The behavior of capital quality highlights the differences between the constant quality index of capital input and capital stock. There are important changes in capital quality over time and persistent differences among countries, so that heterogeneity in capital input must be taken into account in international comparisons of economic performance. Canada was the international leader in capital quality throughout the period 1980-2001, while Japan ranked at the bottom of the G7.

I summarize growth in capital input and capital stock per capita, as well as capital quality for the G7 nations in Table 3.8. Italy was the international leader in capital input growth from 1980-1989, while Canada was the laggard. The U.K. led from 1989-1995, while Canada lagged considerably behind the rest of the G7. The U.S. took the lead after 1995. There was a slowdown in capital input growth throughout the G7 after 1989, except for the U.K., and a revival after 1995 in the U.S., Canada, France, and Italy.

A constant quality index of labor input weights hours worked for different categories by labor compensation per hour. An index of hours worked fails to take quality differences into account. The ratio of labor input to hours worked measures the average quality of an hour of labor, as reflected in its marginal product. This represents the difference between the constant quality index of labor input and the index of hours worked employed, for example, by Kuznets (1971) and Solow (1970).

In Table 3.11 I present labor input per capita for the G7 nations for the period 1980-2001 relative to the U.S. in 2000. Japan was the international leader throughout the period and France and Italy the laggards. Labor input in

Japan was nearly double that of Italy. The U.S. led the remaining G7 nations throughout the period. The U.K. ranked third among the G7 through 1995. Italy and France lagged behind the rest of the G7 for the entire period.

The picture for hours worked per capita has some similarities to labor input, but there are important differences. Japan was the international leader in hours worked per capita. The U.S., Canada, and the U.K. moved roughly in parallel. The U.K. ranked second in 1980 and 1989, while the U.S. ranked second in 1995 and 2001. France and Italy lagged the rest of the G7 from 1980-2001.

The behavior of labor quality highlights the differences between labor input and hours worked. Germany was the leader in labor quality throughout the period 1980-2001 with the U.S. close behind. Canada, the U.K., France, and Japan had similar levels of labor quality throughout the period, but fell short of German and U.S. levels. Italy was the laggard among the G7 in labor quality.

I summarize growth in labor input and hours worked per capita, as well as labor quality for the period 1980-2001 in Table 3.12. Canada and Japan led the G7 nations in labor input growth during the 1980's, France led from 1989-1995 but relinquished its leadership to Italy after 1995. Labor input growth was negative for France during the 1980's, for the U.K., Germany, Italy, and Japan during the period 1989-1995, and for Japan after 1995.

Hours worked per capita fell continuously throughout the period 1980-2001 for Japan and declined for all the G7 nations during the period 1989-1995. Growth in labor quality was positive for the G7 nations in all time periods. Japan was the leader during the 1980's, relinquishing its lead to France during the early 1990's and Italy in the late 1990's. Growth in labor quality and hours worked are equally important as sources of growth in labor input for the G7.

3.3. Investment in Information Technology.

Using data from Tables 3.1 and 3.2, I can assess the relative importance of investment and productivity as sources of economic growth for the G7 nations. Investments in tangible assets and human capital greatly predominated over

productivity during the period 1980-2001. While productivity fell in Italy during this period, the remaining G7 countries had positive productivity growth for the period as a whole.

Similarly, using data from Table 3.5 I can assess the relative importance of growth in capital stock and capital quality. Capital input growth was positive for all countries for the period 1980-2001 and all three sub-periods. Capital quality growth was positive for the period as a whole for all G7 countries. Although capital stock predominated in capital input growth, capital quality was also quantitatively significant, especially after 1995.

Finally, using data from Table 3.11 I can assess the relative importance of growth in hours worked and labor quality. Hours worked per capita declined for France, Germany, and Japan, while labor quality rose in these nations during the period 1980-2001. For the U.S., Canada, the U.K., and Italy, both hours worked per capita and labor quality rose. I conclude that labor quality growth is essential to the analysis of growth in labor input.

3.3.1. Investment in IT Equipment and Software

The final step in the comparison of patterns of economic growth among the G7 nations is to analyze the impact of investment in information technology equipment and software. In Table 3.6 I present levels of IT capital input per capita for the G7 for the period 1980-2001, relative to the U.S. in 2000. The U.S. overtook Germany in 1989 and remained the leader through 2001. Canada and Japan lagged behind the rest of the G7 through 1995, but France fell into last place in 2001.

Table 3.6 reveals substantial differences between IT capital stock and IT capital input. The G7 nations began with very modest stocks of IT equipment and software per capita in 1980. These stocks expanded rapidly during the period 1980-2001. The U.S. led in IT capital stock throughout the period, while Japan moved from the third lowest level in 1980 to the second highest in 2001.

IT capital quality reflects differences in the composition of IT capital input, relative to IT capital stock. A rising level of capital quality indicates a shift toward short-lived assets, such as computers and software. This shift is particularly dramatic for the U.S., Canada, and Japan, while the composition of IT capital stock changed relatively less for the U.K., France, Germany, and Italy. Patterns for Non-IT capital input, capital stock, and capital quality largely reflect those for capital as a whole, presented in Table 3.5.

I give growth rates for IT capital input per capita, capital stock per capita, and capital quality in Table 3.9. The G7 nations have exhibited double-digit growth in IT capital input per capita since 1995. Canada was the international leader during this period with Japan close behind. Japan was the leader in growth of IT capital input during the 1980's, another period of double-digit growth in the G7. However, Japanese IT growth slowed substantially during 1989-1995 and Canada gained the lead.

Patterns of growth for IT capital stock per capita are similar to those for IT capital input for the four European countries. Changes in the composition of IT capital stock per capita were important sources of growth of IT capital input per capita for the U.S., Canada, and Japan. IT capital stock also followed the pattern of IT capital input with substantial growth during the 1980's, followed by a pronounced lull during the period 1989-1995. After 1995 the growth rates of IT capital stock surged in all the G7 countries, except Germany, but exceeded the rates of the 1980's only for the U.S. and Japan.

Finally, growth rates for IT capital quality reflect the rates at which shorter-lived IT assets are substituted for longer-lived assets.
Japan led in the growth of capital quality during the 1980's, but relinquished its lead to Canada in 1989. IT capital quality growth for the Canada substantially outstripped that of the remaining G7 countries for the period 1989-2001. Patterns of growth in Non-IT capital input per capita, Non-IT capital

stock per capita, and Non-IT capital quality given in Table 3.10 largely reflect those for capital as a whole presented in Table 3.8.

Table 3.13 and Figure 3.1 present the contribution of capital input to economic growth for the G7 nations, divided between IT and Non-IT. The powerful surge of IT investment in the U.S. after 1995 is mirrored in similar jumps in growth rates of the contribution of IT capital through the G7. The contribution of IT capital input was similar during the 1980's and the period 1989-1995 for all the G7 nations, despite the dip in rates of economic growth after 1989. Japan is an exception to this general pattern with a contribution of IT capital comparable to that of the U.S. during the 1980's, followed by a decline in this contribution from 1989-1995, reflecting the sharp downturn in Japanese economic growth.

The contribution of Non-IT capital input to economic growth after 1995 exceeded that for IT capital input for four of the G7 nations; the exceptions were Canada, the U.K., and Japan. The U.S. stands out in the magnitude of the contribution of capital input after 1995. Both IT and Non-IT capital input contributed to the U.S. economic resurgence of the last half of the 1990's. Despite the strong performance of IT investment in Japan after 1995, the contribution of capital input declined substantially; this contribution also declined for the U.K. and Germany.

3.3.2. The Relative Importance of Investment and Productivity.

Table 3.14 and Figure 3.2 present contributions to economic growth from productivity, divided between the IT-producing and Non-IT-producing industries. The methodology for this division follows Triplett (1996). The contribution of IT-producing industries is positive throughout the period 1980-2001 and jumps substantially after 1995. Since the level of productivity in Italy is higher in 1980 than in 2001, it is not surprising that the contribution of productivity growth in the Non-IT industries was negative throughout the period. Productivity

in these industries also declined during 1989-1995 in Canada, the U.K., and France and after 1989 in Germany as well as Italy.

Table 3.15 and Figure 3.3 give a comprehensive view of the sources of economic growth for the G7. The contribution of capital input alone exceeds that of productivity for most nations and most time periods. The contribution of Non-IT capital input predominates over IT capital input for most countries and most time periods with Canada in 1989-2001, and the U.K. and Japan after 1995 as exceptions. This can be attributed to the unusual weakness in the growth of aggregate demand in these countries. The contribution of labor input varies considerably among the G7 nations with negative contributions after 1995 in Japan, during the 1980's in France, and during the period 1989-1995 in the U.K. and Germany.

Finally, Table 3.16 and Figure 3.4 translate sources of growth into sources of growth in average labor productivity (ALP). ALP, defined as output per hour worked, must be carefully distinguished from overall productivity, defined as output per unit of both capital and labor inputs. Output growth is the sum of growth in hours worked and growth in ALP. ALP growth depends on the contribution of capital deepening, the contribution of growth in labor quality, and productivity growth.

Capital deepening is the contribution of growth in capital input per hour worked and predominates over productivity as a source of ALP growth for the G7 nations. IT capital deepening predominates over Non-IT capital deepening in the U.S. throughout the period 1980-2001 and in Canada after 1989, the U.K., France, and Japan after 1995. Finally, the contribution of labor quality is positive for all the G7 nations through the period.

3.4. Alternative Approaches

Edward Denison's (1967) pathbreaking volume, *Why Growth Rates Differ*, compared differences in growth rates for national income net of capital consumption per capita for the period 1950-62 with differences of levels in 1960

for eight European countries and the U.S. The European countries were characterized by much more rapid growth and a lower level of national income per capita. However, this association did not hold for all comparisons between the individual countries and the U.S. Nonetheless, Denison concluded:[68]

> Aside from short-term aberrations Europe should be able to report higher growth rates, at least in national income per person employed, for a long time. Americans should expect this and not be disturbed by it.

Maddison (1987, 1991) constructed estimates of aggregate output, input, and productivity growth for France, Germany, Japan, The Netherlands, and the United Kingdom for the period 1870-1987. Maddison (1995) extended estimates for the U.S., the U.K., and Japan backward to 1820 and forward to 1992. He defined output as gross of capital consumption throughout the period and constructed constant quality indices of labor input for the period 1913-1984, but not for 1870-1913.

Maddison employed capital stock as a measure of the input of capital, ignoring the changes in the composition of capital stock that are such an important source of growth for the G7 nations. This omission is especially critical in assessing the impact of investment in information technology. Finally, he reduced the growth rate of the price index for investment by one percent per year for all countries and all time periods to correct for biases like those identified by Wyckoff (1995).

3.4.1. Comparisons without Growth Accounts

Kuznets (1971) provided elaborate comparisons of growth rates for fourteen industrialized countries. Unlike Denison (1967), he did not provide level comparisons. Maddison (1982) filled this lacuna by comparing levels of national product for sixteen countries. These comparisons used

---

[68]See Denison (1967), especially Chapter 21, "The Sources of Growth and the Contrast between Europe and the United States", pp. 296-348.

estimates of purchasing power parities by Irving Kravis, Alan Heston, and Robert Summers (1978).[69]

Maddison (1995) extended his long-term estimates of the growth of national product and population to 56 countries, covering the period 1820-1992. Maddison (2001) updated these estimates to 1998 in his magisterial volume, *The World Economy: A Millennial Perspective*. He provided estimates for 134 countries, as well as seven regions of the world – Western Europe, Western Offshoots (Australia, Canada, New Zealand, and the United States), Eastern Europe, Former USSR, Latin America, Asia, and Africa.

Purchasing power parities have been updated by successive versions of the Penn World Table. A complete list of these tables through Mark 5 is given by Summers and Heston (1991). The current version of the Penn World Table is available on the Center for International Comparisons website at the University of Pennsylvania (CICUP). This covers 168 countries for the period 1950-2000 and represents one of the most significant achievements in economic measurement of the postwar period.[70]

3.4.2. Convergence

Data presented by Kuznets (1971), Maddison, and successive versions of the Penn World Table have made it possible to reconsider the issue of convergence raised by Denison (1967). Moses Abramovitz (1986) was the first to take up the challenge by analyzing convergence of output per capita among Maddison's sixteen countries. He found that convergence characterized the postwar period, while there was no tendency toward convergence before 1914 and during the interwar period. Baumol (1986) formalized these results by running a regression of growth

[69]For details see Maddison (1982), pp. 159-168.
[70]See Heston, Summers, and Aten (2002). The CICUP website is at: http://pwt.econ.upenn.edu/aboutpwt.html.

rate of GDP per capita over the period 1870-1979 on the 1870 level of GDP per capita.[71]

In a highly innovative paper on "Crazy Explanations for the Productivity Slowdown" Paul Romer (1987) derived Baumol's "growth regression" from Solow's (1970) growth model with a Cobb-Douglas production function. Romer's empirical contribution was to extend the growth regressions from Maddison's (1982) sixteen advanced countries to the 115 countries in the Penn World Table (Mark 3). Romer's key finding was an estimate of the elasticity of output with respect to capital close to three-quarters. The share of capital in GNP implied by Solow's model was less than half as great.

Gregory Mankiw, David Romer, and David Weil (1992) defended the traditional framework of Kuznets (1971) and Solow (1970). The empirical part of their study is based on data for 98 countries from the Penn World Table (Mark 4). Like Paul Romer (1987), Mankiw, David Romer, and Weil derived a growth regression from the Solow (1970) model; however, they augmented this by allowing for investment in human capital.

The results of Mankiw, David Romer, and Weil (1992) provided empirical support for the augmented Solow model. There was clear evidence of the convergence predicted by the model; in addition, the estimated elasticity of output with respect to capital was in line with the share of capital in the value of output. The rate of convergence of output per capita was too slow to be consistent with 1970 version of the Solow model, but supported the augmented version.

---

[71]Baumol's "growth regression" has spawned a vast literature, recently summarized by Steven Durlauf and Danny Quah (1999, Ellen McGrattan and James Schmitz (1999), and Islam (2003). Much of this literature is based on data from successive versions of the Penn World Table.

3.4.2. Modeling Productivity Differences.

Finally, Islam (1995) exploited an important feature of the Penn World Table overlooked in prior studies. This panel data set contains benchmark comparisons of levels of the national product at five year intervals, beginning in 1960. This made it possible to test an assumption maintained in growth regressions. These regressions had assumed identical levels of productivity for all countries included in the Penn World Table.

Substantial differences in levels of productivity among countries have been documented by Denison (1967), by my papers with Christensen and Cummings (1981), Dougherty (1996, 1999), and Yip (2000) and in Section 2 above. By introducing econometric methods for panel data Islam (1995) was able to allow for these differences. He corroborated the finding of Mankiw, David Romer, and Weil (1992) that the elasticity of output with respect to capital input coincided with the share of capital in the value of output.

In addition, Islam (1995) found that the rate of convergence of output per capita among countries in the Penn World Table substantiated the *unaugmented* version of the Solow (1970) growth model. In short, "crazy explanations" for the productivity slowdown, like those propounded by Paul Romer (1987, 1994), were unnecessary. Moreover, the model did not require augmentation by endogenous investment in human capital, as proposed by Mankiw, David Romer, and Weil (1992).

Islam concluded that differences in technology among countries must be included in econometric models of growth rates. This requires econometric techniques for panel data, like those originated by Gary Chamberlain (1982), rather than the regression methods of Baumol, Paul Romer, and Mankiw, David Romer, and Weil. Panel data techniques have now superseded regression methods in modeling differences in output per capita.

3.5. Conclusions.

I conclude that a powerful surge in investment in information technology and equipment after 1995 characterizes all of the G7 economies. This accounts for a large portion of the resurgence in U.S. economic growth, but contributes substantially to economic growth in the remaining G7 economies as well. Another significant source of the G7 growth resurgence after 1995 is a jump in productivity growth in IT-producing industries.

For Japan the dramatic upward leap in the impact of IT investment after 1995 was insufficient to overcome downward pressures from deficient growth of aggregate demand. This manifests itself in declining contributions of Non-IT capital and labor inputs. Similar downturns are visible in Non-IT capital input in France, Germany, and especially the U.K. after 1995.

These findings are based on new data and new methodology for analyzing the sources of economic growth. Internationally harmonized prices for information technology equipment and software are essential for capturing differences among the G7 nations. Constant quality indices of capital and labor inputs are necessary to incorporate the impacts of investments in information technology and human capital.

Exploiting the new data and methodology, I have been able to show that investment in tangible assets is the most important source of economic growth in the G7 nations. The contribution of capital input exceeds that of productivity for all countries for all periods. The relative importance of productivity growth is far less than suggested by the traditional methodology of Kuznets (1971) and Solow (1970), which is now obsolete.

The conclusion from Islam's (1995) research is that the Solow (1970) model is appropriate for modeling the endogenous accumulation of tangible assets. It is unnecessary to endogenize human capital accumulation as well. The transition path to balanced growth equilibrium after a change in policies that affects

investment in tangible assets requires decades, while the transition after a change affecting investment in human capital requires as much as a century.

4. Economics on Internet Time.

The steadily rising importance of information technology has created new research opportunities in all areas of economics. Economic historians, led by Chandler (2000) and Moses Abramovitz and Paul David (1999, 2001)[72], have placed the information age in historical context. Abramovitz and David present sources of U.S. economic growth for the nineteenth and twentieth centuries. Their estimates, beginning in 1966, are based on the official productivity statistics published by the Bureau of Labor Statistics (1994).

The Solow (1987) Paradox, that we see computers everywhere but in the productivity statistics[73], has been displaced by the economics of the information age. Computers have now left an indelible imprint on the productivity statistics. The remaining issue is whether the breathtaking speed of technological change in semiconductors differentiates this resurgence from previous periods of rapid growth?

Capital and labor markets have been severely impacted by information technology. Enormous uncertainty surrounds the relationship between equity valuations and future growth prospects of the American economy[74]. One theory attributes rising valuations of equities since the growth acceleration began in 1995 to the accumulation of intangible assets, such as intellectual property and organizational capital. An alternative theory treats the high valuations of technology stocks as a bubble that burst during the year 2000.

---

[72] See also: David (1990, 2000) and Gordon (2000).

[73] Griliches (1994), Brynjolfsson and Shinkyu Yang (1996), and Triplett (1999) discuss the Solow Paradox.

[74] Campbell and Shiller (1998) and Shiller (2000) discuss equity valuations and growth prospects. Michael Kiley (1999), Brynjolfsson and Hitt (2000), and Robert Hall (2000, 2001), present models of investment with internal costs of adjustment.

The behavior of labor markets also poses important puzzles. Widening wage differentials between workers with more and less education has been attributed to computerization of the workplace. A possible explanation could be that high-skilled workers are complementary to IT, while low-skilled workers are substitutable. An alternative explanation is that technical change associated with IT is skill-biased and increases the wages of high-skilled workers relative to low-skilled workers[75].

Finally, information technology is altering product markets and business organizations, as attested by the large and growing business literature[76], but a fully satisfactory model of the semiconductor industry remains to be developed[77]. Such a model would derive the demand for semiconductors from investment in information technology in response to rapidly falling IT prices. An important objective is to determine the product cycle for successive generations of new semiconductors endogenously.

The semiconductor industry and the information technology industries are global in their scope with an elaborate international division of labor[78]. This poses important questions about the American growth resurgence. Where is the evidence of a new economy in other leading industrialized countries? I have shown in Section 3 that the most important explanation is the relative paucity of constant quality price indexes for semiconductors and information technology in national accounting systems outside the U.S.

---

[75] Daron Acemoglu (2002) and Katz (2000) survey the literature on labor markets and technological change.

[76] See, for example, Andrew Grove (1996) on the market for computers and semiconductors and Clayton Christensen (1997) on the market for storage devices.

[77] Douglas Irwin and Peter Klenow (1994), Flamm (1996), pp. 305-424, and Elhanan Helpman and Manuel Trajtenberg (1998), pp. 111-119, present models of the semiconductor industry.

[78] The role of information technology in U.S. economic growth is discussed by the Economics and Statistics Administration (2000); comparisons among OECD countries are given by the Organisation for Economic Co-operation and Development (2000, 2003).

The stagflation of the 1970's greatly undermined the Keynesian Revolution, leading to a New Classical Counter-revolution led by Lucas (1981) that has transformed macroeconomics. The unanticipated American growth revival of the 1990's has similar potential for altering economic perspectives. In fact, this is already foreshadowed in a steady stream of excellent books on the economics of information technology[79]. We are the fortunate beneficiaries of a new agenda for economic research that will refresh our thinking and revitalize our discipline.

2002	1.06	6,188.7	6,576.3	1.01	147,721	32.9	26.0	252,399

Notes: Value is in billions of current dollars. Quantity is in billions of 1996 dollars. Price and quality are normalized to one in 1996. Employment is in thousands of workers. Weekly hours is hours per worker, divided by 52. Hourly compensation is in current dollars. Hours worked are in millions of hours.

Table 2.6: Sources of Gross Domestic Product Growth

Externalities and Growth

December 2004

Abstract

Externalities play a central role in most theories of economic growth. We argue that international externalities, in particular, are essential for explaining a number of empirical regularities about growth and development. Foremost among these is that many countries appear to share a common long run growth rate despite persistently different rates of investment in physical capital, human capital, and research. With this motivation, we construct a hybrid of some prominent growth models that have international knowledge externalities. When calibrated, the hybrid model does a surprisingly good job of generating realistic dispersion of income levels with modest barriers to technology adoption. Human capital and physical capital contribute to income differences both directly (as usual), and indirectly by boosting resources devoted to technology adoption. The model implies that most of income above subsistence is made possible by international diffusion of knowledge.

This is a preliminary and incomplete draft of a chapter prepared for the Handbook of Economic Growth, edited by Philippe Aghion and Steven Durlauf, North Holland Press, Amsterdam. For helpful comments we are grateful to Bob Hall, Chad Jones, Ben Malin, Paul Romer, and seminar participants at Berkeley, the IADB, MIT, Stanford and USC. Email: Pete@Klenow.com and AndresRo@IADB.org.

If ideas are the engine of growth and if an excess of social over private returns is an essential feature of the production of ideas, then we want to go out of our way to introduce external effects into growth theory, not try to do without them.

Robert E. Lucas (2002, p. 6)

1. Introduction

A number of facts suggest that international knowledge externalities are critical for understanding growth and development. The growth slowdown that began in the early 1970s was world-wide, not an OECD-only phenomenon. Countries with high investment rates exhibit higher income levels more than higher growth rates. Country growth rate differences are not very persistent from decade to decade, whereas differences in country incomes and investment rates are highly persistent. These patterns hold for investment rates in physical, human, and research capital. Together, they suggest that investment rates affect country transitional growth rates and long run relative incomes rather than long run growth rates. They also suggest countries are subject to the same long run growth rate. We argue that this represents evidence of very large international spillovers at the heart of the long run growth process.

We organize this chapter as follows. In Section 2 we describe two broad types of externalities and the growth models that do (and do not) feature them. Section 3 presents cross-country evidence that, we argue, is very hard to reconcile with the models that have no international externalities. Section 4 calibrates a model of growth with international externalities in the form of technology diffusion. The implied externalities are huge. Section 5 concludes and points out directions for future research.

2. A Brief Guide to Externalities in Growth Models

In this section we briefly discuss the role that externalities play in prominent theories of economic growth. One class of growth theories features externalities in the accumulation of knowledge possessed by firms (organizational capital) or by workers (human capital). Another class of growth models features externalities from the introduction of new goods, in the form of surplus to consumers and/or firms. Other theories

combine knowledge externalities and new good externalities. Finally, some important growth theories include no externalities at all. Table 1 provides examples of growth models categorized in these four ways. At the end of this section, we will dwell a little on the predictions of no-externalities models in order to motivate the evidence we describe in the next section. The evidence in the next section will suggest that models with no externalities cannot explain a number of empirical patterns.

2A. Models with Knowledge Externalities

Romer (1986) modeled endogenous growth due to knowledge externalities: a given firm is more productive the higher the average knowledge stock of other firms. As an example, consider a set of atomistic firms, each with knowledge capital *k,* benefiting from the average stock of knowledge capital in the economy *K* in their production of output *y*:

$$y_{it} = Ak_{it}^{\alpha} K_t^{1-\alpha}, \quad 0 < \alpha < 1. \tag{2.1}$$

Romer showed that, under certain conditions, constant returns to economy-wide knowledge, as in this example, can generate endogenous growth. The external effects are, of course, critical for long-run growth given the diminishing returns to private knowledge capital. Romer was agnostic as to whether the knowledge capital should be thought of as disembodied (knowledge in books) or embodied (physical capital and/or human capital).

Lucas (1988) was more specific, stressing the importance of human capital. Lucas sketched two models, one with human capital accumulated off-the-job and another with human capital accumulated on-the-job (i.e., learning by doing). Both models featured externalities. In the model with human capital accumulated off-the-job, Lucas posited

$$y_{it} = Ak_{it}^{\alpha} [u_{it} h_{it} n_{it}]^{1-\alpha} H_t^{\gamma}, \text{ with } \gamma > 0 \text{ and} \tag{2.2}$$

$$h_{it+1} = h_{it} + Bh_{it}[1 - u_{it}] \text{ with } 0 < u_{it} < 1. \tag{2.3}$$

Here u is the fraction of time spent working, and $1-u$ is the fraction of time spent accumulating human capital; h is an individual worker's human capital, and H is economy-

wide average human capital; *k* and *n* are physical capital and number of workers at a given firm. Because human capital accumulation is linear in the level of human capital, human capital is an engine of growth in this model. This is true with or without the externalities; *across*-dynasty externalities are not necessary for growth. As Lucas discusses, however, *within*-dynasty human capital spillovers are implicit if one imagines (2.3) as successive generations of finite-lived individuals within a dynasty. Within-dynasty externalities, however, would not have the same normative implications as across-dynasty externalities, namely underinvestment in human capital. Lucas (1988) did not argue that across-dynasty externalities were needed to fit particular facts. But he later observed that such across-household externalities could help explain why we see "immigration at maximal allowable rates and beyond from poor countries to wealthy ones" (Lucas 1990, p. 93).

Tamura (1991) analyzed a human capital externality in the production of human capital itself. This formulation conformed better to the intuition that individuals *learn* from the knowledge of others. Tamura specified

$$y_{it} = Ak_{it}^{\alpha}[u_{it}h_{it}n_{it}]^{1-\alpha} \tag{2.4}$$

$$h_{it+1} = h_{it} + B(h_{it}[1-u_{it}])^{\beta} H_t^{1-\beta}. \tag{2.5}$$

Because *H* represents economy-wide average human capital, $\beta < 1$ implies that learning externalities are essential for sustaining growth in Tamura's setup. If applied to each country, this model would suggest that immigrants from poor to rich countries should enjoy fast wage growth after they migrate, as they learn from being around higher average human capital in richer countries. Lucas (2004) used such learning externalities within cities as an ingredient of a model of urbanization and development.

Models not always thought of as having knowledge externalities are Mankiw, Romer and Weil's (1992) augmented Solow model and the original Solow (1956) neoclassical growth model. In Solow's model all firms within the economy enjoy the same level of TFP. This common level of TFP reflects technology accessible to all. The Solow model therefore does feature disembodied knowledge externalities across firms within an economy. In Mankiw et al.'s extension, knowledge externalities flow across countries as

well as across firms within countries. In section 4 we will discuss models with more limited international diffusion of knowledge. In these models imperfect diffusion means differences in TFP can play a role in explaining differences in income levels and growth rates. We stress that the Mankiw et al. model relies on even stronger externalities than the typical model of international technology spillovers, such as Parente and Prescott (1994) or Barro and Sala-i-Martin (1995, chapter 8). We will discuss these models at greater length in Section 4, when we calibrate a hybrid version of them.

2B. Models with Knowledge Externalities *and* New-Good Externalities

Models with both knowledge externalities and new-good externalities are the most plentiful in the endogenous growth literature. By "new-good externalities" we mean surplus to consumers and/or firms from the introduction of new goods. The new goods take the form of new varieties and/or higher quality versions of existing varieties. In Stokey (1988), learning by doing leads to the introduction of new goods over time. The new goods are of higher quality, and eventually displace older goods. The learning is completely external to firms, and what is learned applies to new goods even more than older goods. Hence learning externalities are at the heart of her growth process. In Stokey (1991), intergenerational human capital externalities (the young learn from the old) are critical for human capital accumulation. Human capital accumulation, in turn, facilitates the introduction of higher quality goods, which are intensive in human capital in her model.

