i,t-1} + \varepsilon_{i,t}. \tag{53}$$

The long-run forecast of $s_{i,t}$ is given by $\frac{a_i}{1-\rho_i}$ with $1-\rho_i$ being the rate of convergence towards that value. Canova and Marcet estimate their model using data on the regions of Europe and on 17 western European countries. Restricting the parameters a_i and ρ_i to be constant across i gives a standard β-convergence test and yields an estimated annual rate of convergence of approximately 2%. On the other hand, allowing for heterogeneity in these parameters produces a "substantial", statistically significant, dispersion of the implied long-run $s_{i,t}$ forecasts. Moreover, those forecasts are positively correlated with $s_{i,0}$, the initial values of $s_{i,t}$, implying a dependence of long-run outcomes on initial conditions contrary to the convergence hypothesis. For the country-level data, differences in initial conditions explain almost half the cross-sectional variation in long-run forecasts; in contrast, the role of standard control variables such as rates of physical and human capital accumulation and government spending shares is minor. The latter finding must be tempered by the fact that the sample variation in these controls is less than that in Barro (1991) or Mankiw, Romer, and Weil (1992), for example.

A similar approach is taken by Maddala and Wu (2000) who consider models of the form

$$\log y_{i,t} = \alpha_i + \rho_i \log y_{i,t-1} + u_{i,t} \tag{54}$$

which is of course very similar to the model analyzed by Marcet and Canova (1995). Employing shrinkage estimators for α_i and ρ_i, they conclude that convergence rates, measured as $\beta_i = -\log \rho_i$ exhibit substantial heterogeneity.

iii. nonlinearity and multiple regimes

In this section we discuss several papers that have attempted to disentangle the roles of heterogeneous structural characteristics and initial conditions in determining growth performance. These studies employ a wide variety of statistical methods in attempting to identify how initial conditions affect growth. Despite this, there is substantial congruence in the conclusions of these papers as these studies each provide evidence of the existence of convergence clubs even after accounting for variation in structural characteristics.

An early contribution to this literature is Durlauf and Johnson (1995) who use classification and regression tree (CART) methods to search for nonlinearities in the growth process as implied by the existence of convergence clubs.[48] The CART procedure identifies subgroups of countries that obey a common linear growth model based on the Solow variables. These subgroups are identified by initial income and literacy, a typical subgroup l is defined by countries whose initial income lies within the interval $\underline{\vartheta}_{l,y} \leq y_{i,0} < \overline{\vartheta}_{l,y}$ and whose literacy rate L_i lies in the interval $\underline{\vartheta}_{l,L} \leq L_i < \overline{\vartheta}_{l,L}$. The number of subgroups and the boundaries for the variable intervals that define them are chosen by an algorithm that trades off model complexity (i.e. the number of subgroups) and goodness of fit. Because the procedure sequentially splits the data into finer and finer subgroups, it gives the data a tree structure.

[48]A detailed discussion of regression tree methods appears in Breiman, Friedman, Olshen and Stone (1984). The technical appendix of Durlauf and Johnson (1995) presents a treatment tailored to the specific question of identifying multiple regimes in growth models. Regression tree methods suffer from the absence of a well-developed asymptotic theory for testing the number of regimes that are present in a data set, but the procedure is consistent in the sense that under relatively weak conditions, if there are a finite number of regimes, as the sample size grows to infinity, the correct model will be revealed.

Durlauf and Johnson (1995) also test the null hypothesis of a common growth regime against the alternative hypothesis of a growth process with multiple regimes in which economies with similar initial conditions tend to converge to one another. Using income per capita and the literacy rate (as a proxy for human capital) to measure the initial level of development and, using the same cross-country data set as Mankiw, Romer, and Weil, Durlauf, and Johnson reject the single regime model required for global convergence. That is, even after controlling for the structural heterogeneity implied by Mankiw, Romer, and Weil's augmented version of the Solow model, there is a role for initial conditions in explaining variation in cross-country growth behavior.

Durlauf and Johnson's (1995) findings of multiple convergence clubs appear to be reinforced by subsequent research. Papageorgiou and Masanjala (2004) note that one possible source for Durlauf and Johnson's findings may occur due to the misspecification of the aggregate production function. As observed in Section II, the linear representation of the Solow model represents an approximation around the steady-state when the aggregate production function is Cobb-Douglas. Papageorgiou and Masanjala estimate a version of the Solow model based on a constant elasticity of substitution (CES) production function rather than the Cobb-Douglas, following findings in Duffy and Papageorgiou (2000). They then examine the question of whether or not Durlauf and Johnson's multiple regimes remain under the CES specification. Using Hansen's (2000) approach to sample splitting and threshold estimation, they find statistically significant evidence of thresholds in the data. The sample splits they estimate divide the data in four distinct growth regimes and are broadly consistent with those found by Durlauf and Johnson.[49]

[49]Motivated by the debate over trade openness and growth, Papageorgiou (2002) applies Hansen's method to the Durlauf and Johnson data with the trade share added to the set of variables on which sample splits may occur. He finds that this variable divides the middle-income countries into high and low growth groups obeying different growth processes; however openness does not appear to matter for high and low income countries. This suggests the importance of further work on which variables are most appropriate in characterizing threshold effects. Using the regression tree approach with a large collection of candidate split variables, Johnson and Takeyama (2001) find evidence of thresholds in US state economic growth behavior defined by variables likely to be proxies for capital/labor ratio, agglomeration effects, and communication effects.

These findings are extended in recent work due to Tan (2004) who employs a procedure known as GUIDE (generalized, unbiased interaction detection and estimation) to identify subgroups of countries which obey a common growth model.[50] Relative to CART, the GUIDE algorithm has two advantages: 1) the algorithm explicitly looks for interactions between explanatory variables when identifying splits and 2) some within model testing supplements the penalties for model complexity and thereby reduces the tendency for CART procedures to produce an excessive number of splits in finite samples. Tan (2004) finds strong evidence that measures of institutional quality and ethnic fractionalization define convergence clubs across a wide range of countries. He also finds weaker evidence that geography distinguishes the growth process for sub-Saharan Africa from the rest of the world.

Further research has corroborated the evidence of multiple regimes using alternative statistical methods. One approach that has proven useful is based on projection pursuit methods[51]. Desdoigts (1999) uses these methods in an attempt to separate the roles of microeconomic heterogeneity and initial conditions in the growth experiences of a group of countries and identifies groups of countries with relatively homogeneous growth experiences based on data about the characteristics and initial conditions of each country. The idea of projection pursuit is to find the orthogonal projections of the data into low dimensional spaces that best display some interesting feature of the data. A well-known special case of projection pursuit is principal components analysis. In principal components analysis, one takes only as many components as are necessary to account for "most" of the variation in the data. Similarly, in projection pursuit one should only consider as many dimensions as needed to account for "most" of the clustering in the data.

Desdoigts finds several interesting clusters. The first is the OECD countries. The two projections identifying this cluster put most of their weight on the primary and secondary school enrollment rates, the 1960 income gap and the rate of growth in the labor force. The prominence of variables that Desdoigts argues are proxies for initial

[50]GUIDE originates in Loh (2002).
[51]Projection pursuit is developed in Friedman and Tukey (1974) and Friedman (1987). Appendix A of Desdoigts (1999) provides a useful primer.

conditions among those defining the projections leads him to conclude that initial conditions are more important in defining this cluster than are other country characteristics. Reapplication of the clustering method to the remaining (non-OECD) countries yields three sub-clusters that can be described as Africa, Southeast Asia, and Latin America. Here the projections put most weight on government consumption, the secondary school enrollment rate and investment in electrical machinery and transportation equipment. Most of these variables are argued to proxy for structural characteristics of the economies, suggesting that they, rather than initial conditions, are responsible for the differences in growth experiences across the three geographic sub-clusters. Nevertheless, this approach relies on the judgment of the researcher in determining which variables proxy for initial conditions and which proxy for structural characteristics.

Further evidence of the utility of projection pursuit methods may be found in Kourtellos (2003b). Unlike Desdoigts, Kourtellos (2003b) uses projection pursuit to construct models of the growth process. Formally, he estimates models of the form

$$\gamma_i = \sum_{l=1}^{L} f_l \left(y_{i,0}\beta_l + X_i\psi_l + Z_i\pi_l \right) + \varepsilon_i \tag{55}$$

Each element in the summation represents a distinct projection. Kourtellos uncovers evidence of two steady-states, one for low initial income and low initial human capital countries.

A third approach to multiple regimes is employed by Bloom, Canning, and Sevilla (2003) based on the observation that if long-run outcomes are determined by fundamental forces alone, the relationship between exogenous variables and income levels ought to be unique. If initial conditions play a role there will be multiple relationships – one for each basin of attraction defined by initial conditions. If there are two (stochastic) steady states, and large shocks are sufficiently infrequent, [52] the system will, under suitable regularity

[52]The assumed rarity of large shocks implies that movements between basins of attraction of each of the steady states are sufficiently infrequent that they can be ignored in

conditions, exhibit an invariant probability measure that can be described by a "reduced form" model in which the long-run behavior of $\log y_{i,t}$ depends only on the exogenous variables, m_i, such as

$$\log y_{i,t} = \log y_1^*(m_i) + u_{1,i,t} \text{ with probability } p(m_i) \tag{56}$$

and

$$\log y_{i,t} = \log y_2^*(m_i) + u_{2,i,t} \text{ with probability } 1 - p(m_i) \tag{57}$$

where $u_{1,i,t}$ and $u_{2,i,t}$ are independent, zero-mean deviations from the steady-state log means $\log y_1^*(m_i)$ and $\log y_2^*(m_i)$ respectively, and $p(m_i)$ is the probability that country i is in the basin of attraction of the first of the two steady states. From the perspective of the econometrician, $\log y_{i,t}$ thus obeys a mixture process. The two steady states associated with (56) and (57) are possibly interpretable as a low-income regime or poverty trap and as a high-income or perpetual growth regime respectively. Bloom, Canning and Sevilla estimate a linear version of this model using 1985 income data from 152 countries with the absolute value of the latitude of the (approximate) center of each country as the fundamental exogenous variable. They are able to reject the null hypothesis of a single regime model in favor of the alternative of a model with two regimes – a high-level (manufacturing and services) steady state in which income is independent of latitude and a low-level (agricultural) steady-state in which income depends on latitude (presumably through its influence on climate). In addition, the probability of being in the high-level steady state is found to rise with latitude.

A final approach to multiple regimes is due to Canova (2004) who introduces a procedure for panel data that estimates the number of groups and the assignment of countries or regions to these groups, drawing on Bayesian ideas. This approach has the

---

estimation. This assumption is consistent with, for example, Bianchi's (1997) finding of very little mobility in the cross-country income distribution.

important feature that it allows for parameter heterogeneity across-countries within a given subgroup. The researcher can order the countries or regions by various criteria (for example, output per capita in the pre-sample period) and the estimation procedure then chooses break points and group membership in such a way that the predictive ability of the overall model is maximized. This approach is applied to autoregressive models of per capita output as in eq. (54) above.

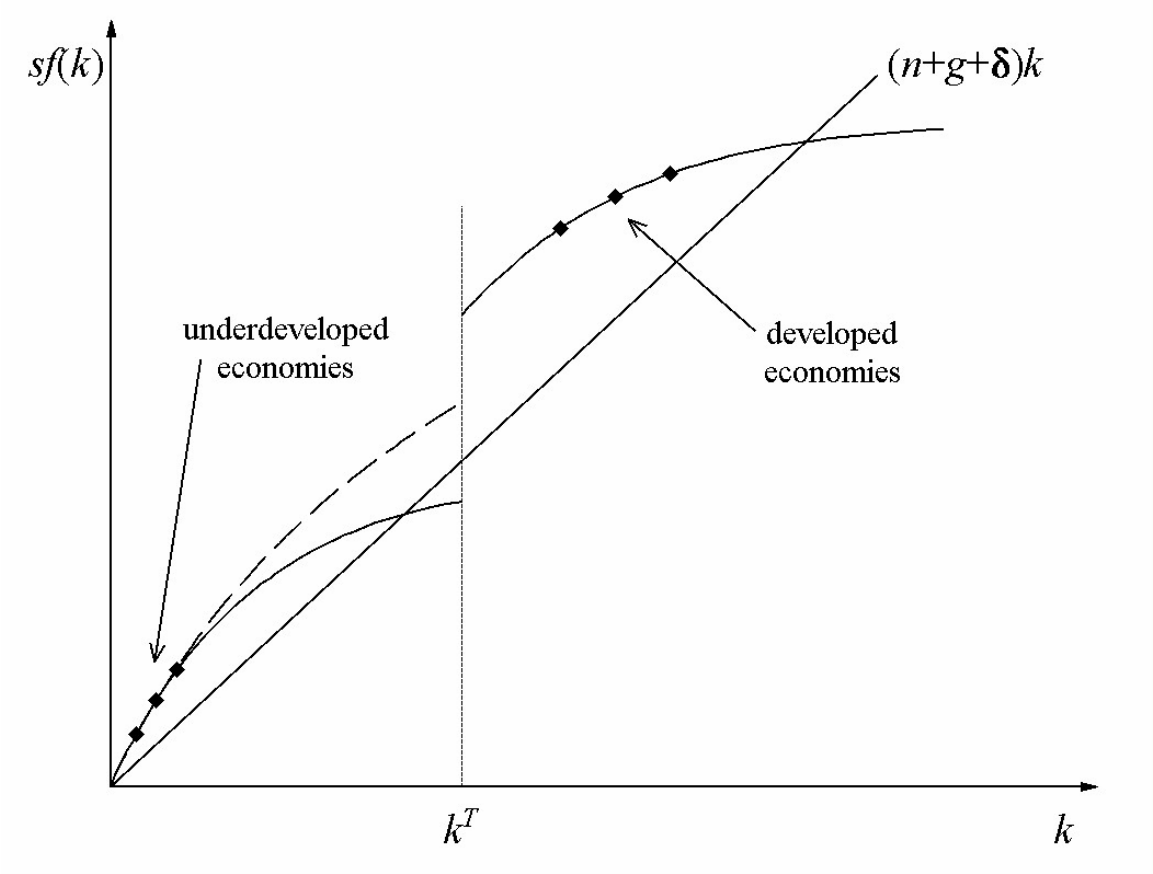
Using data on per capita income data in the regions of Europe, Canova (2004) finds that ordering the data by initial income maximizes the marginal likelihood of the model and breaks the data into 4 clusters. The estimated mean steady-states for each group are significantly different from each other implying that the groups are convergence clubs. The differences in the means are also economically important with the lowest and highest being 45% and 115% of the overall average respectively. Canova finds little across-group mobility especially among those regions that are initially poor. Using data on per capita income in the OECD countries, two clusters are found and, again, initial per capita income is the preferred ordering variable. The estimated model parameters imply an "economically large" long-run difference in the average incomes of countries in the two groups with little mobility between them.

In assessing these analyses, it is important to recognize an identification problem in attempting to link evidence of multiple growth regimes to particular theoretical growth models. As argued in Durlauf and Johnson (1995), this identification problem relates to whether evidence of multiple regimes represents evidence of multiple steady-states as opposed to nonlinearity in the growth process.

To see why this is so, suppose that one has identified two sets of countries that obey separate growth regimes with regime membership determined by a country's initial capital stock, i.e. there exists a capital threshold k^T that divides the two groups of countries. An example of this can be seen in Figure 8. Clearly, the two sets of countries do not obey a common linear model but it is not clear whether or not multiple steady-states exist. The output behavior of low capital countries is compatible with either the solid or dashed curve in the lower part of the figure, but only the solid curve produces multiple steady-states. The identification problem stems from the fact that one does not have observations that allow one to distinguish differences in the long-run behavior of

countries that start with capital stocks in the vicinity of k^T. This argument does not depend on growth regimes determined by the capital stock but it does depend on whether or not the variable or variables that define the regimes are growing over time, as would occur for initial income or initial literacy. For growing variables, the possibility exists that countries currently associated with low levels of the variable will in the future exhibit behaviors that are similar to those countries which are currently associated with high levels of the variables.

Figure 8: Nonlinearity Versus Multiple Steady-States



How might evidence of multiple steady-states be achieved? One possibility is via the use of structural models in empirical analysis. While this has not been done econometrically, Graham and Temple (2003) follow this strategy and calibrate a two-sector general equilibrium model with increasing returns to scale in nonagricultural production. Their empirically motivated choice of calibration parameters produces a model which implies that some countries are in a low-output equilibrium. Another possibility is to exploit time series variation in a single country to identify the presence of jumps from one equilibrium or steady state to another.

VI. Econometric issues I: alternative data structures

Our discussion of growth econometrics now shifts from general issues of hypothesis testing and model specification to explore specific econometric issues that arise in the estimation of growth models. This section reviews econometric issues that arise for the different types of data structures that appear in growth analyses. By data structures, we refer to features such as whether the data are observed in cross-section, time series, or panel as well as to whether particular data series are conceptualized as endogenous or exogenous. At the risk of stating the obvious, choices of method involve significant trade-offs, which depend partly on statistical considerations and partly on the economic context. This means that attempts at universal prescriptions are misguided, and we will try to show the desirability of matching techniques to the economic question at hand.

One example, to be discussed further below, would be the choice between panel data methods and the estimation of separate time series regressions for each country. The use of panel data is likely to increase efficiency and allow richer models to be estimated, but at the expense of potentially serious biases if the parameter homogeneity assumptions are incorrect. This trade-off between robustness and efficiency is another running theme of our survey. The scientific solution would be to base the choice of estimation method on a context-specific loss function, but this is clearly a difficult task, and in practice more subjective decisions are involved.

This section has four main elements. Section VI.i examines econometric issues that arise in the use of time series data to study growth, emphasizing some of the drawbacks of this approach. Section VI.ii discusses the many issues that arise when panel data are employed, an increasingly popular approach to growth questions. We consider the estimation of dynamic models in the presence of fixed effects, and alternatives to standard procedures. Section VI.iii describes another increasingly popular approach, namely the use of "event studies" to analyze growth behavior, based on studying responses to major shocks such as policy reforms. Section VI.iv examines endogeneity and the use of instrumental variables. We argue that the use of instrumental variables in growth contexts is more problematic than is often appreciated and suggest

the importance of combining instrumental variable choice with a systematic approach to model selection.

i. time series approaches

At first glance, the most natural way to understand growth would be to examine time series data for each country in isolation. As we saw previously, growth varies substantially over time, and countries experience distinct events that contribute to this variation, such as changes in government and in economic policy.

In practice a time series approach runs into substantial difficulties. One key constraint is the available data. For many developing countries, some of the most important data are only available on an annual basis, with limited coverage before the 1960s. Moreover, the listing of annual data in widely used sources and online databases can be misleading, because some key variables are measured less frequently. For example, population figures are often based primarily on census data, while measures of average educational attainment are often constructed by interpolating between census observations using school enrollments. When examining published data, it is not always clear where this kind of interpolation has been used. The true extent of information in the time series variation may be less than appears at first glance, and conventional standard errors on parameter estimates will be misleading when interpolated data are used.

Even where reliable data are available, some key growth determinants display relatively little time variation, a point that has been emphasized by Easterly et al (1993), Easterly (2001) and Pritchett (2000a). There do exist other variables that appear to show significant variation, but this variation may not correspond to the concept the researcher has in mind. An example would be political stability. Since Barro (1991), researchers have sometimes used the incidence of political revolutions and coups as a measure of political instability. The interpretation of such an index clearly varies depending on the length of the time period used to construct it. If the hypothesis of interest relates to underlying political uncertainty (say, the ex-ante probability of a transfer of power) then the observations on political instability would need to be averaged over a long time

period. The variation in political instability at shorter horizons only casts light on a different hypothesis, namely the direct impact of revolutions and coups.

There are other significant problems with the time series approach. The hypotheses of most interest to growth theorists are mainly about the evolution of potential output, not deviations from potential output such as business cycles and output collapses. Since measured output is a noisy indicator of potential output, it is easy for the econometric modeling of a growth process to be contaminated by business cycle dynamics. A simple way to illustrate this would be to consider what happens if measured log output is equal to the log of potential output plus a random error. If log output is trend stationary, this is a classical measurement error problem. When lags of output or the growth rate are used as explanatory variables, the parameter estimates will be inconsistent.

Such problems are likely to be even more serious in developing countries, where large slumps or crises are not uncommon, and output may deviate for long periods from any previous structural trend (Pritchett (2000a)). We have already seen the extent to which output behaves very differently in developing countries compared to OECD members, and a major collapse in output is not a rare event. There may be no underlying trend in the sense commonly understood, and conventional time series methods should be applied with caution. Some techniques that are widely used in the literature on business cycles in developed countries, such as the Hodrick-Prescott filter, will often be inappropriate in the context of developing countries.