Quality ladder models − pioneered by Grossman and Helpman (1991, chapter 4) and Aghion and Howitt (1992, 1998) − feature knowledge spillovers in that each quality innovation is built on the previous leading-edge technology. Such intertemporal knowledge spillovers are also fundamental in models with expanding product variety, such as Romer (1990) and Grossman and Helpman (1991, chapter 3). In Romer (1990),

$$Y = H_Y^{\alpha} L^{\beta} \int_0^A x(i)^{1-\alpha-\beta} di \tag{2.6}$$

$$\dot{A} = B H_A A. \tag{2.7}$$

Intermediate goods, the *x(i)*'s, are imperfect substitutes in production. This is the Dixit-Stiglitz "love of variety" model. The stock of varieties, or ideas, is *A*. In (2.7) new ideas are invented using human capital and, critically, the previous stock of ideas. This is the intertemporal knowledge spillover. Jones (1995, 2002) argues that, in contrast to (2.7), there are likely to be diminishing returns to the stock of ideas (an exponent less than 1 on *A*). He bases this on the fact that the number of research scientists and engineers have grown in the U.S. and other rich countries since 1950, yet the growth rate has not risen, as (2.7) would predict. Intertemporal knowledge spillovers still play a pivotal role in Jones' specification; they are just not as strong as in Romer's (2.7).

More recent models, such as Eaton and Kortum (1996) and Howitt (1999, 2000), continue to emphasize both knowledge externalities and new-good externalities. We will elaborate on these in Section 4 below.

2C. Models with New-Good Externalities

It is hard to find a model with new-good externalities but without knowledge externalities. We have identified three papers in the literature featuring such models, but two of the papers also have versions of their models with knowledge externalities.

Rivera-Batiz and Romer (1991) present a variation on Romer's (1990) model, as part of their analysis of the potential growth gains from international integration. In their twist, new intermediate goods are invented using factors in the same proportions as for final goods production in (2.6):

$$\dot{A} = BH^{\alpha}L^{\beta}\int_0^A x(i)^{1-\alpha-\beta}\,di\,. \tag{2.8}$$

They call this the "lab equipment model" to underscore the use of equipment in the research lab, just like in the production of final goods. In this formulation, they emphasize, "Access to the designs for all previous goods, and familiarity with the ideas and know-how that they represent, does not aid the creation of new designs" (p. 536-537). I.e., there are no knowledge externalities, domestic or international. Production of ideas is not even knowledge-intensive. Ideas are embodied in goods, however, and there is surplus to downstream consumers from their availability. Rivera-Batiz and Romer note that this

model allows countries to benefit from ideas developed elsewhere simply by importing the resulting products. Just as important, international trade allows international specialization in research. Countries can specialize in inventing different products, rather than every product being invented everywhere.

In a similar spirit, Romer (1994) considered a model in which knowledge about how to produce different varieties does not flow across countries, but each country can import the varieties that other countries know how to produce. For a small open economy, Romer posited

$$Y_t = A(\sum_{j=1}^{M_t} x_{jt}^{\alpha})N_t^{1-\alpha}, \quad 0 < \alpha < 1. \tag{2.9}$$

x_j represents the quantity of imports of the j^{th} variety of intermediate good. Because $\alpha < 1$, intermediate varieties are imperfectly substitutable in production. Firms in the importing country will have higher labor productivity the more import varieties they can access. If exporters cannot perfectly price discriminate and there is perfect competition among domestic final-goods producers, the higher labor productivity (higher *Y/N*) will benefit domestic workers/consumers. If consumer varieties were imported as well, there would be an additional source of consumer surplus from import varieties. Romer analyzed the impact of import tariffs on the number of varieties *M* imported in the presence of fixed costs of importing each variety in each country. Although Romer's model is static, growth in the number of varieties over time, say due to domestic population growth or falling barriers to trade, would be a source of growth in productivity and welfare in his model.

Kortum (1997) develops a model in which researchers draw techniques of varying efficiency levels from a Poisson distribution. Kortum does consider spillovers in the form of targeted search. But he also considers the case of blind search, wherein draws are independent of the previous draws. (Kortum fixes the set of goods produced but allows endogenous research into discovering better techniques for producing each good.) In the case of blind search, there are no knowledge spillovers. Growth is sustained solely because of population growth that raises the supply of and demand for researchers. It takes more and more draws to obtain a quality deep enough into the right tail to constitute an

improvement. A constant population growth rate sustains a constant flow of quality improvements and, hence, a constant growth rate of income.

2D. Models with No Externalities

The seminal growth models without externalities are the *AK* models of Jones and Manuelli (1990) and Rebelo (1991). In the next section we will present evidence at odds with such models, so we dwell on their implications here. We consider a version close to Rebelo's. Final output is a Cobb-Douglas function of physical and human capital:

$$C_t + I_t = Y_t = AK_{Yt}^{\alpha} H_{Yt}^{1-\alpha}, \tag{2.10}$$

where K_Y and H_Y represent the stocks of physical capital and human capital devoted to producing current output. As shown, current output can be used for either consumption or investment. The accumulation equations for physical and human capital are, respectively,

$$K_{Yt+1} + K_{Ht+1} = K_{t+1} = (1-\delta_K)K_t + I_t \tag{2.11}$$

$$H_{Yt+1} + H_{Ht+1} = H_{t+1} = (1-\delta_H)H_t + BH_{Ht}^{\gamma} K_{Ht}^{1-\gamma}. \tag{2.12}$$

H_H and K_H represent the stocks of human and physical capital, respectively, devoted to accumulating human capital.

We will focus on an equilibrium with a constant fraction of output invested in physical capital ($s_I = I/Y$) and a constant share of human capital deployed in human capital accumulation ($s_H = H_H / H$). We assume that the ratio of marginal products of physical and human capital are equated across the final output and human capital sectors, so that physical capital is devoted to

$$s_K = K_H / K = \frac{s_H(1-\gamma)(1-\alpha)}{s_H(1-\gamma)(1-\alpha) + (1-s_H)\gamma\alpha}. \tag{2.13}$$

The balanced growth rate is defined as

$$1+g = Y_{t+1}/Y_t = K_{t+1}/K_t = H_{t+1}/H_t. \tag{2.14}$$

The level of the balanced growth rate is an implicit function of the investment rates and parameter values:

$$(g+\delta_K)^{1-\gamma}(g+\delta_H)^{1-\alpha} = \left(A(1-s_K)^{\alpha}(1-s_H)^{1-\alpha}s_I\right)^{1-\gamma}\left(Bs_H^{\gamma}s_K^{1-\gamma}\right)^{1-\alpha}. \tag{2.15}$$

Provided $\alpha < 1$, human capital is the engine of growth. The growth rate is monotonically increasing in s_I because physical capital is an input into human capital accumulation whereas consumption is not. Related, the growth rate does not monotonically increase with the share of inputs devoted to producing human capital. This is because devoting more resources to producing current output increases the stock of physical capital, which is an input into human capital accumulation and hence growth.[1] When we look at the data in Section 3, however, we will find no country so high an s_H or s_K as to inhibit its growth according to this model.

When $\alpha = 1$ we have a literal $Y = AK$ model, and the growth rate is solely a function of the physical capital investment rate:

$$g+\delta_K = As_I \tag{2.16}$$

Here there is no point in devoting effort to producing human capital, so $s_H = 0$.

In the special case $\gamma = 1$, human capital is produced solely with human capital. This might be called a *BH* model. Presuming $\alpha < 1$ of course, the growth rate is simply

[1] To reinforce intuition, consider the (unrealistic) case of $\gamma = 0$, wherein new human capital is produced only with physical capital. In this case, growth is not strictly increasing in s_K (the share of capital devoted to human capital production) because some physical capital itself needs to be devoted to its own production.

(2.17) $$g + \delta_H = As_H$$

Unlike when $\gamma < 1$, the growth rate here is monotonically increasing in the effort devoted to adding more human capital. Lucas (1988) and many successors focus on this *BH* model because human capital accumulation is evidently intensive in human capital. Moreover, even *AK* models such as Jones and Manuelli (1990) construe their *K* to incorporate both human capital and physical capital. The consensus for diminishing returns to physical capital ($\alpha < 1$) is strong. Constant returns are entertained only for a broad measure of physical and human capital. We stress (2.15), a hybrid of *AK* and *BH* models, because this generalization allows us to take into account the combined impact of physical and human capital investment rates on growth when physical capital is an input to human capital accumulation ($\gamma < 1$).

3. Cross-Country Evidence

In this section we document a number of facts about country growth experiences over the last fifty years. We show that country growth rates appear to depend critically on the growth and income levels of *other* countries, rather than solely on domestic investment rates in physical and human capital. Cross-country externalities are a promising explanation for this interdependence. In brief, here are the main facts we will present:

- The growth slowdown that began in the mid-1970s was a *world-wide* phenomenon. It hit both rich countries and poor countries, and economies on every continent.

- Richer OECD countries grew much more slowly from 1950 to around 1980, despite the fact that richer OECD economies invested at higher rates in physical and human capital.

- Differences in country investment rates are far more persistent than differences in country growth rates.

- Countries with high investment rates tend to have high levels of income more than they tend to have high growth rates.

3A. The World-Wide Growth Slowdown

As has been widely documented for rich countries, the growth rate of productivity slowed beginning in the early 1970s.[2] Less widely known is that the slowdown has been a *world-wide* phenomenon, rather than just an OECD-specific event.[3] We document this in Table 2. Across 96 countries, the growth rate in PPP GDP per worker fell from 2.7% per year over 1960-1975 to 1.1% per year over 1975-2000. Growth decelerated 1.6 percentage points on average in both the sample of 23 OECD countries and the in the sample of 73 non-OECD countries.[4] The slowdown hit North and South America the hardest (their growth rates fell 2.4 percentage points) and barely brushed Asia (who slowed down just 0.4 of a percentage point). The slowdown hit all income quartiles of the 96 country sample (based on PPP income per worker in 1975). Although each income quartile grew at least one percentage point slower, the slowdown was not as severe in the poorest half as in the richest half. China's growth rate actually accelerated from 1.8 to 5.1, in the wake of reforms that began in the late 1970s. Chile, which experienced rapid growth in the 1990s, accelerated 2.1 percentage points.

Why does a world-wide growth slowdown suggest international externalities? Couldn't it simply reflect declining investment rates world-wide, as suggested by the *AK* model in the previous section? Table 2 also shows what average investment rates in physical and human capital did before and after the mid-1970s. The investment rates in physical capital come from Penn World Table 6.1. As a proxy for the fraction of time devoted to accumulating more human capital, we used years of schooling attainment relative to a 60-year working life. We used data on schooling attainment for the 25 and older population from Barro and Lee (2000). This human capital investment rate, which averages around 7% across countries, reflects the fraction of ages 5 to 65 devoted to schooling as opposed to working. We prefer the attainment of the workforce as opposed to

[2] The causes of the slowdown remain largely a mystery. For example, see Fischer (1988).
[3] An exception is Easterly (2001b).
[4] OECD countries are based on 1975 membership. There were 24 OECD members in 1975, but the Penn World Tables contain data for unified Germany only back to 1970.

the enrollment rates of the school-age population. The latter should take a long time to affect the workforce and therefore the growth rate.

According to Table 2, the average investment rate in physical capital across all countries was virtually unchanged (15.8% before vs. 15.5% after the slowdown), and the investment rate in human capital actually rose strongly (going from 7.1% to 9.7%). The same pattern applies for the OECD and non-OECD separately, and for all four quartiles of initial income. Thus the growth slowdown cannot be attributed to a world-wide decline in investment rates.

The breadth of the growth slowdown suggests *something* linking country growth rates, and ostensibly something other than investment rates.[5] This is contrary to the predictions of *AK* models, in which the growth rate of a country depends on domestic investment rates. The world-wide nature of the slowdown suggests that endogenous growth models, more generally, should not be applied to individual countries but rather to a collection of interdependent countries. Knowledge diffusion through trade, migration, and foreign direct investment are likely sources of interdependence.

Three other examples of interdependence are offered by Parente and Prescott (2004). First, growth rates picked up in the 20th century relative to the 19th century for many countries. Second, the time it takes a country to go from $2000 to $4000 in per capita income has fallen over the 20th century, suggesting the potential to grow rapidly by adopting technology in use elsewhere. Third and related, they stress that "growth miracles" always occur in countries with incomes well beneath the richest countries, again consistent with adoption of technology from abroad.

Knowledge diffusion, broadly construed, could include imitation of successful institutions and policies in other countries. Kremer, Onatski and Stock (2001) argue that such imitation might explain the empirical transition matrix of the world income distribution. If improving institutions leads only to static gains in efficiency, however, then the barriers to imitation have to be large to explain why the best institutions are not in place everywhere. As we will illustrate in section 4 below, the required barriers to technology adoption are modest precisely because the benefits accumulate with investments.

[5] It also casts doubt on explanations for the growth slowdown that are confined to rich countries.

3B. Beta Convergence in the OECD

As documented by Baumol (1986) and many others, incomes have generally been converging in the OECD. Barro and Sala-i-Martin (1995) used the term *sigma convergence* to describe such episodes of declining cross-sectional standard deviations in log incomes. We focus on a related concept that Barro and Sala-i-Martin labeled *beta convergence*, namely a negative correlation between a country's initial income level and its subsequent growth rate. We look at beta convergence year by year in Figure 1. The data on PPP income per worker comes from Penn World Table 6.1 (Heston, Summers and Aten, 2002), and covers 23 OECD countries over 1960-2000. The Figure shows the correlation between current income and growth hovering between –0.50 and –0.75 from 1960 through the early 1980s. The correlation was still negative from the mid-1980s through the mid-1990s, but less so, and turned positive in the latter 1990s.

De Long (1988) pointed out that a country's OECD membership is endogenous to its level of income, so that members at time *t* will tend to converge toward each other's incomes leading up to time *t*. Our focus, however, is not on convergence per se. Our point is instead about how investment rates correlate with income during the period of convergence. Figure 1 also shows the physical capital investment rate, and it is *positively* correlated with a country's income throughout the sample. Figure 2 shows that schooling attainment is also *positively* correlated with income throughout the sample.

How do these investment correlations square with simple *AK* models with no externalities? Expression (2.15) shows that a country's growth rate should be increasing in its investment rates. For beta convergence to occur in this model, a country's investment rates must be *negatively* correlated with a country's level of income. But Figures 1 and 2 show the opposite is true: in every year, richer OECD countries had *higher* investment rates in human and physical capital than poorer OECD countries did. According to this class of models, OECD countries should have been diverging throughout the entire sample, rather than converging through most of it. Now, this reasoning ignores likely differences in efficiency parameters *A* and *B* across countries. But rescuing *AK* models would require that richer countries have *lower* efficiency parameters. We would guess that rich countries tend to have better rather than worse institutions (e.g., Hall and Jones, 1999).

3C. Low Persistence of Growth Rate Differences

Easterly et al. (1993) documented that country growth rate differences do not persist much from decade to decade. They estimated correlations of around 0.1 to 0.3 across decades. In contrast, they found that country characteristics such as education levels and investment rates exhibit cross-decade correlations in the 0.6 to 0.9 range. Just as we do, they suggest country characteristics may determine relative income levels and world-wide technological changes long-run growth. Easterly and Levine (2001) similarly provide evidence that "growth is not persistent, but factor accumulation is."

In Table 3 we present similar findings. We compare average growth rates from 1980-2000 vs. 1960-1980, and from decade to decade within 1960-2000. We find growth rates much less persistent than investment rates for the world as a whole, and for the OECD and non-OECD separately. Again, these facts seem hard to reconcile with the *AK* model in which a country's domestic investment rates determine its growth rate.

Figure 3 illustrates a related pattern: deciles of countries (based on 1960 income per worker) grew at similar average rates from 1960 to 2000. Each decile consists of the unweighted average of income per worker in 9 or 10 countries. The average growth rate is 1.7% in the sample, and the bottom decile in 1960 grew at precisely this rate. This figure suggests movements in relative incomes, but no permanent differences in long-run growth rates, even comparing the richest and poorest countries. This sample contains 96 countries, and therefore many of the poorest countries mired in zero or negative growth.

Pritchett (1997), on the other hand, offers compelling evidence that incomes diverged massively from 1800 to 1960. Doesn't this divergence favor models, such as *AK* without international externalities, in which country growth rates are not intertwined? Not necessarily. As argued by Parente and Prescott (2004), the opening up of large income differences coincided with the onset of modern economic growth. The divergence could reflect the interaction of country-specific barriers to technology adoption with the emergence of modern technology-driven growth. More generally, any given divergence episode could reflect widening barriers to importing technology rather than simply differences in conventional investment rates.

3D. Investment Rates and Growth vs. Levels

The *AK* model we sketched in the previous section predicts that a country's growth rate will be strongly related to its investment rates in physical and human capital. In Table 4 we investigate this empirically in cross-sections of countries over 1960-2000. In four of the six cases, the average investment rate is positively and significantly related to the average growth rate. For the OECD, the physical capital investment rate is not significantly related to country growth, and the human capital investment rate is actually *negatively* and significantly related to country growth. But for the non-OECD and all-country samples, the signs and significance are as predicted. This evidence constitutes the empirical bulwark for *AK* models.

In the four cases where the signs are as predicted, are the magnitudes roughly as an *AK* model would predict? First consider the literal *AK* model. According to (2.16) in the previous section, the coefficient on s_I should be *A*. What might be a reasonable value for *A*? In order to match the average growth rate in GDP per worker (1.8%), given an average investment rate in physical capital (17%) and a customary depreciation rate (8%), the value of *A* would need to be

$$A = \frac{g^{avg} + \delta_K}{s_I^{avg}} = \frac{.018 + .08}{.17} \cong 0.57. \tag{3.1}$$

This level of *A* is more than four times larger than the two significant positive coefficients on s_I in the first column of Table 4, which are around 0.12. The estimated coefficients are small in magnitude compared to what an *AK* model would predict. This discrepancy could reflect classical measurement error in investment rates, but such measurement error would need to account for more than 80% of the variance of investment rates across countries. Plus one would expect *positive* endogeneity bias in estimating the average level of *A*, due to variation in *A* across countries that is positively correlated with variation in s_I.

We next consider the literal *BH* model. According to (2.17), the coefficient on s_H should be *B*. To produce the average growth rate in GDP per worker given the average

investment rate in human capital (8.8%) and a modest depreciation rate (2%), *B* would need to be

$$B = \frac{g^{avg} + \delta_H}{s_H^{avg}} = \frac{.018 + .02}{.088} \cong 0.43. \tag{3.2}$$

The third column of estimates in Table 4 contain coefficients on s_H. Of the two positive coefficients, one is half the predicted level (0.21) whereas the other is not far from the predicted level (0.37).

Finally, consider the hybrid model in (2.15). We assume $\gamma = 0.9$ so that human capital accumulation is intensive in human capital, but does use some physical capital. For producing current output we assume the standard physical capital share of $\alpha = 1/3$. We set the depreciation rates as previously mentioned. We set s_K, the share of physical capital devoted to human capital accumulation, based on (2.13). As (2.15) illustrates, we cannot independently identify *A* and *B*, only their product. We set $A^{1-\gamma}B^{1-\alpha} \cong 0.60,$ so that the average predicted growth rate from (2.15) and observed s_H and s_I investment rates matches the average growth rate in GDP per worker of 1.8%. We then regress actual growth rates on predicted growth rates for a cross-section of 73 countries with available data. The coefficient estimated is 0.26 (standard error 0.08, R^2 of 0.13), far below the theoretical value of 1. Again, the empirical estimate might be low because of measurement error in predicted growth, but it would need to be large.

To recap, only 1 of the 7 coefficients of growth on investment rates considered is in the ballpark of an *AK* model's prediction. In contrast, we obtain uniformly positive and significant coefficients when we regress (log) *levels* of country income on country investment rates. In 5 of the 6 cases, the R^2 is notably higher with levels than with growth rates. Investment rates appear far better at explaining relative income levels than relative growth rates. The driver of growth rates would appear to be something other than simply domestic investment rates.

The preceding discussion focused on the steady-state predictions of *AK* models. It is possible that *AK* models fare better empirically when transition dynamics are taken into

account. But it is worth noting that Klenow and Rodríguez-Clare (1997), Hall and Jones (1999), Bils and Klenow (2000), Easterly (2001a), Easterly and Levine (2001), and Hendricks (2002) all find that no more than half of the variation in growth rates or income levels can be attributed directly to human and physical capital. Pritchett (2004), who considers many different parameterizations of the human capital accumulation technology, likewise finds that human capital does not account for much cross-country variation in growth rates.

3E. R&D and TFP

We now turn away from *AK* models to a model with diminishing returns to physical and human capital, but with R&D as another form of investment. Such a model might be able to explain country growth rates with no reference to cross-country externalities. For example, perhaps a variant of the Romer (1990) model could be applied country by country, with no international knowledge flows. R&D investment would have to behave in a way that leads to a worldwide growth slowdown, beta convergence in the OECD, and low persistence of growth rate differences. And, more directly, R&D investment would have to explain country growth rates. Research effort, like human capital, is difficult to measure. But Lederman and Saenz (2003) have compiled data on R&D spending for many countries. We now ask the same questions of their R&D investment rates that we asked of investment rates in physical and human capital: how correlated are R&D investment rates with country growth rates and country income levels?

The first column in Table 5 says that countries with high R&D spending relative to GDP do not grow systematically faster.[6] Countries with high R&D shares do, however, tend to have high relative incomes. But the correlation with income is not significant outside the OECD. One possibility is that these regressions do not adequately control for the contributions of physical and capital. We therefore move to construct Total Factor Productivity (TFP) growth rates and levels. We subtract estimates of human and physical capital per worker from GDP per worker:

[6] Because R&D data was not available for all country-years between 1960 and 2000, we took time effects out of the variables (growth rates, income levels, investment rates in R&D), then averaged the residuals over time.

(3.3) $$\ln TFP = \ln(Y/L) - \alpha \ln(K/L) - (1-\alpha)\ln(H/L)$$

where Y is real GDP, L is employment, K is the real stock of physical capital, and H is the real stock of human capital. We suppress time and country subscripts in (3.3) for readability. We would prefer to let α vary across countries and across time based on factor shares, but such data is not readily available for most countries in the sample. We instead set $\alpha = 1/3$ for all countries and time periods. Gollin (2002) finds that capital's share varies from 0.20 to 0.35 across a sample of countries, but does not correlate with country income levels or growth rates. We use Penn World Table 6.1 data assembled by Heston, Summers and Aten (2002) for PPP GDP, employment, and PPP investment in physical capital. We assume an 8% geometric depreciation rate and the usual accumulation equation to cumulate investment into physical capital stocks. We approximate initial capital stocks using the procedure in Klenow and Rodríguez-Clare (1997, p. 78). We let human capital per worker be a simple Mincerian function of schooling:

(3.4) $$H = hL = \exp(\phi s)L .$$

Here h represents human capital per worker, and s denotes years of schooling attainment. We use Barro and Lee (2000) data on the schooling attainment of the 25 and older population. This data is available every five years from 1960 to 2000, with the last year an extrapolation based on enrollment rates and the slow-moving stock of workers. A more complete Mincerian formulation would include years of experience in addition to schooling and would sum the human capital stocks of workers with different education and experience levels. In Klenow and Rodríguez-Clare (1997) we found that taking experience and heterogeneity into account had little effect on aggregate levels and growth rates, so we do not pursue it here. We use (3.4) with the Mincerian return $\phi = 0.085$, based on the returns estimated for many countries and described by Psacharopoulos and Patrinos (2002).

The latter columns in Table 5 present regressions of TFP growth rates and levels on R&D investment rates. The sample of countries is smaller given data limitations (67 countries rather than 82). Just like growth in GDP per worker, growth in TFP is not significantly related to R&D investment rates. But TFP levels, like levels of GDP per

worker, are positively and significantly related to R&D investment rates. From this we conclude that even R&D investment rates affect relative income levels, not long-run growth rates. The persistence of R&D investment rate differences across countries, combined with the lack of persistent growth rate differences, supports this interpretation. We are led to consider models in which country growth rates are tethered together.

Before considering a model with international knowledge externalities, we pause to consider a model with "externalities" operating through the terms of trade. We have in mind Acemoglu and Ventura's (2002) model of the world income distribution. In their model, each country operates an *AK* technology, but uses it to produce distinct national varieties. Countries with high *AK* levels due to high investment rates plentifully supply their varieties, driving down their prices on the world market. This results in a *pAK* model with a stationary distribution of income even in the face of permanent differences in country investment rates (and *A* levels, for that matter). Prices tether incomes together in the world distribution, not the flow of ideas. This is a clever and coherent model, but we question its empirical relevance. Hummels and Klenow (2004) find that richer countries tend to export a given product at higher rather than lower prices. They do estimate modestly lower quality-adjusted prices for richer countries, but nowhere near the extent needed to offset *AK* forces and generate "only" a factor of 30 difference in incomes.

To summarize this section, *AK* models tightly connect investment rates and growth rates. Such a tight connection does not hold empirically. This is the case for the world growth slowdown, for OECD convergence, for growth persistence, and for country variation in growth vs. income levels. A version of the *AK* model with endogenous terms of trade might be able to circumvent these empirical hazards but faces empirical troubles of its own. We therefore turn to models with international knowledge externalities that drive long-run growth.

4. Models with common growth driven by international knowledge spillovers

Based on evidence in the previous section, we now focus on models with two features. The first is that, in steady state, all countries grow at the same rate thanks to international knowledge spillovers. The second feature is that differences in policies or

other country parameters generate differences in TFP levels rather than growth rates. Examples of this type of model are Howitt (2000), Parente and Prescott (1994), Eaton and Kortum (1996), as well as the model of technology diffusion in chapter 8 of Barro and Sala-i-Martin (1995).

In these models there is a world technology frontier, and a country's research efforts determine how close the country gets to that frontier. There are three different issues that must be addressed. First, what determines the growth rate of the world technology frontier? Second, how is it that a country's research efforts allow it to "tap into" the world technology frontier? And third, what explains differences across countries in their research efforts? Our goal in this section is to build on the ideas developed in the recent literature to construct a model that offers a unified treatment of these three issues and that is amenable to calibration. The calibration is intended to gauge the model's implications about the strength of the different externalities and the drivers of cross-country productivity differences.[7]

To highlight the different issues relevant for the model, our strategy is to present it in parts. The next subsection (4A) takes world growth and R&D investment as exogenous and discusses how R&D investment determines steady state relative productivity. Subsection 4B discusses different ways of modeling how world-wide R&D investment determines the growth rate of the world technology frontier. Subsection 4C extends the model so as to allow for endogenous determination of countries' R&D investment rates. Subsection 4D calibrates the model. Finally, subsection 4E presents the results of an exercise where we calculate, for each country in our sample, the impact on productivity from international spillovers.

4A. R&D investment and relative productivity

In this section we focus on a single country whose research efforts determine its productivity relative to the world technology frontier. Both the R&D investment rate and the rate of growth of the world technology frontier are exogenous. Output is produced with

[7] Although we refer to research externalities throughout this section, the knowledge externalities could just as well be with respect to human capital. Only when we use data on R&D is the analysis specific to research.

a Cobb-Douglas production function: $Y = K^{\alpha}(AhL)^{1-\alpha}$, where Y is total output, K is the physical capital stock, A is a technology index, h is human capital per person, and L is the total labor force. We assume that h is constant and exogenous. Output can be used for consumption (C), investment (I), or research (R), $Y = C + pI + R$, where p is the relative price of investment and is assumed constant through time. Capital is accumulated according to: $\dot{K} = I - \delta K$. Finally, A evolves according to:

$$\dot{A} = \left(\lambda R / L + \varepsilon A\right)\left(1 - A / A^*\right) \tag{4.1}$$

where λ is a positive parameter and A^* is the world technology frontier, both common across countries.[8]

There are three salient differences between this model and the standard endogenous growth model. Firstly, the productivity of research in generating A-growth is affected by the country's productivity relative to the frontier, as determined by the term $(1 - A/A^*)$ in (4.1). This captures the idea that there are "benefits to backwardness". One reason for this may be that the *effective cost* of innovation and technology adoption falls when a country is further away from the world technology frontier. This is what happens in Parente and Prescott (1994) and in Barro and Sala-i-Martin (1995, chapter 8). Alternatively, being further behind the frontier may confer an advantage because every successful technology adoption entails a *greater improvement* in the national technology level. This is what happens in Howitt (2000) and in Eaton and Kortum (1996).[9]

Secondly, we introduce $\varepsilon \geq 0$ to capture the sources of technology diffusion from abroad that do not depend on domestic research efforts. We have in mind imports of goods that embody technology, and that do not require upfront adoption costs (e.g, equipment

[8] In models like those of Parente and Prescott (1994) and Howitt (2000) research is meant to capture both R&D and technology adoption efforts. In this paper we follow this practice and simply refer to the sum of these two technology investments as R&D or just "research".

[9] In Howitt's model, $(1 - A/A^*)$ arises from the product of two terms: $(1/A^*)(A^* - A)$. The $(1/A^*)$ term arises because, as the world's technology becomes more advanced, more research is required to tap into it; the second term captures the fact that, when the country is more backward, every successful technology adoption entails a *greater improvement* in the national technology level.

which is no harder to use but which operates more efficiently).[10] As we will see below, this is important for the model to match certain features of the data.

Thirdly, in contrast to most endogenous growth models, we divide research effort by L in the *A*-growth expression above. This is done to get rid of scale effects and can be motivated in two ways. First, if *A* represents the quality of inputs, then one can envisage a process where an increase in the labor force leads to an expansion in the variety of inputs (Young, 1998 and Howitt, 1999). With a larger variety of inputs, research effort per variety is diluted. This eliminates the impact of *L* on *A* growth. Second, if research is undertaken by firms to increase their own productivity, then population growth may lead to an expansion in the number of firms and a decrease in the impact of aggregate research on firms' *A*-growth (Parente and Prescott, 1994). In this case, L represents the number of firms.

The measured R&D investment rate is given by $s_R = R/Y$. This implies that $R/(AL) = s_R Y/(AL) = s_R k$ where $k \equiv (K/Y)^{\alpha/(1-\alpha)} h = Y/(AL)$. To proceed, note that in steady state $a \equiv A/A^*$ will be constant, since *A* will grow at the same rate as *A**, which we denote by g_A. Thus, from (4.1)

$$g_A = \left(\lambda s_R k + \varepsilon\right)\left(1 - a\right) \tag{4.2}$$

Solving for a we obtain:

$$a = 1 - \frac{g_A}{\lambda s_R k + \varepsilon} \tag{4.3}$$

The values of k and s_R determine a country's relative A from (4.3). Conceivably, the parameter λ (TFP in research, if you will) could differ across countries and also contribute to differences in *A*. But in this paper we assume λ does not vary across countries. We do,

[10] This free flow of ideas is also likely to depend on the local presence of multinationals, which bring valuable knowledge that diffuses to other local firms without the need for additional R&D.

however, allow researchers to be more productive in countries with more physical and human capital per worker.

The previous results clearly show that policies that lower investment in physical or human capital or R&D do not affect a country's growth rate. Their effect is on a country's steady state relative *A*. Also, as discussed above, there are no scale effects in this model: higher *L* does not lead to higher growth or to a higher relative *A*. This stands in contrast to most growth models based on research (e.g., Romer 1990, Barro and Sala-i-Martin, 1995 – chapter 8).

It is also noteworthy in equation (4.3) that the value of k, which captures physical and human capital intensity, affects a country's TFP level conditional on its R&D investment rate. Thus, large differences in TFP across countries do not necessarily imply that differences in human and physical capital stocks are just a small part of cross country income differences. Indeed, this model suggests that some of the TFP differences may be due to differences in capital intensities across countries. Below we explore this issue quantitatively.

It is instructive to calculate the social rate of return to research at the national level. As shown in Jones and Williams (1998), this can be done even without knowing the details of the model that affect the endogenous determination of the R&D investment rate. Letting $\dot{A} = G(A, R)$, Jones and Williams show that the (within-country) social rate of return $\tilde{r}$ can be expressed as:

$$\tilde{r} = \frac{\partial Y / \partial A}{P_A} + \partial G / \partial A + g_{P_A}. \tag{4.4}$$

Here P_A stands for the price of ideas and is given by $P_A = \left(\partial G / \partial R\right)^{-1}$. As explained by Jones and Williams, the first two terms in (4.4) represent the dividends of research while the third term represents the associated capital gains. The first dividend term is the obvious component, namely the productivity gain from an additional idea divided by the price of ideas. The second dividend term captures how an additional idea affects the productivity of future R&D.

In the model we presented above, it is straightforward to show that, along a steady state path, we have:

$$\tilde{r} = (1-\alpha)\lambda k(1-a) + \left[\varepsilon(1-a) - \frac{a g_A}{1-a}\right] + g_L \tag{4.5}$$

The first term on the right-hand side corresponds to the first dividend term in Jones and Williams' formula. The second term, in square brackets, corresponds to the indirect effect of increasing *A* on the cost of research ($\partial G / \partial A$). The third term, g_L, corresponds to the term capturing the capital gains in Jones and Williams formula. To understand this last term, note that we have implicitly assumed that new varieties or firms start up with the same productivity as existing varieties or firms. Thus, the value of ideas will rise faster with a higher g_L, and the social return to research will correspondingly increase with g_L.

Also note that, since the RHS of (4.5) is decreasing in a and a is increasing in s_R, the social rate of return to research will be decreasing in s_R, as one would expect. If *k* varies less than a in the data, one should also expect to find higher social rates of return to research in poor countries than in rich countries, as found by Lederman and Maloney (2003).

More importantly, if ε is close to zero, then from (4.2) and (4.5) we should have $\tilde{r} \approx (1-\alpha)\lambda k(1-a) \approx (1-\alpha) g_A / s_R$. Using the growth rate of *A* in the OECD in the period 1960-2000 as an approximation of g_A (1.5%), and using $\alpha = 1/3$, then $\tilde{r} \approx 0.01 / s_R$. Noting that the median of s_R in the non-OECD countries we have in our sample is $s_R = 0.5\%$, then $\tilde{r} \geq 200\%$. This seems implausibly high.[11] There are two ways out of this problem. First, one can argue that measured R&D investment does not capture all the research efforts undertaken by countries. Clearly, higher R&D investment rates would lead to lower and more plausible social rates of return to research. Second, one can argue that the implausible implications of the model are due to the assumption that ε is close to zero. In the

[11] The problem is not so pronounced for the U.S. Given its measured R&D investment rate of $s_R = 2.5\%$, we have $\tilde{r} \approx 40\%$, which is in the range of estimates of the social rate of return to R&D in the U.S. See Griliches (1992) and Hall (1996).

calibration exercise in section 4D, we will argue that both of these solutions are needed to make the model consistent with the data.

4B. Modeling growth in the world technology frontier

In this section we extend the model so that g_A is endogenously determined by the research efforts in all countries. The models we mentioned above deal with this in different ways, except Parente and Prescott who leave g_A as exogenous. Barro and Sala-i-Martin (1995, chapter 8) have a Romer-type model of innovation that determines g_A in the "North." We do not pursue this possibility because of the scale effect that arises in their model (larger *L* in the North leads to higher g_A) and because we want to allow research efforts by all countries to contribute to the world growth rate. We first consider an adaptation of Howitt's (2000) formulation. A country's total effective research effort, λR_i, gets diluted by the country's number of varieties or number of firms, both represented by L_i, and is then multiplied by a common spillover parameter, σ, to determine that country's contribution to the growth of the world's technology frontier:

$$\dot{A}^* = \sigma \sum_i \left(\frac{\lambda R_i}{L_i} \right).$$

Given our results above, we obtain:

(H1) $$g_A = \sigma \sum_i \lambda k_i s_{Ri} a_i \, .$$

This formulation has the nice feature that the world growth rate does not depend on the world's level of *L* (no scale effect on growth at the world level), although it does depend positively on R&D investment rates. The main problem with this formulation, and the reason we do not pursue it further, is that larger countries contribute no more to world growth than smaller countries do. This has the implausible implication that subdividing countries would raise the world growth rate.

In footnote 21 of his paper, Howitt discusses an alternative specification wherein country spillovers are diluted by world variety rather than each country's variety. This implies that:

$$\dot{A}^* = \sigma \sum_i \left(\frac{\lambda R_i}{L} \right).$$

where $L = \sum L_i$. Howitt does not pursue this approach because, in the presence of steady-state differences in the rate of growth of L across countries, g_A would be completely determined in the limit by the research effort of the country with the largest rate of growth of L. We believe, however, that it is quite natural to analyze the case in which g_L is the same across countries.[12] In this case, $\omega_i \equiv L_i / L$ is constant through time, and the expression above can be manipulated to yield:

(H2) $$g_A = \sigma \sum_i \lambda k_i s_{Ri} a_i \omega_i \, .$$

If we think of L as the number of firms rather than the number of varieties of capital goods, then (H2) amounts to stating that g_A is determined by the country-workforce-weighted average research intensity across firms world-wide. This seems much more reasonable than (H1), where g_A is determined by the *unweighted* average of research intensity across countries.

Expression (H2) differs from (H1) only in the presence of the weights ω_i that represent shares of world L. This has two advantages: first, large countries contribute more to world growth than small countries do, and second, subdividing countries would not affect the world growth rate. But (H2) has a problematic implication, namely that those countries with higher than average $k_i s_{Ri} a_i$ would be better off disengaging from the rest of

[12] If one country's population did come to dominate world population, however, it might be sensible to say it does almost all of the world's research and, hence, it will virtually determine the world growth rate. We assume equal labor force growth rates across countries not because we think it is accurate for describing what is happening now, but because we think it is a convenient fiction for a steady state model to explore international spillovers.

the world – their growth rate would be higher if they were isolated. That is, a research intensive country would be better off ignoring the research done in other countries.

According to Howitt's variety interpretation of this model, this is because an isolated country's growth rate would be given by $\sigma\lambda k_i s_{Ri} a_i$. Its research intensity would no longer be spread out over the number of world varieties, but instead over the smaller number of the country's own varieties. Thus, when a country disengages, it no longer benefits from spillovers from research conducted by the rest of the world, but there is an important compensating gain that comes from the fact that variety – and therefore dilution – falls for the disengaging country. Since there is no love of variety in Howitt's model, a high research-intensity country would gain from disengagement. By this logic, engagement could not be sustained among any set of asymmetric countries! The higher $k_i s_{Ri} a_i$ countries would always prefer to disengage, leaving all countries isolated in equilibrium.

We now turn to an alternative specification for world spillovers in which variety does not play such a crucial role. The specification will exhibit several of the features we have been looking for: first, no scale effect of world population on the world's growth rate; second, other things equal, larger countries contribute more to world prosperity than small countries do; and third, tapping into rest-of-world research does not require spreading research across more varieties. We believe this is accomplished by adopting the formulation in Jones (1995): instead of dividing by L, the scale effect is avoided by introducing the assumption that advancing the world technology frontier gets harder as the frontier gets higher. This can be captured by the following specification of international spillovers:

$$\dot{A}^* = \left(A^*\right)^{\gamma-1} \sigma \sum_i \lambda R_i \tag{4.6}$$

where $\gamma < 1$. In this setting, sustained growth in A^* depends on a continuously rising population. To see this, notice that we can restate (4.6) as follows:

(J) $$g_A = \left(A^*\right)^{\gamma-1} L\sigma \sum_i \lambda k_i s_{Ri} a_i \omega_i \,.$$

This expression makes clear that g_A is decreasing in A^*; as mentioned above, this is what is going to eliminate the scale effect. Since all of the terms in the summation on the right-hand side of (J) are constant, then – differentiating with respect to time – we get that:

(4.7) $$g_A = \frac{g_L}{1-\gamma} \,.$$

One criticism of this specification is that g_A does not depend on s_R, hence policy-induced increases in research intensity would not increase the world's growth rate (Howitt, 1999). As Jones (2002) argues, however, research intensity has been increasing over the last decades without a concomitant increase in the growth rate, so it is far from clear that we want a model where g_A depends on s_R.[13]

An interesting and relevant feature of the model presented by Eaton and Kortum (1996) is that it allows for spillovers to differ between pairs of countries. We can introduce this feature in the model by doing two things: first, we allow each country to have a different technology frontier, A_i^*; second, we add country-pair specific spillover parameters, η_{il}, to (4.6) so that now:

$$\dot{A}_i^* = \left(A_i^*\right)^{\gamma-1} \sigma \sum_l \lambda R_l \eta_{il} \,.$$

This formulation implies that there will no longer be a world technology frontier in the way it existed in model (J). However, it proves useful for the analysis to introduce a new concept, which we will denote by $\tilde{A}$ and which could be understood as the "frictionless technology frontier." To define this concept, note that if spillovers were the same among

[13] Even though research intensity does not affect the growth rate, it can have sizable effects on welfare, particularly when – as evidence suggests – the social rate of return of research is significantly higher than the private rate of return.

all country pairs ($\eta_{il} = 1$ for all *i* and *l*) – a case we could interpret as frictionless – then countries would have a *common* technology frontier: $A_i^* = A_l^*$ for all *i* and *l*. We define $\tilde{A}$ so that in this case ($\eta_{il} = 1$ for all *i* and *l*) $A_i^* = \tilde{A}$ for all *i*. As we will see below, in steady state $\tilde{A}$ grows at the same rate as A_i^* for all *i*. Letting $z_i \equiv A_i^* / \tilde{A}$, which captures the strength of spillovers from the rest of the world to country *i*, we arrive at the following steady state restriction:

(JEK) $$g_A = \left(A_i^*\right)^{\gamma-1} L(\sigma / z_i) \sum_l \lambda k_l s_{Rl} a_l \omega_l z_l \eta_{il}$$

where JEK stands for Jones, Eaton and Kortum and where a_l is now country *l*'s technology level relative to *its own* technology frontier: $a_l \equiv A_l / A_l^*$. It can be shown that this implies the following restriction for $\tilde{A}$:

(4.8) $$\tilde{A} = (vL)^{1/(1-\gamma)}$$

where $v \equiv (\sigma / g_A) \sum_l \lambda k_l s_{Rl} a_l \omega_l$. It is clear that each country's technology frontier and $\tilde{A}$ will grow at the same rate as A^* did in model (J), given by $g_L /(1-\gamma)$.

It is interesting to pause here to discuss the model's implications regarding the effect of country size on productivity. Imagine, to simplify, that all countries are the same except for size, and assume that $\eta_{ij} = 1$ for $i = j$ and $\eta_{ij} = \eta < 1$ for $i \neq j$. Then it is easy to show that $z_i > z_j$ if $\omega_i > \omega_j$; larger countries are more productive. Intuitively, larger countries benefit more from spillovers because more of the world's research takes place within their borders. As long as borders discretely reduce spillovers, larger countries will capture more spillovers and enjoy higher productivity.

The next step is to impose some restrictions on the international spillover parameters η_{il}'s. The literature has allowed international spillovers to depend on trade (Coe and Helpman, 1995), distance (Eaton and Kortum, 1996), and other variables such as FDI

flows (Caves, 1996). Here we focus on the simplest approach, which is to assume that the parameters η_{il} are completely determined by distance. (This would capture trade and FDI related spillovers that are related to distance.) We do this by assuming that $\eta_{il} = e^{-\theta d(i,l)}$, where *d(i,l)* is bilateral distance between countries *i* and *l*, and θ is some positive parameter. This model collapses to (J) if $\theta = 0$.

This completes our discussion of different ways to model international spillovers. Table 6 summarizes the discussion in this subsection.

4C. Determinants of R&D investment

We mentioned above that there are two ways to motivate the model we presented in subsection 4A. First, we can think of a model like the one presented in Howitt (2000), where research leads to improvements in the quality of capital goods, and population growth leads to an expansion in the total number of varieties available. Second, research may be carried out by firms to increase their own productivity, as in Parente and Prescott (1994). We pursue this second approach because it is simpler and much more convenient for our calibration purposes later on.

As in Parente and Prescott (1994), we assume a constraint on the amount of labor firms can hire. In particular, we assume that firms can hire no more than *F* workers. To simplify notation, we set *F* = 1. This constraint can be motivated as a limitation on the span of control by managers, as in Lucas (1978).[14] Output produced by firm *j* in country *i* at time *t*, which we denote by Y_{jit}, is given by $Y_{jit} = K_{jit}^{\alpha}(A_{jit}h_i)^{1-\alpha}$. (We now use time subscripts because they clarify the maximization problem below.) The firm can convert output into consumption, investment goods or R&D according to $Y_{jit} = C_{jit} + p_i I_{jit} + R_{jit}$, and the firm's capital stock evolves according to $\dot{K}_{jit} = I_{jit} - \delta K_{jit}$. Finally, the firm's technology index A_{jit} evolves according to:

$$\dot{A}_{jit} = \left((1-\mu)\lambda R_{jit} + \mu\lambda \bar{R}_{it} + \varepsilon A_{jit}\right)\left(1 - A_{jit}/A_{it}^{*}\right) \tag{4.9}$$

[14] If one takes *F* = 1 literally, then the externalities are in the human capital investment of individual workers.

where μ is a parameter between zero and one, $\bar{R}_{it}$ is the average of R_{jit} across firms in country *i* (we use the bar over the variable to emphasize that this is the average across firms, and not the aggregate economy-wide variable), and A^*_{it} is the technology frontier for country *i* with $\dot{A}^*_{it} / A^*_{it} = g_A$ for all *i in steady state.*

There are two features in this specification that merit some explanation. First, the "benefits of backwardness" are determined by the term $1 - A_{jit} / A^*_{it}$, which can differ across firms in country *i*: a more backward firm in country *i* would have a higher catch-up term. If instead we specified the catch-up term as $1 - \bar{A}_{it} / A^*_{it}$ (where $\bar{A}_{it}$ is the average technology index across firms in country *i*), then there would be a negative externality because, as a firm does more research, it increases the country's average technology index and decreases the catch-up term for the other firms. Given that there is no particular reason to think that this negative externality is a relevant feature to include in the model, we have chosen to specify the catch-up term as $1 - A_{jit} / A^*_{it}$. Second, there is a positive research externality across firms within each country, represented by the term $\mu\lambda\bar{R}_{it}$. This externality captures the idea that a firm benefits directly from research undertaken by other firms within the same economy.

To relate this to what we had in subsection 4A, note that if firms within a country are identical, then $R_{jit} = \bar{R}_{it}$ and $A_{jit} = \bar{A}_{it}$. Using this in (4.9), we obtain:

$$\dot{\bar{A}}_{it} = \left(\lambda \bar{R}_{it} + \varepsilon \bar{A}_{it}\right)\left(1 - \bar{A}_{it} / A^*_{it}\right)$$

But note that $A_{it} = \bar{A}_{it}$ and $\bar{R}_{it} = R_{it} / L_{it}$, where L_{it} is the total labor force in country *i* and also the number of firms there, given our assumptions above. Using these results and noting that $s_{Ri} = R_{it} / Y_{it}$ we obtain equation (4.2).

Firms in country *i* pay taxes at rate τ_{Ki} on capital income (output less the wage bill) ,and there is an R&D tax (or subsidy, if it is negative) of τ_{Ri}.[15] We stress that this R&D tax parameter does not have to be interpreted strictly as a formal tax or subsidy; when positive, the R&D tax parameter τ_{Ri} could also be interpreted as capturing "barriers to technology adoption", as in Parente and Prescott (1994).[16]

The firm's dynamic optimization problem is to choose a path for R_{jis} and I_{jis} to maximize

$$\int_t^{\infty} \left((1-\tau_{Ki}) \left[Y_{jis} - w_{is} \right] - p_i I_{jis} - (1+\tau_{Ri}) R_{jis} \right) e^{-r(s-t)} ds$$

subject to $\dot{K}_{jis} = I_{jis} - \delta K_{jis}$, $\dot{A}_{is} / A_{is} = \dot{A}^*_{is} / A^*_{is} = g_A$, and

$$\dot{A}_{jis} = \left((1-\mu)\lambda R_{jis} + \mu\lambda \bar{R}_{is} + \varepsilon A_{jis} \right) \left(1 - A_{jis} / A^*_{is} \right)$$

As shown in the Appendix, by imposing the symmetry condition on the two Euler equations for this optimization problem, we obtain the following two conditions for the symmetric equilibrium:

(4.10) $$\frac{p_i K_{it}}{Y_{it}} = \alpha \frac{1-\tau_{Ki}}{r+\delta}$$

(4.11) $$\Omega_i (1-\alpha)\lambda k_i (1-a_i) - g_A a_i / (1-a_i) + \varepsilon (1-a_i) = r$$

where $$\Omega_i \equiv \frac{(1-\tau_{Ki})(1-\mu)}{(1+\tau_{Ri})}.$$

[15] We should note here that the tax rate on capital income also affects the incentive to do research. The notation used for the two tax rates is meant to emphasize that τ_{Ki} affects all forms of accumulation by the firm, whereas τ_{Ri} only affects research expenditures.

[16] We assume that any tax revenue collected is distributed back to consumers in lump-sum fashion.

Equation (4.10) defines the equilibrium capital-output ratio in country *i* and equation (4.11) implicitly defines the equilibrium relative A in country *i*. Given a_i and knowing k_i from the data, we can plug their values into equation (4.3) to obtain the equilibrium steady state R&D investment rate, s_{Ri}. It is easy to see that an increase in the capital income tax or the R&D tax or an increase in the externality parameter, μ, would decrease Ω_i and hence lead to a decline in equilibrium a_i (this is because the left-hand side of (4.11) is decreasing in a_i). This, of course, would imply a decline in the R&D investment rate. The same reasoning shows that a_i is increasing in k_i but it is not necessarily the case that s_{Ri} increases with k_i (see the Appendix).

Combining the result for the social rate of return in equation (4.5) with (4.11), we obtain the following expression for the wedge between the social and private rate of return to R&D:

$$\tilde{r}_i - r = (1-\Omega_i)(1-\alpha)\lambda k_i(1-a_i) + g_L \tag{4.12}$$

The first term on the right-hand side is the distortion created by Ω, which captures the effect of the income tax, τ_K, the R&D tax, τ_R, and the externality parameter, μ. If there are no taxes and $\mu = 0$ (no domestic R&D externalities), then $\Omega_i = 1$ and the wedge between the social and private rate of return to R&D collapses to g_L.[17]

4D. Calibration

The model described in the previous section, together with the (JEK) formulation for international spillovers with $\eta_{il} = e^{-\theta d(i,l)}$, constitutes the model we calibrate in this subsection. Since we will only be working with the symmetric steady state equilibrium, in this subsection we suppress time and firm subscripts to simplify notation. Given N

[17] As explained above, g_L is associated with a positive externality because new firms start up with the same productivity as existing firms. Since the number of firms is equal to the workforce, the value of ideas and the social rate of return are increasing in g_L.

countries, the steady state equilibrium is given by $\{K_i, Y_i, k_i, a_i, s_{Ri}, A_i, A_i^*, z_i$; i = 1… N$\}$ such that:

(4.13) $$g_A = \frac{g_L}{1-\gamma}$$

(4.14) $$\frac{p_i K_i}{Y_i} = \alpha \frac{1-\tau_{Ki}}{r+\delta}$$

(4.15) $$k_i = h_i (K_i / Y_i)^{\alpha/(1-\alpha)}$$

(4.16) $$\Omega_i (1-\alpha)\lambda k_i (1-a_i) - g_A a_i /(1-a_i) + \varepsilon(1-a_i) = r$$

(4.17) $$a_i = 1 - \frac{g_A}{\lambda s_{Ri} k_i + \varepsilon}$$

(4.18) $$A_i = a_i A_i^*$$

(4.19) $$A_i^* = z_i \tilde{A}$$

(4.20) $$\tilde{A} = (vL)^{1/(1-\gamma)}$$

(4.21) $$v = (1/g_A)\sum_l \lambda k_l s_{Rl} a_l \omega_l$$

(4.22) $$z_i^{(1-\gamma)+1} = (\sigma / v g_A)\sum_l \lambda k_l s_{Rl} a_l \omega_l z_l e^{-\theta d(i,l)}$$

where the last equation comes from (JEK) together with (4.8).

If we knew the relevant parameters and tax rates and wanted to solve for an equilibrium, we would first start by solving for g_A from equation (4.13). Given data for exogenous variables h_i, p_i and τ_{Ki} we could then calculate equilibrium k_i using (4.14) and (4.15). Together with g_A and parameter ε, equation (4.16) would yield a_i. From (4.17) we would then obtain s_{Ri}. Up to this point, there is no interaction across countries, so these results do not depend on geography or θ; this dimension becomes relevant in obtaining actual productivity levels, because they depend on the variables z_i, which capture spillovers from the rest of the world to country *i*. To see how this operates, note that given

the value of θ, equation (4.22) configures a system of N equations (where N is the number of countries) in N unknowns ($z_1, z_2, \ldots z_N$). The solution to this system determines z_i. Given parameter σ, equation (4.20) determines $\tilde{A}$, which together with z_i determines each country's technology frontier A_i^* (equation (4.19)). Finally, from equation (4.18), a country's technology frontier together with its relative *A* level a_i determines A_i.

For the calibration exercise, the first step is to specify the variables we observe and how they relate to the model. We take human capital to be $h_i = e^{\varphi * MYS_i}$, where MYS_i is mean years of schooling of the adult population in country *i*, obtained from Barro and Lee (2000). We use R&D data from Lederman and Sáenz (2003). The 48 countries in our sample are the ones for which there is R&D data for 1995, as well as the necessary TFP and capital intensity variables described in section 3. The first two columns of Table A1 reproduce the values of the R&D investment rate and the value of *A* for the 48 countries in our sample.

For the basic parameters we use the following values: $\varphi = 0.085$, $\alpha = 1/3$, $\delta = 0.08$, $g_L = 0.011$ and $g_A = 0.015$. For the first three, see our discussion in section 3. The last two (the growth rates) were obtained from OECD average growth rates of *L* and *A* for the period 1960-2000.[18] Using (4.13), the values for the two growth rates imply $\gamma = 0.31$. To calculate the net private rate of return, *r*, which we assume to be common across countries, we take the capital income tax in the U.S. to be 25% ($\tau_{K,US} = 0.25$).[19] Given the 1995 U.S. nominal capital-output ratio of 1.5 (see section 3 for how we constructed capital-output ratios), this implies from (4.14) that $r = 8.6\%$. Given this level for *r*, we then use equation (4.14) together with country nominal capital-output ratios to obtain each country's implicit income tax τ_{Ki}.

Remaining parameters we must calibrate are ε, λ, μ and θ. Unfortunately, there is no empirical work that we can rely on to pin down ε. Thus, we choose a value for

[18] Specifically, the growth rate of *A* is the annual growth rate of the weighted average of *A* in the OECD with weights given by employment levels in 1960. OECD membership is defined by 1975 status.
[19] Auerbach (1996) estimates an effective tax rate in the U.S. of about 16%, but King and Fullerton (1984) estimate a much higher level of around 35%. We use 25% as an intermediate value.

ε based on the following reasoning. First, ε cannot be much higher than g_A. This is because for $ks_R \geq 0$ equation (4.17) implies that $a \geq 1 - g_A/\varepsilon$. Thus, a high value of ε would imply that some countries' relative empirical *A* becomes lower than the theoretical minimum $1 - g_A/\varepsilon$. In other words, if free technology diffusion is too important, then it would be hard to account for countries with very low *A* levels. Second, if $\varepsilon < g_A$, then countries with a low value of ks_R ($\lambda s_R k < g_A - \varepsilon$) would not be able to keep up with the world's rate of growth in technology, so they would not have a steady state relative *A* level. (Consistent with stable long run relative income levels, Figure 3 showed roughly parallel slopes for average income across deciles over 1960-2000, with each decile based on 1960 income.) Thus, it seems reasonable to impose the intermediate condition that $\varepsilon = g_A$. We believe, however, that future empirical work should attempt to understand the importance of free technology diffusion captured by parameter ε.