The problem of short-run output instability extends further. It is easy to construct examples where the difference between observed output and potential output is correlated with variables that move up and down at high frequencies, with inflation being one obvious example. This means that time series studies of inflation and growth based on observed output will find it hard to isolate reliably an effect of inflation on potential output; for further discussion see Temple (2000a). When considerations like these are combined with the paucity of the available data, it appears a hard task to learn about long-term growth using time series regressions, especially when developing countries are the main focus of interest.

Nevertheless, despite these problems, there are some hypotheses for which time series variation can be informative. We have already seen the gains from time series approaches to convergence issues. Jones (1995) and Kocherlakota and Yi (1997) show how time series models can be used to discriminate between different growth theories. To take the simplest example, the AK model of growth predicts that the growth rate will be a function of the share of investment in GDP. Jones points out that investment rates have trended upwards in many OECD countries, with no corresponding increase in growth rates. Although this might be explained by offsetting changes in other growth determinants, it does provide evidence against simple versions of the AK model.

Jones (1995) and Kocherlakota and Yi (1997) develop a statistical test of endogenous growth models based on regressing growth on lagged growth and a lagged policy variable (or the lagged investment rate, as in Jones). Exogenous growth models predict that the coefficients on the lagged policy variable should sum to zero, indicating no long-run effect of permanent changes in this variable on the growth rate. In contrast, some endogenous growth models imply that the sum of coefficients should be non-zero. A simple time series regression then provides a direct test of the predictions of these models. More formally, as in Jones (1995), for a given country *i* one can investigate a dynamic relationship for the growth rate $\gamma_{i,t}$ where

$$\gamma_{i,t} = A(L)\gamma_{i,t-1} + B(L)z_{i,t} + \varepsilon_{i,t} \tag{58}$$

.

where z is the policy variable or growth determinant of interest, and $A(L)$ and $B(L)$ are lag polynomials assumed to be compatible with stationarity. The hypothesis of interest is whether $B(1) \neq 0$. If the sum of the coefficients in the lag polynomial $B(L)$ is significantly different from zero, this implies that a permanent change in the variable *z* will affect the growth rate indefinitely. As Jones (1995) explicitly discusses, this test is best seen as indicating whether a policy change affects growth over a long horizon, rather than firmly identifying or rejecting the presence of a long-run growth effect in the theoretical sense of that term. The theoretical conditions under which policy variables

affect the long-run growth rate are remarkably strict, and many endogenous growth models are best seen as new theories of potentially sizeable level effects.[53]

This approach is closely related to Granger-causality testing, where the hypothesis of interest would be the explanatory power of lags of $Z_{i,t}$ for $\gamma_{i,t}$ conditional on lagged values of $\gamma_{i,t}$. Blomstrom, Lipsey, and Zejan (1996) carry out Granger-causality tests for investment and growth using panel data with five-year subperiods. They find strong evidence that lagged growth rates have explanatory power for investment rates, but much weaker evidence for causality in the more conventional direction from investment to growth. Hence, the partial correlation between growth and investment found in many cross-section studies may not reflect a causal effect of investment. In a similar vein, Campos and Nugent (2002) find that, once Granger-causality tests are applied, the evidence that political instability affects growth may be weaker than usually believed.

The motivation for these two studies, and others like them, is that evidence of temporal precedence helps to build a case that one variable is influenced by another. When this idea is extended to panels, an underlying assumption is that timing patterns and effects will be similar across units (countries or regions). Potential heterogeneity has sometimes been acknowledged, as in the observation of Campos and Nugent (2002) that their results are heavily influenced by the African countries in the sample. The potential importance of these factors is also established in Binder and Brock (2004) who, by using panel methods to allow for heterogeneity in country-specific dynamics, find feedbacks from investment to growth beyond those that appear in Blomstrom, Lipsey, and Zejan (1996).

A second issue is more technical. Since testing for Granger-causality using panel data requires a dynamic model, the use of a standard fixed effects (within groups) estimator is likely to be inappropriate when individual effects are present. We discuss this further in section VI below. One potential solution is the use of instrumental variable procedures, as in Campos and Nugent (2002). In the context of investment and growth, a comprehensive examination of the associated econometric issues has been carried out by

[53]See Temple (2003) for more discussion of this point and the long-run implications of different growth models.

Bond, Leblebicioglu, and Schiantarelli (2004). Their work shows that these issues are more than technicalities: unlike Blomstrom, Lipsey, and Zejan (1996), they find strong evidence that investment has a causal effect on growth.

A familiar objection to the more ambitious interpretations of Granger-causality is that much economic behavior is forward-looking (see for example Klenow and Rodriguez-Clare (1997b)). The movements of stock markets are one instance where temporal sequences can be misleading about causality. Similarly, when entrepreneurs or governments invest heavily in infrastructure projects, or when unusually high inflows of foreign direct investment are observed, the fact that such investments precede strong growth does not establish a causal effect.

ii. panel data

As we emphasized above, the prospects for reliable generalizations in empirical growth research are often constrained by the limited number of countries available. This constraint makes parameter estimates imprecise, and also limits the extent to which researchers can apply more sophisticated methods, such as semiparametric estimators.

A natural response to this constraint is to use the within-country variation to multiply the number of observations. Using different episodes within the same country is ultimately the only practical substitute for somehow increasing the number of countries. To the extent that important variables change over time, this appears the most promising way to sidestep many of the problems that face growth researchers. Moreover, as the years pass and more data become available, the prospects for informative work of this kind can only improve.

We first discuss the implementation and advantages of panel data estimators in more detail, and then some of the technical issues that arise in the context of growth. Perhaps not surprisingly, these methods introduce a set of problems of their own, and should not be regarded as a panacea. Too often, panel data results are interpreted without sufficient care and risk leading researchers astray. In particular, we highlight the care needed in interpreting estimates based on fixed effects.

We will use T to denote the number of time series observations in a panel of N countries or regions. At first sight, T should be relatively high in this context, because of the availability of annual data. But the concerns about time series analysis raised above continue to apply. Important variables are either measured at infrequent intervals, or show little year-to-year variation that can be used to identify their effects. Moreover, variation in growth rates at annual frequencies may give very misleading answers about the longer-term growth process. For this reason, most panel data studies in the growth field have averaged data over five or ten year periods. Given the lack of data before 1960, this implies that growth panels not only have relatively few cross-sectional units (the number of countries employed is often between 50 and 100) but also very low values of T, often 5 or 6 at most.[54]

Most empirical growth models estimated using panel data are based on the hypothesis of conditional convergence, namely that countries converge to parallel equilibrium growth paths, the levels of which are a function of a few variables. A corollary is that an equation for growth (essentially the first difference of log output) should contain some dynamics in lagged output. In this case, the growth equation can be rewritten as a dynamic panel data model in which current output is regressed on controls and lagged output, as in Islam (1995). In statistical terms this is the same model, the only difference of interpretation being that the coefficient on initial output (originally β) is now $1+\beta$:

$$\log y_{i,t} = (1+\beta)\log y_{i,t-1} + \psi X_{i,t} + \pi Z_{i,t} + \alpha_i + \mu_t + \varepsilon_{i,t} \qquad (59)$$

This regression is a general panel analog to the cross-section regression (18). In this formulation, α_i is a country-specific effect and μ_t is a time-specific effect. The inclusion of time-specific effects is important in the growth context, not least because the means of the log output series will typically increase over time, given productivity growth at the world level.

[54]This is true of the many published studies that have used version 5.6 of the Penn World Tables. Now that more recent data are available, there is more scope for estimating panels with a longer time dimension.

Inclusion of a country-specific effect allows permanent differences in the level of income between countries that are not captured by $X_{i,t}$ or $Z_{i,t}$. In principle, one can also allow the parameters $1+\beta$, ψ, and π to differ across *i*; Lee, Pesaran, and Smith (1997,1998) do this for the coefficients for $\log y_{i,t-1}$ and a linear time trend (the latter allowing for steady-state differences in the rate of technological change, corresponding to non-parallel growth paths in the steady state).

The vast majority of panel data growth studies use a fixed effects (within-group) estimator rather than a random effects estimator. Standard random effects estimators require that the individual effects α_i are distributed independently of the explanatory variables, and this requirement is clearly violated for a dynamic panel such as (59) by construction, given the dependence of $\log y_{i,t}$ on α_i.

Given the popularity of fixed effects estimators, it is important to understand how these estimators work. In a fixed effects regression there is a full set of country-specific intercepts, one for each country, and inference proceeds conditional on the particular countries observed (a natural choice in this context). Identification of the slope parameters, usually constrained to be the same across countries, relies on variation over time within each country. The "between" variation, namely the variation across countries in the long-run averages of the variables, is not used.

The key strength of this method, familiar from the microeconometric literature, is the ability to address one form of unobserved heterogeneity: any omitted variables that are constant over time will not bias the estimates, even if the omitted variables are correlated with the explanatory variables. Intuitively, the country-specific intercepts can be seen as picking up the combined effects of all such variables. This is the usual motivation for using fixed effects in the growth context, especially in estimating conditional convergence regressions, as is further discussed in Islam (1995), Caselli Esquivel, and Lefort (1996) and Temple (1999). A particular motivation for the use of fixed effects arises from the Mankiw, Romer, and Weil (1992) implementation of the Solow model. As discussion in Section III, their version of the model implies that one determinant of the level of the steady-state growth path is the initial level of efficiency ($A_{i,0}$) and cross-section heterogeneity in it should usually be regarded as unobservable,

cf. eq. (15). Islam (1995) explicitly develops a specification in which this term is treated as a fixed effect, while world growth and common shocks are incorporated using time-specific effects.

The use of panel data methods to address unobserved heterogeneity can bring substantial gains in robustness, but is not without costs. The fixed-effects identification strategy cannot be applied in all contexts. Sometimes a variable of interest is measured at only one point in time. Even where variables are measured at more frequent intervals, some are highly persistent, in which case the within-country variation is unlikely to be informative. At one extreme, some explanatory variables of interest are essentially fixed factors, like geographic characteristics or ethnolinguistic diversity. Here the only available variation is "between-country", and empirical work will have to be based on cross-sections or pooled cross-section time-series. Alternatively a two-stage hybrid of these methods can be used, in which a panel data estimator is used to obtain estimates of the fixed effects, which are then explicitly modeled in a second stage as in Hoeffler (2002). As we discuss further below, an important direction for future panel data work may be the analysis of the information content of country-specific effects.

A common failing of panel data studies based on within-country variation is that researchers do not pay enough attention to the dynamics of adjustment. There are many panel data papers on human capital and growth that test only whether a change in school enrollment or years of schooling has an immediate effect on aggregate productivity, which seems an implausible hypothesis. Another example, given by Pritchett (2000a), is the use of panels to study inequality and growth. All too often, changes in the distribution of income are implicitly expected to have an immediate impact on growth. Yet many of the relevant theoretical papers highlight long-run effects, and there is a strong presumption that much of the short-run variation in measures of inequality is due to measurement error. In these circumstances, it is hard to see how the available within-country variation can shed much useful light.

There is also a more general problem. Since the fixed effects estimator ignores the between-country variation, the reduction in bias typically comes at the expense of higher standard errors. Another reason for imprecision is that either of the devices used to eliminate the country-specific intercepts – the within-groups transformation or first-

differencing – will tend to exacerbate the effect of measurement error.[55] As a result, it is common for researchers using panel data models with fixed effects, especially in the context of small *T*, to obtain imprecise sets of parameter estimates.

Given the potentially unattractive trade-off between robustness and efficiency, Barro (1997), Temple (1999), Pritchett (2000a) and Wacziarg (2002) all argue that the use of fixed effects in empirical growth models has to be approached with care. The price of eliminating the misleading component of the between variation – namely, the variation due to unobserved heterogeneity – is that all the between variation is lost.

There are alternative ways to reveal this point, but consider the random effects GLS estimator of the slope parameters, which will be more efficient than the within-country estimator for small *T* when the random-effects assumptions are appropriate. This GLS estimator can be written as a matrix-weighted average of the within-country estimator and the between-country estimator, which is based on averaging the data over time and then estimating a simple cross-section regression by OLS.[56] The weights on the two sets of parameter estimates are the inverses of their respective variances. The corollary of high standard errors using within-country estimation, indicating that the within-country variation is relatively uninformative, is that random effects estimates based on a panel of five-yearly averages are very similar to OLS estimates based on thirty-year averages (Wacziarg (2002)). Informally, the random effects estimator sees the between-country variation as offering the greatest scope for identifying the parameters.[57]

This should not be surprising: growth episodes within countries inevitably look a great deal more alike than growth episodes across countries, and therefore offer less identifying variation. Restricting the analysis to the within variation eliminates one source of bias, but immediately makes it harder to identify growth effects with any degree of precision. This general problem is discussed in Pritchett (2000a). Many of the

[55]See Arellano (2003, p. 47-51) for a more formal treatment of this issue.
[56]This result holds for the GLS estimator of the random effects model. In practice, since the true variance components are unknown, feasible GLS must be used.
[57]Of course, this does not imply that the random effects estimator is the best choice; as we have seen, the underlying assumptions for consistency of the estimator are necessarily invalid for a dynamic panel. Instead, our discussion is intended to draw attention to the trade-off between bias and efficiency in deciding whether or not to use fixed-effects estimation.

explanatory variables currently used in growth research are either highly stable over time, or tending to trend in one direction. Educational attainment is an obvious example. Without useful identifying variation in the time series data, the within-country approach is in trouble. Moreover, growth is quite volatile at short horizons. It will typically be hard to explain this variation using predictors that show little variation over time, or that are measured with substantial errors. The result has been a number of panel data studies suggesting that a given variable "does not matter" when a more accurate interpretation is that its effect cannot be identified using the data at hand.

Some of these problems suggest a natural alternative to the within-country estimator, which is to devote more attention to modeling the heterogeneity, rather than treating it as unobserved (Temple (1999)). To put this differently, current panel data methods treat the individual effects as nuisance parameters. As argued by Durlauf and Quah (1999) this is clearly inappropriate in the growth context. The individual effects are of fundamental interest to growth economists because they appear to be a key source of persistent income differences. This suggests that more attention should be given to modeling the heterogeneity rather than finding ways to eliminate its effects.[58]

Depending on the sources of heterogeneity, even simple recommendations, such as including a complete set of regional dummies, can help to alleviate the biases associated with omitted variables. More than a decade of growth research has identified a host of fixed factors that could be used to substitute for country-specific intercepts. A growth model that includes these variables can still exploit the panel structure of the data, and overall this approach has clear advantages in both statistical and economic terms. It means that the between variation is retained, rather than entirely thrown away, while the explicit modeling of the country-specific effects is directly informative about the sources of persistent income and growth differences.

In practice, the literature has focused on another aspect of using panel data estimators to investigate growth. Nickell (1981) showed that within-groups estimates of a

[58]Note that fixed-effects estimators could retain a useful role, because it would be natural to compare their parameter estimates with those obtained using a specific model for the heterogeneity. Where the estimates of common parameters, such as the coefficient on the lagged dependent variable, are different across the two methods, this could indicate the chosen model for the heterogeneity is misspecified.

dynamic panel data model can be badly biased for small *T*, even as *N* goes to infinity. The direction of this bias is such that, in a growth model, output appears less persistent than it should (the estimate of β is too low) and the rate of conditional convergence will be overestimated.

In other areas of economics, it has become increasingly common to avoid the within-groups estimator when estimating dynamic models. The most widely-used alternative strategy is to difference the model to eliminate the fixed effects, and then use two stage least squares or GMM to address the correlation between the differenced lagged dependent variable and the induced MA(1) error term. To see the need for instrumental variable procedures, first-difference (59) to obtain

$$\Delta \log y_{i,t} = (1+\beta)\Delta \log y_{i,t-1} + \Delta X_{i,t}\psi + \Delta Z_{i,t}\pi + \Delta \mu_i + \varepsilon_{i,t} - \varepsilon_{i,t-1} \qquad (60)$$

and note that (absent an unlikely error structure) the $\log y_{i,t-1}$ component of $\Delta \log y_{i,t-1}$ will be correlated with the ε_{it-1} component of the new composite error term, as is clearly seen by considering equation (59) lagged one period. Hence, at least one of the explanatory variables in the first-differenced equation will be correlated with the disturbances, and instrumental variable procedures are required.

Arellano and Bond (1991), building on work by Holtz-Eakin, Newey, and Rosen (1988), developed the GMM approach to dynamic panels in detail, including methods suitable for unbalanced panels and specification tests. Caselli, Esquivel, and Lefort (1996) applied their estimator in the growth context and, as discussed above, this approach yielded a much faster rate of conditional convergence than found in cross-section studies.

The GMM approach is typically based on using lagged levels of the series as instruments for lagged first differences. If the error terms in the levels equation (ε_{it}) are serially uncorrelated then $\Delta \log y_{i,t-1}$ can be instrumented using $\log y_{i,t-2}$ and earlier lagged levels (where available). This corresponds to a set of moment conditions that can be used to estimate the first-differenced equation by GMM. Bond (2002) provides an accessible introduction to this approach.

As an empirical strategy for growth research, this has some appeal, because it could alleviate biases due to measurement error and endogenous explanatory variables. In practice, many researchers are skeptical that lags are suitable instruments. It is easy to see that a variable such as educational attainment may influence output with a considerable delay, so that the exclusion of lags from the growth equation can look arbitrary. More generally, the GMM approach relies on a lack of serial correlation in the error terms of the growth equation (before differencing). Although this assumption can be tested using the methods developed in Arellano and Bond (1991), and can also be relaxed by an appropriate choice of instruments, it is nevertheless restrictive in some contexts.

Another concern is that the explanatory variables may be highly persistent, as is clearly true of output. Lagged levels can then be weak instruments for first differences, and the GMM panel data estimator is likely to be severely biased in short panels. Bond, Hoeffler, and Temple (2001) illustrate this point by comparing the Caselli, Esquivel, and Lefort (1996) estimates of the coefficient on lagged output with OLS and within-group estimates. Since the OLS and within-group estimates of β are biased in opposing directions then, leaving aside sampling variability and small-sample considerations, a consistent parameter estimate should lie between these two extremes (see Nerlove (1999,2000)). Formally, when the explanatory variables other than lagged output are strictly exogenous, we have

$$p\lim \hat{\beta}_{WG} < p\lim \hat{\beta} < p\lim \hat{\beta}_{OLS} \tag{61}$$

where $\hat{\beta}$ is a consistent parameter estimate, $\hat{\beta}_{WG}$ is the within-groups estimate and $\hat{\beta}_{OLS}$ is the estimate from a straightforward pooled OLS regression. For the data set and model used by Caselli, Esquivel and Lefort, this large-sample prediction is not valid, which raises a question mark over the reliability of the first-differenced GMM estimates.

One device that can be informative in short panels is to make more restrictive assumptions about the initial conditions. If the observations at the start of the sample are distributed in a way that is representative of steady-state behavior, in a sense that can be made more precise, efficiency gains are possible. Assumptions about the initial

conditions can be used to derive a "system" GMM estimator, of the form developed and studied by Arellano and Bover (1995) and Blundell and Bond (1998), and also discussed in Ahn and Schmidt (1995) and Hahn (1999). In this estimator, not only are lagged levels used as instruments for first differences, but lagged first differences are used as instruments for levels, which corresponds to an extra set of moment conditions.

There is some Monte Carlo evidence (Blundell and Bond (1998)) that this estimator is more robust than the Arellano-Bond method in the presence of highly persistent series. As also shown by Blundell and Bond (1998), the necessary assumptions can be seen in terms of an extra restriction, namely that the deviations of the initial values of $\log y_{i,t}$ from their long-run values are not systematically related to the individual effects.[59] For simplicity, we focus on the case where there are no explanatory variables other than lagged output. The required assumption on the initial conditions is that, for all $i = 1, \ldots, N$ we have

$$E\left[\left(\log y_{i,1} - \bar{y}_i\right)\alpha_i\right] = 0 \tag{62}$$

where the $\bar{y}_i$ are the long-run values of the $\log y_{i,t}$ series and are therefore functions of the individual effects α_i and the autoregressive parameter β. This assumption on the initial conditions ensures that

$$E\left[\Delta \log y_{i,2}\alpha_i\right] = 0 \tag{63}$$

and this together with the mild assumption that the changes in the errors are uncorrelated with the individual effects, i.e.

$$E\left[\Delta \varepsilon_{i,t}\alpha_i\right] = 0 \tag{64}$$

[59]Note that the long-run values of log output are evolving over time when time-specific effects are included in the model.

implies $T-2$ extra moment conditions of the form

$$E\left[\Delta \log y_{i,t-1}(\alpha_i + \varepsilon_{i,t})\right] = 0 \text{ for } i = 1,\ldots,N \text{ and } t = 3,\ 4,\ldots,T \qquad (65)$$

Intuitively, as is clear from the new moment conditions, the extra assumptions ensure that the lagged first difference of the dependent variable is a valid instrument for untransformed equations in levels since it is uncorrelated with the composite error term in the levels equation. These extra moment conditions can then be combined with the more conventional conditions used in the Arellano-Bond method. This builds in some insurance against weak identification, because if the series are persistent and lagged levels are weak instruments for first differences, it may still be the case that lagged first differences have some explanatory power for levels.[60]

In principle, the validity of the restrictions on the initial conditions can be tested using the incremental Sargan statistic (or C statistic) associated with the additional moment conditions. Yet the validity of the restriction should arguably be evaluated in wider terms, based on some knowledge of the historical forces giving rise to the observed initial conditions. This point – that key statistical assumptions should not always be evaluated only in statistical terms – is one that we will return to later.