Given this choice for ε, we use two empirical findings to pin down parameters λ and μ, namely that the social rate of return to R&D in the U.S. is three times the net private rate of return (Griliches, 1992) and that the U.S. imposes a subsidy of 20% on R&D (Hall and Van Reenen, 2000), implying that $\tau_{R,US} = -0.2$. Given data for s_R and *k* for the U.S. in 1995 ($s_{RUS} = 2.5\%$ and $k_{US} = 3.6$), then this restriction together with equation (4.17) implies $a_{US} = 0.7$ and $\lambda = 0.38$.[20] From (4.16) we then obtain $\mu = 0.55$.

A parameter remaining to calibrate is θ.[21] Before discussing possible values for this parameter, it is useful to consider the case where $\theta = 0$ – so that there is no effect of distance on international spillovers – and to compare the implications of the model to the data. Using the R&D investment rate data of Lederman and Saenz (2003) and our

[20] Due to the non-linearity of the expression for the social rate of return to R&D, there are actually two values of λ which are compatible with a social rate of return equal to 26% (three times the private rate of return). The higher value of λ, however, would imply a high relative *A* level for the U.S. and consequently – given measured *A* for the U.S. – a value for *A** that would be lower than the measured *A* levels of the high *A* countries, such as Hong Kong and Italy. To avoid this, we choose the lower value of λ.

[21] We must also set a value for σ, which is crucial for determining the level of $\tilde{A}$. We use the value of A_{US} obtained from the data, (4.18)-(4.20), $a_{US} = 0.7$, and a value for z_{US} (equal to one when $\theta = 0$ and a known value from the solution to the above system of equations for the case $\theta > 0$) to arrive at a value for σ.

estimated *k* levels, equation (4.17) yields the model's implied relative *A* level for each country (a_i). We want to compare this against the data. To do so, we use the value of *A* we calculated for the U.S. in the previous section and $a_{US} = 0.7$ to obtain an implied value for the world technology frontier, *A** (recall that with $\theta = 0$ there is a well defined technology frontier that is common to all countries). We can then obtain the model's implied *A* values for all countries using $A_i = a_i A^*$. The result of this exercise is shown in Table 7, where we divide countries into four groups according to their levels of *A* and show the median of the different variables for each group. It is clear that the model does badly for the poorest countries, predicting much lower *A* levels for them than occur in the data. This discrepancy does not occur for the richest countries, so the model is predicting significantly larger *A* differences than in the data. For example, whereas (according to the data) the top group's median *A* is 3.4 times the median *A* of the bottom group, the model implies a ratio of 5.6.

The model implies large differences in productivity in response to small differences in R&D investment rates. As is well known, the neoclassical model – with only around 1/3 share for physical capital – cannot generate large differences in steady state labor productivity in response to modest differences in investment rates (see the discussion in Lucas, 1990). It is worth pausing here to explore some of the reasons behind these divergent properties. Manipulating the neoclassical model, one can show that the semi-elasticity of steady state labor productivity with respect to the investment rate is given by:

$$\frac{\partial \ln y}{\partial s} = \left(\frac{r}{1-\alpha}\right)\left(\frac{1}{\delta + g_A + g_L}\right) \tag{4.23}$$

With the values we used above ($\alpha = 1/3$, $\delta = 0.08$, $g_L = 0.011$ and $g_A = 0.015$), (4.23) yields a semi-elasticity of only 1.22% when evaluated at $r = 8.6\%$. Thus large differences in investment rates would be required to generate sizable differences in labor productivity across countries. Two differences between the way the R&D investment rate operates in our model and the way the physical capital investment rate operates in the neoclassical model stand out: first, the depreciation rate of ideas in our model is zero versus $\delta = 0.08$ for capital in the neoclassical model; second, the elasticity of output with respect to the stock of ideas can exceed 1/3 (we have it at 2/3). To see the importance of these values,

note that with $\alpha = 2/3$ the semi-elasticity doubles to 2.46% (still with $r = 8.6\%$). If we use $\delta = 0$ as well, then the semi-elasticity increases to 9.6%. In our model, the combined share of physical capital and ideas is actually 1. Without the constraint of the world technology frontier, therefore, the long run response of output would be infinite.

It is important to recall that the results shown in Table 7 and discussed above were derived for the case of $\theta = 0$. Is it possible that a positive value of θ could improve the model's fit with the data? As will become clear below, countries with high levels of *k* and high R&D investment rates tend to cluster together. Thus, assuming a positive value for θ would actually make the model *less* consistent with the data, since it would imply an even larger difference between *A* levels across rich and poor countries.

One possible reason why the model is not doing well in matching the data is that measured R&D is not the appropriate empirical counterpart of "research" in the type of models we have been examining. In particular, measured R&D only includes formal research; this is research performed in an R&D department of a corporation or other institution. This fails to capture informal research, which may be particularly important in non-OECD countries. To explore this idea, in the rest of this section we assume that both R&D intensity and the productivity index *A* are measured with error. We estimate "true" R&D intensities by minimizing a loss function equal to the sum of two terms that capture, respectively, the deviation of the "true" R&D intensities from the data and the deviation of the model's implied (log of) *A* values from the data, with weights given by the standard deviation of the corresponding differences.[22] In principle, we could follow this procedure for each value of θ. However, at $\theta = 0$, the partial derivative of our loss function with respect to θ is positive and large, implying that – just as argued above – the model's fit with the data worsens as θ increases from zero. Thus, we restrict ourselves to estimating R&D intensities for $\theta = 0$ and later show what happens if, keeping the same R&D intensities estimated for $\theta = 0$, we have positive values of θ.

[22] We do this in two stages. In the first stage we minimize a loss function without weights. We use the results to calculate the standard deviation of the error terms, or differences between data and "true" values for both R&D intensity and productivity. In the second stage we minimize the loss function with weights given by these calculated standard deviations.

It should be acknowledged that this procedure obviously implies that we can no longer evaluate the model's consistency with the data; our interest is now to explore the implications of the model for the differences in R&D investment rates that would be necessary to explain cross-country differences in *A*, as well as the implied differences in R&D tax rates that would be necessary to bring about those R&D investment rates.

The results of the exercise described above are shown in Figure 4 and Table A1 (columns 3 and 4). There are three points to note from these results. First, it is clear that the procedure leads to only small deviations of *A* from the data, whereas the deviations are more significant for R&D intensities. It would appear that R&D intensities have more significant measurement problems (or are conceptually more different than research intensity in our model) than productivity levels. Indeed, the standard deviation of residuals of s_R with respect to the data is 0.12, whereas the corresponding value for the (log of) *A* is 0.01.[23] Second, there are some countries for which the estimated R&D intensity is much higher than the data. Italy, for example, has a measured R&D intensity of 1.1%, whereas its "true" value is 8.3%. This arises because of Italy's high measured productivity (Italy's *A* is 24% higher than the U.S. level) and low value of *k* (2.6 versus 3.6 in the U.S.). Something similar happens for other high-*A* countries, such as Hong Kong and Ireland. Finally, just as one would expect given the results above, estimated R&D intensities vary much less than the corresponding values in the data. This is the main mechanism by which the procedure allows the model to fit perfectly. It also suggests that measurement error may be behind the low R&D intensities of several poor countries and of some high *A* countries such as Italy, Ireland and Hong Kong.

We can now explore what happens when θ is positive, so that spillovers decline with distance. Given the estimated R&D intensities, productivity levels change with θ only because of the associated changes in the variables z, which capture the effect of distance on spillovers for each country. In principle, we can obtain the values of $(z_1, z_2, \ldots z_{48})$ for any $\theta \geq 0$ from the solution of a system of 48 non-linear equations represented by (4.22). Equation *i* of this system can be expressed as:

[23] These standard deviations are the ones that arise after the two stage procedure described in the previous footnote. After the first stage, the standard deviations for the R&D rate and the (log of) *A* are 0.11 and 0.03, respectively.

$$z_i^{(1-\gamma)+1} = \frac{\sum_{j=1}^{48} \lambda k_l s_{Rl} a_l z_l \omega_l e^{-\theta d(i,l)}}{\sum_{l=1}^{48} \lambda k_l s_{Rl} a_l \omega_l} \tag{4.24}$$

Solving this system numerically for the parameter values we have discussed and the R&D intensities derived before, we arrive at a value of z_i for each country, from which we can then obtain the country's level of *A* by using $A_i = a_i z_i \tilde{A}$ from (4.18) and (4.19).

What are reasonable values to use for the parameter θ? Using industry level data on productivity and research spending across the G-5 countries, Keller (2002) estimated a reduced form model where cumulative industry research affects own productivity and also affects productivity in the same industry in other countries through international spillovers that decline with distance.[24] Given the similarity between Keller's system and a reduced form of our model, it seems reasonable to use Keller's estimate of θ, namely $\theta_K \equiv 0.0009$ in the calibration of our model. It turns out, however, that with $\theta = \theta_K$ our model cannot match the data – in particular, there is no solution to the system of equations (4.24), at least for the parameters used for the exercises above. This is because θ_K is unreasonably high. One way to see this is by noting that it implies a half distance of 746 miles: this implies that spillovers from the U.S. to Japan would be only one tenth of those to Mexico, and spillovers from the U.S. to New Zealand would be only one fifth of those to Japan.

We were able to find solutions for the system with $\theta = \theta_K / 5$. For comparison, we also obtained solutions for two other values of θ, namely $\theta = \theta_K / 10$ and $\theta = \theta_K / 100$. A group of European countries (Belgium, France, United Kingdom, Germany, Ireland, Italy, and Netherlands) always come out with the highest values of z, whereas New Zealand always comes out with the lowest value. For $\theta = \theta_K / 100$, $\theta = \theta_K / 10$ and $\theta = \theta_K / 5$, the minimum and maximum values of z are (93%, 96%), (48%, 68%) and (24%, 50%), respectively. Clearly, for high values of θ, geography by itself can lead to large differences in productivity across countries.

[24] For other estimates of international spillovers from R&D, see Coe and Helpman (1995) and Coe, Helpman and Hoffmaister (1997). For a study of agricultural R&D spillovers, see Evenson and Gollin (2003). Becker, Philipson and Soares (2003) present evidence consistent with international spillovers of health technology.

In the rest of this section, we focus on the case $\theta = 0$, since – as explained above – the model's fit with the data is best at this point. (Recall that the model fits perfectly because we are using the estimated research intensities and the implied *A* values). Table 8 presents summary statistics for the solution for the case of $\theta = 0$. Our discussion of these results will focus on the comparison of the poorest and richest quartiles (ordered, as above, in terms of *A* levels) in this table.

There are several points that we want to highlight in relation to these results. First, the median income tax is 13% and 6% for the poorest and richest countries, respectively. Everything else equal, this would lead to a lower R&D investment rate in the poorest countries. Second, as expected, rich countries have a higher *k* than poor countries: the level of *k* in these two groups is 2 and 2.9, respectively. As commented in Section 4B, higher *k* has a direct effect on relative *A* (see equation (4.17)) and an indirect effect (it could be positive or negative) through its impact on R&D investment rates (see equation (4.16)). A natural question arises: is it the case that once we take into account the effect of *k* on TFP we can resuscitate the "neoclassical revolution" mantra that differences in physical and human capital accumulation rates account for most of cross-country income differences? More concretely, how much of the variation in *A* levels across countries is due to the variation in levels of *k*? A simple way to answer this question is to note from equation (4.17) that differences in relative *A* levels are driven by differences in the product $s_R k$ across countries. Running a regression of s_R on the log of this product yields a coefficient of 0.8, which implies that when $s_R k$ increases by one percent, we should expect s_R to increase by 0.8%. Clearly, most of the variance of the product $s_R k$ is accounted for by the variance of s_R.

Third, the social return to R&D is higher for poor countries. This is consistent with the findings in Lederman and Maloney (2003) and also with the idea that poor countries have policies and institutions that negatively affect the quantity of research.

Fourth, the column with heading τ_R indicates the R&D tax rate required to produce the "true" R&D investment rates given each country's levels of τ_K. The main question we address here is whether differences in income tax rates, which affect both the rate of

investment in physical capital and R&D, are sufficient to explain differences in estimated research intensities. The answer is clearly negative: the required R&D tax rate in the poorest countries is 102% compared to -16% in the richest countries. To address the same question from a different angle, the last column calculates each country's implied relative *A* level if all countries had the same R&D tax as the U.S. but kept their own levels of τ_K. It is clear that differences in τ_K alone are too small to account for the wide dispersion in productivity levels across countries.

Finally, as emphasized above, the results in Table 8 suggest that small differences in steady-state R&D investment rates have large effects on steady state relative *A* levels. For example, in the calibrated model, by increasing its R&D investment rate by 1% from 0.6% India could double its steady state relative *A* level from 17% to 34%, clearly a very large effect. India's social rate of return to research, however, is a moderate 30%. The apparent contradiction arises because the large effect of the increase in the R&D intensity on the relative *A* level is a steady-state comparative-statics result, and hence does not take into account the transition, which is a crucial component in the calculation of the social rate of return to R&D. As a result, in spite of the large effect of differences in R&D investment rates on relative *A* levels in steady state, the required implicit taxes on R&D are not huge.

4E. The benefits of engagement

One of the benefits of the model we have constructed is that it allows us to perform an interesting exercise. We can ask: how much do countries benefit from spillovers from the rest of the world?

First, note that a country's equilibrium a_i is not affected by being isolated or engaged. Thus, the whole benefit of engagement is going to captured by the way engagement affects the term z_i. Now, if a country is isolated, or disengaged, its equilibrium z would be characterized by the solution to the system (4.24) when $\theta \to \infty$. It is easy to check that this yields

(4.25) $$\breve{z}_i = \left(\frac{\lambda k_i s_{Ri} a_i \omega_i}{\sum_l \lambda k_l s_{Rl} a_l \omega_l} \right)^{1/(1-\gamma)}$$

Thus, the benefits of engagement are captured by $z_i / \breve{z}_i$. From (4.17) we get

$$z_i / \breve{z}_i = z_i \left(\frac{\sum_l \omega_l \upsilon_l}{\omega_i \upsilon_i} \right)^{1/(1-\gamma)}$$

where $\upsilon_i \equiv a_i \lambda k_i s_{Ri} = \lambda R_i / A_i^* L_i$ is a measure of research intensity. Letting $\bar{\upsilon} \equiv \sum_j \omega_j \upsilon_j$ be the world's weighted average of υ_i, we obtain

(4.26) $$\frac{z_i}{\breve{z}_i} = z_i \left(\frac{1}{\omega_i} \right)^{1/(1-\gamma)} \left(\frac{\bar{\upsilon}}{\upsilon_i} \right)^{1/(1-\gamma)}$$

The first term on the RHS of this equation, z_i, captures the fact that even when fully engaged, a country's technology frontier is inferior to the world's frictionless frontier if $\theta > 0$, in which case $z_i < 1$ for all i. The second term is the pure scale effect that arises in this model. The third term, which we call the "Silicon Valley" effect, captures the fact that richer countries benefit less from being part of the world than poor countries do because of their higher effective research intensity.

Table 9 presents results based on these values and assuming $\theta = 0$, which implies $z_i = 1$ for all i. The results suggest huge benefits of engagement. At the extreme, Senegal's productivity is 187 thousand times higher than it would be if it was isolated! Of course, if $\theta > 0$ then $z_i < 1$ and the overall effect would be small. Still, it is our conjecture that any reasonable value of θ would still imply enormous benefits of engagement. Of course, in a more general model, it is reasonable to think that productivity could not fall below a certain level because of Malthusian forces. Specifically, suppose there is a fixed factor such as land. Then, for sufficiently low *A*, population would decline until income per capita was equal to the subsistence level. Instead of very low levels of *A*, disengagement would mean

very low population sizes. Put differently, an important part of the benefits of engagement may be realized through larger population rather than higher productivity. The implications are clear: if it were not for the benefits of sharing knowledge internationally, countries would have much lower productivity levels and populations than they now do.

4F. Discussion of main results

We finish this section with a discussion of the main results we want to emphasize.

First, the usual separation between capital and productivity – or between investment and technological change – is not always valid. For a given R&D investment rate, higher investment rates in physical and human capital lead naturally to higher TFP productivity levels. Thus, one should not jump from cross-country dispersion in TFP to the conclusion that differences in physical and human capital play a minority role in accounting for international income differences. When we calibrate our model, however, we find that differences in R&D investment rates account for most of the cross country variation in productivity.

Second, international variation in R&D investment appears *more* than large enough to generate the international variation in productivity. But it seems likely that measured R&D does not capture all of the investment associated with adoption of foreign technology. Indeed, we find that countries such as Indonesia, Peru and Senegal have R&D investment rates that are much too low to be consistent with their productivity levels. It is likely that their true research intensities are much higher than the measured ones. We hope to see more research in understanding how to capture and measure "research".

Third, differences in (implicit) capital income tax rates are not large enough to account for the observed differences in R&D investment rates and productivity levels. The calibrated model suggests that sizable differences in R&D taxes are needed. These R&D taxes are clearly not formal or explicit taxes, but the result of policies and institutions that make research more costly or reduce its associated returns. Exploring the nature and source of these differences in implicit R&D taxes across countries is an important topic for future research.

Finally and most importantly, the calibrated model indicates that countries benefit enormously from international knowledge spillovers. We think any reasonable value of θ (which governs the rate at which spillovers decline with distance) would yield results similar to those we presented above.

5. Conclusion

Externalities are not theoretically necessary to sustain growth. But they appear essential for understanding why many countries grow at similar rates despite differing investment rates. A dramatic way to summarize the importance of international knowledge externalities is to calculate world GDP in the absence of such externalities. According to our calibrated model, world GDP would be only 6% of its current level, or on the order of $3 trillion rather than $50 trillion, if countries did not share ideas. Such scale effects from the nonrivalry of knowledge are a central theme in the works of Romer (1990), Kremer (1993), Diamond (1997), Jones (2001, 2004) and many others.

Because diffusion is not costless, however, differences in knowledge investments may explain a significant portion of income differences across countries. We show that modest barriers to technology adoption could account for differences in TFP of a factor of four or more, as observed in the data. But we have not documented such barriers to knowledge diffusion in practice. We consider this a priority for future research.

We have also left for future research the identification of the primary channels of international knowledge spillovers. Trade, joint ventures, FDI, migration of key personnel, and imitation may all play important roles. See Keller (2004) for a survey of recent empirical work on this topic. A model with trade would lead naturally to some countries having a comparative advantage in doing innovative R&D and other countries focusing on adoption and imitation R&D. The evidence on international patenting supports the notion that innovative R&D is concentrated in rich countries. Of course, countries can imitate other imitators as well as the original innovators. We hope to see future research documenting not only the vehicles for knowledge diffusion, but their specific routes.

Appendix

The firm's maximization problem can be restated as choosing $\dot{A}_{jis}$ and $\dot{K}_{jis}$ to maximize:

$$\int_t^{\infty}\left((1-\tau_{Ki})K_{jis}^{\alpha}(A_{jis}h_i)^{1-\alpha}-p_i\dot{K}_{jis}-p_i\delta K_{jis}-\frac{(1+\tau_{Ri})}{(1-\mu)\lambda}\left(\frac{\dot{A}_{jis}}{1-A_{jis}/A_{is}^{*}}-\varepsilon A_{jis}-\mu\lambda\bar{R}_{is}\right)\right)e^{-r(s-t)}ds$$

Letting Q represent the expression in the integral, then we know that a solution to this problem must satisfy the following Euler Equations: $\partial Q/\partial K_{jis}=\frac{d}{ds}(\partial Q/\partial\dot{K}_{jis})$ and $\partial Q/\partial A_{jis}=\frac{d}{ds}(\partial Q/\partial\dot{A}_{jis})$. The first Euler equation is:

$$\frac{\alpha Y_{jis}}{p_i K_{jis}}=\frac{r+\delta}{1-\tau_{Ki}}$$

Since in a symmetric equilibrium the capital-output ratio of firm j is the same as the aggregate capital output ratio, then this implies that:

$$\frac{p_i K_{it}}{Y_{it}}=\alpha\frac{1-\tau_{Ki}}{r+\delta}$$

As to the second Euler equation, differentiation yields (we are using the symmetry condition for the equilibrium):

$$\frac{\partial Q}{\partial A_{jis}}=\left((1-\tau_{Ki})(1-\alpha)Y_{jis}/A_{jis}-\frac{(1+\tau_{Ki})}{(1-\mu)\lambda}\left(\frac{g_A a_i}{(1-a_i)^2}-\varepsilon\right)\right)e^{-r(s-t)}$$

and

$$\partial Q/\partial\dot{A}_{jis}=-\frac{(1+\tau_{Ri})}{(1-\mu)\lambda(1-a_i)}e^{-r(s-t)}$$

Hence,

$$\frac{d}{ds}(\partial Q/\partial\dot{A}_{jis})=\frac{r(1+\tau_{Ri})}{(1-\mu)\lambda(1-a_i)}e^{-r(s-t)}$$

Thus, the Euler equation is:

$$(1-\tau_{Ki})(1-\alpha)Y_{jis}/A_{jis}-\frac{(1+\tau_{Ri})}{(1-\mu)\lambda}\left(\frac{g_A a_i}{(1-a_i)^2}-\varepsilon\right)=\frac{r(1+\tau_{Ri})}{(1-\mu)\lambda(1-a_i)}$$

Noting that in a symmetric equilibrium we must have $Y_{jis}/A_{jis}=Y_{is}/A_{is}L_{is}=k_i$, and manipulating, we get:

$$\Omega_i(1-\alpha)\lambda k_i(1-a_i)-g_A a_i/(1-a_i)+\varepsilon(1-a_i)=r$$

where $\Omega_i \equiv \frac{(1-\tau_{Ki})(1-\mu)}{(1+\tau_{Ri})}$.

Comparative statics

(From here onwards we drop the subscripts). It is easy to show that a is increasing in both Ω and k. In particular:

$$\frac{\partial a}{\partial k} = \frac{\Omega(1-\alpha)\lambda(1-a)}{\Omega(1-\alpha)\lambda k + \left(g_A/(1-a)\right)(1+1/(1-a)) + \varepsilon} > 0$$

Differentiating $g_A = (\lambda k s + \varepsilon)(1-a)$ (using s for s_R) we get

$$(\lambda s dk + \lambda k ds)(1-a) - da(\lambda k s + \varepsilon) = 0$$

This implies that:

$$\lambda k(\partial s/\partial k) = \frac{(\partial a/\partial k)(\lambda k s + \varepsilon)}{(1-a)} - \lambda s$$

Plugging in from the result above we finally get:

$$k(\partial s/\partial k) = \frac{\Omega(1-\alpha)(\lambda k s + \varepsilon)}{\Omega(1-\alpha)\lambda k + \left(g_A/(1-a)\right)(1+1/(1-a)) + \varepsilon} - s$$

Summing on the RHS and noting that the denominator is clearly positive we get that $\partial s/\partial k > 0$ if and only if:

$$\Omega(1-\alpha)\varepsilon - s(g_A/(1-a))(1+1/(1-a)) - \varepsilon s$$

This could well be negative!

Notes: Variables are country averages over years in 1960-2000 with data relative to time effects. *Y/L* is GDP per worker. *TFP* nets out contributions from human and physical capital, as described in the text. Each entry is from a single regression. Bold entries indicate p-values of 2% or less. Data Sources: Barro and Lee (2000), Penn World Table 6.1 (Heston, Summers and Aten, 2002), and Lederman and Saenz (2003).

Table 6

Alternative Ways of Modeling International Spillovers

	Spillovers	**Growth rate**	**Advantages**	**Disadvantages**
H1	$\dot{A}^* = \sigma \sum_i \left(\frac{\lambda R_i}{L_i} \right)$	$g_A = \sigma \sum_i \lambda k_i s_{Ri} a_i$	No scale effects	Larger countries contribute no more to g_A than do small countries
H2	$\dot{A}^* = \sigma \sum_i \left(\frac{\lambda R_i}{L} \right)$	$g_A = \sigma \sum_i \lambda k_i s_{Ri} a_i \omega_i$ where $\omega_i = L_i / L$	Previous ones plus: Size matters for a country's contribution to g_A	Countries with higher than average $k_i s_{Ri} a_i$ would be better off ignoring research from the rest of the world
J	$\dot{A}^* = \left(A^* \right)^{\gamma - 1} \sigma \sum_i \lambda R_i$	$g_A = g_L / (1 - \gamma)$	Previous ones plus: Research-intensive countries do not prefer to disengage from the rest of the world.	g_A does not depend on R&D efforts…but is this a disadvantage? (See Jones, 1995)
JEK	$\dot{A}_i^* = \left(A_i^* \right)^{\gamma - 1} \sigma \sum_l \lambda R_l \eta_{il}$	$g_A = g_L / (1 - \gamma)$	Previous ones plus: The model takes into account effect of distance on spillovers.	We will find it hard to see the cost of geographic isolation in the TFP data.

Table 7

Model *A* versus data *A* ($\theta = 0$ case)

Country	Data k	Data s_R	Data *A*	Model *A*
Quartile 1	2.0	0.4%	4,478	2,184
Quartile 2	2.5	0.5%	9,574	5,358
Quartile 3	3.1	1.7%	11,111	11,763
Quartile 4	2.9	1.7%	15,441	12,286

Table 8

Implied R&D tax rates

	"True"						a for
Country	τ_K	k	s_R	a	**SRR**	τ_R	$\tau_{Ri} = \tau_{R,US}$
Quartile 1	**13%**	**2.0**	**0.60%**	**20%**	**42%**	**102%**	**58%**
Quartile 2	**0%**	**2.5**	**1.13%**	**43%**	**37%**	**93%**	**68%**
Quartile 3	**4%**	**3.1**	**1.97%**	**50%**	**29%**	**31%**	**72%**
Quartile 4	**6%**	**2.9**	**2.98%**	**70%**	**21%**	**-16%**	**70%**

Notes: τ_R is calculated as the level of τ_R needed to generate the "true" research intensity. For each country, we use its own implied income tax level (τ_K) and its own capital intensity level k. The last column presents the equilibrium steady state relative *A* level (a) for the hypothetical case in which all countries have the same R&D tax as the U.S. ($\tau_{Ri} = \tau_{R,US}$) but have different income tax rates and capital intensity levels.

Human Capital and Technology Diffusion*

Jess Benhabib and Mark M. Spiegel†

December 9, 2002

Abstract

This paper generalizes the Nelson-Phelps catch-up model of technology diffusion. We allow for the possibility that the pattern of technology difusion can be exponential, which would predict that nations would exhibit positive catch-up with the leader nation, or logistic, in which a country with a sufficiently small capital stock may exhibit slower total factor productivity growth than the leader nation.

We derive a nonlinear specification for total factor productivity growth that nests these two specifications. We estimate this specification for a cross-section of nations from 1960 through 1995. Our results support the logistic specification, and are robust to a number of sensitivity checks.

Our model also appears to predict slow total factor productivity growth well. 22 of the 27 nations that we identify as lacking the critical human capital levels needed to achieve faster total factor productivity growth than the leader nation in 1960 did achieve lower growth over the next 35 years.

1. Introduction

In a short paper in 1966 Nelson and Phelps offered a new hypothesis to explain economic growth. Their explanation had two distinct components. The first component postulated that while the growth of the technology frontier reflects the rate at which new discoveries are made, the growth of total factor productivity depends on the implementation of these discoveries, and varies positively with the distance between the technology frontier and the level of current productivity. Applied to the diffusion of technology between countries, with the country leading in total factor productivity representing the technology frontier, this is a formalization of the catch-up hypothesis that was originally proposed by Gerschenkron (1962). The second component of the Nelson-Phelps hypothesis suggested that the rate at which the gap between the technology frontier and the current level of productivity is closed depends on the level of human capital. This was a break with the view that human capital is an input into the production process. Nelson and Phelps make this point starkly in the concluding sentence of their paper: "Our view suggests that the usual, straightforward insertion of some index of educational attainment in the production function may constitute a gross mis-specification of the relation between education and the dynamics of production."

The catch-up or technology diffusion component of the Nelson-Phelps hypothesis raises a basic question. If a country, or a firm within an industry, has to incur costs in order to innovate, then why should it not sit back and wait for technology diffusion that flows costlessly? Modern theories of economic growth have paid a great deal of attention to the incentives for innovation and to the market structures that are necessary to sustain R&D. Inventions are typically assumed to give rise to new (often intermediate) products which generate monopoly rents over their lifetime. These rents provide the financial incentives to innovate and to cover the costs of innovation. The costs of invention typically reflect the wages or the patent incomes of researchers. The labor markets allocate workers between

research and production, and in certain cases the allocation of workers across different occupations can involve decisions to acquire costly human capital. When a vintage structure is present, newer and technologically more efficient intermediate goods or production processes may coexist with older ones that remain inside the technology frontier. A critical by-product of an innovation, not captured by the monopoly rents that it generates, is the expansion of the stock of basic knowledge This basic knowledge, freely available to all, enhances the productivity of future research, facilitates future innovations and is the source of scale effects.

In the Nelson-Phelps framework, disembodied technical know-how flows from the technology leader to its followers and augments their total factor productivity. Patent protection or blueprint ownership is not explicitly postulated, and therefore an alternative mechanism must be in operation to sustain inventive activity and to prevent free-riding. A number of models have directly addressed the impact of imitation that dissipates rents on innovative activity by explicitly introducing costs of imitation. In an early investigation by Grossman and Helpman (1991, Chapter 11, see also Helpman (1993), Segerstrom (1991)), the North, where patent protection is in effect, innovates, and the South, where labor costs are lower, imitates at a cost. Aghion, Harris and Vickers (1997), building on Grossman and Helpman (1991), suggest a leapfrogging model where firms can, by incurring an appropriate cost, catch-up and overtake their rivals to capture a larger share of the profits. Eaton and Kortum (1999) construct a model with patenting costs where patens decrease but not eliminate the hazard of imitation. To construct an equilibrium with technology diffusion, Barro and Sala-i Martin [1995, also (1997)] introduce a model where in the leading country the costs of innovation are low relative to the costs of imitation, while in the follower country the reverse is true. Basu and Weil (1998) propose a model where technological barriers to imitation in the South arise from significant differences in factor proportions between North and South, with the possible emergence of "convergence clubs." Such differences in

endowments may not provide the most "appropriate" opportunities for imitation, and fail to direct technical change towards efficient cost savings (see Acemoglu (2002)). Technology may nevertheless flow between convergence clubs, with imitation costs rather than patent protection sustaining innovative activity within the clubs. Eeckhout and Jovanovic (2002) construct a model where imitators can implement technology only with a lag, and this implicit imitation cost means that innovators find it optimal to maintain their lead. It seems clear then that some costs of imitation and certain advantages to innovation must be present if technology diffusion is to play a role in economic growth. Therefore, underlying the Nelson-Phelps model there must be an appropriate market structure with an economic equilibrium that sustains innovative activity in the face of technology diffusion.

The empirical literature on technology diffusion has been growing, despite difficulties in measurements. The survey of Griliches (1992) lends support to the view that there are significant R&D spillovers. Coe and Helpman (1995) find that R&D abroad benefits domestic productivity, possibly through the transfer of technological know-how via trade. Branstetter (1996), looking at disaggregated data, finds research spillovers across firms that are close in "technology space." Nadiri and Kim (1996) suggest that the importance of research spillovers across countries varies with the country: domestic research seems important in explaining productivity in the US but the contribution of foreign research is more important for countries like Italy or Canada. The role of human capital in facilitating technology adoption is documented by Welch (1975), Bartel and Lichtenberg (1987) and Foster and Rosenzweig (1995). Benhabib and Spiegel (1994), using cross-country data, investigate the Nelson-Phelps hypothesis and conclude that technology spills over from leaders to followers, and that the rate of the flow depends on levels of education. In fact a good deal of the recent empirical literature has focused on whether the level of education speeds technology diffusion and leads to growth, as

suggested by Nelson Phelps, or whether education acts as a factor of production, either directly or through facilitating technology use. (See for example, Islam (1995), Eaton and Kortum (1996), Temple (1999), Krueger and Lindahl (2001), Pritchett, Klenow and Rodriguez-Clare (1997), Hall and Jones (1999), Bils and Klenow (2000), Duffy and Papageorgiou (2000), and Hanushek and Kimko (2000)).

The policy implications of distinguishing between the role of education as a factor of production and a factor that facilitates technology diffusion are significant. In the former, the benefit of an increase in education is its marginal product. In the latter, because the level of education affects the growth rate of total factor productivity and technology diffusion, its benefit will be measured in terms of the sum of its impact on all output levels in the future. Following Nelson and Phelps (1966), in Benhabib and Spiegel (1994) we characterize the latter relationship through a specification to explain growth that includes a term interacting the stock of human capital with backwardness, measured as a country's distance from the technology leader.

There are potentially important implications of distinguishing between different functional forms for the technology diffusion process. The technology diffusion process specified by Nelson and Phelps and widely used in the literature is known as the confined exponential diffusion [Banks (1994)]. An alternative diffusion process is the logistic model of technology diffusion. A priori, there appears to be no reason to favor one of these technology diffusion specifications over the other, and their specification appears to differ very little. Nevertheless, as we demonstrate below, these specifications can have very different implications for a nation's growth path: For the exponential diffusion process, the steady state is, for all parametrizations, a balanced growth path, with all followers growing at the pace determined by the leader nation that acts as the locomotive. In contrast, the logistic model allows for a dampening of the diffusion process so that the gap between the leader and a follower can keep growing. Indeed, we demonstrate that

if the human capital stock of a follower is sufficiently low, the logistic diffusion model implies divergence in total factor productivity growth rates, not catch-up. On this point, also see Howitt and Mayer-Foulkes (2002).

Below we derive an empirical specification that nests these two forms of technology diffusion in a model where total factor productivity growth depends on initial backwardness relative to the stock of potential world knowledge, proxied in our model as the total factor productivity level of the leader country. We then test this specification for a cross-section of total factor productivity growth of 84 countries from 1960 through 1995. We obtain robust results supporting a positive role for human capital as an engine of innovation, as well as a facilitator of catch-up in total factor productivity.

As our results favor a logistic form of technology diffusion, some countries may indeed experience divergence in total factor productivity growth. To investigate this result, we derive a point estimate from our estimation results for the minimum initial human capital level necessary to exhibit catch-up in total factor productivity relative to the leader nation, which is the United States in our sample. The point estimate in our favored specification indicates that an average of 1.78 years of schooling was required in 1960 to achieve convergence in total factor productivity growth with the United States.

Under this criterion, we identify 27 countries in our sample that our point estimates predict will exhibit slower total factor productivity growth than the United States. Our data shows that over the next 35 years, 22 of these 27 countries did indeed fall farther behind the United States in total factor productivity, while the remaining bulk of the nations in our sample exhibited positive catch-up in total factor productivity. While this result is not a formal test of our model, its ability to correctly identify countries that would subsequently exhibit slower total factor productivity growth than the United States is reassuring.

We then repeat our exercise using 1995 figures to identify the set of nations

that are still falling behind in total factor productivity growth. Because the United States had higher education levels in 1995, we estimate a higher threshold level for total factor productivity growth convergence with the United States. Our estimate was that 1.95 average years of schooling in the population over the age of 25 was necessary for faster total factor productivity growth than the leader nation. Fortunately, the higher overall education levels achieved by most countries over the past 35 years left few countries falling the threshold levels in education to achieve catch-up in growth rates. We identified only four countries as still below the threshold in 1995: Mali, Mozambique, Nepal, and Niger. With the exception of these four nations, our results indicate that most of the world is not in a permanent development trap, at least in terms of total factor productivity growth. Nevertheless, it should be pointed out that catch-up in total factor productivity is not a guarantee of convergence in per capita income, as nations must also be successful in attracting physical capital to achieve the latter goal.

The remainder of the paper is divided into five sections. Section 2 introduces the exponential and logistic specifications of the Nelson-Phelps model and examines their steady-state implications. Section 3 compares the diffusion models with that of Barro and Sala-i-Martin (1997). Section 4 derives a non-linear growth specification that nests the exponential and logistic technology diffusion functional forms. Section 5 estimates this model using maximum likelihood for a cross-section of countries. Section 6 uses the point estimates from our estimation to identify nations that are predicted to fail to exhibit divergence in total factor productivity growth in 1960 and 1995. Lastly, Section 7 concludes.

2. Variations on the Nelson-Phelps Model

We will examine the implications of two types processes often studied in the context of disaggregated models of technology diffusion (Banks (1994)). We can

express the original Nelson-Phelps model of technology diffusion as follows:

$$\frac{\dot{A}_i(t)}{A_i(t)} = g\left(H_i\left(t\right)\right) + c\left(H_i\left(t\right)\right)\left(\frac{A_m\left(t\right)}{A_i\left(t\right)} - 1\right) \tag{2.1}$$

where $A_i(t)$ is the TFP, $g_i\left(H_i\left(t\right)\right)$ is the component of TFP growth that depends on the level of education $H_i\left(t\right)$ in country i and $c\left(H_i\left(t\right)\right)\left(\frac{A_m(t)}{A_i(t)} - 1\right)$ represents the rate of technology diffusion from the leader country m to country i. We assume that $c_i\left(\cdot\right)$ and $g_i\left(\cdot\right)$ are increasing functions. The level of education $H_i\left(t\right)$ affects the rate at which the technology gap $\left(\frac{A_m(t)}{A_i(t)} - 1\right)$ is closed. If the ranking of $g_i\left(H_i\left(t\right)\right)$ across countries do not change, or if $H_i's$ are constant, a technology leader will emerge in finite time with $g_m = g\left(H_m\left(t\right)\right) > g\left(H_i\left(t\right)\right) = g_i$. After that the leader will grow at rate g_m and the followers will fall behind in levels of TFP until the point at which their growth rate will match the leader's growth rate g_m This can be seen from the solution of the above equation when H_i's are constant [1]:

$$A_i\left(t\right) = \left(A_i\left(0\right) - \Omega A_m\left(0\right)\right)e^{(g_i - c_i)t} + \Omega A_m\left(0\right)e^{g_m t} \tag{2.2}$$

where $c_i = c\left(H_i\right)$, $g_i = g\left(H_i\right)$ and

$$\Omega = \frac{c_i}{c_i - g_i + g_m} > 0.$$

It is clear, since $g_m > g_i$, that

$$\lim_{t\to\infty} \frac{A_i\left(t\right)}{A_m\left(t\right)} = \Omega$$

[1] The general solution when H_i's are not constant is given by:

$$A_i\left(t\right) = A_i\left(0\right)e^{-\int_0^t (g(H_i(s)) - c(H_i(s)))ds}$$
$$\cdot\left[1 + \frac{1}{A_i\left(0\right)}\left(\int_0^t c\left(H_i\left(\tau\right)\right)\left(A_m\left(0\right)e^{\int_0^\tau g(H_m(\zeta))d\zeta}\right)e^{\int_0^\tau (g(H_i(\xi)) - c(H_i(\xi)))d\xi}d\tau\right)\right]$$

This is, for all parametrizations, a world balanced growth path with the leader acting as the "locomotive." Technology diffusion and "catch-up" assures that despite scale effects and educational differences, all countries eventually grow at the same rate.[2]

The technology diffusion and catch-up processes outlined above are also known as the confined exponential diffusion process (see Banks(1994)) An alternative formulation that is similar in spirit is the logistic model of technology diffusion (see Sharif and Ramanthran (1981)). It is given by

$$\begin{aligned}\frac{\dot{A}_i(t)}{A_i(t)} &= g\left(H_i\left(t\right)\right) + c\left(H_i\left(t\right)\right)\left(1 - \frac{A_i\left(t\right)}{A_m\left(t\right)}\right) \\ &= g\left(H_i\left(t\right)\right) + c\left(H_i\left(t\right)\right)\left(\frac{A_i\left(t\right)}{A_m\left(t\right)}\right)\left(\frac{A_m\left(t\right)}{A_i\left(t\right)} - 1\right)\end{aligned} \tag{2.3}$$

The difference of the dynamics under the logistic model of technology diffusion and the confined exponential one is due to the presence of the extra term $\left(\frac{A_i(t)}{A_m(t)}\right)$. This term acts to dampen the rate rate of diffusion as the distance to the leader increases, reflecting perhaps the difficulty of adopting distant technologies. As shown by Basu and Weil (1998), the frontier technology may not be immediately "appropriate" for the follower if differences in factor proportions between leader and follower are large. We may observe convergence clubs, as documented by Durlauf and Johnson (1995), from which follower countries can break out only by investing in physical and human capital. Catch-up therefore may be slower when the leader is either too distant or too close, and is fastest at intermediate distances.[3]

If we assume, as before, that H_i's (and therefore, c_i's and g_i's) are constant

[2] Note however that in transition, the higher is initial $A_i\left(0\right)$, the smaller is the technology gap to the leader and therefore the slower is the growth. This negative dependence on initial conditions is similar to standard convergence results in the neoclassical growth model, but the logic of catch-up is different.

[3] An alternative view of technology adoption through diffusion that follows a logistic pattern

such that $H_m > H_i$, and therefore that $c(H_m) > c(H_i)$, then the solution to the logistic technology diffusion equation is given by [4][5][6]

$$A_i(t) = \frac{A_i(0)\, e^{(g_i+c_i)t}}{\left(1 + \frac{A_i(0)}{A_m(0)} \frac{c_i}{(c_i+g_i-g_m)} \left(e^{(c_i+g_i-g_m)t} - 1\right)\right)} > 0 \tag{2.4}$$

This equation can be written as

$$A_i(t) = \frac{A_m(0)\, e^{g_m t}}{\left(e^{-(c_i+g_i-g_m)t} \left(\frac{A_m(0)}{A_i(0)} - \frac{c_i}{(c_i+g_i-g_m)}\right) + \frac{c_i}{(c_i+g_i-g_m)}\right)} \tag{2.5}$$

so that in the limit,

$$\lim_{t\to\infty} \frac{A_i(t)}{A_m(t)} = \left\{ \begin{array}{ccc} \frac{(c_i+g_i-g_m)}{c_i} & & (c_i+g_i-g_m) > 0 \\ \frac{A_i(0)}{A_m(0)} & if & (c_i+g_i-g_m) = 0 \\ 0 & & (c_i+g_i-g_m) < 0 \end{array} \right\}. \tag{2.6}$$

Equation (2.6) implies that in the case of the logistic diffusion model, the steady state growth relationship will depend on the relative magnitude of the

borrows from epidemiology. The rate of adoption in a fixed population may depend on the rate of contact between adopters and hold-outs (those that are infected and those that are healthy). The adoption rate is highest when there are an equal number of both types, and lower when there is either a small or a large proportion of adopters. Also observing the successes and implementation errors of the first adopters, together with the competitive pressures that first adopters create, may result in a speeding up of adoption rates. See Mansfield (1968).

[4] Provided that $(c_i + g_i - g_m) \neq 0$. If $(c_i + g_i - g_m) = 0$, then the equation reduces to exponential form $A_i(t) = A_i(0)e^{(g_i+c_i)t}$.

[5] The general solution where H_i's are functions of time can be computed by defining $B_i = (A_i)^{-1}$ and transforming the logistic form into the confined exponential. After some computations, the general form can be obtained as

$$A_i(t) = \frac{A_i(0)\, e^{\int_0^t (g(H_i(s))+c(H_i(s)))ds}}{\left(1 + A_i(0)\left(\int_0^t c(H_i(\tau))\left(\left(A_m(0)^{-1}\right) e^{-\int_0^\tau g(H_m(\zeta))d\zeta}\right) e^{\int_0^\tau (g(H_i(\xi))+c(H_i(\xi)))d\xi} d\tau\right)\right)}$$

[6] $A_i(t) > 0$ because when $c_i + g_i - g_m \neq 0$, $\frac{c_i}{(c_i+g_i-g_m)}\left(e^{(c_i+g_i-g_m)t} - 1\right) > 0$.

catch-up rate and the difference in the growth rate due to innovation, $g_m - g_i$. If the catch-up rate exceeds the differential growth rate solely due to educational differences between the leader and follower, that is if $c(H_i) + g(H_i) - g(H_m) > 0$, then the leader will have a locomotive effect and pull the followers along. In such a case growth rates will converge. However, if the education level of a follower is so low that $c(H_i) + g(H_i) - g(H_m) < 0$, then the follower will not be able to keep up, growth rates will diverge, and the income ratio of the follower to the leader will go to zero.

This highlights the critical role of the type of technology diffusion process and its interaction with education in fostering economic growth: a country with a low level of education may still keep within the gravitational pull of the technology leader, provided that the level of education is high enough to permit sufficient diffusion. If technology diffusion is of the logistic type, countries with educational levels that are too low will get left behind and we may observe the phenomenon of "convergence clubs." Escaping from the lower "club" is nevertheless possible through investments in human capital, as discussed by Basu and Weil (1998) [7]. The implications of logistic versus exponential technology diffusion for economic growth can therefore be quite divergent.

Note that we can append the Nelson-Phelps framework, either in the logistic or the confined exponential form, to the Romer (1990) model by adding the catch-up term the research sector producing the blueprints A. The marginal product of H in the research sector will now reflect an effect from the catch-up term, and increase the allocation of H towards the research sector away from production or leisure. If, as in Romer, we assume that H is constant while knowledge, A, is accumulated, and also assume that goods use labor but not H, we may focus on the allocation of H to imitation through catch-up or to innovation. Adopting a

[7] We should note that $c(H_i)$ may also depend on barrers to innovation as in Parente and Prescott (1994), so that in fact we have $c(H_i, X)$, where X represents the level of barriers.

linear specification with $g(H_i) = gH_i$, $c(H_i) = cH_i$, the marginal product of H in innovation is given by $gA_i(t)$ while in imitation, for the confined exponential case, it is $cA_i(t)\left(\frac{A_m(t)}{A_i(t)} - 1\right)$. These marginal products are independent of H_i so we may have a bang-bang solution, with all of H_i allocated towards catch-up and imitation up to a threshold, and to innovation otherwise[8]. In what follows we will, for he time being, abstract from issues regarding the allocation of H_i, and assume that all of it enters both imitation and catch-up as a non-excludable public good.

3. Some Microfoundations based on the diffusion model of Barro and Sala-i-Martin

To set the stage first we express the confined exponential and logistic growth equations discussed above in stationary variables by defining

$$B(t) = \frac{A_i(t)}{A^*(0)} e^{-g_m t} \tag{3.1}$$

for all i. Then, for the logistic case, we have

$$\begin{aligned} \frac{\dot{B}}{B} &= c(H_i)(1 - B) + g(H_i) - g(H_m) \\ \dot{B} &= (c(H_i) + g(H_i) - g(H_m))B - c(H_i)B^2 \end{aligned} \tag{3.2}$$

If $H_i's$ are fixed the solution is,

$$B(t) = \left(\frac{c_i + g_i - g_m}{c_i}\right)\left[1 + \left(\left(\frac{c_i + g_i - g_m}{c_i}\right)\left(\frac{A^*(0)}{A(0)}\right) - 1\right)e^{-\left(\frac{c_i + g_i - g_m}{c_i}\right)t}\right]^{-1} \tag{3.3}$$

[8] A further consideration is the allocation of resources between imitative and innovatiove uses, where the efficient allocation changes as the distance to the technology frontier narrows. The market allocation may differ from the efficient allocation due to to a variety of factors, and policy interventions may improve welfare. See Acemoglu, Aghion and Zilibotti (2002).

So if $c_i + g_i - g_m > 0$,

$$\lim_{t\to\infty} B(t) = \left(\frac{c_i + g_i - g_m}{c_i}\right),$$

while if $c_i + g_i - g_m < 0$, $\lim_{t\to\infty} B(t) = 0$.[9] Note from equation (3.2) that in the latter case where $c_i + g_i - g_m < 0$, there is no steady state with $B > 0$.

In the confined exponential case

$$\begin{aligned}\frac{\dot{B}}{B} &= c(H_i)\left(B^{-1} - 1\right) + g(H_i) - g(H_m)\\ \dot{B} &= c(H_i) - \left(c(H_i) + g(H_m) - g(H_i)\right)B \qquad (3.4)\end{aligned}$$

Since $c(H_i) + g(H_m) - g(H_i) > 0$, it is clear from (3.4) that there exists a stable steady state at $B = \frac{c(H_i)}{c(H_i)+g(H_m)-g(H_i)}$.

In the Barro and Sala-i-Martin (1997) model, the North, where innovation is cheap, is the leader. It innovates by introducing new intermediate goods, and receives no diffusion through imitation from the South. As in a typical growth model of the Romer type, it grows at a constant rate γ.The South introduces new intermediate goods through imitation. In both countries the production of final goods is given by:

$$Y_i = A_i (L_i)^{1-\alpha} \sum_{j=1}^{N_i} (X_{ij})^{\alpha} \qquad i = 1, 2$$

where the North is country 1 and the South is country 2, so that $N_1 > N_2$. The profits of the $j'th$ intermediate goods producer is given by $\pi_{2j} = (P_{2j} - 1) X_{2j}$ where P_{2j} is the price of the intermediate good in terms of the final good in the South. The cost of imitation in the South is $v_2\left(\frac{N_2}{N_1}\right)$.In a symmetric equilibrium investment in R&D is given by

$$v_2 \dot{N}_2 = Y_2 - C_2 - N_2 X_2 \qquad (3.5)$$

[9] In the case $c_i + g_i - g_m > 0$, $B(t)$ should (if the assumption that $H_i's$ are constant holds) exhibit the S-shaped logistic diffusion.

where the LHS is the cost of introducing a new intermediate good through imitation, and the RHS is income minus consumption minus the cost of operating the existing intermediate goods (since $X_{i2} = X_2$ for all i). Barro and Sala-i-Martin show that in equilibrium X_2 and $\frac{Y_2}{N_2}$ are constants.[10], [11] For simplicity of exposition we will also assume a constant consumption propensity out of income, so that $C_2 = \mu (Y_2 - NX_2)$, so that

$$\frac{\dot{N}_2}{N_2} = \frac{1}{v_2}\left(\frac{Y_2}{N_2} - X_2\right)(1-\mu) \equiv \frac{1}{v_2}P$$

and

$$\frac{\dot{B}}{B} = \frac{1}{v_2}P - \gamma \tag{3.6}$$

where $B = \frac{N_2}{N_1}$.[12].

Barro and Sala-i-Martin assume that

$$v_2 = \eta\left(\frac{N_2}{N_1}\right)^{\sigma} \equiv \eta B^{\sigma}, \qquad \sigma > 0$$

Imitations costs are higher, the closer the follower is to the leader. We can now assume that η depends negatively on human capital, so that the cost of imitation declines with H. Introducing this specification into (3.6) we get

$$\dot{B} = \eta^{-1}B^{1-\sigma}P - \gamma B = B\left(\eta^{-1}PB^{-\sigma} - \gamma\right)$$

[10] In particular, $X_2 = L_2 (A_2)^{\frac{1}{1-\alpha}} (\alpha)^{\frac{2}{1-\alpha}}$ and $\frac{Y_2}{N_2} = (A_2)^{\frac{1}{1-\alpha}} \alpha^{\frac{2\alpha}{1-\alpha}} L_2$ where L_2 is, for simplicity, the constant the labor supply in the South.

[11] In BSM, consumption growth depends on the interest rate, which reflects the value of the stream of profits divided by the cost of imitation. Since the cost of imitation depends on N_2/N_1, the dynamic system is two-dimensional in N_2/N_1 and C_2/N_1. For details, see Barro and Sala-i-Martin (1997).

[12] To see that $Y_2 - N_2X_2$ corresponds to income note that in a symmetric equilibrium $\left(Y_2 - \int_0^{N_2} P_{2j}X_{2j}dj\right) + \int_0^{N_2} \pi_{2j}dj = Y_2 - N_2(P_2X_2 - \pi_2)$. Thus we must show that $P_2X_2 - \pi_2 = X_2$ where π_2 is profits. Since in equilibrium $\pi_2 = \left(\alpha^{-1} - 1\right)\left(\alpha^2 AL_2^{1-\alpha}\right)^{\frac{1}{1-\alpha}}$, $X_2 = L_2 (A_2)^{\frac{1}{1-\alpha}} (\alpha)^{\frac{2}{1-\alpha}}$ and $P_2 = \alpha^{-1}$, we have $P_2X_2 - \pi_2 = \alpha^{-1}\left(\alpha^2 AL_2^{1-\alpha}\right)^{\frac{1}{1-\alpha}} - \left(\alpha^{-1} - 1\right)\left(\alpha^2 AL_2^{1-\alpha}\right)^{\frac{1}{1-\alpha}} = \left(\alpha^2 AL_2^{1-\alpha}\right)^{\frac{1}{1-\alpha}} = X_2$

which has a stable steady state at $B = \left(\frac{\eta\gamma}{P}\right)^{-\frac{1}{\sigma}}$. Therefore this specification of imitation costs yields the same qualitative conclusions as the confined exponential diffusion used by Nelson and Phelps: the leader acts as the engine of growth pulling the followers along.

We now modify the imitation costs to correspond to the case of logistic technology diffusion. Let

$$v_2 = \eta (1 - B)^{-1}$$

where again v_2 is increasing in B. Now the diffusion equation becomes

$$\dot{B} = \eta^{-1} P (1 - B) B - \gamma B = (\eta^{-1} P - \gamma) B - \eta^{-1} P B^2 \tag{3.7}$$

which has the same logistic structure as (3.2). In particular, there is a positive steady state $B = \frac{\eta^{-1}P - \gamma}{\eta^{-1}P}$ only if $\eta^{-1}P > \gamma$ Otherwise B converges to 0, and there is no catch-up. More generally since the non-zero steady state is given by $v_2(B^*) = \frac{P}{\gamma}$, if $v_2(0) > \frac{P}{\gamma}$ there will not be a positive steady state $B^* > 0$, but the steady state $B = 0$ will be stable.[13,14]

If η is decreasing in H so that imitation costs decline with human capital, for sufficiently low levels of H we may have $\eta^{-1}P < \gamma$, and the South will never catch

[13] If on the other hand, we adopt the confined exponetial $\left(\nu_2(B) = \eta\left(B^{-1} - 1\right)\right)$ or the Barro and Sala-i Martin specification $(\nu_2(B) = \eta B^{\sigma})$, then $\nu_2(0) = 0$, so that the diffusion rate approaches infinity and the imitation costs go to zero when N_2 and B tend to zero, a strong and unlikely assumption.

[14] In Barro and Sala-i Martin's more general model consumption growth, given by the Euler equation, depends on the rate of return on intermediate goods, which varies through time with the distance to the frontier. At a steady state with $B > 0$, we obtain $\frac{C_2}{N_2} = \frac{(1+\alpha)}{\alpha}\pi_2 - \gamma v_2(B)$ where π_2 is the profit rate. Plugging this into (3.5) and simplifying, we get $v_2(B) = \frac{\pi_2}{(\theta\gamma+\rho)}$ where ρ is the discount rate and θ^{-1} is the intertemporal consumption elasticity. For the Barro and Sala-i Martin specification, $v_2(B) = \eta B^{\sigma},\ v_2(0) = 0$. If however $v_2(0) > \frac{\pi_2}{(\theta\gamma+\rho)}$, no positive steady state B exists. This is likely if v_2 also depends (inversely) on human capital and if human capital levels are low.

up in growth rates. In such circumstances there may be incentives to accumulate human capital. If however there are market imperfections in the accumulation of capital, or if H mostly provides external effects, there may not exist sufficient market incentives for the accumulation of H, so that subsidies to education may be necessary to improve growth and welfare.