Alternatives to GMM have been proposed. Kiviet (1995,1999) derives an analytical approximation to the Nickell bias that can be used to construct a bias-adjusted within-country estimator for dynamic panels. The simulation evidence reported in Judson and Owen (1999) and Bun and Kiviet (2001) suggests that this estimator performs well relative to standard alternatives when *N* and *T* are small. One minor limitation is that it cannot yet be applied to an unbalanced panel. A more serious limitation, relative to GMM, is that it does not address the possible correlation between the explanatory variables and the disturbances due to simultaneity and measurement error. Nevertheless, for researchers determined to use fixed effects estimation, there is a clear case for implementing this bias adjustment, at least as a complement to other methods.

[60] An alternative approach would be to use small-sample bias adjustments for GMM panel data estimators, such as those described in Hahn, Hausman, and Kuersteiner (2001).

A further issue that arises when estimating dynamic panel data models is that of parameter heterogeneity. If a slope parameter such as β varies across countries, and the explanatory variable is serially correlated, this will induce serial correlation in the error term. If we focus on a simple case where a researcher wrongly assumes $\beta_i = \beta$ for all $i = 1, \ldots, N$ then the error process for a given country will contain a component that resembles $(\beta_i - \beta) \log y_{i,t-1}$. Hence there is serial correlation in the errors, given the persistence of output. The estimates of a dynamic panel data model will be inconsistent even if GMM methods are applied.

This problem was analyzed in more general terms by Robertson and Symons (1992) and Pesaran and Smith (1995) and has been explored in great depth for the growth context by Lee, Pesaran, and Smith (1997,1998). Since an absence of serial correlation in the disturbances is usually a critical assumption for the GMM approach, parameter heterogeneity can be a serious concern. Some of the possible solutions, such as regressions applied to single time series, or the pooled mean group estimator developed by Pesaran, Shin, and Smith (1999), have limitations in studying growth for reasons already discussed. An alternative solution is to split the sample into groups that are more likely to share similar parameter values. Groupings by regional location or level of development are a natural starting point.

Perhaps the state of the art in analyzing growth using panel data and allowing for parameter heterogeneity is represented by Phillips and Sul (2003). They allow for heterogeneity in parameters not only across countries, but also over time. Temporal heterogeneity is rarely investigated in panel studies, but may be important, especially if observed growth patterns combine transitional dynamics towards a country's steady state with fluctuations around that steady-state. Phillips and Sul find some evidence of convergence towards steady states for OECD economies as well as US regions.

We close our discussion of panel data approaches by noting some unresolved issues in their application. It is important to be aware how panel data methods change the substantive interpretation of regression results, and care is needed when moving between the general forms of the estimators and the economic hypotheses under study. Relevant examples occur in analyses of β-convergence. If one finds β-convergence in a panel

study having allowed for fixed effects, the interpretation of this finding is very different than if one finds evidence of convergence in the absence of fixed effects. Specifically, the presence of fixed effects represents an immediate violation of our convergence definitions (20) or (22) as different economies must exhibit steady-state differences in per capita income regardless of whether they have identical saving rates and population growth rates.[61] Fixed effects may even control for the presence of unmodelled determinants of steady state growth, an identification problem analogous to the one that was previously discussed in the context of interpreting the control variables Z in equations (17) and (18) above. Similarly, allowing for differences in time trends for per capita output, as done in Lee, Pesaran, and Smith (1997,1998) means that the finding of extremely rapid β-convergence is consistent with long-run divergence of per capita output across the economies they study; the long-run balanced growth paths are no longer parallel. In an interesting exchange, Lee, Pesaran, and Smith (1998) criticize Islam (1995) for failing to allow for different time trends across countries. In response, Islam (1998) argues that Lee, Pesaran, and Smith are assessing an economically uninteresting form of convergence when they allow for trend differences. This debate is an excellent example of the issues of interpretation that are raised in moving between specific economic hypotheses and more general statistical models.

One drawback of many current panel studies is that the construction of the time series observations can appear arbitrary. There is no inherent reason why 5 or 10 years represent natural spans over which to average observations. Similarly, there is arbitrariness with respect to which time periods are aggregated. A useful endeavor would be the development of tools to ensure that panel findings are robust with respect to the assumptions employed in creating the panel from the raw data.

More fundamentally, the empirical growth literature has not fully addressed the question of the appropriate time horizons over which growth models should be assessed. For example, it remains unclear when business cycle considerations (or instances of output collapses) may be safely ignored when modeling the growth process. While cross-section studies that examine growth over 30-40 year periods might be exempt from this

[61] The impact of controlling fixed effects for interpreting β-convergence is recognized in the conclusion to Islam (1995).

consideration, it is less clear that panel studies employing 5-year averages are genuinely informative about medium-run growth dynamics.

iii. event study approaches

Although we have focused on the limitations of panel data methods, it is clear that the prospects for informative work of this kind should improve over time. The addition of further time periods is valuable in itself, and the history of developing countries in the 1980s and 1990s offers various events that introduce richer time series variation into the data. These events include waves of democratization, macroeconomic stabilization, financial liberalization, and trade liberalization, and panel data methods can be used to investigate their unfolding consequences for growth.

An alternative approach has become popular, and proceeds in a similar way to event studies in the empirical finance literature. In event studies, researchers look for systematic changes in asset returns after a discrete event, such as a profits warning. In fields outside finance, before-and-after studies like this have proved an informative way to gauge the effects of devaluations (see Pritchett (2000a) for references), of inflation stabilization (Easterly (1996)) and the consequences of the debt crisis for investment, as in Warner (1992).

Pritchett (2000a) argues that there is a great deal of scope for studying the growth impact of major events and policy changes in a similar way. The obvious approach is to study the time paths of variables such as output growth, investment and TFP growth, examined before and after such events. In empirical growth research, Henry (2000,2003) has applied this form of analysis to the effects of stock market liberalization on investment and growth, Giavazzi and Tabellini (2004) have considered economic and political liberalizations, while Wacziarg and Welch (2003) have studied the effects of trade liberalization. Depending on the context, one can also study the response of other variables in a way that is informative about the channels of influence. For example, in the case of trade liberalization, it is natural to study the response of the trade share, as in the work of Wacziarg and Welch.

The rigor of this method should not be overplayed. As with any other approach to empirical growth, one has to be cautious about inferring a causal effect. This is clear from exploring the analogy with treatment effects, a focus of recent research in microeconometrics and labor economics.[62] In the study of growth, the treatments – such as democratization – are clearly not exogenously assigned, but are events that have arisen endogenously. Moreover, the treatment effects will be heterogeneous and could depend, for example, on whether a policy change is seen as temporary or permanent (Pritchett (2000a)). In these circumstances, the ability to quantify even an average treatment effect is strongly circumscribed. It may be possible to identify the direction of effects, and here the limited number of observations does have one advantage. With a small number of cases to examine, it is easy for the researcher to present a graphical analysis that allows readers to gauge the extent of heterogeneity in responses, and the overall pattern. At the very least, this offers a useful complement to regression-based methods.

iv. endogeneity and instrumental variables

A final set of data-based issues concerns the identification of instrumental variables in cross-section and time series contexts. An obvious and frequent criticism of growth regressions is that they do little to establish directions of causation. At one level, there is the standard problem that two variables may be correlated but jointly determined by a third. It is very easy to construct growth examples. Variables such as growth and political stability could be seen as jointly determined equilibrium outcomes associated with, say, a particular set of institutions. In this light, a correlation between growth and political stability, even if robust in statistical terms, does not appear especially informative about the structural determinants of growth.

There are many instances in growth research when explanatory variables are clearly endogenously determined (in the economic, not the statistical sense). The most familiar example would be a regression that relates growth to the ratio of investment to

[62]This connection with the treatment effect literature is sometimes explicitly made, as in Giavazzi and Tabellini (2004) and Persson and Tabellini (2003). The connection helps to understand the limitations of the evidence, but the scope for resolving the associated identification problems may be limited in cross-country data sets.

GDP. This may tell us that the investment share and growth are associated, but stops short of identifying a causal effect. Even if we are confident that a change in investment would affect growth, in a sense this just pushes the relevant question further back, to an understanding of what determines investment.

When variables are endogenously determined in the economic sense, there is also a strong chance that they will be endogenous in the technical sense, namely correlated with the disturbances in the structural equation for growth. To give an example, consider what happens if political instability lowers growth, but slower economic growth feeds back into political instability. The estimated regression coefficient will tend to conflate these two effects and will be an inconsistent estimate of the causal effect of instability.[63]

Views on the importance of these considerations differ greatly. One position is that the whole growth research project effectively capsizes before it has even begun, but Mankiw (1995) and Wacziarg (2002) have suggested an alternative view. According to them, one should accept that reliable causal statements are almost impossible to make, but use the partial correlations of the growth literature to rule out some possible hypotheses about the world. Wacziarg uses the example of the negative partial correlation between corruption and growth found by Mauro (1995). Even if shown to be robust, this correlation does not establish that somehow reducing corruption will be followed by higher growth rates. But it does make it harder to believe some of the earlier suggestions, rarely based on evidence, that corruption could be actively beneficial.

One approach is to model as many as possible of the variables that are endogenously determined. A leading example is Tavares and Wacziarg (2001), who estimate structural equations for various channels through which democracy could influence development. In their analysis, democracy affects growth via factors such as its effect on human capital accumulation, physical capital accumulation, inequality and government expenditures. They conclude the net effect of democracy on growth is

[63]Although this 'reverse causality' interpretation of endogeneity is popular and important, it should be remembered that a correlation between an explanatory variable and the error term can arise for other reasons, including omitted variables and measurement error. As we discuss, it is important to bear this more general interpretation of the error term in mind when judging the plausibility of exclusion restrictions in instrumental variable procedures.

slightly negative, despite the positive contributions that are made from the role of democracy in promoting greater human capital and reduced inequality.

This approach has some important advantages in both economic and statistical terms. It can be informative about underlying mechanisms in a way that much empirical growth research is not. From a purely statistical perspective, if the structural equations are estimated jointly by methods such as three stage least squares or full information maximum likelihood, this is likely to bring efficiency gains. That said, systems estimation is not necessarily the best route: it has the important disadvantage that specification errors in one of the structural equations could contaminate the estimates obtained for the others.

The most common response to the endogeneity of growth determinants has been the application of instrumental variable procedures to a single structural equation, with growth as the dependent variable. As mentioned in Section IV, two growth studies that employ instrumental variables estimators based on lagged explanatory variables are Barro and Lee (1994) and Caselli, Esquivel, and Lefort (1996). Appendices 3 and 4 describe a wide range of other instrumental variables that have been proposed for the Solow variables and other growth determinants respectively, where the focus has been on the endogeneity of particular variables. The variety of instruments that have been proposed illustrates that it is relatively straightforward to find an instrument that is correlated with the endogenous explanatory variable(s).

This apparent success may be illusory. In our view, the belief that it is easy to identify valid instrumental variables in the growth context is deeply mistaken. We regard many applications of instrumental variable procedures in the empirical growth literature to be undermined by the failure to address properly the question of whether these instruments are valid, i.e. whether they may be plausibly argued to be uncorrelated with the error term in a growth regression. When the instrument is invalid, instrumental variables estimates will of course be inconsistent. Not enough is currently known about the consequences of "small" departures from validity, but it is certainly possible to envisage circumstances under which ordinary least squares would be preferable to instrumental variables on, say, a mean square error criterion.

A common misunderstanding, perhaps based on confusing the economic and statistical versions of "exogeneity", is that predetermined variables, such as geographical characteristics, are inevitably strong candidates for instruments. There is, however, nothing in the predetermined nature of these variables to ensure either that they are not direct growth determinants or that they are uncorrelated with omitted growth determinants. Even if we take the extreme (from the perspective of being predetermined) example of geographic characteristics, there are many channels through which these could affect growth, and therefore many ways in which they could be correlated with the disturbances in a growth model. Brock and Durlauf (2001a) use this type of reasoning to make a very general critique of the use of instrumental variables in growth economics, basing it on the notion of theory open-endedness that we have described earlier. Since growth theories are mutually compatible, the validity of an instrument requires a positive argument that it cannot be a direct growth determinant or correlated with an omitted growth determinant. For many of the instrumental variables that have been proposed, this is clearly not the case.

Discussions of the validity of instruments inevitably suffer from some degree of imprecision because of the need to make qualitative and subjective judgments. When one researcher claims that it is implausible that a given instrument is valid, unless this claim is made on the basis of a joint model of the instruments and the variable of original interest, another researcher can always simply reject the assertion as unpersuasive. To be clear, this element of subjectivity does not mean that arguments about validity are pointless.[64] Rather, one must recognize that not all statistical questions can be adjudicated on the basis of mathematical analysis.

To see how different instruments might be assigned different levels of plausibility, we consider two examples. Brock and Durlauf (2001a) single out Frankel and Romer's (1999) geographic instruments as an example where instrument validity

[64]Put differently, one does not require a precise definition of what makes an instrument valid in order to argue whether a given instrument is valid or not. To take an example due to Taylor (1998), the absence of a precise definition of money does not weaken my belief that the currency in my wallet is a form of money, whereas the computer on which this paper is written is not. To claim such arguments cannot be made is known as the Socratic fallacy.

appears suspect as such variables are likely correlated with features of a country's economic, political, legal, and social institutions.[65] In our view, the large body of theoretical and empirical evidence on the role of institutions on growth, as well as even a cursory reading of history, renders the orthogonality assumptions required to use the instruments questionable.[66] For example, it is a standard historical claim that the fact that Great Britain is an island had important implications for its political development. While Frankel (2003) suggests that this worry is contrived, the argument against instrument validity flows quite naturally from modern growth theory and the many possible ways in which geographic characteristics such as remoteness could influence development.

As an example where instrument validity may be more plausible, consider Cook (2002a). He employs measures of damage caused by World War II as instruments for various growth regressors such as savings rates. The validity of Cook's instruments again relies on the orthogonality of World War II damage with omitted postwar growth determinants. It may be that levels of wartime damage had consequences for post-War growth performance in other respects (such as institutional change) but this argument is perhaps less straightforward than in the case of geographic characteristics.

To be clear, this discussion is nowhere near sufficient to conclude that Frankel and Romer's instruments are invalid whereas Cook's are valid. Rather our point is that conclusions concerning the relative plausibility of one set of instruments versus another need to rest on explicit arguments. It is not enough to appeal to a variable being predetermined, because this does not ensure that it is uncorrelated with the disturbances in the structural equation being estimated. A key implication of our discussion is that historical information has a vital role to play in facilitating formal growth analyses and evaluating exclusion restrictions.

---

[65]While questions about the validity of instrumental variables arise in virtually all contexts, the force of these concerns differs across contexts. For example, in rational expectations models, lagged variables are natural instruments with respect to variables that, from the perspective of the theoretical model, are martingale differences, as occurs for excess holding returns. Objections to particular instruments in these contexts typically rely on alternative specifications of preferences or some other modification of the economic logic of the original model. This is quite different from the openendedness of growth theories.

[66]The body of work on institutions and growth excellently summarized in Acemoglu, Johnson, and Robinson (2004) is strongly supportive of this claim.

This discussion of instrumental variables indicates another important, albeit neglected, issue in empirical growth analysis: the relationship between model specification and instrumental variable selection. One cannot discuss the validity of particular instruments independently from the choice of the specific growth determinants under study. An important outstanding research question is whether model uncertainty and instrumental variable selection can be integrated simultaneously into some of the methods we have described, including model averaging and automated model selection. The recent work of Hendry and Krolzig (2005) on automated methods includes an ambitious approach to systematic model selection for simultaneous equation models in which identifying restrictions are determined by the data.

VII. Econometric issues II: data and error properties

In this section we consider a range of questions that arise in growth econometrics from the properties of data and errors. Starting with data issues, Section VII.i examines how one may handle outliers in growth data. Section VII.ii examines the problem of measurement error. This is an important issue since there are good reasons to believe that the quality of the data is sometimes poor for less developed economies. In Section VII.iii we consider the case where data are not even measured, i.e are missing. Turning to issues of the properties of model errors, Section VII.iv examines the analysis of heteroskedasticity in growth contexts. Finally, Section VII.v addresses the problem of cross-section correlation in model errors.

i. outliers

Empirical growth researchers often work with small data sets and estimate relatively simple models. In these circumstances, OLS regressions are almost meaningless unless they have been accompanied by systematic investigation of the data, including the sensitivity of the results to outlying observations.

There are various reasons why some observations may be unrepresentative. It is possible for variables to be measured with error for that particular region or country. Alternatively, the model specified by the researcher may omit a relevant consideration, and so a group of country observations will act as outliers. By construction, least squares estimates can be highly sensitive to the presence of small groups of observations. The practical implication is that OLS can give a misleading account of the patterns in the majority of the data. The dangers of using OLS were forcibly expressed by Swartz and Welsch (1986, p. 171): "In a world of fat-tailed or asymmetric error distributions, data errors, and imperfectly specified models, it is just those data in which we have the least faith that often exert the most influence on the OLS estimates".

Some researchers respond to this concern using leverage measures or single-case diagnostics such as Cook's distance statistic. There are well-known problems with these approaches, because where more than one outlier is present, its effect can easily be hidden by another (known in the statistics literature as "masking"). By far the best response is to use a more robust estimator, such as least trimmed squares, at least as a preliminary way of investigating the data.[67] These issues are discussed in more detail in Temple (1998,2000b).

ii. measurement error

We now turn to a more general discussion of measurement error. It is clear that measurement errors are likely to be pervasive, especially in data that relate to developing countries. Concepts that appear straightforward in economic models can present huge measurement problems in practice, as in the example of the capital stock discussed by Pritchett (2000b). Yet relatively few empirical studies of growth consider the impact of measurement error in any detail.

[67]This estimator should not be confused with trimmed least squares, and other methods based on deleting observations with high residuals in the OLS estimates. A residual-based approach is inadequate for obvious reasons.

The best-known statistical result applies to a bivariate model where the independent variable is measured with error.[68] The estimate of the slope coefficient will be biased towards zero, even in large samples, because measurement error induces covariance between the observable form of the regressor and the error term. This attenuation bias is well known, but sometimes misleads researchers into suggesting that measurement error will only mask effects, a claim that is not true in general. When there are multiple explanatory variables, but only one is measured with error, then typically all the parameter estimates will be biased. Some parameter estimates may be biased away from zero and, although the direction of the bias can be estimated consistently, this is rarely done. When several variables are measured with error, the assumption that measurement error only hides effects is even less defensible.

Where measurement error is present, the coefficients are typically not identified unless other information is used. The most popular solution is to use instrumental variables, if an instrument can be found which is likely to be independent of the measurement error. A more complex solution is to exploit higher-order sample moments to construct more sophisticated estimators, as in Dagenais and Dagenais (1997). These procedures may be unreliable in small samples since the use of higher-order moments will make them especially sensitive to outliers.

Sometimes partial identification is possible, in the sense that bounds on the extent of measurement error can be used to derive consistent estimates of bounds on the slope parameters. Although it can be difficult for researchers to agree on sensible bounds on the measurement error variances, there are easier ways of formulating the necessary restrictions, as discussed by Klepper and Leamer (1984). Their reverse regression approach was implemented by Persson and Tabellini (1994) and Temple (1998), but has rarely been used by other researchers. Another strategy is to investigate sensitivity to varying degrees of measurement error, based on method-of-moments corrections. Again, this is easy to implement in linear models, and should be applied more routinely than it is at present. Temple (1998) provides a discussion of both approaches in the context of

[68]This and the following discussion assume classical measurement error. Under more general assumptions, it is usually even harder to identify the consequences of measurement error for parameter estimates.

estimating technology parameters and the rate of conditional convergence within the Mankiw, Romer, and Weil (1992) model.

iii. missing data

Some countries never appear in growth data sets, partly by design: it is common to leave out countries with very small populations, oil producers, and transition economies. These are countries that seem especially unlikely to lie on a regression surface common to the majority of the OECD countries or the developing world. Countries with small populations should not be allowed to carry a great deal of weight in attempting to draw generalizations about growth for larger countries.

Other countries are left out for different reasons. When a nation experiences political chaos, or lacks economic resources, the collection of national accounts statistics will be a low priority. This means that countries like Afghanistan, Ethiopia and Somalia rarely appear in comparative growth studies. In other cases, countries appear in some studies but not in others, depending on the availability of particular variables of interest.

Missing data are of course a potentially serious problem. If one started from a representative data set and then deleted countries at random, this would typically increase the standard errors but not lead to biased estimates. More serious difficulties arise if countries are missing in a systematic way, because then parameter estimates are likely to be biased. This problem is given relatively little attention in mainstream econometrics textbooks, despite a large body of research in the statistics literature.

A variety of solutions are possible, with the simplest being one form or another of imputation, with an appropriate adjustment to the standard errors. Hall and Jones (1999) and Hoover and Perez (2004) are among the few empirical growth studies to carry out imputation in a careful and systematic way. This approach may be especially useful when countries are missing from a data set because a few variables are not observed for their particular cases. It is then easy to justify using other available information to predict the missing data, and thereby exploit the additional information in the variables that are observed. Alternative approaches to missing data are also available, based on likelihood or Bayesian methods, which can be extended to handle missing observations.

iv. heteroskedasticity

It is common in cross-section regressions for the underlying disturbances to have a non-constant variance. As is well known, the coefficient estimates remain unbiased, but OLS is inefficient and the estimates of the standard errors are biased. Most empirical growth research simply uses the heteroskedasticity-consistent standard errors developed by Eicker (1967) and White (1980). These estimates of the standard errors are consistent but not unbiased, which suggests that alternative solutions to the problem may be desirable. For data sets of the size found in cross-country empirical work, the alternative estimators developed by MacKinnon and White (1985) are likely to have better finite sample properties, as discussed in Davidson and MacKinnon (1993) and supported by simulations in Long and Ervin (2000).

There are at least two other concerns with the routine application of White's heteroskedasticity correction as the only response to heteroskedasticity. The first is that by exploiting any structure in the variance of the disturbances, using weighted least squares, it may be possible to obtain efficiency gains. The second and more fundamental objection is that heteroskedasticity can often arise from serious model misspecification, such as omitted variables or neglected parameter heterogeneity. Evidence of heteroskedasticity should then prompt revisions of the model for the conditional mean, rather than mechanical adjustments to the standard errors. See Zietz (2001) for further discussion and references.

v. cross-section error correlation

An unresolved issue in growth econometrics is the treatment of cross-section correlation in model errors. Such correlation may have important consequences for inference; as noted by DeLong and Summers (1991) in the growth context, failure to account for cross-sectional dependence can lead to incorrect calculation of standard errors and hence, incorrect inferences. One would certainly expect cross-sectional dependence to be present when studying growth. For example, countries that are geographically close together, or trading partners, may experience common shocks.

Whether this effect is sizeable remains an open question, but one that might be addressed using ideas developed in Baltagi et al. (2003) and Driscoll and Kraay (1998), among others. In the context of growth regressions, work on cross-section dependence may be divided into two lines. One direction concerns the identification of the presence of cross-section dependence. Pesaran (2004a) develops tests for cross-section dependence that do not rely on any prior ordering; this framework in essence sums the cross-section sample error correlations in a panel and evaluates whether they are consistent with the null hypothesis that the population correlations are zero. Specifically, he proposes (recalling that N denotes the cross-section dimension and T the time dimension) a cross-section dependence statistic CD

$$CD = \sqrt{\frac{2T}{N(N-1)}}\left(\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}\hat{\rho}_{i,j}\right) \tag{66}$$

where $\hat{\rho}_{i,j}$ is the sample correlation between $\varepsilon_{i,t}$ and $\varepsilon_{j,t}$; Pesaran gives conditions under which this statistic converges to a Normal (0,1) random variable (as N and T become infinite) under the null hypothesis of no cross-section correlation. This test statistic is based on earlier work by Breusch and Pagan (1980) and appears to possess good finite sample properties in comparison to this earlier work. Using a country-level panel, Pesaran (2004a) finds strong rejections of the null of no cross-section correlation both for the world as a whole as well as within several geographic groupings.

The second and primary direction for the analysis of cross-section correlation has been concerned not so much with testing for its presence, but rather accounting for its presence in growth exercises. One approach relies on formulating a statistical model of the dependence. Phillips and Sul (2003) model the residuals in a growth panel as

$$\varepsilon_{i,t} = \delta_i \theta_t + u_{i,t} \tag{67}$$

where θ_t and $u_{i,t}$ are independent random variables; $u_{i,t}$ is assumed to be i.i.d. across countries and across time. Phillips and Sul (2002) describe the properties of panel estimators under this assumption.

Another possibility in analyzing cross-sectional dependence is to treat the problem as one of spatial correlation in errors. The problem of spatial correlation has been much studied in the regional science literature, and statisticians in this field have developed spatial analogues of many time series concepts, see Anselin (2001) for an overview. Spatial methods have, in our view, an important role to play in growth econometrics. However, when these methods are adapted from the spatial statistics literature, they raise the problem of identifying the appropriate notion of space. One can imagine many reasons for cross-section correlation. If one is interested in technological spillovers, it may well be the case that in the space of technological proximity, the United Kingdom is closer to the United States than is Mexico. Put differently, unlike the time series and spatial cases, there is no natural cross-section ordering to elements in the standard growth data sets. Following language due to Akerlof (1997) countries are perhaps best thought of as occupying some general socio-economic-political space defined by a range of factors; if one could identify their locations, then spatial methods could be implemented.

An interesting approach to addressing the relevant spatial location of countries is pursued by Conley and Ligon (2002). In their analysis, they attempt to construct estimates of the spatial covariation of the residuals ε_i in a cross-section. In order to do this, they construct different measures of socioeconomic distance between countries. They separately consider geographic distance (measured between capital cities), as well as measures of the costs of transportation between these cities. Once a distance metric is constructed, these are used to construct a residual covariance matrix. Estimation methods for this procedure are developed in Conley (1999). Conley and Ligon (2002) find that allowing for cross-section dependence in this way is relatively unimportant in terms of appropriate calculation of standard errors for growth model parameters. Their methods could be extended to allow for comparisons of different variables as the source for cross-section correlation as is done in Conley and Topa (2002) in the context of residential neighborhoods. A valuable generalization of this work would be the modeling of cross-

section correlations as a function of multiple variables. Such an analysis would make further progress on the measurement of distances in socioeconomic space, which, as we have suggested, presumably are determined by multiple channels.

A generally unexplored possibility for studying cross-section dependence in growth (and other contexts) is to model these correlations structurally as the outcome of spillover effects.[69] The theoretical literature on social interactions studies cross-sectional dependences in precisely this way (see Brock and Durlauf (2001b) for a survey of this literature). While such models have the potential for providing firm microfoundations for cross-section dependence, the presence of such spillovers has consequences for identification that are not easily resolved (Brock and Durlauf (2001b), Manski (1993)) and which have yet to be explored in growth contexts; Binder and Pesaran (2001) and Brock and Durlauf (2001b) analyze identification and estimation problems for intertemporal environments that are particularly germane to growth contexts.

VIII. Conclusions: the future of growth econometrics

In this section, we offer some closing thoughts on the most promising directions for empirical growth research. We are not the first authors to set out manifestoes for the field, and we explicitly draw on previous contributions, many of which deserve wider currency. It is also interesting to compare the current state of the field against the verdicts offered in the early survey by Levine and Renelt (1991). One dominant theme will be that the empirical study of growth requires an eclectic approach, and that the field has been harmed by a tendency for research areas to evolve independently, without enough interaction.[70] This is not simply a question of using a variety of techniques: it also means that there needs to be a closer connection between theory and evidence, a willingness to

[69] An exception is Easterly and Levine (1997b).

[70] To give a specific example, the macroeconomic literature on international technology differences only rarely acknowledges relevant work by trade economists, including estimates of the Heckscher-Ohlin-Vanek model that suggest an important role for technology differences. See Klenow and Rodriguez-Clare (1997b) for more discussion.

draw on ideas from areas such as trade theory, and more attention to particular features of the countries under study.

We start with Pritchett (2000a), who lists three questions for growth researchers to address:

- What are the conditions that initiate an acceleration of growth or the conditions that set off sustained decline?
- What happens to growth when policies – trade, macroeconomic, investment – or politics change dramatically in episodes of reform?
- Why have some countries absorbed and overcome shocks with little impact on growth, while others seem to have been overwhelmed by adverse shocks?

This agenda seems to us very appropriate, not least because it focuses attention on substantive economic issues rather than the finer points of estimating aggregate production functions. The importance of the first of Pritchett's questions is evident from the many instances where countries have moved from stagnation to growth and vice versa. A paper by Hausmann, Pritchett, and Rodrik (2004) explicitly models transitions to fast growth ("accelerations") and makes clear the scope for informative work of this kind. The second question we have discussed above, and research in this vein is becoming prominent, as in Henry (2000, 2003), Giavazzi and Tabellini (2004), and Wacziarg and Welch (2003). Here, one of the major challenges will be to relax the (sometimes only implicit) assumption that policies are randomly assigned. Finally, an important paper by Rodrik (1999) has addressed the third question, namely what determines varying responses to major shocks.

In all three cases, it is clear that econometric work should be informed by detailed studies of individual countries, such as those collected in Rodrik (2003). Too much empirical growth research proceeds without enough attention to the historical and institutional context. For example, a newcomer to this literature might be surprised at the paucity of work that integrates growth regression findings with, say, the known consequences of the 1980s debt crisis.

Another reason for advocating case studies is that much of the empirical growth literature essentially points only to reduced-form partial correlations. These can be useful, but it is clear that we often need to move beyond this. A partial correlation is more persuasive if it can be supported by theoretical arguments. The two combined are more persuasive if there is evidence of the intermediating effects or mechanisms that are emphasized in the relevant theory. There is plenty of scope for informative work that tries to isolate mechanisms by which variables such as financial depth, inequality, and political institutions shape the growth process. Wacziarg (2002), in particular, highlights the need for a structural growth econometrics, one that aims to recover channels of causation, and hence supports (or undermines) the economic significance of the partial correlations identified in the literature.

A more extreme view is that growth econometrics should be supplanted by the calibration of theoretical models. Klenow and Rodriguez-Clare (1997b) emphasize the potential of such an approach and note that Mankiw, Romer, and Weil's (1992) influential analysis can be seen partly as a comparison of estimated parameter values with those associated with specific theoretical models. Relatively little of the empirical work that has followed has achieved a similarly close connection between theory and evidence, and this has been a recurring criticism of the literature (for example, Levine and Renelt (1991) and Durlauf (2001)).

It may be premature to say that econometric approaches should be entirely replaced by calibration exercises, but the two methods could surely inform each other more often than at present. Calibrated models can help to interpret parameter estimates, not least in comparing the magnitude of the estimates with the implications of plausible models. Klenow and Rodriguez-Clare (1997b) discuss examples of this in more detail. At the same time, the partial correlations identified in growth econometrics can help to act as a discipline on model-building and can indicate where model-based quantitative investigations are most likely to be fruitful. This role for growth econometrics is likely to be especially useful in areas where the microeconomic evidence used to calibrate structural models is relatively weak, or the standard behavioral assumptions may be flawed.

The need for a tighter connection between theory and evidence is especially apparent in certain areas. The workhorse model for many empirical growth papers continues to be Solow-Swan, a closed economy model which leaves out aspects of interdependence that are surely important. Howitt (2000) has shown that growth regression evidence can be usefully reinterpreted in the light of a multi-country theoretical model with a role for technology diffusion. More generally, there is a need for researchers to develop empirical growth frameworks that acknowledge openness to flows of goods, capital and knowledge. These issues are partly addressed by the theoretical analysis of Barro, Mankiw, and Sala-i-Martin (1995) and empirical work that builds on such ideas deserves greater prominence. Here especially, research that draws on the quantitative implications of specific models, as in the work of Eaton and Kortum (1999, 2001) on technology diffusion and the role of imported capital goods, appears to be an important advance.

The neglect of open economy aspects of the countries under study is mirrored elsewhere. Much of the empirical literature uses a theoretical framework that was originally developed to explain the growth experiences of the USA and other developed nations. Yet this framework is routinely applied to study developing countries, and there appears plenty of scope for models that incorporate more of the distinctive features of poorer countries. These could include the potentially important roles of agricultural employment, dualism, and structural change, and in some cases, extensive state involvement in production. This is an area in which empirical growth researchers have really only scratched the surface.

Some of these issues are connected to an important current research agenda, namely the need to distinguish between different types of growth and their distributional consequences. For example, the general equilibrium effects of productivity improvements in agriculture may be very different to those in services and industry. Identifying the nature of "pro-poor" growth will require more detailed attention to particular features of developing countries. Given that the main source of income for the poor is usually labour income, growth researchers will need to integrate their models with theory and evidence from labour economics, in order to study how growth and labour markets interact.

Agénor (2004) considers some of the relevant issues, and again this appears to be a vital direction for future research.

Ideally, research along these various lines will utilize not only statistics, but also the power of case studies in generating hypotheses, and in deepening our understanding of the economic, social and political forces at work in determining growth outcomes. Case studies may be especially valuable in two areas. The first of these is the study of technology transfer. As emphasized in the survey by Klenow and Rodriguez-Clare (1997b), we do not know enough about why some countries are more successful than others in climbing the "ladder" of product quality and technological complexity. What are the relative contributions of human capital, foreign direct investment and trade? In recent years some of these issues have been intensively studied at the microeconomic level, especially the role of foreign direct investment and trade, but there remains work to be done in mapping firm and sector-level evidence into a set of aggregate implications.

A second area in which case studies are likely to prove valuable is the study of political economy, in its modern sense. It is a truism that economists, particularly those considering development, have become more aware of the need to account for the two-way interaction between economics and politics. A case can be made that the theoretical literature has outpaced the empirical literature in this regard. Studies of individual countries, drawing on both economic theory and political science, would help to close this gap.

Thus far, we have highlighted a number of limitations of existing work, and directions in which further research seems especially valuable. Some of the issues we have considered were highlighted much earlier by Levine and Renelt (1991), and that might lead to pessimism over the long-term prospects of this literature.[71] This also shows that our prescriptions for future research could seem rather pious, since the improvements we recommend are easier said than done. We end our review by considering some areas in which genuine progress has been made, and where further progress appears likely.

One reason for optimism is the potential that recently developed model averaging

[71]Only now are researchers beginning to engage with some of the issues they raised, such as the varying conditions under which it is appropriate to use international rather than national prices in making productivity comparisons and constructing capital stocks.

methods have for shedding new light on growth questions. These methods help to address the model selection and robustness issues that have long been identified as a major weakness of cross-country growth research. By framing the problem explicitly in terms of model uncertainty, in the way envisaged by Leamer (1978), it is possible to consider many candidate explanatory variables simultaneously, and identify which effects appear to be systematic features of the data, as reflected in posterior probabilities of inclusion. The Bayesian approach to model averaging also provides an index of model adequacy, the posterior model probability, that is easy to interpret, and that allows researchers to gauge the extent of overall model uncertainty. Above all, researchers can communicate the degree of support for a particular hypothesis with more faith that the results do not depend on an arbitrary choice of regression specification. Although the application of Bayesian model averaging inevitably has limitations of its own, it appears more rigorous than many of the alternatives, and we expect a number of familiar growth questions to be revisited using these methods.

Another reason for optimism is that the quality of available data is likely to improve over time. The development of new and better data has clearly been one of the main achievements of the empirical growth literature since the early 1990s, and one that was not foreseen by critics of the field. Researchers have developed increasingly sophisticated proxies for drivers of growth that appeared resistant to statistical analysis. One approach, pioneered in the growth literature by Knack and Keefer (1995) and Mauro (1995), has been country-specific ratings compiled by international agencies. Such data increasingly form the basis for measures of corruption, government efficiency, and protection of property rights. More recent work such as that of Kaufmann et al. (1999a,1999b,2003) has established unusually comprehensive measures of various aspects of institutions.

The construction of proxies is likely to make increasing use of latent variable methods. These aim to reduce a set of observed variables to a smaller number of indicators that are seen as driving the majority of the variation in the original data, and that could represent some underlying variable of interest. For example, the extent of democracy is not directly observed, but is often obtained by applying factor analysis or extracting principal components from various dimensions of political freedom. There are

obvious dangers with this approach, but the results can be effective proxies for concepts that are otherwise hard to measure.[72] They also help to overcome the dimensionality problem associated with cross-country empirical work. To be successfully employed, the rigorous use of a latent variable as a regressor will generally need to acknowledge the presence of measurement error.[73]

Using latent variables makes especially good sense under one view of the proper aims of growth research. It is possible to argue that empirical growth studies will never give good answers to precise hypotheses, but can be informative at a broader level. For example, a growth regression is unlikely to tell us whether the growth effect of inflation is more important than the effect of inflation uncertainty, because these two variables are usually highly correlated. It may even be difficult to distinguish the effects of inflation from the effects of sizeable budget deficits.[74] Instead a growth regression might be used to address a less precise hypothesis, such as the growth dividend of macroeconomic stability, broadly conceived. In this context, it is natural to use latent variable approaches to measure the broader concept.

Another valuable development is likely to be the creation of rich panel data sets at the level of regions within countries. Regional data offer greater scope for controlling for some variables that are hard to measure at the country level, such as cultural factors. By comparing experiences across regions, there may also be scope for identifying events that correspond more closely to natural experiments than those found in cross-country data. Work such as that by Besley and Burgess (2000,2002,2004) using panel data on Indian

[72]A relevant question, not often asked, is how high the correlation between the proxy and the true predictor has to be for the estimated regression coefficient on the proxy to be of the "true" sign. Krasker and Pratt (1986,1987) have developed methods that can be used to establish this under surprisingly general assumptions.

[73]In principle this can be addressed by structural equation modeling, using software like EQS or LISREL to estimate a system of equations that includes explicit models for latent variables, an approach used elsewhere in the social sciences. Most economists are not familiar with this approach, and this makes the assumptions and results hard to communicate. It is therefore not clear that a full latent variable model should be preferred to a simpler solution, such as one of those we discuss in the measurement error section above.

[74]As Sala-i-Martin (1991) has argued, various specific indicators of macroeconomic instability should perhaps be seen as symptoms of some deeper, underlying characteristic of a country.

states shows the potential of such an approach. In working with such data more closely, one of the main challenges will be to develop empirical frameworks that incorporate movements of capital and labour between regions: clearly, regions within countries should only rarely be treated as closed economies. Shioji (2001b) is an example of how analysis using regional data can take this into account.

Even with better data, at finer levels of disaggregation, the problem of omitted variables can only be alleviated, not resolved. It is possible to argue that the problem applies equally to historical research and case studies, but at least in these instances, the researcher may have some grasp of important forces that are difficult to quantify. Since growth researchers naturally gravitate towards determinants of growth that can be analyzed statistically, there is an ever-present danger that the empirical literature, even taken as a whole, yields a rather partial and unbalanced picture of the forces that truly matter. Even a growth model with high explanatory power, in a statistical sense, has to be seen as a rather provisional set of ideas about the forces that drive growth and development.

This brings us to our final points. We once again emphasize that empirical progress on the major growth questions requires attention to the evidence found in qualitative sources such as historical narratives and studies by country experts. One example we have given in the text concerns the validity of instrumental variables: understanding the historical experiences of various countries seems critical for determining whether exclusion restrictions are plausible. In this regard work such as that of Acemoglu, Johnson, and Robinson (2001,2002) is exemplary. More generally, nothing in the empirical growth literature suggests that issues of long-term development can be disassociated from the historical and cultural factors that fascinated commentators such as Max Weber. Where researchers have revisited these issues, as in Barro and McCleary (2003), the originality resides less in the conception of growth determinants and more in the scope for new statistical evidence. Of course, the use of historical analysis also leads back to the value of case studies, a point that has recurred throughout this discussion.

In conclusion, growth econometrics is an area of research that is still in its infancy. To its credit, the field has evolved in response to the substantive economic questions that arise in growth contexts. The nature of the field has also led

econometricians to introduce a number of statistical methods into economics, including classification and regression tree algorithms, robust estimation, threshold models and Bayesian model averaging, that appear to have wide utility. As with any new literature, especially one tackling questions as complex as these, it is possible to identify significant limitations of the existing evidence and the tools that are currently applied. But the progress that has been made in growth econometrics in the brief time since its emergence gives reason for continued optimism.