4. A nested specification

We can also, for purposes of estimation, specify a diffusion process that nests the logistic and confined exponential diffusion processes. Using the definition of B given in (3.1), we can modify (3.2) as

$$\frac{\dot{B}}{B} = \frac{c(H_i)}{s}\left(1 - B^s\right) + g(H_i) - g(H_m) \tag{4.1}$$

$$\dot{B} = \left(\frac{c(H_i) + sg(H_i) - sg(H_m)}{s}\right) B - \frac{c(H_i)}{s} B^{s+1} \tag{4.2}$$

$$\dot{B} = \left(\frac{c(H_i) + sg(H_i) - sg(H_m)}{s}\right) B \left(1 - \left(\frac{B^s}{\left(1 + \frac{s(g_i - g_m)}{c_i}\right)}\right)\right) \tag{4.3}$$

with $s \in [-1, 1]$. Note that if $s = 1$, this specification collapses to the logistic, and if $s = -1$, it collapses to the confined exponential[15]. In its general form this is a Bernoulli equation, whose solution, when H_i and H_m are constants so that $c_i = c(H_i)$, $g_m = g(H_m)$, $g_i = g(H_i)$, is given by :

$$B(t) = \left(\frac{\left(1 + \frac{s(g_i - g_m)}{c_i}\right)}{\left(1 + \left(\left(1 + \frac{s(g_i - g_m)}{c_i}\right) B(0)^{-s}\right) - 1\right) e^{-(c_i + s(g_i - g_m))t}}\right)^{\frac{1}{s}} \tag{4.4}$$

[15] See Richards (1959).

Since the leader has more human capital, $H_m > H_i$, we have $g_m > g_i$. It follows that if either $c_i + s(g_i - g_m) > 0$,or if $s < 0$,

$$\lim_{t\to\infty} B(t) = \left(1 + \frac{s(g_i - g_m)}{c_i}\right)^{\frac{1}{s}},$$

while if $\left(1 + \frac{s(g_i-g_m)}{c_i}\right) < 0$, and $s > 0$, $\lim_{t\to\infty} B(t) = \lim_{t\to\infty} \frac{A_i(t)}{A_m(t)} = 0$ [16] In the latter case, as noted in the previous section, the South never catches up and growth rates diverge. [17]

To test this nested specification empirically we can specify it as:

$$\Delta a_{it} = \left(g + \frac{c}{s}\right) h_{it} - \frac{c}{s} h_{it} \left(\frac{A_{it}}{A_{mt}}\right)^{s}.$$

where Δa_{it} is the growth of TFP for country i, h_{it} is its initial or average human capital and $\left(\frac{A_{it}}{A_{mt}}\right)$is the ratio of the country′s TFP to that of the leader. Note

[16]If c_i and g_i vary with time because H_i changes with time, (4.1) is the classic Bernoulli equation which we can write as:

$$\dot{B} = f(t) B + g(t) B^{s+1}$$

where $f(t) = \frac{c(H_i(t))}{s} + g(H_i(t)) - g(H_m(t))$and $g(t) = -\frac{c(H_i(t))}{s}$ as in equation (4.2). The solution is:

$$B(t) = \left(Ce^{\phi(t)} + se^{\phi(t)} \int e^{\phi(\tau)} g(\tau)\, d\tau\right)^{-\frac{1}{s}}$$

where $\phi(t) = s\int f(\tau)\, d\tau$ and C is an integration constant such that $C^{-\frac{1}{s}} = B(0)$.

[17]When $s \to 0$, the diffusion process converges to the Gompertz growth model:

$$B = \lim_{s\to 0} \left(1 + \frac{s(g_i - g_m)}{c_i}\right)^{\frac{1}{s}} \exp\left(-e^{k-c_i t}\right) = \exp\left(\frac{(g_i - g_m)}{c_i}\right) \exp\left(-e^{k-c_i t}\right) \tag{4.5}$$

$$\dot{B} = c_i B\, \ell n \left(\frac{\exp\left(\frac{(g_i-g_m)}{c_i}\right)}{B}\right) \tag{4.6}$$

where $e^k = \left(\frac{(g_i-g_m)}{c_i}\right) - \ell n(B(0))$. So $\lim_{t\to\infty} B = \exp\left(\frac{(g_i-g_m)}{c_i}\right) > 0$. To see this note that, using LHopital's Rule, the right side of equation (4.3) collapses to $c_i B\, \ell n \left(\frac{\exp\left(\frac{(g_i-g_m)}{c_i}\right)}{B}\right)$.

again that this specification nests the logistic ($s = 1$) and exponential ($s = -1$) models. As discussed above, the values of c, g and s will determine whether a country will converge to the growth rate of the leader or whether the the growth rates will diverge. In particular, or our linear specification $c(h_{it}) = c_i = ch_{it}$, $g(h_{it}) = g_i = gh_{it}$ and $g(h_{mt}) = g_m = gh_{mt}$, "the catch-up condition" for the growth rate of a country to converge to the growth rate of the leader becomes (for $s \in (0, 1]$) :

$$c^* = 1 + \frac{c}{sg} > \frac{h_{mt}}{h_{it}} \tag{4.7}$$

Countries for which $\left(\frac{h_{mt}}{h_{it}}\right) > c^*$ will not converge to the leader's growth rate unless they invest in their human capital to reverse this inequality.[18]

5. Empirical Evidence

5.1. Measurement of Total Factor Productivity

Data for real income and population growth were obtained from the Penn World Tables, version 6.1.Data for human capital, which is proxied by average years of schooling in the population above 25 years of age, was obtained from the updated version of the Barro Lee (1993) data set. Our sample consists of 85 countries with data for the period 1960-1995. We estimate this sample both as a cross-section of 35 years of growth and as a panel of five-year growth rates.

Physical capital stocks were calculated according to the method used in Klenow and Rodriguez-Clare (1997). Initial capital stocks are calculated according to the

[18] As noted earlier however te catch-up coefficient $c(h_{it})$ may depend on other institutional factors in addition to human capital, like barriers to innovation as in Parente and Prescott (1994). In such a case we may want to modify the catch-up coefficient to $c_i = \alpha_i ch_{it}$ where α_i reflects country speific barriers to innovation.

following formula

$$\frac{K}{Y}_{1960} = \frac{I/Y}{\gamma + \delta + n} \tag{5.1}$$

where I/Y is the average share of physical investment in output from 1960 through 2000, γ represents the average rate of growth of output per capita over that period, n represents the average rate of population growth over that period, and δ represents the rate of depreciation, which is set equal to 0.03. Given initial capital stock estimates, the capital stock of country i in period t satisfies

$$K_{it} = \sum_{j=0}^{t} (1-\delta)^{t-j} I_{ij} + (1-\delta)^{t} K_{1960}. \tag{5.2}$$

Total factor productivity growth was estimated from a constant returns to scale Cobb-Douglas production function with the capital share set at 1/3 and the labor share set at 2/3.[19] For country i in period t

$$a_{it} = y_{it} - \frac{1}{3}k_{it} - \frac{2}{3}l_{it} \tag{5.3}$$

where a_{it} represents the long of total factor productivity, y_{it} represents the log of real output, k_{it} represents the log of the physical capital stock, and l_{it} represents the log of the population.

Total factor productivity estimates for 1960 and 1995, as well as estimates of average annual growth in total factor productivity over the period are shown in Table 1. The results seem pretty intuitive, as the Asian Tiger countries, including Taiwan, Singapore, Korea, Hong Kong and Thailand, lie notably at or near the top in terms of total factor productivity growth, while the five countries exhibiting the lowest growth in total factor productivity are Mozambique, Niger, Central African

[19] Gollin (2002) estimates that the share of labor lies between 0.65 and 0.80 for a cross-section of world economies. Keller (2002) estimated TFP with both the factor shares used above and the capital and labor shares set equal to one-half and obtained similar ordinal rankings of total factor productivity levels across countries.

Republic, Nicaragua, and Zambia. All of these countries experienced negative total factor productivity growth over the sample period, as did Mali, Senegal, Venezuela, Togo and Cameroon. Out of this group of ten negative total factor productivity growth countries, only Venezuela's appearance is surprising, and that can probably be attributed to its buildup of physical capital for oil production. In the case of the five highest total factor productivity growth countries, our results would no doubt differ slightly if our sample included the Asia crisis of 1997. Nevertheless, the set of countries exhibiting high total factor productivity growth seems intuitive as well.

A simple scatter plot of initial human capital levels and subsequent total factor productivity growth over the estimation period is shown in Figure 1. The raw correlation between these two variables is clearly positive, suggesting that nations with larger initial human capital stocks tend to exhibit higher total factor productivity growth holding all else constant. There are a number of interesting outliers. The Asian tiger nations are noteworthy as nations that exhibited fast total factor productivity growth and began the estimation period with relatively stocks of initial human capital.[20] On the other hand, there are a number of countries that exhibited total factor productivity declines that began the period with exceptionally low levels of initial human capital, including Mali, Niger, Togo, Mozambique, and the Central African Republic.

[20]It is unfortunate that our sample ends in 1995, because the Asian "tiger" nations suffered large declines in the 1997 crisis. However, we confirmed that total factor productivity growth of these nations was still exceptionally high for the Asian tiger nations for which longer 39 year data from 1960 to 1999 was available. This included all of the tigers except Singapore.

5.2. Model Specification

As discussed above, the following non-linear cross-sectional specification nests the exponential and logistic functional forms of technology diffusion

$$\Delta a_i = b + \left(g + \frac{c}{s}\right) h_i - \left(\frac{c}{s}\right) h_i \left(\frac{A_i}{A_m}\right)^s + \varepsilon_i \tag{5.4}$$

where Δa_i represents the average annual growth rate in TFP of country i, h_i represents the log of country $i's$ stock of human capital, A_i represents the level of country $i's$ stock of TFP, A_m represents the level of TFP of the leader nation, and ε_i is an i.i.d. disturbance term. The coefficients to be estimated represent b, $\left(g + \frac{c}{s}\right)$, -$\left(\frac{c}{s}\right)$, and s respectively.

We are agnostic as to whether it is appropriate to include the constant term b. This term could be interpreted as exogenous technological progress that is independent of human capital and technology diffusion. It is difficult to envision any type of technological progress that would be common across our sample and completely independent of the levels of national human capital. In the case where "accidental technological progress" truly does take place, it is far more likely that it would appear in our error term as it would be confined to specific nations within our sample. Nevertheless, we report our estimation results both without and with the constant terms included as a measure of their robustness.

Our model nests two alternative hypotheses. First, we have our Nelson-Phelps type model of technology diffusion, dependent on human capital and technological backwardness, that is of the confined exponential type. As we noted above, this model would correspond to the above specification with s equal -1. Second, we have our logistic specification for the technology diffusion process, which would correspond to s being equal to 1. We therefore estimate the above nested model to let the data determine the appropriate value of s.

Because our model is non-linear, we cannot use the differenced panel estimators for cross-country growth regressions that have become popular in the literature

[e.g. Caselli, Esquivel and Lefort (1996), Easterly, Loayza and Montiel (1997), and Benhabib and Spiegel (2000)]. Instead, we estimate the nested specification above in a cross-sectional sample of long-term growth using maximum likelihood. In order to minimize problems with endogeneity, we use initial values for human capital stocks and initial total factor productivity. As we are comparing these initial values to the nations' subsequent growth experiences over the next 35 years, endogeneity issues are unlikely to be a problem.

We also conduct a number of robustness checks. First, there is a concern about the quality of initial human capital values as a proxy of the human capital stock available over the estimation period. Recall that our specification implies that human capital is a measure of a nation's capacity to conduct innovation activity (accounted by the first term in the specification), and technology adoption from abroad (captured by the second term in the specification). However, many of the nations in our sample exhibited dramatic growth in their human capital stocks over this period, as measured by average years of schooling. A number of nations, including Nepal, Togo, Iran, Ghana, Syria, and the Central African Republic, actually had more than a five-fold increase in their average years of schooling in the population over the age of 25. This implies that the initial stocks of human capital in 1960 may poorly represent the stocks of human capital available to a nation later on in the sample period. We therefore also report results using average human capital levels over the estimation period.[21] However, this measure is likely to suffer more from endogeneity issues than initial human capital levels, as a nation's financial ability to increase the average human capital levels of its citizens is likely to be increasing in its rate of output and total factor productivity growth. Fortunately, as we demonstrate below, our results are fairly robust to either measure of the stock of human capital.

[21] Average human capital levels are calculated as the simple averages of beginning (1960) and ending (1995) human capital levels.

Second, since we are estimating a cross-section, we are unable to condition on country-specific fixed effects. In response, we further examine the robustness of our results to the introduction of a number of conditioning variables. Using data obtained from Sachs and Warner (1997), we introduce a number of geo-political characteristics, including a Sub-Saharan Africa dummy, a dummy for countries that are not landlocked, a dummy for tropical countries, a dummy for initial life expectancy, a dummy for ethnolinguistic fractionalization, and a dummy for openness over the estimation period.

5.3. Results

5.3.1. Base specification

Our results with initial stocks of human capital are shown in Table 2. Our base specification is reported in Model 1. It can be seen that the coefficient on human capital, which represents $(g + c/s)$ in the specification above, enters significantly with a positive coefficient in log levels at a 5 percent confidence level, consistent with the notion of human capital as a facilitator of own innovation predicted by the theory. The next term represents the coefficient on the catch-up term, -(c/s) in the above specification. This term enters as predicted with a negative and statistically significant sign at a five-percent confidence level. Finally, our point estimate of s is equal to 2.304. This number is not significantly different from 1, but is significantly greater than 0 at a ten percent confidence level. These results therefore favor the logistic specification, suggesting that there is some initial human capital level below which a country would fall farther and farther behind the leader national in total factor productivity over time. We investigate this possibility in more detail below.

One disappointing result in our base specification is that our point estimate for human capital lies below that of the catch-up term in absolute value. This implies

that our point estimate for g is negative, which is implausible. However, this point estimate is insignificantly different from 0 and does include positive values for any standard confidence level. Nevertheless, the negative point estimate does become a problem for our data exploration. In particular, using the negative point estimate for g precludes the existence of a positive critical human capital stock below which catch up in total factor productivity cannot occur.

As discussed above, the problem with the specification of Model 1 is that our theory does not call for for the a constant term independent of human capital to account for total factor productivity growth. Consequently, Model 2 repeats our base specification with the constant term excluded. It can be seen that our qualitative results are robust to the exclusion of a constant term. Human capital in log levels again enters significantly with a positive coefficient at a 5 percent confidence level, while the catch-up term is again significantly negative at a 5 percent confidence level, as predicted by the theory. Our point estimate of s is a little higher, at 3.164, but as before we cannot reject the hypothesis that s is equal to 1 at standard confidence levels, although we again reject the hypothesis that s is less than or equal to 0 at a 10 percent confidence level. Moreover, it can be seen that our point estimate for g is positive with this specification, allowing us to calculate a critical human capital stock below which catch-up in growth rates will not occur.

Models 3 and 4 repeat our estimation with and without a constant term, with s constrained to equal 1. This results in a linear specification and provides a robustness check of the coefficients obtained in our non-linear specification. It can be seen that our point and standard error estimates are very close to those obtained with s unconstrained. Both with and without a constant term, human capital enters significantly with a positive coefficient in log levels at a 5 percent confidence level. Moreover, the catch-up term coefficient is again negative and significant at a 5 percent confidence level, as predicted. These results suggest

that our findings are not dependent on the non-linear estimation of s to obtain coefficient estimates consistent with the notion of human capital playing a positive role in facilitating both innovation and catch-up.

5.3.2. Average human capital levels

Our first set of robustness checks repeats our estimation using average levels of human capital over the estimation period rather than initial human capital values.[22] As discussed above, we do this to address the concern some nations' stocks of human capital changed dramatically over the estimation period, and therefore that initial human capital values may be relatively noisy indicators of the average levels of human capital over the estimation period that determined their TFP growth .

The results incorporating this change are shown in Table 3. It can be seen that our qualitative results are fairly robust. Average human capital levels enter positively and significantly, as predicted, at a 5 percent confidence level, as do the coefficient estimates for the catch-up term. The magnitudes of these coefficients are similar to those obtained with initial human capital stocks, but they are both somewhat larger in absolute value. This increase is interesting because average measured human capital levels are larger than initial human capital levels, as all nations experienced some increase in average years of schooling over the estimation period.

Our estimates of s in Models 1 and 2 are very close to 1, which would again favor our logistic specification, but the large standard errors associated with our estimates of s leave it insignificantly different from 0 at standard confidence levels.

[22] Average stocks are estimated using simple averages of period beginning and ending values.

5.3.3. Conditioning on Country Characteristics

Because we are estimating a cross-section, we obviously are precluded from using panel estimators, such as country fixed and random effects, to control for differences in country characteristics outside of our theory that may independently influence total factor productivity growth. To account for these other possible influences, we introduce a number of conditioning variables into our specification from the Sachs and Warner (1997) data set.[23] The conditioning variables introduced are *Sub-Sahara,* a dummy indicating Sub-Saharan African nations, *Landlocked,* a dummy indicating a nation lacking navigable access to the sea, *Tropics,* a variable measuring the share of land area subject to a tropical climate, *Life,* the log of life expectancy at birth measured between 1965 and 1970, *Ethling,* a measure of ethno-linguistic fractionalization, and *Openness,* an indicator of the degree to which domestic policy favors free trade.

We first present our results with all of the conditioning variables included, and then sequentially drop the *Sub-Sahara* and *Openness* variables. Our results are shown in Table 4. Note that the inclusion of these conditioning variables reduces our sample size from 84 to 75 countries. Models 1 and 2 report our results for our base specifications with all of the conditioning variables included. It can be seen that human capital in log levels is not positive at a statistically significant level in either specification. This result is attributable more to a substantial increase in our standard error estimate rather than a change in the point estimate of the coefficient, which does not change much in value. On the other hand, it appears that the catch-up term is robust to the inclusion of these conditioning variables, as it enters significantly with a negative coefficient at a five percent confidence level, as predicted. Finally, our point estimates of s are still close to 1. We cannot reject that s is negative at standard confidence levels when our intercept

[23] See Sachs and Warner (1997) for original data sources.

term is included, but we can with it excluded (Model 2).[24]

Models 3 and 4 omit the *Sub-Sahara* dummy. It can be seen that human capital in log levels is still insignificant when the constant term is included, but is now significant at a 10 percent confidence level when the constant term is excluded. The catch-up term is still significantly negative at a 5 percent confidence level, as predicted. Our point estimates for s are still close to 1, with s entering significantly with a greater than zero coefficient at a 10 percent confidence level with and without the inclusion of a constant term.

Finally, Models 5 and 6 omit the *Openness* variable. Human capital in log levels is insignificant with the constant term included, but is positive and significant, as predicted, with the exclusion of the constant term at a 10 percent confidence level. The catch-up term is still significantly negative at a 5 percent confidence level, as predicted. Our point estimates for s are again close to 1, although s is insignificantly different from zero both with and without the inclusion of a constant term in our specification.

In summary, it appears that the catch-up term is strongly robust to the inclusion of the conditioning variables, while the estimates of s are still close to one, but of mixed significance. It would therefore be fair to characterize these coefficient estimates to be fairly robust to the inclusion of the conditioning variables.[25]

[24] To determine whether the differences here were attributable to the inclusion of the conditioning variables or the reduction in sample size, we estimated our models with the smaller 75 country sample reported here with the conditioning variables excluded. We obtained similar results to those in the larger sample. In particular, we obtained a positive and significant coefficient on human capital in log levels. This indicates that the differences in results reported here are attributable to the inclusion of the conditioning variables.

[25] To investigate the possibility that technological catch-up was facilitated by other variables than human capital, we substituted our *Life* and *Openness* conditioning variables for human capital in our base specification. The estimate for s was positive, but insignificant in all specifications. The coefficients on *Life,* both on their own and interacted with backwardness,

However, human capital in log levels was somewhat less robust. This result may not be surprising for a number of reasons: First, the conditioning variables, such as initial life expectancy and subsequent openness, are likely to be correlated with initial human capital levels. Indeed, initial life expectancy may be considered to be an alternative indicator of investment in human capital for many developing countries. Second, Benhabib and Spiegel (1994) found that initial human capital, which determines the rate of own-country innovation, was unimportant for a sub-sample of poorer developing countries. The introduction of our conditioning may have exposed the relatively weak role that innovation plays in total factor productivity growth for the poorer nations in our sample.[26]

---

were consistent with the theory and significant with the constant term included, but insigifnicant with it excluded. The coefficients on *Openness,* however, both on their own and interacted with backwardness, were very insignificant. As a whole, this exercise provided weak evidence of robustness for the logistic specification. Yet the imprecision of our measurements and the high correlation between country characteristic measures makes it difficult to evaluate the precise contribution of human capital relative to other potential institutuional characteristics that can facilitate catch-up. For example, the correlation coefficient between h_{i60} and $Life$ is 0.85. These results are available from the authors on request.

[26] We also examined the robustness of our results to splitting the sample with the conditioning variables included. We split the sample into OECD and non-OECD nations. Our coefficient values for both sub-samples were of the correct sign and significant. However, we also found that the point estimate of the innovation term was larger for the OECD sub-sample, while that for the catch-up term was larger in absolute value for the non-OECD sample. This supports our findings in Benhabib and Spiegel (1994) that innovation is more important for the developed countries, while catch-up is more important for the developing nations. These regression results are also available upon request from the authors.

6. Model Prediction

6.1. Model Forecasting

Given a nation's initial values of H_{i60} and $B_i(60)$, our transition equation 4.4 gives us a predicted value of B at the end of our sample in 1995. Figure 2 displays the predicted values of $B_i(95)$ conditional on H_{i60} and $B_i(60)$. One can see the logistic "s" form, consistent with a logistic model of technology diffusion, of our predicted values from our estimation above. Countries which have both low initial total factor productivity relative to the leader and low levels of human capital are in the low-growth portion of the plane: their predicted 1995 total factor productivity levels relative to the leader lie close to, or even below, their 1960 values. There is then a rapid acceleration in the middle range, tapering off as nations approach the total factor productivity levels of the leader.

We show both the actual realizations and the predictons of our model in Figure 3. Expected values of $B_i(95)$ for the nations in our sample based on equation 4.4 are plotted against their realized values in 1995. The model does a fairly good job of predicting relative future productivity levels. As a measure of our goodness of fit, we calculated the coefficient of determination of the model. The ratio of residual sum-of-squared errors to the variation in the sample was only, 0.115, which would correspond to an R-squared of 88.5 percent.

However, there does appear to be some systematic errors in our forrecasts. In particular, we seem to be systematically overestimating relative total factor productivity growth for the least backward, highest initial productivity countries like the Asian Tigers, so that the residuals for these countries are nearly all negative. This result, which suggests an even more prounced 's' curve, is puzzling, but appears to leave room for future refinements in our theory.

6.2. Negative Catch-up Countries

A more qualitative metric of the quality of fit of our model is how well it makes the discrete prediction of whether coutries will be on a positive catch-up path or not. The theory above suggests that below a certain threshold level of human capital, relative to the leader nation, a country could find its total factor productivity growth sufficiently slow that it would not exhibit convergence in total factor productivity, but would instead fall farther and farther behind the leader nation over time. In particular, we can re-write the "catch-up condition" in equation 4.7 as

$$H_{it}^{*} = \exp\left(\frac{sgh_{mt}}{sg+c}\right) \tag{6.1}$$

where h_{mt} represents the log of human capital in the leader nation at time t. Countries that find themselves with human capital stocks below H_{it}^{*} will experience total factor productivity growth at a slower pace than the leader country.

Table 5 shows the point estimates for g, c, and s based on our estimation results for models 1 through 4 in Tables 2 and 3. As we discussed above, we cannot calculate a critical human capital stock for Model 1 in Table 2 because of our negative point estimate for g. Consequently, we concentrate on the point estimates obtained in Model 2 of Table 2, where the specification excludes a constant term independent of human capital. As we show below, our estimates of the critical human capital stocks are similar for all of our models.

With the United States as our leader in total factor productivity, the point estimates obtained with Model 2 indicate that countries with average schooling in the population over the age of 25 below 1.78 years will display slower total factor productivity growth than the leader nation. We note that the critical human capital stocks were relatively insensitive to model specification or the use of initial or average human capital levels.

Similarly, we can also calculate the average years of schooling in the population needed to experience faster total factor productivity growth than the United States

in 1995. Because of the increase in average years of schooling in the United States, the point estimates for H^*_{i95} are uniformly larger than those for H^*_{i60}. Again using our point estimates from Model 2, we estimate the critical level of average years of schooling in the population to be 1.95. This increase in the threshold level of human capital is due to the fact that with a larger stock of human capital, the leader nation will be innovating at a faster pace. Consequently, other nations will need to exhibit a faster pace of catch-up to experience faster total factor productivity growth than the leader.

We use these estimated critical human capital stocks to conduct 2 explorations in the data. First, we can identify nations in our sample that would be predicted to exhibit slower growth in total factor productivity than the United States in 1960. This would include all nations with human capital levels in 1960 below 1.78 years of schooling. Our results are shown in Table 2. Based on our point estimates, we identify 27 nations as being below the critical human capital stock level in 1965. These nations are listed in Table 6, along with their average initial human capital stock levels.

The second column examines the growth performance of these nations over the subsequent 35 years in our sample. While it is not a formal test of our model, it is rather striking that 22 of the 27 nations predicted to exhibit slower total factor productivity growth than the United States actually did so over the course of our sample. This is markedly different than the overall sample share, where 49 of the 84 countries exhibited faster total factor productivity growth than the United States. Consequently, the subsequent performance of these nations appears to support the possibility of a logistic form of technology diffusion.

Our second data exploration concerns the question of whether there are any nations that are still below the critical human capital stock, so that they are expected to have slower total factor productivity growth than the United States in the future. We investigate this question using our 1995 data. As mentioned

above, the critical human capital stock using any model specification is estimated to have increased slightly between 1960 and 1995, from 1.78 average years of schooling to 1.95. Nevertheless, the good news is that because many developing nations have made substantial efforts to increase primary education rates in their populations, there are few countries who failed to meet this criterion in 1995.

The four nations that fell below the critical human capital level in 1995 are listed in Table 7. They are Mali, Niger, Mozambique and Nepal. While the success of the rest of the world in acquiring sufficient human capital to be on positive catch-up path in total factor productivity is reassuring, the situation faced by these four nations is still alarming. As shown in Table 7, none of these nations has a total factor productivity level exceeding 15 percent of that in the United States. In contrast, the average ratio of the total factor productivity of a nation in our sample to that of the United States is approximately 44 percent. Our model therefore predicts that these nations will remain notably poor in the absence some sort of policy intervention.

7. Conclusion

This paper generalizes the Nelson-Phelps catch-up model of technology diffusion facilitated by levels of human capital. We allow for the possibility that the pattern of technology diffusion is exponential. This specification predicts that nations will exhibit positive catch-up in growth rates. In contrast a logistic diffusion specification implies that a country with a sufficiently small capital stock may exhibit slower total factor productivity growth than the leader nation.We then derive a nonlinear specification for total factor productivity growth that nests these two specifications. We test this specification for a cross-section of 84 countries. Our results favor the logistic specification over the exponential, and other estimated parameters are consistent with our theoretical predictions. The

catch-up term in our specification is robust to a number of sensitivity checks, including the use of average rather than initial levels of human capital and the inclusion of a variety of geo-political conditioning variables commonly used in the literature. This supports the notion that human capital plays a positive role in the determination of total factor productivity growth rates through its influence on the rate of catch-up. However, the direct performance of the human capital term on its own is somewhat less robust.

Using the coefficient estimates from our parametric estimation, we then calculate the critical human capital stocks needed to achieve positive total factor productivity growth in 1960 and 1995. Our results identify 27 nations as falling below the critical human capital level in 1960, while only 4 nations remain below the critical human capital level in 1995.

The historic experiences of these nations support our theory well. 22 of the 27 nations predicted to have slower growth than the leader nation (the United States) actually did so over the subsequent 35 years. This contrasts markedly with the overall experience of the nations in our sample, where 49 of the 84 nations experienced faster total factor productivity growth than the leader nation.

ABSTRACT

This is an attempt to derive broad, strategic lessons from the diverse experience with economic growth in last fifty years. The paper revolves around two key arguments. One is that neoclassical economic analysis is a lot more flexible than its practitioners in the policy domain have generally given it credit. In particular, first-order economic principles—protection of property rights, market-based competition, appropriate incentives, sound money, and so on—do not map into unique policy packages. Reformers have substantial room for creatively packaging these principles into institutional designs that are sensitive to local opportunities and constraints. Successful countries are those that have used this room wisely. The second argument is that igniting economic growth and sustaining it are somewhat different enterprises. The former generally requires a limited range of (often unconventional) reforms that need not overly tax the institutional capacity of the economy. The latter challenge is in many ways harder, as it requires constructing over the longer term a sound institutional underpinning to endow the economy with resilience to shocks and maintain productive dynamism. Ignoring the distinction between these two tasks leaves reformers saddled with impossibly ambitious, undifferentiated, and impractical policy agendas.