Appendix 1: Data

Key to the 102 countries

AGO, Angola, ARG, Argentina, AUS, Australia, AUT, Austria, BDI, Burundi, BEL, Belgium, BEN, Benin, BFA, Burkina Faso, BGD, Bangladesh, BOL, Bolivia, BRA, Brazil, BWA, Botswana, CAF, Central African Republic, CAN, Canada, CHE, Switzerland, CHL, Chile, CHN, China, CIV, Cote d'Ivoire, CMR, Cameroon, COG, Rep. of Congo, COL, Colombia, CRI, Costa Rica, CYP, Cyprus, DNK, Denmark, DOM, Dominican Republic, ECU, Ecuador, EGY, Egypt, ESP, Spain, ETH, Ethiopia, FIN, Finland, FJI, Fiji, FRA, France, GAB, Gabon, GBR, United Kingdom, GHA, Ghana, GIN, Guinea, GMB, The Gambia, GNB, Guinea-Bissau, GRC, Greece, GTM, Guatemala, GUY, Guyana, HKG, Hong Kong, HND, Honduras, IDN, Indonesia, IND, India, IRL, Ireland, IRN, Iran, ISR, Israel, ITA, Italy, JAM, Jamaica, JOR, Jordan, JPN, Japan, KEN, Kenya, KOR, Rep. of Korea, LKA, Sri Lanka, LSO, Lesotho, MAR, Morocco, MDG, Madagascar, MEX, Mexico, MLI, Mali, MOZ, Mozambique, MRT, Mauritania, MUS, Mauritius, MWI, Malawi, MYS, Malaysia, NAM, Namibia, NER, Niger, NGA, Nigeria, NIC, Nicaragua, NLD, Netherlands, NOR, Norway, NPL, Nepal, NZL, New Zealand, PAK, Pakistan, PAN, Panama, PER, Peru, PHL, Philippines, PNG, Papua New Guinea, PRT, Portugal, PRY, Paraguay , ROM, Romania, RWA, Rwanda, SEN, Senegal, SGP, Singapore, SLV, El Salvador, SWE, Sweden, SYR, Syria, TCD, Chad, TGO, Togo, THA, Thailand, TTO, Trinidad & Tobago, TUR, Turkey, TWN, Taiwan, TZA, Tanzania, UGA, Uganda, URY, Uruguay, USA, USA, VEN, Venezuela, ZAF, South Africa, ZAR, Dem. Rep. Congo, ZMB, Zambia, ZWE, Zimbabwe

Extrapolation

Where data on GDP per worker for the year 2000 are missing from PWT 6.1, but are available for 1996 or after, we extrapolate using the growth rate between 1990 and the latest available year. This procedure helps to alleviate the biases that can occur when countries are missing from the sample for systematic reasons, such as political or economic collapse.

The countries involved are Angola (extrapolated from 1990-1996), Botswana (1999), Central African Republic (1998), Democratic Republic of Congo (1997), Cyprus (1996), Fiji (1999), Guyana (1999), Mauritania (1999), Namibia (1999), Papua New Guinea (1999), Singapore (1996), and Taiwan (1998).

Appendix 2: Variables in Cross-Country Growth Regressions

+/- = sign of coefficient in the corresponding growth regression
? = sign not reported

.Appendix 3: Instruments Variables for Solow Growth Determinants

Variable	Instrument	Study
GDP growth	Rainfall variation	Miguel, Satyanath, and Sergenti (2003)
GDP – initial	Lagged values	Barro and Sala-i-Martin (2004)
GDP – initial (per capital stock)	Newsprint consumption, and number of radios	Romer (1990)
GDP – initial	Log population initial and trade measure	Bosworth and Collins (2003)
Human Capital	Natural Disasters	Toya, Skidmore, and Robertson (2003)
Investment - Equipment	Equipment prices, WCR survey variables, national savings rates	DeLong and Summers, (1991)
Investment - Education	Age demographics (16) and lagged capital	Cook (2002b)
Investment - Education	Age demographic variables	Higgins (1998)
Investment - Education	Average level	Beaudry, Collard, and Green (2002)
Investment	Initial values of investment/GDP, population growth and GDP	Cho (1996)
Investment	Lagged investment, lagged output, lagged inflation, trade/GDP and gov spend/GDP	Bond, Leblebicioglu, and Schiantarelli (2004).
Investment	Initial investment in sub-period, average savings rate in sub-period,	Beaudry, Collard, and Green (2002)
Population Growth	Initial values of investment/GDP,	Cho (1996)

	population growth and GDP	
Population Growth	Average population growth over sub-period	Beaudry, Collard, and Green (2002)
Neoclassical convergence RHS variables	Civilian fatalities as %of population (and squared), Number of months of occupation by German forces, and number of months of land battles in country	Cook (2002a)

Appendix 4: Instruments Variables for non-Solow Growth Determinants

Variable		Instrument	Study
Capital market imperfections		Degree of insider trading	Bekaert, Harvey, and Lundblad (2001)
Capital Controls		Lagged Values	McKenzie (2001)
Capital Controls		Lagged Values	Grilli and Milesi-Ferretii (1995)
Corruption		Ethnolinguistic Fractionalization	Mauro (1995)
Coups		All variables (some lagged)	Londregan and Poole (1990)
Defense variables		Initial levels of investment, openness, military expenditure and GDP per capita	Guaresma and Reitschuler (2003).
Democracy		Various	Tavares and Wacziarg (2001)
Demography - Urban concentration		Lagged values	Henderson (2000)
Economic freedom		Lagged values	Lundström (2002)
Education	Male and Female level	Religion and civil liberty measures	Dollar and Gatti. (1999)
	Changes in attainment and female/male ratio of change	Change in total fertility rate, educational spend/GDP, initial fertility level	Klasen (2002).
	Change and level	Kyriacou schooling data	Krueger and Lindahl (2001).
Enterprise Size		Legal origin, resource endowments, religious composition, ethnic diversity, and others	Beck, Demirguc-Kunt, and Levine (2003)

Finance	Development	Legal origins and initial income	Demetriades and Law (2004).
	Competition	Legal origin	Claessens and Laeven (2003).
	Various indicators	Initial values of same	King and Levine (1993).
	Depth	"Legal origin" and lagged versions of all explanatory variables	Levine, Loayza, and Beck (2000)
	Depth	Consumption, GDP, and others	Levine and Zervos (1998).
	Depth	Lagged versions of all explanatory variables	Loayza and Ranciere (2002)
	Various "factors"	Wide variety of initial values of regressors and initial inflation	Rousseau and Sylla (2001).
	Depth	Initial values of inflation and financial depth	Rousseau and Wachtel (2002)
Gini Coefficient		Number of municipal townships in 1962, share of labor force in manufacturing in 1990, percentage of revenue from intergovernmental transfers in 1962	Alesina and La Ferrera (2002)
Government Change		Lagged government change and variable reflected composition change in the executive without a government change	Alesina, Ozler, Roubini, and Swagel (1996)
Government Expenditure and Taxation		Various	Agell, Ohlsson, and Thoursie (2003)

Health	Change in Malaria Infection rate	Six variable for % land coverage of type of forest and desert	Gallup, Mellinger, and Sachs (2000).
	Expenditure	Physicians, visits, dialysis, insurance coverage, alcohol, over 65, beds	Rivera and Currais (1999)
Inflation		Lagged explanatory variables	Li and Zou (2002).
Inflation		Initial values of inflation and financial depth	Rousseau and Wachtel (2002)
Infrastructure		Lagged values	Esfahani and Ramirez (2003).
Institutions	Various	Settler mortality rate	Acemoglu, Johnson, and Robinson (2002)
	Various	Historically determined component of current institutional quality	Acemoglu, Johnson, and Robinson (2002).
	Various	Geographically determined component of trade as fraction of GDP AND linguistic origins	Alcalá and Ciccone (2004).
	Various and trust	Lagged values	Keefer and Knack (1997).
	Quality	Mortality rates and initial income)	Demetriades and Law (2004).
Manufacturing Exports		Lagged values	Calderón, Chong, and Zanforlin (2001).
Religiosity		Presence of state religion, regulation of religion, indicator of religious pluralism, and others	Barro and McCleary (2003)

Social Infrastructure		State antiquity	Bockstette, Chanda, and Putterman (2003)
Social Infrastructure		Distance from equator, fraction speaking primary European language, fraction speaking English, Frankel and Romer's log predicted trade share	Hall and Jones (1999).
Stock markets		Lagged stock market activity	Harris (1997)
Technology Gap (first difference)		Lagged (second difference)	Hultberg, Nadiri, and Sickles (2003)
Trade	As Share of GDP	Geographically determined component of trade as fraction of GDP AND linguistic origins	Alcalá and Ciccone (2001).
	Policy indices	Lagged values and others unreported by author	Edwards (1998).
	Policy indices	Lagged values	Amable (2000)
		Geographically determined component of trade as fraction of GDP	Frankel and Romer (1996,1999)
Various - Log initial GDP, broad money to GDP, gov expenditure to GDP		Lagged values	Rousseau (2002)

ACCOUNTING FOR GROWTH IN THE INFORMATION AGE

by

Dale W. Jorgenson

1. The Information Age.*

1.1. Introduction.

The resurgence of the American economy since 1995 has outrun all but the most optimistic expectations. Economic forecasting models have been seriously off track and growth projections have been revised repeatedly to reflect a more sanguine outlook[1]. It is not surprising that the unusual combination of more rapid growth and slower inflation touched off a strenuous debate about whether improvements in America's economic performance could be sustained.

The starting point for the economic debate is the thesis that the 1990's are a mirror image of the 1970's, when an unfavorable series of "supply shocks" led to stagflation -- slower growth and higher inflation[2]. In this view, the development of information technology (IT) is one of a series of positive, but

* Department of Economics, Harvard University, 122 Littauer Center, Cambridge, MA 02138-3001. The Program on Technology and Economic Policy at Harvard University provided financial support. The Economic and Social Research Institute of the Cabinet Office of the Government of Japan supported the research reported in Section 4 from its program for international collaboration through the Nomura Research Institute. I am greatly indebted to Jon Samuels for excellent research assistance, as well as useful comments. J. Steven Landefeld, Clinton McCully, and David Wasshausen of the Bureau of Economic Analysis provided valuable data on information technology in the U.S. Tom Hale, Mike Harper, Tom Nardone and Larry Rosenblum (BLS), Kurt Kunze (BEA), Eldon Ball (ERS), Mike Dove and Scott Segerman (DMDC) also provided data for the U.S. and helpful advice. I am grateful to John Baldwin and Tarek Harchaoui of Statistics Canada for data on Canada, Kazuyuki Motohashi and Koji Nomura for data on Japan, and Alessandra Colecchia, Marcel Timmer and Bart Van Ark for data on Europe. Colleagues far too numerous to mention have contributed useful suggestions. I am grateful to all of them but retain sole responsibility for any remaining deficiencies.

[1] See Congressional Budget Office (2000) on official forecasts and Economics and Statistics Administration (2000), p. 60, on private forecasts.

[2] Robert Gordon (1998, 2000); Barry Bosworth and Jack Triplett (2000).

temporary, shocks. The competing perspective is that IT has produced a fundamental change in the U.S. economy, leading to a *permanent* improvement in growth prospects[3]. The resolution of this debate in favor of a permanent improvement has been the "killer application" of a new framework for productivity measurement summarized in Paul Schreyer's (2001) OECD Manual, *Measuring Productivity*.

A consensus has emerged that the development and deployment of information technology is the foundation of the American growth resurgence. A mantra of the "new economy" -- *faster, better, cheaper* -- captures the speed of technological change and product improvement in semiconductors and the precipitous and continuing fall in semiconductor prices. The price decline has been transmitted to the prices of products that rely heavily on semiconductor technology, like computers and telecommunications equipment. This technology has also helped to reduce the cost of aircraft, automobiles, scientific instruments, and a host of other products.

Swiftly falling IT prices provide powerful economic incentives for the substitution of IT equipment for other forms of capital and for labor services. The rate of the IT price decline is a key component of the cost of capital, required for assessing the impacts of rapidly growing stocks of computers, communications equipment, and software. Constant quality price indexes are essential for identifying the change in price for a given level of performance. Accurate and timely computer prices have been part of the U.S. National Income and Product Accounts (NIPA) since 1985. Unfortunately, important information gaps remain, especially on trends in prices for closely related investments, such as software and communications equipment.

Capital input has been the most important source of U.S. economic growth throughout the postwar period. More rapid substitution toward information

[3] Alan Greenspan (2000).

technology has given much additional weight to components of capital input with higher marginal products. The vaulting contribution of capital input since 1995 has boosted growth by close to a percentage point. The contribution of investment in IT accounts for more than half of this increase. Computers have been the predominant impetus to faster growth, but communications equipment and software have made important contributions as well.

The accelerated information technology price decline signals faster productivity growth in IT-producing industries. In fact, these industries have been a rapidly rising source of aggregate productivity growth throughout the 1990's. The IT-producing industries generate less than five percent of gross domestic income, but have accounted for nearly half the surge in productivity growth since 1995. However, it is important to emphasize that faster productivity growth is not limited to these industries.

The dramatic effects of information technology on capital and labor markets have already generated a substantial and growing economic literature, but many important issues remain to be resolved. For capital markets the relationship between equity valuations and growth prospects merits much further study. For labor markets more research is needed on investment in information technology and substitution among different types of labor.

1.2. Faster, Better, Cheaper.

Modern information technology begins with the invention of the *transistor*, a semiconductor device that acts as an electrical switch and encodes information in binary form. A binary digit or *bit* takes the values zero and one, corresponding to the off and on positions of a switch. The first transistor, made of the semiconductor germanium, was constructed at Bell Labs in 1947 and

won the Nobel Prize in Physics in 1956 for the inventors -- John Bardeen, Walter Brattain, and William Shockley[4].

The next major milestone in information technology was the co-invention of the *integrated circuit* by Jack Kilby of Texas Instruments in 1958 and Robert Noyce of Fairchild Semiconductor in 1959. An integrated circuit consists of many, even millions, of transistors that store and manipulate data in binary form. Integrated circuits were originally developed for data storage and retrieval and semiconductor storage devices became known as *memory chips*[5].

The first patent for the integrated circuit was granted to Noyce. This resulted in a decade of litigation over the intellectual property rights. The litigation and its outcome demonstrate the critical importance of intellectual property in the development of information technology. Kilby was awarded the Nobel Prize in Physics in 2000 for discovery of the integrated circuit; regrettably, Noyce died in 1990[6].

1.2.1. Moore's Law.

In 1965 Gordon Moore, then Research Director at Fairchild Semiconductor, made a prescient observation, later known as *Moore's Law*[7]. Plotting data on memory chips, he observed that each new chip contained roughly twice as many transistors as the previous chip and was released within 18-24 months of its predecessor. This implied exponential growth of chip capacity at 35-45 percent per year! Moore's prediction, made in the infancy of the semiconductor industry, has tracked chip capacity for thirty-five years. He recently extrapolated this trend for at least another decade[8].

[7] Moore (1965). Vernon Ruttan (2001), pp.316-367, provides a general reference on the economics of semiconductors and computers. On semiconductor technology, see: http://euler.berkeley.edu/~esrc/csm.

[8] Moore (1997).

In 1968 Moore and Noyce founded Intel Corporation to speed the commercialization of memory chips[9]. Integrated circuits gave rise to *microprocessors* with functions that can be programmed by software, known as *logic chips*. Intel's first general purpose microprocessor was developed for a calculator produced by Busicom, a Japanese firm. Intel retained the intellectual property rights and released the device commercially in 1971.

The rapidly rising trends in the capacity of microprocessors and storage devices illustrate the exponential growth predicted by Moore's Law. The first logic chip in 1971 had 2,300 transistors, while the Pentium 4 released on November 20, 2000, had 42 million! Over this twenty-nine year period the number of transistors increased by thirty-four percent per year. The rate of productivity growth for the U.S. economy during this period was slower by two orders of magnitude.

1.2.2. Semiconductor Prices.

Moore's Law captures the fact that successive generations of semiconductors are *faster* and *better*. The economics of semiconductors begins with the closely related observation that semiconductors have become *cheaper* at a truly staggering rate! Figure 1.1 gives semiconductor price indexes constructed by Bruce Grimm (1998) of the Bureau of Economic Analysis (BEA) and employed in the U.S. National Income and Product Accounts since 1996. These are divided between memory chips and logic chips. The underlying detail includes seven types of memory chips and two types of logic chips.

Between 1974 and 1996 prices of memory chips *decreased* by a factor of 27,270 times or at 40.9 percent per year, while the implicit deflator for the gross domestic product (GDP) *increased* by almost 2.7 times or 4.6 percent per year! Prices of logic chips, available for the shorter period 1985 to 1996, *decreased* by a factor of 1,938 or 54.1 percent per year, while the GDP deflator

[9] Moore (1996).

increased by 1.3 times or 2.6 percent per year! Semiconductor price declines closely parallel Moore's Law on the growth of chip capacity, setting semiconductors apart from other products.

Figure 1.1 also reveals a sharp acceleration in the decline of semiconductor prices in 1994 and 1995. The microprocessor price decline leapt to more than ninety percent per year as the semiconductor industry shifted from a three-year product cycle to a greatly accelerated two-year cycle. This is reflected in the *2000 Update* of the International Technology Road Map for Semiconductors[10], prepared by a consortium of industry associations. Ana Aizcorbe, Stephen Oliner, and Daniel Sichel (2003) have identified and analyzed break points in prices of microprocessors and storage devices.

1.2.3. Constant Quality Price Indexes.

The behavior of semiconductor prices is a severe test for the methods used in the official price statistics. The challenge is to separate observed price changes between changes in semiconductor performance and changes in price that hold performance constant. Achieving this objective has required a detailed understanding of the technology, the development of sophisticated measurement techniques, and the introduction of novel methods for assembling the requisite information.

Ellen Dulberger (1993) introduced a "matched model" index for semiconductor prices. A matched model index combines price relatives for products with the same performance at different points of time. Dulberger presented constant quality price indexes based on index number formulas, including the *Fisher* (1922) *ideal index* used in the in the U.S. national accounts[11]. The Fisher index is the geometric average of the familiar Laspeyres and Paasche indexes.

---

[10] On International Technology Roadmap for Semiconductors (2000), see: http://public.itrs.net/.

[11] See Steven Landefeld and Robert Parker (1997).

Erwin Diewert (1976) defined a *superlative* index number as an index that *exactly* replicates a *flexible* representation of the underlying technology (or preferences). A flexible representation provides a second-order approximation to an arbitrary technology (or preference system). A.A. Konus and S. S. Byushgens (1926) first showed that the Fisher ideal index is superlative in this sense. Laspeyres and Paasche indexes are not superlative and fail to capture substitutions among products in response to price changes accurately.

Grimm (1998) combined matched model techniques with hedonic methods, based on an econometric model of semiconductor prices at different points of time. A hedonic model gives the price of a semiconductor product as a function of the characteristics that determine performance, such as speed of processing and storage capacity. A constant quality price index isolates the price change by holding these characteristics of semiconductors fixed.[12]

Beginning in 1997, the Bureau of Labor Statistics (BLS) incorporated a matched model price index for semiconductors into the Producer Price Index (PPI) and since then the national accounts have relied on data from the PPI. Reflecting long-standing BLS policy, historical data were not revised backward. Semiconductor prices reported in the PPI prior to 1997 do not hold quality constant, failing to capture the rapid semiconductor price decline and the acceleration in 1995.

1.2.4. Computers.

The introduction of the Personal Computer (PC) by IBM in 1981 was a watershed event in the deployment of information technology. The sale of Intel's 8086-8088 microprocessor to IBM in 1978 for incorporation into the PC was a major business breakthrough for Intel[13]. In 1981 IBM licensed the MS-DOS operating system from the Microsoft Corporation, founded by Bill Gates and Paul

[12]Triplett (2003) has drafted a manual for the OECD on constructing constant quality price indexes for information technology and communications equipment and software.
[13]See Moore (1996).

Allen in 1975. The PC established an Intel/Microsoft relationship that has continued up to the present. In 1985 Microsoft released the first version of Windows, its signature operating system for the PC, giving rise to the Wintel (Windows-Intel) nomenclature for this ongoing collaboration.

Mainframe computers, as well as PC's, have come to rely heavily on logic chips for central processing and memory chips for main memory. However, semiconductors account for less than half of computer costs and computer prices have fallen much less rapidly than semiconductor prices. Precise measures of computer prices that hold product quality constant were introduced into the NIPA in 1985 and the PPI during the 1990's. The national accounts now rely on PPI data, but historical data on computers from the PPI, like the PPI data on semiconductors, do not hold quality constant.

Gregory Chow (1967) pioneered the use of hedonic techniques for constructing a constant quality index of computer prices in research conducted at IBM. Chow documented price declines at more than twenty percent per year during 1960-1965, providing an initial glimpse of the remarkable behavior of computer prices. In 1985 the Bureau of Economic Analysis incorporated constant quality price indexes for computers and peripheral equipment constructed by IBM into the NIPA. Triplett's (1986) discussion of the economic interpretation of these indexes brought the rapid decline of computer prices to the attention of a very broad audience.

The BEA-IBM constant quality price index for computers provoked a heated exchange between BEA and Edward Denison (1989), one of the founders of national accounting methodology in the 1950's and head of the national accounts at BEA from 1979 to 1982. Denison sharply attacked the BEA-IBM methodology and argued vigorously against the introduction of constant quality price indexes into the national accounts[14]. Allan Young (1989), then Director of BEA, reiterated BEA's

[14] Denison cited his 1957 paper, "Theoretical Aspects of Quality Change, Capital

rationale for introducing constant quality price indexes.

Dulberger (1989) presented a more detailed report on her research on the prices of computer processors for the BEA-IBM project. Speed of processing and main memory played central roles in her model. Triplett (1989, 2003) has provided exhaustive surveys of research on hedonic price indexes for computers. Gordon (1989, 1990) gave an alternative model of computer prices and identified computers and communications equipment, along with commercial aircraft, as assets with the highest rates of price decline.

Figure 1.2 gives BEA's constant quality index of prices of computers and peripheral equipment and its components, including mainframes, PC's, storage devices, other peripheral equipment, and terminals. The decline in computer prices follows the behavior of semiconductor prices presented in Figure 1.1, but in much attenuated form. The 1995 acceleration in the computer price decline parallels the acceleration in the semiconductor price decline that resulted from the changeover from a three-year product cycle to a two-year cycle in 1995.

1.2.5. Communications Equipment and Software.

Communications technology is crucial for the rapid development and diffusion of the Internet, perhaps the most striking manifestation of information technology in the American economy[15]. Kenneth Flamm (1989) was the first to compare the behavior of computer prices and the prices of communications equipment. He concluded that the communications equipment prices fell only a little more slowly than computer prices. Gordon (1990) compared Flamm's results with the official price indexes, revealing substantial bias in the official indexes.

Consumption, and Net Capital Formation," as the definitive statement of the traditional BEA position.

[15] General references on the economics of the Internet are Soon-Yong Choi and Andrew Whinston (2000) and Robert Hall (2002). On Internet indicators see: http://www.internetindicators.com/.

Communications equipment is an important market for semiconductors, but constant quality price indexes cover only a portion of this equipment. Switching and terminal equipment rely heavily on semiconductor technology, so that product development reflects improvements in semiconductors. Grimm's (1997) constant quality price index for digital telephone switching equipment, given in Figure 3.3, was incorporated into the national accounts in 1996. The output of communications services in the NIPA also incorporates a constant quality price index for cellular phones.

Much communications investment takes the form of the transmission gear, connecting data, voice, and video terminals to switching equipment. Technologies such as fiber optics, microwave broadcasting, and communications satellites have progressed at rates that outrun even the dramatic pace of semiconductor development. An example is dense wavelength division multiplexing (DWDM), a technology that sends multiple signals over an optical fiber simultaneously. Installation of DWDM equipment, beginning in 1997, has doubled the transmission capacity of fiber optic cables every 6-12 months[16].

Mark Doms (2004) has provided comprehensive price indexes for terminals, switching gear, and transmission equipment. These have been incorporated into the Federal Reserve's Index of Industrial Production, as described by Carol Corrado (2003), but are not yet included in the U.S. National Income and Product Accounts. The analysis of the impact of information technology on the U.S. economy described below is based on the national accounts and remains incomplete.

Both software and hardware are essential for information technology and this is reflected in the large volume of software expenditures. The eleventh comprehensive revision of the national accounts, released by BEA on October 27,

[16] Rick Rashad (2000) characterizes this as the "demise" of Moore's Law. Jeff Hecht (1999) describes DWDM technology and provides a general reference on fiber optics.

1999, re-classified computer software as investment[17]. Before this important advance, business expenditures on software were treated as current outlays, while personal and government expenditures were treated as purchases of nondurable goods. Software investment is growing rapidly and is now much more important than investment in computer hardware.

Parker and Grimm (2000) describe the new estimates of investment in software. BEA distinguishes among three types of software -- prepackaged, custom, and own-account software. Prepackaged software is sold or licensed in standardized form and is delivered in packages or electronic files downloaded from the Internet. Custom software is tailored to the specific application of the user and is delivered along with analysis, design, and programming services required for customization. Own-account software consists of software created for a specific application. However, only price indexes for prepackaged software hold performance constant.

Parker and Grimm (2000) present a constant quality price index for prepackaged software, given in Figure 3.3. This combines a hedonic model of prices for business applications software and a matched model index for spreadsheet and word processing programs developed by Oliner and Sichel (1994). Prepackaged software prices decline at more than ten percent per year over the period 1962-1998. Since 1998 the BEA has relied on a matched model price index for all prepackaged software from the PPI; prior to 1998 the PPI data do not hold quality constant.

BEA's prices for own-account and custom software are based on programmer wage rates. This implicitly assumes no change in the productivity of computer programmers, even with growing investment in hardware and software to support the creation of new software. Custom and own-account software prices are a

[17] Brent Moulton (2000) describes the 11th comprehensive revision of NIPA and the 1999 update.

weighted average of prepackaged software prices and programmer wage rates with arbitrary weights of 75 percent for programmer wage rates and 25 percent for prepackaged software. These price indexes do not hold the software performance constant and present a distorted picture of software prices, as well as software output and investment.

1.2.6. Research Opportunities.

The official price indexes for computers and semiconductors provide the paradigm for economic measurement. These indexes capture the steady decline in IT prices and the recent acceleration in this decline. The official price indexes for central office switching equipment and prepackaged software also hold quality constant. BEA and BLS, the leading statistical agencies in price research, have carried out much of the best work in this area. However, a critical role has been played by price research at IBM, long the dominant firm in information technology[18].

It is important to emphasize that information technology is not limited to applications of semiconductors. Switching and terminal equipment for voice, data, and video communications have come to rely on semiconductor technology and the empirical evidence on prices of this equipment reflects this fact. Transmission gear employs technologies with rates of progress that far outstrip those of semiconductors. This important gap in our official price statistics has been filled by constant quality price indexes for all types of communications equipment constructed by Doms (2004), but these indexes have not been incorporated into the national accounts.

Investment in software is more important than investment in hardware. This was essentially invisible until BEA introduced new measures of prepackaged, custom, and own-account software investment into the national accounts in 1999. This is a crucial step in understanding the role of information technology in

[18] See Alfred Chandler (2000), Table 1.1, p. 26.

the American economy. Unfortunately, software prices are a statistical blind spot with only prices of prepackaged software adequately represented in the official system of price statistics. The daunting challenge that lies ahead is to construct constant quality price indexes for custom and own-account software.

1.3. Impact of Information Technology.

In Section 2 I consider the "killer application" of the new framework for productivity measurement – the impact of information technology (IT) on economic growth. Despite differences in methodology and data sources, a consensus has emerged that the remarkable behavior of IT prices provides the key to the surge in U.S. economic growth after 1995. The relentless decline in the prices of information technology equipment and software has steadily enhanced the role of IT investment. Productivity growth in IT-producing industries has risen in importance and a productivity revival is underway in the rest of the economy.

A substantial acceleration in the IT price decline occurred in 1995, triggered by a much sharper acceleration in the price decline of semiconductors, the key component of modern information technology. Although the decline in semiconductor prices has been projected to continue for at least another decade, the recent acceleration may be temporary. This can be traced to a shift in the product cycle for semiconductors from three years to two years as a consequence of intensifying competition in markets for semiconductor products.

In Section 3 I show that the surge of IT investment in the United States after 1995 has counterparts in all other industrialized countries. It is essential to use comparable data and methodology in order to provide rigorous international comparisons. A crucial role is played by measurements of IT prices. The U.S. national accounts have incorporated measures of IT prices that hold performance constant since 1985. Schreyer (2000) has extended these

measures to other industrialized countries by constructing "internationally harmonized prices".[19]

I show that the acceleration in the IT price decline in 1995 triggered a burst of IT investment in all of the G7 nations – Canada, France, Germany, Italy, Japan, the U.K., as well as the U.S. These countries also experienced a rise in productivity growth in the IT-producing industries. However, differences in the relative importance of these industries have generated wide disparities in the impact of IT on economic growth. The role of the IT-producing industries is greatest in the U.S., which leads the G7 in output per capita. Section 4 concludes.

2. Aggregate Growth Accounting.

2.1. The Role of Information Technology.

At the aggregate level IT is identified with the outputs of computers, communications equipment, and software. These products appear in the GDP as investments by businesses, households, and governments along with net exports to the rest of the world. The GDP also includes the services of IT products consumed by households and governments. A methodology for analyzing economic growth must capture the substitution of IT outputs for other outputs of goods and services.

While semiconductor technology is the driving force behind the spread of IT, the impact of the relentless decline in semiconductor prices is transmitted through falling IT prices. Only net exports of semiconductors, defined as the difference between U.S. exports to the rest of the world and U.S. imports appear in the GDP. Sales of semiconductors to domestic manufacturers of IT products are precisely offset by purchases of semiconductors and are excluded from the GDP.

[19] The measurement gap in IT prices between the U.S. and other OECD countries was first identified by Andrew Wyckoff (1995).

Constant quality price indexes, like those reviewed in the previous section, are a key component of the methodology for analyzing the American growth resurgence. Computer prices were incorporated into the NIPA in 1985 and are now part of the PPI as well. Much more recently, semiconductor prices have been included in the NIPA and the PPI. The official price indexes for communications equipment do not yet reflect the important work of Doms (2004). Unfortunately, evidence on the price of software is seriously incomplete, so that the official price indexes are seriously misleading.

2.1.1. Output.

The output data in Table 2.1 are based on the most recent benchmark revision of the national accounts through 2002[20]. The output concept is similar, but not identical, to the concept of gross domestic product used by the BEA. Both measures include final outputs purchased by businesses, governments, households, and the rest of the world. Unlike the BEA concept, the output measure in Table 2.1 also includes imputations for the service flows from durable goods, including IT products, employed in the household and government sectors.

The imputations for services of IT equipment are based on the cost of capital for IT described in more detail below. The cost of capital is multiplied by the nominal value of IT capital stock to obtain the imputed service flow from IT products. In the business sector this accrues as capital income to the firms that employ these products as inputs. In the household and government sectors the flow of capital income must be imputed. This same type of imputation is used for housing in the NIPA. The rental value of renter-occupied housing accrues to real estate firms as capital income, while the rental value of owner-occupied housing is imputed to households.

[20] See Jorgenson and Stiroh (2000b), Appendix A, for details on the estimates of output.

Current dollar GDP in Table 2.1 is $11.3 trillions in 2002, including imputations, and real output growth averaged 3.46 percent for the period 1948-2002. These magnitudes can be compared to the current dollar value of $10.5 trillions in 2002 and the average real growth rate of 3.36 percent for period 1948-2002 for the official GDP. Table 2.1 presents the current dollar value and price indexes of the GDP and IT output. This includes outputs of investment goods in the form of computers, software, communications equipment, and non-IT investment goods. It also includes outputs of non-IT consumption goods and services as well as imputed IT capital service flows from households and governments.

The most striking feature of the data in Table 2.1 is the rapid price decline for computer investment, 15.8 percent per year from 1959 to 1995. Since 1995 this decline has increased to 33.1 percent per year. By contrast the relative price of software has been flat for much of the period and began to fall only in the 1980's. The price of communications equipment behaves similarly to the software price, while the consumption of capital services from computers and software by households and governments shows price declines similar to computer investment.

The top panel of Table 2.2 summarizes the growth rates of prices and quantities for major output categories for 1989-95 and 1995-2002. Business investments in computers, software, and communications equipment are the largest categories of IT spending. Households and governments have also spent sizable amounts on computers, software, communications equipment and the services of information technology. Figure 2.1 shows that the share of software output in the GDP is largest, followed by the shares of computers and communications equipment.

2.1.2. Capital Services.

This section presents capital estimates for the U.S. economy for the period 1948 to 2002[21]. These begin with BEA investment data; the perpetual inventory method generates estimates of capital stocks and these are aggregated, using service prices as weights. This approach, originated by Jorgenson and Zvi Griliches (1967), is based on the identification of service prices with marginal products of different types of capital. The service price estimates incorporate the cost of capital[22].

The cost of capital is an annualization factor that transforms the price of an asset into the price of the corresponding capital input. This includes the nominal rate of return, the rate of depreciation, and the rate of capital loss due to declining prices. The cost of capital is an essential concept for the economics of information technology[23], due to the astonishing decline of IT prices given in Table 2.1.

The cost of capital is important in many areas of economics, especially in modeling producer behavior, productivity measurement, and the economics of taxation[24]. Many of the important issues in measuring the cost of capital have been debated for decades. The first of these is incorporation of the rate of decline of asset prices into the cost of capital. The assumption of perfect foresight or rational expectations quickly emerged as the most appropriate formulation and has been used in almost all applications of the cost of capital[25].

---

[21] See Jorgenson and Stiroh (2000b), Appendix B, for details on the estimates of capital input.

[22] Jorgenson and Kun-Young Yun (2001) present the model of capital input used in the estimates presented in this section. BLS (1983) describes the version of this model employed in the official productivity statistics. For a recent updates, see the BLS multifactor productivity website: http://www.bls.gov/mfp/home.htm. Charles Hulten (2001) surveys the literature.

[23] Jorgenson and Stiroh (1995), pp. 300-303.

[24] Lawrence Lau (2000) surveys applications of the cost of capital.

[25] See, for example, Jorgenson, Gollop, and Fraumeni (1987), pp. 40-9, and Jorgenson and Griliches (1967).

The second empirical issue is the measurement of economic depreciation. The stability of patterns of depreciation in the face of changes in tax policy and price shocks has been carefully documented. The depreciation rates presented by Jorgenson and Stiroh (2000b) summarize a large body of empirical research on the behavior of asset prices[26]. A third empirical issue is the description of the tax structure for capital income. This depends on the tax laws prevailing at each point of time. The resolution of these issues has cleared the way for detailed measurements of the cost of capital for all assets that appear in the national accounts, including information technology equipment and software[27].

The definition of capital includes all tangible assets in the U.S. economy, equipment and structures, as well as consumers' and government durables, land, and inventories. The capital service flows from durable goods employed by households and governments enter measures of both output and input. A steadily rising proportion of these service flows are associated with investments in IT. Investments in IT by business, household, and government sectors must be included in the GDP, along with household and government IT capital services, in order to capture the full impact of IT on the U.S. economy.

Table 2.3 gives capital stocks from 1948 to 2002, as well as price indexes for total domestic tangible assets and IT assets -- computers, software, and communications equipment. The estimate of domestic tangible capital stock in Table 2.3 is $45.9 trillions in 2002, considerably greater than the estimate by BEA. The most important differences reflect the inclusion of inventories and land in Table 2.3.

---

[26] Jorgenson and Stiroh (2000b), Table B4, pp. 196-7 give the depreciation rates employed in this section. Fraumeni (1997) describes depreciation rates used in the NIPA. Jorgenson (1996) surveys empirical studies of depreciation.

[27] See Jorgenson and Yun (2001) for details on the U.S. tax structure for capital income. Diewert and Denis Lawrence (2000) survey measures of the price and quantity of capital input.

Business IT investments, as well as purchases of computers, software, and communications equipment by households and governments, have grown spectacularly in recent years, but remain relatively small. The stocks of all IT assets combined account for only 3.79 percent of domestic tangible capital stock in 2002. Table 2.4 presents estimates of the flow of capital services and corresponding price indexes for 1948-2002.

The difference between growth in capital services and capital stock is the improvement in capital quality. This represents the substitution towards assets with higher marginal products. The shift toward IT increases the quality of capital, since computers, software, and communications equipment have relatively high marginal products. Capital stock estimates fail to account for this increase in quality and substantially underestimate the impact of IT investment on growth.

The growth of capital quality is slightly more than twenty percent of capital input growth for the period 1948-2002. However, improvements in capital quality have increased steadily in relative importance. These improvements jumped to 46.1 percent of total growth in capital input during the period 1995-2002, reflecting very rapid restructuring of capital to take advantage of the sharp acceleration in the IT price decline. Capital stock has become progressively less accurate as a measure of capital input and is now seriously deficient.

Figure 2.2 gives the IT capital service flows as a share of gross domestic income. The second panel of Table 2.2 summarizes the growth rates of prices and quantities of capital inputs for 1989-1995 and 1995-2002. Growth of IT capital services jumps from 12.39 percent per year in 1989-1995 to 18.11 percent in 1995-2002, while growth of non-IT capital services increases from 1.94 percent to 3.07 percent. This reverses the trend toward slower capital growth through 1995.

2.1.3. Labor Services.

This section presents estimates of labor input for the U.S. economy from 1948 to 2002. These incorporate individual data from the Censuses of Population for 1970, 1980, and 1990, as well as the annual Current Population Surveys. Constant quality indexes for the price and quantity of labor input account for the heterogeneity of the workforce across sex, employment class, age, and education levels. This follows the approach of Jorgenson, Gollop, and Fraumeni (1987)[28].

The distinction between labor input and labor hours is analogous to the distinction between capital services and capital stock. The growth in labor quality is the difference between the growth in labor input and hours worked. Labor quality reflects the substitution of workers with high marginal products for those with low marginal products. Table 2.5 presents estimates of labor input, hours worked, and labor quality.

The value of labor expenditures in Table 2.5 is $6.6 trillions in 2002, 58.3 percent of the value of output. This share accurately reflects the concept of gross domestic income, including imputations for the value of capital services in household and government sectors. As shown in Table 2.7, the growth rate of labor input decelerated to 1.50 percent for 1995-2002 from 1.64 percent for 1989-1995. Growth in hours worked rose from 1.02 percent for 1989-1995 to 1.16 percent for 1995-2002 as labor force participation increased and unemployment rates declined.

The growth of labor quality has declined considerably since 1995, dropping from 0.61 percent for 1989-1995 to 0.33 percent for 1995-2002. This slowdown captures well-known demographic trends in the composition of the work force, as well as exhaustion of the pool of available workers. Growth in hours worked does

[28]See Jorgenson and Stiroh (2000b), Appendix C, for details on the estimates of labor input. Gollop (2000) discusses the measurement of labor quality.

not capture these changes in labor quality growth and is a seriously misleading measure of labor input.

2.2. The American Growth Resurgence.

The American economy has undergone a remarkable resurgence since the mid-1990's with accelerating growth in output, labor productivity, and total factor productivity. The purpose of this section is to quantify the sources of growth for 1948-2002 and various sub-periods. An important objective is to account for the sharp acceleration in the growth rate since 1995 and, in particular, to document the role of information technology.

The appropriate framework for analyzing the impact of information technology is the production possibility frontier, giving outputs of IT investment goods as well as inputs of IT capital services. An important advantage of this framework is that prices of IT outputs and inputs are linked through the price of IT capital services. This framework successfully captures the substitutions among outputs and inputs in response to the rapid deployment of IT. It also encompasses costs of adjustment, while allowing financial markets to be modeled independently.

As a consequence of the swift advance of information technology, a number of the most familiar concepts in growth economics have been superseded. The aggregate production function heads this list. Capital stock as a measure of capital input is no longer adequate to capture the rising importance of IT. This completely obscures the restructuring of capital input that is such an important wellspring of the growth resurgence. Finally, hours worked must be replaced as a measure of labor input.

2.2.1. Production Possibility Frontier.

The production possibility frontier describes efficient combinations of outputs and inputs for the economy as a whole. Aggregate output Y consists of outputs of investment goods and consumption goods. These outputs are produced from aggregate input X, consisting of capital services and labor services.

Productivity is a "Hicks-neutral" augmentation of aggregate input. The

$$Y(I_n, I_c, I_s, I_t, C_n, C_c) = A \cdot X(K_n, K_c, K_s, K_t, L),$$

production possibility frontier takes the form:

where the outputs include non-IT investment goods I_n and investments in computers I_c, software I_s, and communications equipment I_t, as well as non-IT consumption goods and services C_n and IT capital services to households and governments C_c. Inputs include non-IT capital services K_n and the services of computers K_c, software K_s, and telecommunications equipment K_t , as well as labor input L.[29] Productivity is denoted by A.