GROWTH STRATEGIES

Dani Rodrik

"[A]s far as the LDCs are concerned, it is probably fair to say that at least a crude sort of 'justice' prevails in the economic policy realm. Countries that have run their economies following the policy tenets of the professionals have on the whole reaped good fruit from the effort; likewise, those that have flown in the face of these tenets have had to pay the price."

-- Arnold C. Harberger (1985, p. 42)

"When you get right down to business, there aren't too many policies that we can say with certainty deeply and positively affect growth."

-- Arnold C. Harberger (2003, p. 215)

I. Introduction

Real per-capita income in the developing world grew at an average rate of 2.3 percent per annum during the four decades between 1960 and 2000.[1] This is a high growth rate by almost any standard. At this pace incomes double every 30 years, allowing each generation to enjoy a level of living standards that is twice as high as the previous generation's. To provide some historical perspective on this performance, it is worth noting that Britain's per-capita GDP grew at a mere 1.3 percent per annum during its period of economic supremacy in the middle of the 19th century (1820-1870) and that the United States grew at only 1.8 percent during the half century before World War I when it overtook Britain as the world's economic leader (Maddison 2001, Table B-22, 265). Moreover, with few exceptions, economic growth in the last few decades has been accompanied by significant improvements in social indicators such as literacy, infant mortality, life expectation, and the like. So on balance the recent growth record looks quite impressive.

However, since the rich countries themselves grew at a very rapid clip of 2.7 percent during the period 1960-2000, few developing countries consistently managed to

[1] This figure refers to the exponential growth rate of GDP per capita (in constant 1995 US$) for the group of low- and middle-income countries. The data come from the World Development Indicators 2002 CD-ROM of the Word Bank.

close the economic gap between them and the advanced nations. As Figure 1 indicates, the countries of East and Southeast Asia constitute the sole exception. Excluding China, this region experienced per-capita GDP growth of 4.4 percent over 1960-2000. Despite the Asian financial crisis of 1997-98 (which shows as a slight dip in Figure 1), countries such as South Korea, Thailand and Malaysia ended the century with productivity levels that stood significantly closer to those enjoyed in the advanced countries.

<Figure 1 here>

Elsewhere, the pattern of economic performance has varied greatly across different time periods. China has been a major success story since the late 1970s, experiencing a stupendous growth rate of 8.0 percent (as compared to 2.0 percent in 1960-80). Less spectacularly, India has roughly doubled its growth rate since the early 1980s, pulling South Asia's growth rate up to 3.3 percent in 1980-2000 from 1.2 percent in 1960-1980. The experience in other parts of the world was the mirror image of these Asian growth take-offs. Latin America and Sub-Saharan Africa both experienced robust economic growth prior to the late 1970s and early 1980s—2.9 percent and 2.3 percent respectively—but then lost ground subsequently in dramatic fashion. Latin America's growth rate collapsed in the "lost decade" of the 1980s, and has remained anemic despite some recovery in the 1990s. Africa's economic decline, which began in the second half of the 1970s, continued throughout much of the 1990s and has been aggravated by the onset of HIV/AIDS and other public-health challenges. Measures of total factor productivity run parallel to these trends in per-capita output (see Table 1).

Hence the aggregate picture hides tremendous variety in growth performance, both geographically and temporally. We have high growth countries and low growth countries; countries that have grown rapidly throughout, and countries that have experienced growth spurts for a decade or two; countries that took off around 1980 and countries whose growth collapsed around 1980.

This paper is devoted to the question: what do we learn about *growth strategies* from this rich and diverse experience? By "growth strategies" I refer to economic policies and institutional arrangements aimed at achieving economic convergence with the living standards prevailing in advanced countries. My emphasis will be less on the relationship between specific policies and economic growth—the stock-in-trade of cross-national growth empirics—and more on developing a broad understanding of the contours of successful strategies. Hence my account harks back to an earlier generation of studies that distilled operational lessons from the observed growth experience, such as Albert Hirschman's *The Strategy of Economic Development* (1958), Alexander Gerschenkron's *Economic Backwardness in Historical Perspective* (1962) or Walt Rostow's *The Stages of Economic Growth* (1965). This paper follows an unashamedly inductive approach in this tradition.

A key theme in these works, as well as in the present paper, is that growth-promoting policies tend to be context specific. We are able to make only a limited number of generalizations on the effects on growth, say, of liberalizing the trade regime,

opening up the financial system, or building more schools. The experience of the last two decades has frustrated the expectations of policy advisers who thought we had a good fix on the policies that promote growth—see the shift in mood that is reflected in the two quotes from Harberger that open this paper. And despite a voluminous literature, cross-national growth regressions ultimately do not provide us with much reliable and unambiguous evidence on such operational matters.[2] An alternative approach, and the one I adopt here, is to shift our focus to a higher level of generality and to examine the broad design principles of successful growth strategies. This entails zooming away from the individual building blocks and concentrating on how they are put together.

The paper revolves around two key arguments. One is that neoclassical economic analysis is a lot more flexible than its practitioners in the policy domain have generally given it credit. In particular, first-order economic principles—protection of property rights, contract enforcement, market-based competition, appropriate incentives, sound money, debt sustainability—do not map into unique policy packages. Good institutions are those that deliver these first-order principles effectively. There is no unique correspondence between the functions that good institutions perform and the form that such institutions take. Reformers have substantial room for creatively packaging these principles into institutional designs that are sensitive to local constraints and take advantage of local opportunities. Successful countries are those that have used this room wisely.

The second argument is that igniting economic growth and sustaining it are somewhat different enterprises. The former generally requires a limited range of (often unconventional) reforms that need not overly tax the institutional capacity of the economy. The latter challenge is in many ways harder, as it requires constructing a sound institutional underpinning to maintain productive dynamism and endow the economy with resilience to shocks over the longer term. Ignoring the distinction between these two tasks leaves reformers saddled with impossibly ambitious, undifferentiated, and impractical policy agendas.

The plan for the paper is as follows. The next section sets the stage by evaluating the standard recipes for economic growth in light of recent economic performance. Section III develops the argument that sound economic principles do not map into unique institutional arrangements and reform strategies. Section IV re-interprets recent growth experience using the conceptual framework of the previous section. Section V discusses a two-pronged growth strategy that differentiates between the challenges of igniting growth and the challenges of sustaining it. Concluding remarks are presented in section VI.

II. What we know that (possibly) ain't so

[2] Easterly (2003) provides a good overview of these studies. See also Temple (1999), Brock and Durlauf (2001), and Rodriguez and Rodrik (2001).

Development policy has always been subject to fads and fashions. During the 1950s and 1960s, "big push," planning, and import-substitution were the rallying cries of economic reformers in poor nations. These ideas lost ground during the 1970s to more market-oriented views that emphasized the role of the price system and outward-orientation.[3] By the late 1980s a remarkable convergence of views had developed around a set of policy principles that John Williamson (1990) infelicitously termed the "Washington Consensus." These principles remain at the heart of today's conventional understanding of a desirable policy framework for economic growth, even though they have been greatly embellished and expanded in the years since.

The left panel in Table 2 shows Williamson's original list, which focused on fiscal discipline, "competitive" currencies, trade and financial liberalization, privatization and deregulation. These were perceived to be the key elements of what Krugman (1995, 29) has called the "Victorian virtue in economic policy," namely "free markets and sound money". Towards the end of the 1990s, this list was augmented in the thinking of multilateral agencies and policy economists with a series of so-called second-generation reforms that were more institutional in nature and targeted at problems of "good governance." A complete inventory of these Washington Consensus-plus reforms would take too much space, and in any case the precise listing differs from source to source.[4] I have shown a representative sample of ten items (to preserve the symmetry with the original Washington Consensus) in the right panel of Table 2. They range from anti-corruption and corporate governance to social safety nets and targeted anti-poverty programs.

The perceived need for second-generation reforms arose from a combination of sources. First, there was growing recognition that market-oriented policies may be inadequate without more serious institutional transformation, in areas ranging from the bureaucracy to labor markets. For example, trade liberalization may not reallocate an economy's resources appropriately if the labor markets are "rigid" or insufficiently "flexible." Second, there was a concern that financial liberalization may lead to crises and excessive volatility in the absence of a more carefully delineated macroeconomic framework and improved prudential regulation. Hence the focus on non-intermediate exchange-rate regimes, central bank independence, and adherence to international financial codes and standards. Finally, in response to the complaint that the Washington Consensus represented a trickle-down approach to poverty, the policy framework was augmented with social policies and anti-poverty programs.

It is probably fair to say that a listing along the lines of Table 2 captures in broad brushstrokes mainstream thinking about the key elements of a growth program *circa* 2000. How does such a list fare when held against the light of contemporary growth

[3] Easterly (2001) provides an insightful and entertaining account of the evolution of thinking on economic development. See also Lindauer and Pritchett (2002) and Krueger (1997).

[4] For diverse perspectives on what the list should contain, see Stiglitz (1998), World Bank (1998), Naim (1999), Birdsall and de la Torre (2001), Kaufmann (2002), Ocampo (2002), and Kuczynski and Williamson (2003).

experience? Imagine that we gave Table 2 to an intelligent Martian and asked him to match the growth record displayed in Figure 1 and Table 1 with the expectations that the list generates. How successful would he be in identifying which of the regions adopted the standard policy agenda and which did not?

Consider first the high performing East Asian countries. Since this region is the only one that has done consistently well since the early 1960s, the Martian would reasonably guess that there is a high degree of correspondence between its policies and the list in Table 2. But he would be at best half-right. South Korea's and Taiwan's growth policies, to take two important illustrations, exhibit significant departures from the Washington Consensus. Neither country undertook significant deregulation or liberalization of their trade and financial systems well into the 1980s. Far from privatizing, they both relied heavily on public enterprises. South Korea did not even welcome direct foreign investment. And both countries deployed an extensive set of industrial policies that took the form of directed credit, trade protection, export subsidization, tax incentives, and other non-uniform interventions. Using the minimal scorecard of the original Washington Consensus (left panel of Table 2), the Martian would award South Korea a grade of 5 (out of 10) and Taiwan perhaps a 6 (Rodrik 1996).

The gap between the East Asian "model" and the more demanding institutional requirements shown on the right panel of Table 2 is, if anything, even larger. I provide a schematic comparison between the standard "ideal" and the East Asian reality in Table 3 for a number of different institutional domains such as corporate governance, financial markets, business-government relationships, and public ownership. Looking at this, the Martian might well conclude that South Korea, Taiwan, and (before them) Japan stood little chance to develop. Indeed, such were the East Asian anomalies that when the Asian financial crisis of 1997-98 struck, many observers attributed the crisis to the moral hazard, "cronyism," and other problems created by East Asian-style institutions (see MacLean 1999, Frankel 2000).

The Martian would also be led astray by China's boom since the late 1970s and by India's less phenomenal, but still significant growth pickup since the early 1980s. While both of these countries have transformed their attitudes towards markets and private enterprise during this period, their policy frameworks bear very little resemblance to what is described in Table 2. India deregulated its policy regime slowly and undertook very little privatization. Its trade regime remained heavily restricted late into the 1990s. China did not even adopt a private property rights regime and it merely appended a market system to the scaffolding of a planned economy (as discussed further below). It is hardly an exaggeration to say that had the Chinese economy stagnated in the last couple of decades, the Martian would be in a better position to rationalize it using the policy guidance provided in Table 2 than he is to explain China's actual performance.[5]

[5] Vietnam, a less well known case than China, has many of the same characteristics: rapid growth since the late 1980s as a result of heterodox reform. Vietnam has benefited from a gradual turn toward markets and greater reliance on private entrepreneurship, but as Van Arkadie and Mallon (2003) argue, it is hard to square the extensive role of the state and the nature of the property rights regime with the tenets of the Washington Consensus.

The Martian would be puzzled that the region that made the most determined attempt at remaking itself in the image of Table 2, namely Latin America, has reaped so little growth benefit out of it. Countries such as Mexico, Argentina, Brazil, Colombia, Bolivia, and Peru did more liberalization, deregulation and privatization in the course of a few years than East Asian countries have done in four decades. Figure 2 shows an index of structural reform for these and other Latin American countries, taken from Lora (2001a). The index measures on a scale from 0 to 1 the extent of trade and financial liberalization, tax reform, privatization, and labor-market reform undertaken. The regional average for the index rises steadily from 0.34 in 1985 to 0.58 in 1999. Yet the striking fact from Figure 1 is that Latin America's growth rate has remained significantly below its pre-1980 level. The Martian would be at a loss to explain why growth is now lower given that the quality of Latin America's policies, as judged by the list in Table 2, has improved so much.[6] A similar puzzle, perhaps of a smaller magnitude, arises with respect to Africa, where economic decline persists despite an overall (if less marked) "improvement" in the policy environment.[7]

<Figure 2 here>

The Martian would recognize that the growth record is consistent with some of the *higher-order* economic principles that inspire the standard policy consensus. A semblance of property rights, sound money, fiscal solvency, market-oriented incentives—these are elements that are common to all successful growth strategies.[8] Where they have been lacking, economic performance has been lackluster at best. But the Martian would also have to conclude that the mapping from our more detailed policy preferences (such

---

[6] Lora (2001b) finds that structural reforms captured by this index do correlate with growth rates in the predicted manner, but that the impacts (taking the decade of the 1990s as a whole) are not that strong. Another econometric study by Loayza et al. (2002) claims that Latin America's reforms added significantly to the region's growth. However the latter paper uses outcome variables such as trade/GDP and financial depth ratios as its indicators of "policy," and therefore is unable to link economic performance directly to the reforms themselves. Lin and Liu (2003) attribute the failure of the Washington Consensus to the non-viability of enterprises created under the previous "distorted" policy regime and the political impossibility of letting these go bust.

[7] See also Milanovic (2003) for a closely related Martian thought experiment. Milanovic emphasizes that economic growth has declined in most countries despite greater globalization.

[8] Here is how Larry Summers (2003) summarizes the recent growth evidence: "[The] rate at which countries grow is substantially determined by three things: their ability to integrate with the global economy through trade and investment; their capacity to maintain sustainable government finances and sound money; and their ability to put in place an institutional environment in which contracts can be enforced and property rights can be established. I would challenge anyone to identify a country that has done all three of these things and has not grown at a substantial rate." Note how these recommendations are couched not in terms of specific policies (maintain tariffs below *x* percent, raise the government primary surplus above *y* percent, privatize state enterprises, and so on), but in terms of "abilities" and "capacities" to get certain outcomes accomplished. I will suggest below that these "abilities" and "capacities" do not map neatly into the standard policy preferences, and can be generated in a variety of ways.

as those in Table 2) to economic success is quite imperfect. He would wonder if we cannot do better.

III. The indeterminate mapping from economic principles to institutional arrangements

Here is another thought experiment. Imagine a Western economist was invited to Beijing in 1978 in order to advise the Chinese leadership on a reform strategy. What would she recommend and why?

The economist would recognize that reform must start in the rural areas since the vast majority of the poor live there. An immediate recommendation would be the *liberalization of agricultural markets* and the *abolition of the state order system* under which peasants had to make obligatory deliveries of crops at low, state-controlled prices. But since price liberalization alone would be inadequate to generate the appropriate supply incentives under a system of communal land ownership, the economist would also recommend the *privatization of land.* Next, the economist would have to turn her attention to the broader implications of price liberalization in agriculture. Without access to cheap grains, the state would be left without a source of implicit tax revenue, so *tax reform* must be on the agenda as well. And in view of the rise of food prices, there must be a way to respond to urban workers' demand for higher wages. State enterprises in urban areas must be *corporatized*, so that their managers are in a position to adjust their wages and prices appropriately.

But now there are other problems that need attention. In an essentially closed and non-competitive economy, price-setting autonomy for the state behemoths entails the exercise of monopoly power. So the economist would likely recommend *trade liberalization* in order to "import" price discipline from abroad. Openness to trade in turn calls for other complementary reforms. There must be *financial sector reform* so that financial intermediaries are able to assist domestic enterprises in the inevitable adjustments that are called forth. And of course there must be *social safety nets* in place so that those workers who are temporarily displaced have some income support during the transition.

The story can be embellished by adding other required reforms, but the message ought to be clear. By the time the Western economist is done, the reform agenda she has formulated looks very similar to the Washington Consensus (see Table 4). The economist's reasoning is utterly plausible, which underscores the point that the Washington Consensus is far from silly: it is the result of systematic thinking about the multiple, often complementary reforms needed to establish property rights, put market incentives to work, and maintain macroeconomic stability. But while this particular reform program represents a logically consistent way achieving these end goals, it is not the only one that has the potential of doing so. In fact, in view of the administrative and political constraints that such an ambitious agenda is likely to encounter, it is not implausible that there would be better ways of getting there.

How can we be sure of this? We know this because China took a very different approach to reform—one that was experimental in nature and relied on a series of institutional innovations that departed significantly from Western norms. What is important to realize about these innovations is that in the end they delivered—for a period of a couple of decades at least—the very same goals that the Western economist would have been hoping for: market-oriented incentives, property rights, macroeconomic stability. But they did so in a peculiar fashion that, given the Chinese historical and political context, had numerous advantages.

For example, the Chinese authorities liberalized agriculture only *at the margin* while keeping the plan system intact. Farmers were allowed to sell surplus crops freely at a market-determined price only after they had fulfilled their obligations to the state under the state order system. As Lau, Qian, and Roland (2000) explain, this was an ingenious system that generated efficiency without creating any losers. In particular, it was a shortcut that neatly solved a conundrum inherent in wholesale liberalization: how to provide microeconomic incentives to producers while insulating the central government from the fiscal consequences of liberalization. As long as state quotas were set below the fully liberalized market outcome (so that transactions were conducted at market prices at the margin) and were not ratcheted up (so that producers did not have to worry about the quotas creeping up as a result of marketed surplus), China's dual-track reform in effect achieved full allocative efficiency. But it entailed a different infra-marginal distribution—one that preserved the income streams of initial claimants. The dual track approach was eventually employed in other areas as well, such as industrial goods (e.g. coal and steel) and labor markets (employment contracts). Lau et al. (2000) argue that the system was critical to achieve political support for the reform process, maintain its momentum, and minimize adverse social implications.

Another important illustration comes from the area of property rights. Rather than privatize land and industrial assets, the Chinese government implemented novel institutional arrangements such as the Household Responsibility System (under which land was "assigned" to individual households according to their size) and Township and Village Enterprises (TVEs). The TVEs were the growth engine of China until the mid-1990s (Qian 2003), with their share in industrial value added rising to more than 50 percent by the early 1990s (Lin et al. 1996, 180), so they deserve special comment. Formal ownership rights in TVEs were vested not in private hands or in the central government, but in local communities (townships or villages). Local governments were keen to ensure the prosperity of these enterprises as their equity stake generated revenues directly for them. Qian (2003) argues that in the environment characteristic of China, property rights were effectively more secure under direct local government ownership than they would have been under a private property-rights legal regime. The efficiency loss incurred due to the absence of private control rights was probably outweighed by the implicit security guaranteed by local government control. It is difficult to explain otherwise the remarkable boom in investment and entrepreneurship generated by such enterprises.

Qian (2003) discusses other examples of "transitional institutions" China employed to fuel economic growth—fiscal contracts between central and local governments, anonymous banking—and one may expand his list by including arrangements such as Special Economic Zones. The main points to take from this experience are the following. First, China relied on highly unusual, non-standard institutions. Second, these unorthodox institutions worked precisely because they produced orthodox results, namely market-oriented incentives, property rights, macroeconomic stability, and so on. Third, it is hard to argue, in view of China's stupendous growth, that a more standard, "best-practice" set of institutional arrangements would have necessarily done better.

The Chinese experience helps lay out the issues clearly because its institutional innovations and growth performance are both so stark. But China's experience with non-standard growth policies is hardly unusual; in fact it is more the rule than the exception. The (other) East Asian anomalies noted previously (Table 3) can be viewed as part of the same pattern: non-standard practices in the service of sound economic principles. I summarize a few non-Chinese illustrations in Table 5.

Consider for example the case of financial controls. I noted earlier that few of the successful East Asian countries undertook much financial liberalization early on in their development process. Interest rates remained controlled below market-clearing levels and competitive entry (by domestic or foreign financial intermediaries) was typically blocked. It is easy to construct arguments as to why this was beneficial from an economic standpoint. Table 5 summarizes the story laid out by Hellman, Morduck, and Stiglitz (1997), who coin the term "financial restraint" for the Asian model. Where asymmetric information prevails and the level of savings is sub-optimal, Hellman et al. argue that creating a moderate amount of rents for incumbent banks can generate useful incentives. These rents induce banks to do a better job of monitoring their borrowers (since there is more at stake) and to expand effort to mobilize deposits (since there are rents to be earned on them). The quality and level of financial intermediation can both be higher than under financial liberalization. These beneficial effects are more likely to materialize when the pre-existing institutional landscape has certain properties—for example when the state is not "captured" by private interests and the external capital account is restricted (see last two columns of Table 5). When these preconditions are in place, the economic logic behind financial restraint is compelling.

The second illustration in Table 5 comes from South Korea's and Taiwan's experiences with industrial policy. The governments in these countries rejected the standard advice that they take an arms' length approach to their enterprises and actively sought to coordinate private investments in targeted sectors. Once again, it is easy to come up with economic models that provide justification for this approach. In Rodrik (1995), I argued that the joint presence of scale economies and inter-industry linkages can depress the private return to investment in non-traditional activities below the social return. Industrial policy can be viewed as a "coordination device" to stimulate socially profitable investments. In particular, the socialization of investment risk through implicit bailout guarantees may be economically beneficial despite the obvious moral hazard risk

it poses. However, once again, there are certain prerequisites and institutional complements that have to be in place for this approach to make sense (see Table 5).

The third illustration in Table 5 refers to Japan and concerns the internal organization of the workplace, drawing on Aoki's (1997) work. Aoki describes the peculiar institutional foundations of Japan's postwar success as having evolved from a set of arrangements originally designed for wartime mobilization and centralized control of resources. He presents Japan's team-centered approach to work organization and its redistribution of economic resources from advanced to backward sectors—arrangements that he terms "horizontal hierarchy" and "bureau-pluralism," respectively—as solutions to particular informational and distributive dilemmas the Japanese economy faced in the aftermath of World War II. Unlike the previous authors, however, he views this fit between institutions and economic challenges as having been unintended and serendipitous.

Lest the reader think this is solely an East Asian phenomenon, an interesting example of institutional innovation comes from Mauritius (Rodrik 1999). Mauritius owes a large part of its success to the creation in 1970 of an export-processing zone (EPZ), which enabled an export boom in garments to European markets. Yet, instead of liberalizing its trade regime across the board, Mauritius combined this EPZ with a domestic sector that was highly protected until the mid-1980s, a legacy of the policies of import-substituting industrialization (ISI) followed during the 1960s. The industrialist class that had been created with these policies was naturally opposed to the opening up of the trade regime. The EPZ scheme provided a neat way around this difficulty (Wellisz and Saw 1993). The creation of the EPZ generated new profit opportunities, without taking protection away from the import-substituting groups. The segmentation of labor markets was particularly crucial in this regard, as it prevented the expansion of the EPZ (which employed mainly female labor) from driving wages up in the rest of the economy, and thereby disadvantaging import-substituting industries. New profit opportunities were created at the margin, while leaving old opportunities undisturbed. At a conceptual level, the story here is essentially very similar to the two-track reforms in China described earlier. To produce the results it did, however, the EPZ also needed a source of investible funds, export-oriented expertise, and market access abroad, which were in turn provided by a terms-of-trade boom, entrepreneurs from Hong Kong, and preferential market access in Europe, respectively (Rodrik 1999; Subramanian and Roy 2003).

In reviewing cases such as these, there is always the danger of reading too much into them after the fact. In particular, we need to avoid several fallacies. First, we cannot simply assume that institutions take the form that they do <u>because</u> of the functions that they perform (the functionalist fallacy). Aoki's account of Japan is a particularly useful reminder that a good fit between form and function might be the unintended consequence of historical forces. Second, it is not correct to ascribe the positive outcomes in the cases just reviewed only to their anomalies (the ex-post rationalization fallacy). Many accounts of East Asian success emphasize the standard elements--fiscal conservatism, investment in human resources, and export orientation (see for example World Bank 1993). As I will discuss below, East Asian institutional anomalies have often produced perverse

results when employed in other settings. And it is surely not the case that all anomalies are economically functional.

The main point I take from these illustrations is robust to these fallacies, and has to do with the "plasticity" of the institutional structure that neoclassical economics is capable of supporting. All of the above institutional anomalies are compatible with, and can be understood in terms of, neoclassical economic reasoning ("good economics"). Neoclassical economic analysis does not determine the form that institutional arrangements should or do take. What China's case and other examples discussed above demonstrate is that the higher-order principles of sound economic management do not map into unique institutional arrangements.

In fact, principles such as appropriate incentives, property rights, sound money, and fiscal solvency all come institution-free. We need to operationalize them through a set of policy actions. The experiences above show us that there may be multiple ways of packing these principles into institutional arrangements. Different packages have different costs and benefits depending on prevailing political constraints, levels of administrative competence, and market failures. The pre-existing institutional landscape will typically offer both constraints and opportunities, requiring creative shortcuts or bold experiments. From this perspective, the "art" of reform consists of selecting appropriately from a potentially infinite menu of institutional designs.

A direct corollary of this line of argument is that there is only a weak correspondence between the higher-order principles of neoclassical economics and the specific policy recommendations in the standard list (as enumerated in Table 2). To see this, consider for example one of the least contentious recommendations in the list, having to do with trade liberalization. Can the statement "trade liberalization is good for economic performance" be derived from first principles of neoclassical economics? Yes, but only if a number of side conditions are met:

- The liberalization must be complete or else the reduction in import restrictions must take into account the potentially quite complicated structure of substitutability and complementarity across restricted commodities.[9]
- There must be no microeconomic market imperfections other than the trade restrictions in question, or if there are some, the second-best interactions that are entailed must not be adverse.[10]

[9] There is a large theoretical literature on partial trade reform, which shows the difficulty of obtaining unambiguous characterizations of the welfare effects of incomplete liberalization. See Hatta (1977), Anderson and Neary (1992), and Lopez and Panagariya (1993). For an applied general equilibrium analysis of how these issues can complicate trade reform in practice, see Harrison, Rutherford, and Tarr (1993).

[10] For an interesting empirical illustration on how trade liberalization can interact adversely with environmental externalities, see Lopez (1997).

- The home economy must be "small" in world markets, or else the liberalization must not put the economy on the wrong side of the "optimum tariff."[11]
- The economy must be in reasonably full employment, or if not, the monetary and fiscal authorities must have effective tools of demand management at their disposal.
- The income redistributive effects of the liberalization should not be judged undesirable by society at large, or if they are, there must be compensatory tax-transfer schemes with low enough excess burden.[12]
- There must be no adverse effects on the fiscal balance, or if there are, there must be alternative and expedient ways of making up for the lost fiscal revenues.
- The liberalization must be politically sustainable and hence credible so that economic agents do not fear or anticipate a reversal.[13]

All these theoretical complications could be sidestepped if there were convincing evidence that in practice trade liberalization systematically produces improved economic performance. But even for this relatively uncontroversial policy, it has proved difficult to generate unambiguous evidence (see Rodriguez and Rodrik 2001, Vamvakidis 2002, and Yanikkaya 2003).[14]

The point is that even the simplest of policy recommendations—"liberalize foreign trade"—is contingent on a large number of judgment calls about the economic and political context in which it is to be implemented.[15] Such judgment calls are often made implicitly. Rendering them explicit has a double advantage: it warns us about the potential minefields that await the standard recommendations, and it stimulates creative

[11] This is not a theoretical curiosum. Gilbert and Varangis (2003) argue that the liberalization of cocoa exports in West African countries has depressed world cocoa prices, with most of the benefits being captured by consumers in developed countries.