The most important advantage of the production possibility frontier is the explicit role that it provides for constant quality prices of IT products. These are used as deflators for nominal expenditures on IT investments to obtain the quantities of IT outputs. Investments in IT are cumulated into stocks of IT capital. The flow of IT capital services is an aggregate of these stocks with service prices as weights. Similarly, constant quality prices of IT capital services are used in deflating the nominal values of consumption of these services.

Another important advantage of the production possibility frontier is the incorporation of costs of adjustment. For example, an increase in the output of IT investment goods requires foregoing part of the output of consumption goods and non-IT investment goods, so that adjusting the rate of investment in IT is costly. However, costs of adjustment are external to the producing unit and are fully reflected in IT prices. These prices incorporate forward-looking expectations of the future prices of IT capital services.

The aggregate production function employed, for example, by Kuznets (1971) and Solow (1957, 1960, 1970) and, more recently, by Jeremy Greenwood, Zvi

[29] Services of durable goods to governments and households are included in both inputs and outputs.

Hercowitz, and Per Krusell (1997, 2000), Hercowitz (1998), and Arnold Harberger (1998) is a competing methodology. The production function gives a single output as a function of capital and labor inputs. There is no role for separate prices of investment and consumption goods and, hence, no place for constant quality IT price indexes for outputs of IT investment goods.

Another limitation of the aggregate production function is that it fails to incorporate costs of adjustment. Robert Lucas (1967) presented a production model with internal costs of adjustment. Fumio Hayashi (2000) shows how to identify these adjustment costs from Tobin's (1969) Q-ratio, the ratio of the stock market value of the producing unit to the market value of the unit's assets. Implementation of this approach requires simultaneous modeling of production and asset valuation. If costs of adjustment are external, as in the production possibility frontier, asset valuation can be modeled separately from production[30].

2.2.2. Sources of Growth.

Under the assumption that product and factor markets are competitive producer equilibrium implies that the share-weighted growth of outputs is the sum of the share-weighted growth of inputs and growth in total factor productivity:

$$\overline{w}_{I,n}\Delta\ln I_n + \overline{w}_{I,c}\Delta I_c + \overline{w}_{I,s}\Delta I_s + \overline{w}_{I,t}\Delta I_t + \overline{w}_{C,n}C_n + \overline{w}_{C,c}\Delta\ln C_c =$$
$$\overline{v}_{K,n}\Delta\ln K_n + \overline{v}_{K,c}\Delta\ln K_c + \overline{v}_{K,s}\Delta\ln K_s + \overline{v}_{K,t}\Delta\ln K_t + \overline{v}_L\Delta\ln L + \Delta\ln A$$

where $\overline{w}$ and $\overline{v}$ denote average value shares. The shares of outputs and inputs add to one under the additional assumption of constant returns,

$$\overline{w}_{I,n} + \overline{w}_{I,c} + \overline{w}_{I,s} + \overline{w}_{I,t} + \overline{w}_{C,n} + \overline{w}_{C,c} = \overline{v}_{K,n} + \overline{v}_{K,c} + \overline{v}_{K,s} + \overline{v}_{K,t} + \overline{v}_L = 1 .$$

The growth rate of output is a weighted average of growth rates of investment and consumption goods outputs. The contribution of each output is its

[30] See, for example, John Campbell and Robert Shiller (1998).

weighted growth rate. Similarly, the growth rate of input is a weighted average of growth rates of capital and labor services and the contribution of each input is its weighted growth rate. The contribution of productivity, the growth rate of the augmentation factor A, is the difference between growth rates of output and input.

Table 2.6 presents results of a growth accounting decomposition for the period 1948-2002 and various sub-periods, following Jorgenson and Stiroh (1999, 2000b). Economic growth is broken down by output and input categories, quantifying the contribution of information technology to investment and consumption outputs, as well as capital inputs. These estimates identify computers, software, and communications equipment as distinct types of information technology.

The results can also be presented in terms of average labor productivity (ALP), defined as $y = Y / H$, the ratio of output Y to hours worked H, and $k = K / H$ is the ratio of capital services K to hours worked:

$$\Delta \ln y = \bar{v}_K \Delta \ln k + \bar{v}_L \left(\Delta \ln L - \Delta \ln H \right) + \Delta \ln A .$$

This equation allocates ALP growth among three sources. The first is capital deepening, the growth in capital input per hour worked, and reflects the capital-labor substitution. The second is improvement in labor quality and captures the rising proportion of hours by workers with higher marginal products. The third is total factor productivity growth, which contributes point-for-point to ALP growth.

2.2.3. Contributions of IT Investment.

Figure 2.2 depicts the rapid increase in the importance of IT services, reflecting the accelerating pace of IT price declines. In 1995-2002 the capital service price for computers fell 25.92 percent per year, compared to an increase of 32.09 percent in capital input from computers. While the value of computer

services grew, the current dollar value was only 1.13 percent of gross domestic income in 2002.

The rapid accumulation of software appears to have different sources. The price of software services has fallen only 1.48 percent per year for 1995-2002. Nonetheless, firms have been accumulating software very rapidly, with real capital services growing 14.02 percent per year. A possible explanation is that firms respond to computer price declines by investing in complementary inputs like software. However, a more plausible explanation is that the price indexes used to deflate software investment fail to hold quality constant. This leads to an overstatement of inflation and an understatement of growth.

Although the price decline for communications equipment during the period 1995-2002 is greater than that of software, investment in this equipment is more in line with prices. However, prices of communications equipment also fail to hold quality constant. The technology of switching equipment, for example, is similar to that of computers; investment in this category is deflated by a constant-quality price index developed by BEA. Conventional price deflators are employed for transmission gear, such as fiber-optic cables. This leads to an underestimate of the growth rates of investment, capital stock, capital services, and the GDP, as well as an overestimate of the rate of inflation.

Figures 2.3 and 2.4 highlight the rising contributions IT outputs to U.S. economic growth. Figure 2.3 shows the breakdown between IT and non-IT outputs for sub-periods from 1948 to 2002, while Figure 2.4 decomposes the contribution of IT into its components. Although the importance of IT has steadily increased, Figure 2.3 shows that the recent investment and consumption surge nearly doubled the output contribution of IT. Figure 2.4 shows that computer investment is the largest single IT contributor after 1995, but that investments in software and communications equipment are becoming increasingly important.

Figures 2.5 and 2.6 present a similar decomposition of IT inputs into production. The contribution of these inputs is rising even more dramatically.

Figure 2.5 shows that the contribution of IT now accounts for more than 48.0 percent of the total contribution of capital input. Figure 2.6 reveals that computer hardware is the largest component of IT, reflecting the growing share and accelerating growth rate of computer investment in the late 1990's.

Private business investment predominates in the output of IT, as shown by Jorgenson and Stiroh (2000b) and Oliner and Sichel (2000)[31]. Household purchases of IT equipment and services are next in importance. Government purchases of IT equipment and services, as well as net exports of IT products, must be included in order to provide a complete picture. Firms, consumers, governments, and purchasers of U.S. exports are responding to relative price changes, increasing the contributions of computers, software, and communications equipment.

Table 2.2 shows that the price of computer investment fell by 30.99 percent per year, the price of software fell by 1.31 percent, the price of communications equipment dropped by 4.16 percent, and the price of IT services fell by 13.91 percent during the period 1995-2002, while non-IT investment goods prices rose 0.38 percent. In response to these price changes, firms, households, and governments have accumulated computers, software, and communications equipment much more rapidly than other forms of capital.

2.2.4. Productivity.

The price or "dual" approach to productivity measurement employed by Triplett (1996) makes it possible to identify the role of IT production as a source of productivity growth at the industry level[32]. The rate of productivity growth is measured as the decline in the price of output, plus a weighted average of the growth rates of input prices with value shares of the inputs as weights. For the computer industry this expression is dominated by two terms:

---

[31] Bosworth and Triplett (2000) and Baily (2002) compare the results of Jorgenson and Stiroh with those of Oliner and Sichel, who incorporate data from the BLS measures of multifactor productivity.

[32] The dual approach is presented by Jorgenson, Gollop, and Fraumeni (1987), pp. 53-63.

the decline in the price of computers and the contribution of the price of semiconductors. For the semiconductor industry the expression is dominated by the decline in the price of semiconductors[33].

Jorgenson, Gollop, and Fraumeni (1987) have employed Domar's (1961) model to trace aggregate productivity growth to its sources at the level of individual industries[34]. More recently, Harberger (1998), William Gullickson and Michael Harper (1999), and Jorgenson and Stiroh (2000a, 2000b) have used the model for similar purposes. Productivity growth for each industry is weighted by the ratio of the gross output of the industry to GDP to estimate the industry contribution to aggregate productivity growth.

If semiconductor output were only used to produce computers, then its contribution to computer industry productivity growth, weighted by computer industry output, would precisely offset its independent contribution to the growth of aggregate productivity. This is the ratio of the value of semiconductor output to GDP, multiplied by the rate of semiconductor price decline. In fact, semiconductors are used to produce telecommunications equipment and many other products. However, the value of semiconductor output is dominated by inputs into IT production.

The Domar aggregation formula can be approximated by expressing the declines in prices of computers, communications equipment, and software relative to the price of gross domestic income, an aggregate of the prices of capital and labor services. The rates of relative IT price decline are weighted by ratios of the outputs of IT products to the GDP. Table 2.8 reports details of this decomposition of productivity for 1989-1995 and 1995-2002; the IT and non-IT contributions are presented in Figure 2.7. The IT products contribute 0.47

---

[33]Models of the relationships between computer and semiconductor industries presented by Dulberger (1993), Triplett (1996), and Oliner and Sichel (2000) are special cases of the Domar (1961) aggregation scheme.

[34] See Jorgenson, Gollop, and Fraumeni (1987), pp. 63-66, 301-322.

percentage points to productivity growth for 1995-2002, compared to 0.23 percentage points for 1989-1995. This reflects the accelerating decline in relative price changes resulting from shortening the product cycle for semiconductors.

2.2.5. Output Growth.

This section presents the sources of GDP growth for the entire period 1948 to 2002. Capital services contribute 1.75 percentage points, labor services 1.05 percentage points, and productivity growth only 0.67 percentage points. Input growth is the source of nearly 80.6 percent of U.S. growth over the past half century, while productivity has accounted for 19.4 percent. Figure 2.11 shows the relatively modest contributions of productivity in all sub-periods.

Almost four-fifths of the contribution of capital reflects the accumulation of capital stock, while improvement in the quality of capital accounts for about one-fifth. Similarly, increased labor hours account for 68 percent of labor's contribution; the remainder is due to improvements in labor quality. Substitutions among capital and labor inputs in response to price changes are essential components of the sources of economic growth.

A look at the U.S. economy before and after 1973 reveals familiar features of the historical record. After strong output and productivity growth in the 1950's, 1960's and early 1970's, the U.S. economy slowed markedly through 1989, with output growth falling from 3.78 percent to 3.06 percent and productivity growth declining from 0.80 percent to 0.38 percent. The contribution of capital input also slowed from 1.94 percent for 1948-73 to 1.53 percent for 1973-89. This contributed to sluggish ALP growth -- 2.72 percent for 1948-73 and 1.46 percent for 1973-89.

Relative to the period 1989-1995, output growth increased by 1.50 percent in 1995-2002. The contribution of IT production jumped by 0.38 percent, relative to 1989-1995, but still accounted for only 21.9 percent of the increased growth of output. Although the contribution of IT has increased steadily throughout the

period 1948-2002, there has been a sharp response to the acceleration in the IT price decline in 1995. Nonetheless, almost three-quarters of the increased output growth can be attributed to non-IT products.

Between 1989-1995 and 1995-2002 the contribution of capital input jumped by 0.80 percentage points, the contribution of labor input declined by 0.10 percent, and productivity accelerated by 0.79 percent. Growth in ALP rose 1.36 percent as more rapid capital deepening and growth in productivity offset slower improvement in labor quality. Growth in hours worked slowed as labor markets tightened considerably, even as labor force participation rates increased.[35]

The contribution of capital input reflects the investment boom of the late 1990's as businesses, households, and governments poured resources into plant and equipment, especially computers, software, and communications equipment. The contribution of capital, predominantly IT, is considerably more important than the contribution of labor. The contribution of IT capital services has grown steadily throughout the period 1948-2002, but Figure 2.6 reflects the impact of the accelerating decline in IT prices.

After maintaining an average rate of 0.38 percent for the period 1973-89, productivity growth declined to 0.35 percent for 1989-95 and then vaulted to 1.14 percent per year for 1995-2002. This is a major source of growth in output and ALP for the U.S. economy (Figures 2.11 and 2.12). Productivity growth for 1995-2002 is considerably higher than the rate of 1948-73 and the U.S. economy is recuperating from the anemic productivity growth of the past two decades. Although less than half of the acceleration in productivity from 1989-5 to 1995-2002 can be attributed to IT production, this is far greater than the 5.01 percent share of IT in the GDP in 2002.

---

[35] Lawrence Katz and Alan Krueger (1999) analyze the recent performance of the U.S. labor market.

2.2.6. Average Labor Productivity.

Output growth is the sum of growth in hours and average labor productivity. Table 2.7 shows the breakdown between growth in hours and ALP for the same periods as in Table 2.6. For the period 1948-2002, ALP growth predominated in output growth, increasing 2.23 percent per year, while hours worked increased 1.23 percent per year. As shown above, ALP growth depends on capital deepening, a labor quality effect, and overall productivity growth.

Figure 2.12 reveals the well-known productivity slowdown of the 1970's and 1980's, emphasizing the sharp acceleration in labor productivity growth in the late 1990's. The slowdown through 1989 reflects reduced capital deepening, declining labor quality growth, and decelerating growth in total factor productivity. The growth of ALP recovered slightly during the early 1990's with a slump in capital deepening more than offset by a revival in labor quality growth and an up-tick in total factor productivity growth. A slowdown in hours combined with middling ALP growth during 1989-1995 to produce a further slide in the growth of output. In previous cyclical recoveries during the postwar period, output growth accelerated during the recovery, powered by more rapid growth of hours and ALP.

Accelerating output growth during 1995-2002 reflects modest growth in labor hours and a sharp increase in ALP growth[36]. Comparing 1989-1995 to 1995-2002, the rate of output growth jumped by 1.50 percent -- due to an increase in hours worked of 0.14 percent and an upward bound in ALP growth of 1.36 percent. Figure 2.12 shows the acceleration in ALP growth is due to capital deepening as well as faster total factor productivity growth. Capital deepening contributed 0.74 percentage points, counterbalancing a negative contribution of labor quality of 0.16 percent. The acceleration in total factor productivity growth added 0.79 percentage points.

[36] Stiroh (2002) shows that ALP growth is concentrated in IT-producing and IT-using industries.

2.2.7. Research Opportunities.

The use of computers, software, and communications equipment must be carefully distinguished from the production of IT[37]. Massive increases in computing power, like those experienced by the U.S. economy, have two effects on growth. First, as IT producers become more efficient, more IT equipment and software is produced from the same inputs. This raises productivity in IT-producing industries and contributes to productivity growth for the economy as a whole. Labor productivity also grows at both industry and aggregate levels.

Second, investment in information technology leads to growth of productive capacity in IT-using industries. Since labor is working with more and better equipment, this increases ALP through capital deepening. If the contributions to aggregate output are captured by capital deepening, aggregate productivity growth is unaffected[38]. Increasing deployment of IT affects productivity growth only if there are spillovers from IT-producing industries to IT-using industries.

Jorgenson, Ho, and Stiroh (2004) trace the increase in aggregate productivity growth to its sources in individual industries. Jorgenson and Stiroh (2000a, 2000b) present the appropriate methodology and preliminary results. Stiroh (2000) shows that aggregate ALP growth can be attributed to productivity growth in IT-producing and IT-using industries.

2.3. Demise of Traditional Growth Accounting.

2.3.1. Introduction.

The early 1970's marked the emergence of a rare professional consensus on economic growth, articulated in two strikingly dissimilar books. Kuznets

---

[37] Economics and Statistics Administration (2000), Table 3.1, p. 23, lists IT-producing industries.

[38] Baily and Gordon (1988).

summarized his decades of empirical research in *Economic Growth of Nations* (1971). "[39] Solow's book *Economic Growth* (1970), modestly subtitled "An Exposition", contained his 1969 Radcliffe Lectures at the University of Warwick. In these lectures Solow also summarized decades of theoretical research, initiated by the work of Roy Harrod (1939) and Domar (1946).[40]

Let me first consider the indubitable strengths of the perspective on growth that emerged victorious over its many competitors in the early 1970's. Solow's neo-classical theory of economic growth, especially his analysis of steady states with constant rates of growth, provided conceptual clarity and sophistication. Kuznets generated persuasive empirical support by quantifying the long sweep of historical experience of the United States and thirteen other developed economies. He combined this with quantitative comparisons among a developed and developing economies during the postwar period.

With the benefit of hindsight the most obvious deficiency of the traditional framework of Kuznets and Solow was the lack of a clear connection between the theoretical and the empirical components. This lacuna can be seen most starkly in the total absence of cross references between the key works of these two great economists. Yet they were working on the same topic, within the same framework, at virtually the same time, and in the very same geographical Location --*Cambridge, Massachusetts*!

Searching for analogies to describe this remarkable coincidence of views on growth, we can think of two celestial bodies on different orbits,

---

[39]The enormous impact of this research was recognized in the same year by the Royal Swedish Academy of Sciences in awarding the third Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel to Kuznets "for his empirically founded interpretation of economic growth which has led to new and deepened insight into the economic and social structure and process of development." See Assar Lindbeck (1992), p. 79.

[40]Solow's seminal role in this research, beginning with his brilliant and pathbreaking essay of 1956, "A Contribution to the Theory of Economic Growth", was recognized, simply and elegantly, by the Royal Swedish Academy of Sciences inawarding Solow the Nobel Prize in Economics in 1987 "for his contributions to the theory of economic growth." See Karl-Goran Maler (1992), p. 191. Solow (1999) presents an updated version of his exposition of growth theory.

momentarily coinciding from our earth-bound perspective at a single point in the sky and glowing with dazzling but transitory luminosity. The indelible image of this extraordinary event has been burned into the collective memory of economists, even if the details have long been forgotten. The resulting professional consensus, now obsolete, remained the guiding star for subsequent conceptual development and empirical observation for decades.

2.3.2. Human Capital.

The initial challenge to the framework of Kuznets and Solow was posed by Denison's magisterial study, *Why Growth Rates Differ* (1967). Denison retained NNP as a measure of national product and capital stock as a measure of capital input, adhering to the conventions employed by Kuznets and Solow. Denison's comparisons among nine industrialized economies over the period 1950-1962 were cited extensively by both Kuznets and Solow.

However, Denison departed from the identification of labor input with hours worked by Kuznets and Solow. He followed his earlier study of U.S. economic growth, *The Sources of Economic Growth in the United States and the Alternatives Before Us*, published in 1962. In this study he had constructed constant quality measures of labor input, taking into account differences in the quality of hours worked due to the age, sex, and educational attainment of workers.

Kuznets (1971), recognizing the challenge implicit in Denison's approach to measuring labor input, presented his own version of Denison's findings.[41] He carefully purged Denison's measure of labor input of the effects of changes in educational attainment. Solow, for his part, made extensive references to Denison's findings on the growth of output and capital stock, but avoided a detailed reference to Denison's measure of labor input. Solow adhered instead to

[41]Kuznets (1971), Table 9, part B, pp. 74-75.

hours worked (or "man-hours" in the terminology of the early 1970's) as a measure of labor input.[42]

Kuznets showed that "... with one or two exceptions, the contribution of the factor inputs per capita was a minor fraction of the growth rate of per capita product."[43] For the United States during the period 1929 to 1957, the growth rate of productivity or output per unit of input exceeded the growth rate of output per capita. According to Kuznets' estimates, the contribution of increases in capital input per capita over this extensive period was negative!

2.3.3. Solow's Surprise.

The starting point for our discussion of the demise of traditional growth accounting is a notable but neglected article by the great Dutch economist Jan Tinbergen (1942), published in German during World War II. Tinbergen analyzed the sources of U.S. economic growth over the period 1870-1914. He found that efficiency accounted only a little more than a quarter of growth in output, while growth in capital and labor inputs accounted for the remainder. This was precisely the opposite of the conclusion that Kuznets (1971) and Solow (1970) reached almost three decades later!

The notion of efficiency or "total factor productivity" was introduced independently by George Stigler (1947) and became the starting point for a major research program at the National Bureau of Economic Research. This program employed data on output of the U.S. economy from earlier studies by the National Bureau, especially the pioneering estimates of the national product by Kuznets (1961). The input side employed data on capital from Raymond Goldsmith's (1962) system of national wealth accounts. However, much of the data was generated by John Kendrick (1956, 1961), who employed an explicit

---

[42]Solow (1970), pp. 2-7. However, Solow (1988), pp. 313-314, adopted Denison's perspective on labor input in his Nobel Prize address. At about the same time this view was endorsed by Becker (1993a), p. 24, in his 1989 Ryerson Lecture ad the University of Chicago. Becker (1993b) also cited Denison in his Nobel Prize address.

[43]Kuznets (1971), p. 73.

system of national production accounts, including measures of output, input, and productivity for national aggregates and individual industries.[44]

The econometric models of Paul Douglas (1948) and Tinbergen were integrated with data from the aggregate production accounts generated by Abramovitz (1956) and Kendrick (1956) in Solow's justly celebrated 1957 article, "Technical Change and the Aggregate Production Function". Solow identified "technical change" with shifts in the production function. Like Abramovitz, Kendrick, and Kuznets, he attributed almost all of U.S. economic growth to "residual" growth in productivity.[45]

Kuznets' (1971) international comparisons strongly reinforced the findings of Abramovitz (1956), Kendrick (1956), and Solow (1957), which were limited to the United States.[46] According to Kuznets, economic growth was largely attributable to the Solow residual between the growth of output and the growth of capital and labor inputs, although he did not use this terminology. Kuznets' assessment of the significance of his empirical conclusions was unequivocal:

> (G)iven the assumptions of the accepted national economic accounting framework, and the basic demographic and institutional processes that control labor supply, capital accumulation, and initial capital-output ratios, this major conclusion -- that the distinctive feature of modern economic growth, the high rate of growth of per capita product is for the most part attributable to a high rate of growth in productivity -- is inevitable.[47]

---

[44]Updated estimates based on Kendrick's framework are presented by Kendrick (1973) and Kendrick and Grossman (1980).

[45]This finding is called "Solow's Surprise" by William Easterly (2001) and is listed as one of the "stylized facts" about economic growth by Robert King and Sergio Rebelo (1999).

[46]A survey of international comparisons, including Tinbergen (1942)and Kuznets (1971), is given in my paper with Christensen and Cummings (1980), presented at the forty-fourth meeting of the Conference on Research and Wealth, held at Williamsburg, Virginia, in 1975.

[47]Kuznets (1971), p. 73; see also, pp. 306-309.

The empirical findings summarized by Kuznets have been repeatedly corroborated in investigations that employ the traditional approach to growth accounting. This approach identifies output with real NNP, labor input with hours worked, and capital input with real capital stock.[48] Kuznets (1978) interpreted the Solow residual as due to exogenous technological innovation. This is consistent with Solow's (1957) identification of the residual with technical change. Successful attempts to provide a more convincing explanation of the Solow residual have led, ultimately, to the demise of the traditional framework.[49]

2.3.4. Radical Departure.

The most serious challenge to the traditional approach growth accounting was presented in my 1967 paper with Griliches, "The Explanation of Productivity Change". Griliches and I departed far more radically than Denison from the measurement conventions of Kuznets and Solow. We replaced NNP with GNP as a measure of output and introduced constant quality indexes for both capital and labor inputs.

The key idea underlying our constant quality index of labor input, like Denison's, was to distinguish among different types of labor inputs. We combined hours worked for each type into a constant quality index of labor input, using the index number methodology Griliches (1960) had developed for U.S. agriculture. This considerably broadened the concept of substitution employed by Solow (1957). While he had modeled substitution between capital and labor inputs, Denison, Griliches and I extended the concept of substitution to include

---

[48]For recent examples, see Michael Dertouzos, Solow, and Richard Lester (1989) and Hall (1988, 1990a).

[49]A detailed survey of research on sources of economic growth is given in my 1990 article, "Productivity and Economic Growth", presented at the The Jubilee of the Conference on Research in Income and Wealth, held in Washington, D.C., in 1988, commemorating the fiftieth anniversary of the founding of the Conference by Kuznets. More recent surveys are presented in Griliches' (2000) posthumous book, *R&D, Education, and Productivity,* and Charles Hulten's (2001) article, "Total Factor Productivity: A Short Biography".

different types of labor inputs as well. This altered, irrevocably, the allocation of economic growth between substitution and technical change.[50]

Griliches and I introduced a constant quality index of capital input by distinguishing among types of capital inputs. To combine different types of capital into a constant quality index, we identified the prices of these inputs with rental prices, rather than the asset prices used in measuring capital stock. For this purpose we used a model of capital as a factor of production I had introduced in my 1963 article, "Capital Theory and Investment Behavior". This made it possible to incorporate differences among depreciation rates on different assets, as well as variations in returns due to the tax treatment of different types of capital income, into our constant quality index of capital input.[51]

Finally, Griliches and I replaced the aggregate production function employed by Denison, Kuznets, and Solow with the production possibility frontier introduced in my 1966 paper, "The Embodiment Hypothesis". This allowed for joint production of consumption and investment goods from capital and labor inputs. I had used this approach to generalize Solow's (1960) concept of embodied technical change, showing that economic growth could be interpreted, equivalently, as "embodied" in investment or "disembodied" in productivity growth. My 1967 paper with Griliches removed this indeterminacy by introducing constant quality price indexes for investment goods.[52]

---

[50]Constant quality indexes of labor input are discussed detail by Jorgenson, Gollop, and Fraumeni (1987), Chapters 3 and 8, pp. 69-108 and 261-300, and Jorgenson, Ho, and Stiroh (2004).

[51]I have presented a detailed survey of empirical research on the measurement of capital input in my 1989 paper, "Capital as a Factor of Production". Earlier surveys were given in my 1973 and 1980 papers and Diewert's (1980) contribution to the forty-fifth meeting of the Conference on Income and Wealth, held at Toronto, Ontario, in 1976. Hulten (1990) surveyed conceptual aspects of capital measurement in his contribution to the Jubilee of the Conference on Research in Income and Wealth in 1988.

[52]As a natural extension of Solow's (1956) one-sector neo-classical model of economic growth, his 1960 model of embodiment had only a single output and did

Griliches and I showed that changes in the quality of capital and labor inputs and the quality of investment goods explained most of the Solow residual. We estimated that capital and labor inputs accounted for eighty-five percent of growth during the period 1945-1965, while only fifteen percent could be attributed to productivity growth. Changes in labor quality explained thirteen percent of growth, while changes in capital quality another eleven percent.[53] Improvements in the quality of investment goods enhanced the growth of both investment goods output and capital input; the net contribution was only two percent of growth.[54]

2.3.5. The Rees Report.

The demise of the traditional framework for productivity measurement began with the Panel to Review Productivity Statistics of the National Research Council, chaired by Albert Rees. The Rees Report of 1979, *Measurement and Interpretation of Productivity*, became the cornerstone of a new measurement framework for the official productivity statistics. This was implemented by the Bureau of Labor Statistics (BLS), the U.S. government agency responsible for these statistics.

Under the leadership of Jerome Mark and Edwin Dean the BLS Office of Productivity and Technology undertook the construction of a production account for the U.S. economy with measures of capital and labor inputs and total factor

---

not allow for the introduction of a separate price index for investment goods. Recent research on Solow's model of embodiment is surveyed by Greenwood and Boyan Jovanovic (2001) and discussed by Solow (2001). Solow's model of embodiment is also employed by Whelan (2002).

[53]See Jorgenson and Griliches (1967), Table IX, p. 272. We also attributed thirteen percent of growth to the relative utilization of capital, measured by energy consumption as a proportion of capacity; however, this is inappropriate at the aggregate level, as Denison (1974), p. 56, pointed out. For additional details, see Jorgenson, Gollop, and Fraumeni (1987), especially pp. 179-181.

[54]Using Gordon's (1990) estimates of improvements in the quality of producers' durables, Hulten (1992b) estimated this proportion as 8.5 percent of the growth of U.S. manufacturing output for the period 1949-1983.

productivity, renamed multifactor productivity.[55] The BLS (1983) framework was based on GNP rather than NNP and included a constant quality index of capital input, displacing two of the key conventions of the traditional framework of Kuznets and Solow.[56]

However, BLS retained hours worked as a measure of labor input until July 11, 1994, when it released a new multifactor productivity measure including a constant quality index of labor input as well. Meanwhile, BEA (1986) had incorporated a constant quality price index for computers into the national accounts -- over the strenuous objections of Denison (1989). This index was incorporated into the BLS measure of output, completing the displacement of the traditional framework of economic measurement by the conventions employed in my papers with Griliches.[57]

The official BLS (1994) estimates of multifactor productivity have over-turned the findings of Abramovitz (1956) and Kendrick (1956), as well as those of Kuznets (1971) and Solow (1970). The official statistics have corroborated the findings summarized in my 1990 survey paper, "Productivity and Economic Growth". These statistics are now consistent with the original findings of Tinbergen (1942), as well as my paper with Griliches (1967), and the results I have presented in Section 2.2.

The approach to growth accounting presented in my 1987 book with Gollop and Fraumeni and the official statistics on multifactor productivity published by the BLS in 1994 has now been recognized as the international standard. The new framework for productivity measurement is presented in *Measuring Productivity*, a Manual published by the Organisation for Economic Co-Operation and Development (OECD) and written by Schreyer (2001). The expert advisory group

[55]A detailed history of the BLS productivity measurement program is presented by Dean and Harper (2001).

[56]The constant quality index of capital input became the international standard for measuring productivity in Blades' (2001) OECD manual, *Measuring Capital*.

[57]The constant quality index of labor input became the international standard in the United Nations (1993) *System of National Accounts*.

for this manual was chaired by Dean, former Associate Commissioner for Productivity at the BLS, and leader of the successful effort to implement the Rees Report (1979).

3. International Comparisons

3.1. Introduction.

In this section I present international comparisons of economic growth among the G7 nations – Canada, France, Germany, Italy, Japan, the U.K., and the U.S. These comparisons focus on the impact of investment in information technology (IT) equipment and software over the period 1980-2001. In 1998 the G7 nations accounted for nearly sixty percent of world output[58] and a much larger proportion of world investment in IT. Economic growth in the G7 has experienced a strong revival since 1995, driven by a powerful surge in IT investment.

The resurgence of economic growth in the United States during the 1990's and the crucial role of IT investment has been thoroughly documented and widely discussed.[59] Similar trends in the other G7 economies have been more difficult to detect, partly because of discrepancies among official price indexes for IT equipment and software identified by Andrew Wyckoff.[60] Paul Schreyer has constructed "internationally harmonized" IT prices that eliminate many of these discrepancies.[61]

Using internationally harmonized prices, I have analyzed the role of investment and productivity as sources of growth in the G7 countries over the period 1980-2001. I have subdivided the period in 1989 and 1995 in order to

---

[58]See Angus Maddison (2001) for 1998 data for world GDP and the GDP of each of the G7 countries.

[60]See Wyckoff (1995)
[61]See Schreyer (2000). Alessandra Colecchia and Schreyer (2002) have employed these internationally harmonized prices in measuring the impact of IT investment.

focus on the most recent experience. I have decomposed growth of output for each country between growth of input and productivity. Finally, I have allocated the growth of input between investments in tangible assets, especially information technology and software, and human capital.

Growth in IT capital input per capita jumped to double-digit levels in the G7 nations after 1995. This can be traced to acceleration in the rate of decline of IT prices, analyzed in my Presidential Address to the American Economic Association.[62] The powerful surge in investment was most pronounced in Canada, but capital input growth in Japan, the U.S., and the U.K. was only slightly lower. France, Germany, and Italy also experienced double-digit growth, but lagged considerably behind the leaders.

During the 1980's productivity played a minor role as a source of growth for the G7 countries except Japan, where productivity accounted for thirty percent of economic growth. Productivity accounted for only sixteen percent of growth in the U.S., thirteen percent in France, twelve percent in the U.K., and eleven percent in Germany; only two percent of growth in Canada was due to productivity, while the decline of productivity retarded growth by fourteen percent in Italy. Between 1989 and 1995 productivity growth declined further in the G7 nations, except for Italy and Germany. Productivity declined for France and the U.K. but remained positive for the U.S., Canada, and Japan.

Productivity growth revived in all the G7 countries after 1995, again with the exception of Germany and Italy. The resurgence was most dramatic in Canada, The U.K., and France, partly offsetting years of dismal productivity growth. Japan exhibited the highest growth in output per capita among the G7 nations from 1980 to 1995. Japan's level of output per capita rose from the lowest in the G7 to the middle of the group. Although this advance owed more to input per capita than productivity, Japan's productivity growth far outstripped the other

[62]See Jorgenson (2001).

members of the G7. Nonetheless, Japan's productivity remained the lowest among the G7 nations.

The U.S. led the G7 in output per capita for the period 1989-2000. Canada's edge in output per capita in 1980 had disappeared by 1989. The U.S. led the G7 countries in input per capita during 1980-2000, but U.S. productivity languished below the levels of Canada, France, and Italy.

In Section 3.2 I outline the methodology for this study, based on Section 2 above. I have revised and updated the U.S. data presented there through 2001. Comparable data on investment in information technology have been have been constructed for Canada by Statistics Canada.[63] Data on IT for France, Germany, Italy, and the U.K. have been developed for the European Commission by Bart Van Ark, *et al*.[64] Finally, data for Japan have been assembled by myself and Kazuyuki Motohashi for the Research Institute on Economy, Trade, and Industry.[65] I have linked these data by means of the OECD's purchasing power parities for 1999.[66]

In Section 3.3 I consider the impact of IT investment and the relative importance of investment and productivity in accounting for economic growth among the G7 nations. Investments in human capital and tangible assets, especially IT equipment and software, account for the overwhelming proportion of growth. Differences in the composition of capital and labor inputs are essential for identifying persistent international differences in output and accounting for the impact of IT investment.

In Section 3.4 I consider alternative approaches to international comparisons. The great revival of interest in economic growth among economists dates from Maddison's (1982) updating and extension of Simon Kuznets' (1971) long-term estimates of the growth of national product and population for

fourteen industrialized countries, including the G7 nations. Maddison (1982, 1991) added Austria and Finland to Kuznets' list and presented growth rates covering periods beginning as early as 1820 and extending through 1989.

Maddison (1987, 1991) also generated growth accounts for major industrialized countries, but did not make level comparisons like those presented in Section 3.2 below. As a consequence, productivity differences were omitted from the canonical formulation of "growth regressions" by William Baumol (1986). This proved to be a fatal flaw in Baumol's regression model, remedied by Nazrul Islam's (1995) panel data model. Section 3.5 concludes.

3.2. Investment and Productivity.

My papers with Laurits Christensen and Dianne Cummings (1980, 1981) developed growth accounts for the United States and its major trading partners -- Canada, France, Germany, Italy, Japan, Korea, The Netherlands, and the United Kingdom for 1947-1973. We employed GNP as a measure of output and incorporated constant quality indices of capital and labor input for each country. Our 1981 paper compared levels of output, inputs, and productivity for all nine nations.

I have updated the estimates for the G7 - Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States - through 1995 in earlier work. The updated estimates are presented in my papers with Chrys Dougherty (1996, 1997) and Eric Yip (2000). We have shown that productivity accounted for only eleven percent of economic growth in Canada and the United States over the period 1960-1995.

My paper with Yip (2000) attributed forty-seven percent of Japanese economic growth during the period 1960-1995 to productivity growth. The proportion attributable to productivity approximated forty percent of growth for the four European countries – France (.38), Germany (.42), Italy (.43), and the United Kingdom (.36). Input growth predominated over productivity growth for all the G7 nations.

I have now incorporated new data on investment in information technology equipment and software for the G7. I have also employed internationally harmonized prices like those constructed by Schreyer (2000). As a consequence, I have been able to separate the contribution of capital input to economic growth into IT and Non-IT components. While IT investment follows similar patterns in all the G7 nations, Non-IT investment varies considerably and helps to explain important differences in growth rates among the G7.

3.2.1. Comparisons of Output, Input, and Productivity.

My first objective is to extend my estimates for the G7 nations with Christensen, Cummings, Dougherty, and Yip to the year 2001. Following the methodology of my Presidential Address, I have chosen GDP as a measure of output. I have included imputations for the services of consumers' durables as well as land, buildings, and equipment owned by nonprofit institutions. I have also distinguished between investments in information technology equipment and software and investments in other forms of tangible assets.

A constant quality index of capital input is based on weights that reflect differences in capital consumption, tax treatment, and the rate of decline of asset prices. I have derived estimates of capital input and property income from national accounting data. Similarly, a constant quality index of labor input is based on weights by age, sex, educational attainment, and employment status. I have constructed estimates of hours worked and labor compensation from labor force surveys for each country.

In Table 3.1 I present output per capita for the G7 nations from 1980 to 2001, taking the U.S. as 100.0 in 2000. Output and population are given separately in Tables 3.2 and 3.3. I use 1999 purchasing power parities from the OECD to convert output from domestic prices for each country into U.S. dollars. The U.S. gained the lead among the G7 countries in output per capita after 1995. Canada led the U.S. in 1980, but fell behind during the 1995. The U.S.-Canada gap widened considerably during the 1990’s.

The four major European nations – the U.K., France, Germany, and Italy - had similar levels of output per capita throughout the period 1980-2001. Japan rose from last place in 1980 to fourth among the G7 in 2001, lagging considerably behind the U.S. and Canada, but only slightly behind the U.K. in 2001. Japan led the G7 in the growth of output per capita from 1980-1995, but fell behind the U.S., Canada, the U.K., France, and Italy after 1995.

In Table 3.1 I present input per capita for the G7 over the period 1980-2000, taking the U.S. as 100.0 in 2000. I express input per capita in U.S. dollars, using purchasing power parities constructed for this study.[67] The U.S. was the leader among the G7 in input per capita throughout the period. In 2001 Canada ranked next to the U.S. with Japan third and Germany fourth. France and Italy started at the bottom of the ranking and remained there throughout the period.

In Table 3.1 I also present productivity levels for the G7 over the period 1980-2001. Productivity is defined as the ratio of output to input, including both capital and labor inputs. Italy led in 1980 and Canada was the productivity leader throughout the period 1989-2001 with France close behind. Japan made substantial gains in productivity during the period, while there were more modest increases in the U.S., Canada, the U.K., France, and Germany, and a decline in Italy.

I summarize growth in output and input per capita and productivity for the G7 nations in Table 3.4. I present growth rates of output and population for the period 1980-2001 in Tables 3.2 and 3.3. Output growth slowed in the G7 after 1989, but revived for all nations except Japan and Germany after 1995. Output per capita followed a similar pattern with Canada barely expanding during the period 1990-1995.

---

[67]The purchasing power parities for outputs are based on OECD (2002). Purchasing power parities for inputs follow the methodology described in detail by Jorgenson and Yip (2001).

Japan led in growth of output and output per capita through 1995, but fell to the lower echelon of the G7 after 1995. Japan also led in productivity growth throughout the period 1980-2001. For all countries and all time periods, except for Germany during the period 1989-1995 and Japan after 1995, the growth of input per capita exceeded growth of productivity by a substantial margin. Productivity growth in the G7 slowed during the period 1989-1995, except for Germany and Italy, where productivity slumped after 1995.

Italy led the G7 in growth of input per capita for the periods 1980-1989 and 1995-2001, but relinquished leadership to the U.K. for the period 1989-1995. Differences among input growth rates are smaller than differences among output growth rates, but there was a slowdown in input growth during 1989-1995 throughout the G7. After 1995 growth of input per capita increased in every G7 nation except Japan.

3.2.2. Comparisons of Capital and Labor Quality.

A constant quality index of capital input weights capital inputs by property compensation per unit of capital. By contrast an index of capital stock weights different types of capital by asset prices. The ratio of capital input to capital stock measures the average quality of a unit of capital. This represents the difference between the constant quality index of capital input and the index of capital stock employed, for example, by Kuznets (1971) and Robert Solow (1970).

In Table 3.5 I present capital input per capita for the G7 countries over the period 1980-2001 relative to the U.S. in 2000. The U.S. was the leader in capital input per capita throughout the period, while the U.K. was the laggard. Canada led the remaining six countries in 1980, but was overtaken by Germany and Italy in 1995. Italy led the rest of the G7 through 2001, but lagged considerably behind the United States.

The picture for capital stock per capita has some similarities to capital input, but there are important differences. Capital stock levels do not

accurately reflect the substitutions among capital inputs that accompany investments in tangible assets, especially investments in IT equipment and software. The U.S. led the G7 in capital stock per capita as well as capital input after 1989, while Japan led in 1980 and was second to the U.S. after 1989. The U.K. lagged the remaining countries of the G7 throughout the period.