[12] The standard workhorse model of international trade, the factor-endowments model and its associated Stolper-Samuelson theorem, comes with sharp predictions on the distributional effects of import liberalization (the "magnification effect").

[13] Calvo (1989) was the first to point out that lack of credibility acts as an intertemporal distortion. See also Rodrik (1991).

[14] Recent empirical studies have begun to look for non-linear effects of trade liberalization. In a study of India's liberalization, Aghion et al. (2003) find that trade liberalization appears to have generated differentiated effects across Indian firms depending on prevailing industrial capabilities and labor market regulations. Firms that were close to the technological frontier and in states with more "flexible" regulations responded positively while others responded negatively. See also Helleiner (1994) for a useful collection of country studies that underscores the contingent nature of economies' response to trade liberalization.

[15] This is one reason why policy discussions on standard recommendations such as trade liberalization and privatization now often take the formulaic form: "policy *x* is not a panacea; in order to work, it must be supported by reforms in the areas of *a, b, c, d,* and so on."

thinking on alternatives (as in China) that can sidestep those minefields. By contrast, when the policy recommendation is made unconditionally, as in the Washington Consensus, the gamble is that the policy's prerequisites will coincide with our actual draw from a potentially large universe of possible states of the world.

I summarize this discussion with the help of Tables 6, 7, and 8 dealing with microeconomic policy, macroeconomic policy, and social policy, respectively. Each table contains three columns. The first column displays the ultimate goal that is targeted by the policies and institutional arrangements in the three domains. Hence microeconomic policies aim to achieve static and dynamic efficiency in the allocation of resources. Macroeconomic policies aim for macroeconomic and financial stability. Social policies target poverty reduction and social protection.

The next column displays some of the key higher-order principles that economic analysis brings to the table. Allocative efficiency require property rights, the rule of law, and appropriate incentives. Macroeconomic and financial stability requires sound money, fiscal solvency, and prudential regulation. Social inclusion requires incentive compatibility and appropriate targeting. These are the "universal principles" of sound economic management. They are universal in the sense that it is hard to see what any country would gain by systematically defying them. Countries that have adhered to these principles—no matter how unorthodox their manner of doing so may have been—have done well while countries that have flouted them have typically done poorly.

From the standpoint of policy makers, the trouble is that these universal principles are not operational as stated. In effect, the answers to the real questions that preoccupy policy makers—how far should I go in opening up my economy to foreign competition, should I free up interest rates, should I rely on payroll taxes or the VAT, and the others listed in the third column of each table--cannot be directly deduced from these principles. This opens up space for a multiplicity of institutional arrangements that are compatible with the universal, higher-order principles.

These tables clarify why the standard recommendations (Table 2) correlates poorly with economic performance around the world. The Washington Consensus, in its various forms, has tended to blur the line that separates column 2 from column 3. Policy advisors have been too quick in jumping from the higher-order principles in column 2 to taking unconditional stands on the specific operational questions posed in column 3. And as their policy advice has yielded disappointing results, they have moved on to recommendations with even greater institutional specificity (as with "second generation reforms"). As a result, sound economics has often been delivered in unsound form.

I emphasize that this argument is not one about the advantages of gradualism over shock therapy. In fact, the set of ideas I have presented are largely orthogonal to the long-standing debate between the adherents of the two camps (see for example Lipton and Sachs 1990, Aslund et al. 1996, Williamson and Zagha 2002). The strategy of gradualism presumes that policy makers have a fairly good idea of the institutional arrangements that they want to acquire ultimately, but that for political and other reasons

they can proceed only step-by-step in that direction. The argument here is that there is typically a large amount of uncertainty about what those institutional arrangements are, and therefore that the process that is required is more one of "search and discovery" than one of gradualism. The two strategies may coincide when policy changes reveal information and small-scale policy reforms have a more favorable ratio of information revelation to risk of failure.[16] But it is best not to confuse the two strategies. What stands out in the real success cases, as I will further illustrate below, is not gradualism per se but an unconventional mix of standard and non-standard policies well attuned to the reality on the ground.

IV. Back to the real world

Previously we had asked our Martian to interpret economic performance in the real world from the lens of the standard reform agenda. Suppose we now remove the constraint and ask him to summarize the stylized facts as he sees them. Here is a list of four stylized facts that he may come up with.

1. In practice, growth spurts are associated with a narrow range of policy reforms.

One of the most encouraging aspects of the comparative evidence on economic growth is that it often takes very little to get growth started. To appreciate the point, it is enough to turn to Table 9, which lists 83 cases of growth accelerations. The table shows all cases of significant growth accelerations since the mid-1950s that can be identified statistically. The definition of a growth acceleration is the following: an increase in an economy's per-capita GDP growth of 2 percentage points or more (relative to the previous 5 years) that is sustained over at least 8 years. The timing of the growth acceleration is determined by fitting a spline centered on the candidate break years, and selecting the break that maximizes the fit of the equation (see Hausmann, Pritchett, and Rodrik 2004 for details on the procedure).[17]

Most of the usual suspects are included in the table: for example Taiwan 1961, Korea 1962, Indonesia 1967, Brazil 1967, Mauritius 1971, China 1978, Chile 1986, Uganda 1989, Argentina 1990, and so on. But the exercise also yields a large number of much less well-known cases, such as Egypt 1976 or Pakistan 1979. In fact, the large number of countries that have managed to engineer at least one instance of transition to high growth may appear as surprising. As I will discuss later, most of these growth spurts have eventually collapsed. Nonetheless, an increase in growth of 2 percent (and typically more) over the better part of a decade is nothing to sneer at, and it is worth asking what produces it.

---

[16] For example, Dewatripont and Roland (1995) and Wei (1997) present models in which gradual reforms reveal information and affect subsequent political constraints.

[17] The selection strategy allows multiple accelerations, but they must be at least five years apart. We require post-acceleration growth to be at least 3.5 percent, and also rule out recoveries from crises.

In the vast majority of the cases listed in Table 9, the "shocks" (policy or otherwise) that produced the growth spurts were apparently quite mild. Asking most development economists about the policy reforms of Pakistan in 1979 or Syria in 1969 would draw a blank stare. This reflects the fact that not much reform was actually taking pace in these cases. Relatively small changes in the background environment can yield significant increase in economic activity.

Even in the well-known cases, policy changes at the outset have been typically modest. The gradual, experimental steps towards liberalization that China undertook in the late 1970s were discussed above. South Korea's experience in the early 1960s was similar. The military government led by Park Chung Hee that took power in 1961 did not have strong views on economic reform, except that it regarded economic development as its key priority. It moved in a trial-and-error fashion, experimenting at first with various public investment projects. The hallmark reforms associated with the Korean miracle, the devaluation of the currency and the rise in interest rates, came in 1964 and fell far short of full liberalization of currency and financial markets. As these instances illustrate, an attitudinal change on the part of the top political leadership towards a more market-oriented, private-sector-friendly policy framework often plays as large a role as the scope of policy reform itself (if not larger). Perhaps the most important example of this can be found in India: such an attitudinal change appears to have had a particularly important effect in the Indian take-off of the early 1980s, which took place a full decade before the liberalization of 1991 (de Long 2003; Rodrik and Subramanian 2004).

This is good news because it suggests countries do not need an extensive set of institutional reforms in order to start growing. Instigating growth is a lot easier in practice than the standard recipe, with its long list of action items, would lead us to believe. This should not be surprising from a growth theory standpoint. When a country is so far below its potential steady-state level of income, even moderate movements in the right direction can produce a big growth payoff. Nothing could be more encouraging to policy makers, who are often overwhelmed and paralyzed by the apparent need to undertake policy reforms on a wide and ever-expanding front.

2. The policy reforms that are associated with these growth transitions typically combine elements of orthodoxy with unorthodox institutional practices.

No country has experienced rapid growth without minimal adherence to what I have termed higher-order principles of sound economic governance—property rights, market-oriented incentives, sound money, fiscal solvency. But as I have already argued, these principles were often implemented via policy arrangements that are quite unconventional. I illustrated this using examples such as China's two-track reform strategy, Mauritius' export processing zone, and South Korea's system of "financial restraint."

It is easy to multiply the examples. When Taiwan and South Korea decided to reform their trade regimes to reduce anti-export bias, they did this not via import

liberalization (which would have been a Western economist's advice) but through selective subsidization of exports. When Singapore decided to make itself more attractive to foreign investment, it did this not by reducing state intervention but by greatly expanding public investment in the economy and through generous tax incentives (Young 1992). Botswana, which has an admirable record with respect to macroeconomic stability and the management of its diamond wealth, also has one of the largest levels of government spending (in relation to GDP) in the world. Chile, a country that is often cited as a paragon of virtue by the standard check list, has also departed from it in some important ways: it has kept its largest export industry (copper) under state ownership; it has maintained capital controls on financial inflows through the 1990s; and it has provided significant technological, organizational, and marketing assistance to its fledgling agro-industries.

In all these instances, standard desiderata such as market liberalization and outward orientation were combined with public intervention and selectivity of some sort. The former element in the mix ensures that any economist so inclined can walk away from the success cases with a renewed sense that the standard policy recommendations really "work." Most egregiously, China's success is often attributed to its turn towards market—which is largely correct—and then with an unjustified leap of logic is taken as a vindication of the standard recipe—which is largely incorrect. It is not clear how helpful such evaluations are when so much of what these countries did is unconventional and fits poorly with the standard agenda.[18]

It is difficult to identify cases of high growth where unorthodox elements have not played a role. Hong Kong is probably the only clear-cut case. Hong Kong's government has had a hands-off attitude towards the economy in almost all areas, the housing market being a major exception. Unlike Singapore, which followed a free trade policy but otherwise undertook extensive industrial policies, Hong Kong's policies have been as close to laissez-faire as we have ever observed. However, there were important prerequisites to Hong Kong's success, which illuminate once again the context-specificity of growth strategies. Most important, Hong Kong's important entrepôt role in trade, the strong institutions imparted by the British, and the capital flight from communist China had already transformed the city-state into a high investment, high entrepreneurship economy by the late 1950s. As Figure 3 shows, during the early 1960s Hong Kong's investment rate was more than three times higher than that in South Korea or Taiwan. The latter two economies would not reach Hong Kong's 1960 per-capita GDP until the early 1970s.[19] Hence Hong Kong did not face the same challenge that Taiwan, South Korea, and Singapore did to crowd in private investment and stimulate entrepreneurship.

---

[18] Another source of confusion is the mixing up of policies with outcomes. Successful countries end up with much greater participation in the world economy, thriving private sectors, and a lot of financial intermediation. What we need to figure out, however, are the policies that produce these results. It would be a great distortion of the strategy followed by countries such as China, South Korea, Taiwan and others to argue that these outcomes were the result of trade and financial liberalization, and privatization.

[19] These and investment data are from the Penn World Tables 6.1.

<Figure 3 here>

It goes without saying that not all unorthodox remedies work. And those that work sometimes do so only for a short while. Consider for example Argentina's experiment in the 1990s with a currency board. Most economists would consider a currency board regime as too risky for an economy of Argentina's size insofar as it prevents expenditure switching via the exchange rate. (Hong Kong has long operated a successful marketing board.) However, as the Argentinean economy began to grow rapidly in the first half of the 1990s, many analysts altered their views. Had the Asian crisis of 1997-98 and the Brazilian devaluation of 1999 not forced Argentina off its currency board, it would have been easy to construct a story ex post about the virtues of the currency board as a growth strategy. The currency board sought to counteract the effects of more than a century of financial mismanagement through monetary discipline. It was a shortcut aimed at convincing foreign and domestic investors that the rules of the game had changed irrevocably. Under better external circumstances, the credibility gained might have more than offset the disadvantages. The problem in this case was the unwillingness to pull back from the experiment even when it became clear that the regime had left the Argentine economy with a hopelessly uncompetitive real exchange rate. The lesson is that institutional innovation requires a pragmatic approach which avoids ideological lock-in.

3. Institutional innovations do not travel well.

The more discouraging aspect of the stylized facts is that the policy packages associated with growth accelerations—and particularly the elements therein that are non-standard—tend to vary considerably from country to country. China's two-track strategy of reform differs significantly from India's gradualism. South Korea's and Taiwan's more protectionist trade strategy differs markedly from the open trade policies of Singapore (and Hong Kong). Even within strategies that look superficially similar, closer look reveals large variation. Taiwan and South Korea both subsidized non-traditional industrial activities, but the former did it largely through tax incentives and the latter largely through directed credit.[20]

Attempts to emulate successful policies elsewhere often fail. When Gorbachev tried to institute a system similar to China's Household Responsibility System and two-track pricing in the Soviet Union during the mid- to late-1980s, it produced few of the beneficial results that China had obtained.[21] Most developing countries have export processing zones of one kind or another, but few have been as successful as the one in

[20] On the institutional differences among East Asian economies, see Haggard (2003).

[21] Murphy, Shleifer, and Vishny (1992) analyze this failure and attribute it to the inability of the Soviet state to enforce the plan quotas once market pricing was allowed (albeit at the margin). This had been critical to the success of the Chinese approach.

Mauritius. Import-substituting industrialization (ISI) worked in Brazil, but not in Argentina.[22]

In light of the arguments made earlier, this experience should not be altogether surprising. Successful reforms are those that package sound economic principles around local capabilities, constraints and opportunities. Since these local circumstances vary, so do the reforms that work. An immediate implication is that growth strategies require considerable local knowledge. It does not take a whole lot of reform to stimulate economic growth—that is the good news. The bad news is that it may be quite difficult to identify where the binding constraints or promising opportunities lie. A certain amount of policy experimentation may be required in order to discover what will work. China represents the apotheosis of this experimental approach to reform. But it is worth noting that many other instances of successful reform were preceded by failed experiments. In South Korea, President Park's developmental efforts initially focused on the creation of white elephant industrial projects that ultimately went nowhere (Soon 1994, 27-28). In Chile, Pinochet's entire first decade can be viewed as a failed experiment in "global monetarism."

Economists can have a useful role to play in this process: they can identify the sources of inefficiency, describe the relevant trade offs, figure out general-equilibrium implications, predict behavioral responses, and so on. But they can do these well only if their analysis is adequately embedded within the prevailing institutional and political reality. The hard work needs to be done at home.

4. Sustaining growth is more difficult than igniting it, and requires more extensive institutional reform.

The main reason that few of the growth accelerations listed in Table 9 are etched in the consciousness of development economists is that most of them did not prove durable. In fact, as discussed earlier, over the last four decades few countries except for a few East Asian ones have steadily converged to the income levels of the rich countries. The vast majority of growth spurts tend to run out of gas after a while. The experience of Latin America since the early 1980s and the even more dramatic collapse of Sub-Saharan Africa are emblematic of this phenomenon. In a well-known paper, Easterly, Kremer, Pritchett and Summers (1993) were the first to draw attention to a related finding, namely the variability in growth performance across time periods. The same point is made on a broader historical canvas by Goldstone (forthcoming).

Hence growth in the short- to medium-term does not guarantee success in the long-term. A plausible interpretation is that the initial reforms need to be deepened over time with efforts aimed at strengthening the institutional underpinning of market economies. It would be nice if a small number of policy changes—which, as argued above, is what produces growth accelerations—could produce growth over the longer

[22] TFP growth averaged 2.9 and 0.2 percent per annum in Brazil and Argentina, respectively, during 1960-73. See Rodrik (1999) and Collins and Bosworth (1996).

term as well, but this is obviously unrealistic. I will discuss some of the institutional prerequisites of sustained growth in greater detail later in the paper. But the key to longer-term prosperity, once growth is launched, is to develop institutions that maintain productive dynamism and generate resilience to external shocks.

For example, the growth collapses experienced by many developing countries in the period from the mid-1970s to the early 1980s seem to be related mainly to the inability to adjust to the volatility exhibited by the external environment at that time. In these countries, the effects of terms-of-trade and interest-rate shocks were magnified by weak institutions of conflict management (Rodrik 1999b). This, rather than the nature of microeconomic incentive regimes in place (e.g., import substituting industrialization), is what caused growth in Africa and Latin America to grind to a halt after the mid-1970s and early 1980s (respectively). The required macroeconomic policy adjustments set off distributive struggles and proved difficult to undertake. Similarly, the weakness of Indonesia's institutions explains why that country could not extricate itself from the 1997-98 East Asian financial crisis (see Temple 2003), while South Korea, for example, did a rapid turnaround. These examples are also a warning that continued growth in China cannot be taken for granted: without stronger institutions in areas ranging from financial markets to political governance, the Chinese economy may well find itself having outgrown its institutional underpinnings.[23]

V. A two-pronged growth strategy

As the evidence discussed above reveals, growth accelerations are feasible with minimal institutional change. The deeper and more extensive institutional reforms needed for long-term convergence take time to implement and mature. And they may not be the most effective way to raise growth at the outset because they do not directly target the most immediate constraints and opportunities facing an economy. At the same time, such institutional reforms can be much easier to undertake in an environment of growth rather than stagnation. These considerations suggest that successful growth strategies are based on a two-pronged effort: a short-run strategy aimed at stimulating growth, and a medium- to long-run strategy aimed at sustaining growth.[24] The rest of this section takes these up in turn.

1. An investment strategy to kick-start growth

From the standpoint of economic growth, the most important question in the short run for an economy stuck in a low-activity equilibrium is: how do you get entrepreneurs

[23] Young (2000) argues that China's reform strategy may have made things worse in the long run, by increasing the number of distorted margins.

[24] A similar distinction is also made by Ocampo (2003), who emphasizes that many of the long-run correlates of growth (such as improved institutions) are the result, and not the instigator, of growth. There is also an analogue in the political science literature in the distinction between the political prerequisites of initiating and sustaining reform (see Haggard and Kaufman 1983).

excited about investing in the home economy? "Invest" here has to be interpreted broadly, as referring to all the activities that entrepreneurs undertake, such as expanding capacity, employing new technology, producing new products, searching for new markets, and so on. As entrepreneurs become energized, capital accumulation and technological change are likely to go hand in hand—too entangled with each other to separate out cleanly.

What sets this process into motion? There are two kinds of views on this in the literature. One approach emphasizes the role of government-imposed barriers to entrepreneurship. In this view, policy biases towards large and politically-connected firms, institutional failures (in the form of licensing and other regulatory barriers, inadequate property rights and contract enforcement), and high levels of policy uncertainty and risk create dualistic economic structures and repress entrepreneurship. The removal of the most egregious forms of these impediments is then expected to unleash a flurry of new investments and entrepreneurship. According to the second view, the government has to play a more pro-active role than simply getting out of the private sector's way: it needs to find means of crowding in investment and entrepreneurship with some positive inducements. In this view, economic growth is not the natural order of things, and establishing a fair and level playing field may not be enough to spur productive dynamism. The two views differ in the importance they attach to prevailing, irremovable market imperfections and their optimism with regard to governments' ability to design and implement appropriate policy interventions.

(a) Government failures

A good example of the first view is provided by the strategy of development articulated in Stern (2001). In a deliberate evocation of Hirschman's *The Strategy of Economic Development* (1958), Stern outlines an approach with two pillars: building an appropriate "investment climate" and "empowering poor people." The former is the relevant part of his approach in this context. Stern defines "investment climate" quite broadly, as "the policy, institutional, and behavioral environment, both present and expected, that influences the returns and risks associated with investment" (2001, 144-45). At the same time, he recognizes the need for priorities and the likelihood that these priorities will be context specific. He emphasizes the favorable dynamics that are unleashed once a few, small things are done right.

In terms of actual policy content, Stern's illustrations make clear that he views the most salient features of the investment climate to be government-imposed imperfections: macroeconomic instability and high inflation, high government wages that distort the functioning of labor markets, a large tax burden, arbitrary regulations, burdensome licensing requirements, corruption, and so on. The strategy he recommends is to use enterprise surveys and other techniques to uncover which of these problems bite the most, and then to focus reforms on the corresponding margin. Similar perspectives can be found in Johnson et al. (2000), Friedman et al. (2000), and Aslund and Johnson (2003). Besley and Burgess (2002) provide evidence across Indian states on the productivity depressing effects of labor market regulations. The title of Shleifer and Vishny's (1998)

book aptly summarizes the nature of the relevant constraint in this view: The Grabbing Hand: Government Pathologies and Their Cures.

(b) Market failures

The second approach focuses not on government-imposed constraints, but on market imperfections inherent in low-income environments that block investment and entrepreneurship in non-traditional activities. In this view, economies can get stuck in a low-level equilibrium due to the nature of technology and markets, even when government policy does not penalize entrepreneurship. There are many versions of this latter approach, and some of the main arguments are summarized in the taxonomy presented in Table 10. I distinguish here between stories that are based on learning spillovers (a non-pecuniary externality) and those that are based on market-size externalities induced by scale economies. See also the useful discussion of these issues in Ocampo (2003), which takes a more overtly structuralist perspective.

As Acemoglu, Aghion, and Zilibotti (2002) point out, two types of learning are relevant to economic growth: (a) adaptation of existing technologies; and (b) innovation to create new technologies. Early in the development process, the kind of learning that matters the most is of the first type. There are a number of reasons why such learning can be subject to spillovers. There may be a threshold level of human capital beyond which the private return to acquiring skills becomes strongly positive (as in Azariadis and Drazen 1990). There may be learning-by-doing which is either external to individual firms, or cannot be properly internalized due to imperfections in the market for credit (as in Matsuyama 1992). Or there may be learning about a country's own cost structure, which spills over from the incumbents to later entrants (as in Hausmann and Rodrik 2002). In all these cases, the relevant learning is under-produced in a decentralized equilibrium, with the consequence that the economy fails to diversify into non-traditional, more advanced lines of activity.[25] There then exist policy interventions that can improve matters. With standard externalities, the first-best takes the form of a corrective subsidy targeted at the relevant distorted margin. In practice, revenue, administrative or informational constraints may make resort to second-best interventions inevitable.

For example, Hausmann and Rodrik (2002) suggest a carrot-and-stick strategy to deal with the learning barrier to industrialization that they identify. In that model, costs of production in non-traditional activities are uncertain, and they are revealed only after an upfront investment by an incumbent. Once that initial investment is made, the cost information becomes public knowledge. Entrepreneurs engaged in the cost discovery process incur private costs, but provide social benefits that can vastly exceed their anticipated profits. The first-best policy here, which is an entry subsidy, suffers from an

[25] Imbs and Wacziarg (2003) demonstrate that sectoral diversification is a robust correlate of economic growth at lower levels of income. This is in tension with standard models of trade and specialization under constant returns to scale. Sectoral concentration starts to increase only after a relatively high level of income is reached, with the turning point coming somewhere between $8,500 and $9,500 in 1985 U.S. dollars.

inextricable moral hazard problem. Subsidized entrants have little incentive to engage subsequently in costly activities to discover costs. A second-best approach takes the form of incentives contingent on good performance. Hausmann and Rodrik (2002) evaluate East Asian and Latin American industrial policies from this perspective. They argue that East Asian policies were superior in that they effectively combined incentives with discipline. The former was provided through subsidies and protection, while the latter was provided through government monitoring and the use of export performance as a productivity yardstick. Latin American firms under import substituting industrialization (ISI) received considerable incentives, but faced very little discipline. In the 1990s, these same firms arguably faced lots of discipline (exerted through foreign competition), but little incentives. This line of argument provides one potential clue to the disappointing economic performance of Latin America in the 1990s despite a much improved "investment climate" according to the standard criteria.

The second main group of stories shown in Table 10 relates to the existence of coordination failures induced by scale economies. The big-push theory of development, articulated first by Rosenstein-Rodan (1943) and formalized by Murphy, Shleifer and Vishny (1989), is based on the idea that moving out of a low-level steady state requires coordinated and simultaneous investments in a number of different areas. A general formulation of such models can provided as follows. Let the level of profits in a given modern-sector activity depend on n, the proportion of the economy that is already engaged in modern activities: $\pi^m(n)$, with $d\pi^m(n)/dn > 0$. Let profits in traditional activities be denoted π^t. Suppose modern activities are unprofitable for an individual entrant if no other entrepreneur already operates in the modern sector, but highly profitable if enough entrepreneurs do so: $\pi^m(0) < \pi^t$ and $\pi^m(1) > \pi^t$. Then $n = 0$ and $n = 1$ are both possible equilibria, and industrialization may never take hold in an economy that starts with $n = 0$. The precise mechanism that generates profit functions of this form depends on the model in question. Murphy, Shleifer, and Vishny (1989) develop models in which the complementarity arises from demand spillovers across final goods produced under scale economies or from bulky infrastructure investments. Rodriguez-Clare (1996), Rodrik (1996), and Trindade (2003) present models in which the effect operates through vertical industry relationships and specialized intermediate inputs. Hoff and Stiglitz (2001) discuss a large class of models with coordination failure characteristics.

The policy implications of such models can be quite unconventional, requiring the crowding in of private investment through subsidization, jawboning, public enterprises and the like. Despite the "big push" appellation, the requisite policies need not be wide-ranging. For example, socializing investment risk through implicit investment guarantees, a policy followed in South Korea, is welfare enhancing in Rodrik's (1996) framework because it induces simultaneous entry into the modern sector. It is also costless to the government, because the guarantees are never called on insofar as the resulting investment boom pays for itself. Hence, when successful, such policies will leave little trail on government finances or elsewhere.[26]

[26] On South Korea's implicit investment guarantees, see Amsden (1989). During the Asian financial crisis, these guarantees became an issue and they were portrayed as evidence of crony capitalism (MacLean 1999).

Both types of models listed in Table 10 suggest that the propagation of modern, non-traditional activities is not a natural process and that it may require positive inducements. One such inducement that has often worked in the past is a sizable and sustained depreciation of the real exchange rate. For a small open economy, the real exchange rate is defined as the relative price of tradables to non-tradables. In practice, this price ratio tends to move in tandem with the nominal exchange rate, the price of foreign currency in terms of home currency. Hence currency devaluations (supported by appropriate monetary and fiscal policies) increase the profitably of tradable activities across the board. From the current perspective, this has a number of distinct advantages. Most of the gains from diversification into non-traditional activities are likely to lie within manufactures and natural resource based products (i.e., tradables) rather than services and other non-tradables. Second, the magnitude of the inducement can be quite large, since sustained real depreciations of 50 percent or more are quite common. Third, since tradable activities face external competition, the activities that are encouraged tend to be precisely the ones that face the greatest market discipline. Fourth, the manner in which currency depreciation subsidizes tradable activities is completely market-friendly, requiring no micromanagement on the part of bureaucrats. For all these reasons, a credible, sustained real exchange rate depreciation may constitute the most effective industrial policy there is.

Large real exchange rate changes have played a big role in some of the more recent growth accelerations. Figure 4 shows two well-known cases: Chile and Uganda since the mid-1980s. In both cases, a substantial swing in relative prices in favor of tradables accompanied the growth take-off. In Chile, the more than doubling of the real exchange rate following the crisis of 1982-83 (the deepest in Latin America at the time) is commonly presumed to have played an instrumental role in promoting diversification into non-traditional exports and stimulating economic growth. It is worth noting that import tariffs were raised significantly as well (during 1982-85), giving import-substituting activities an additional boost. As the bottom panel of Figure 3 shows, the depreciation In Uganda was even larger. These depreciations are unlikely to have been the result of growth, since growth typically generates an appreciation of the real exchange rate through the Balassa-Samuelson effect. By contrast, large real depreciations did not play a major role in early growth accelerations in East Asia during the 1960s (Rodrik 1997).[27]

<Figure 4 here>

(c) Where to start?

The two sets of views outlined above—the government failure and market failure approaches—can help frame policy discussions and identify important ways of thinking

---

[27] Polterovich and Popov (2002) provide theory and evidence on the role of real exchange rate undervaluations in generating economic growth.

about policy priorities in the short run. The most effective point of leverage for stimulating growth obviously depends on local circumstances. It is tempting to think that the right first step is to remove government-imposed obstacles to entrepreneurial activity before worrying about "crowding in" investments through positive inducements. But this may not always be a better strategy. Certainly when inflation is in triple digits or the regulatory framework is so cumbersome that it stifles any private initiative, removing these distortions will be the most sensible initial step. But beyond that, it is difficult to say in general where the most effective margin for change lies. Asking businessmen their views on the priorities can be helpful, but not decisive. When learning spillovers and coordination failures block economic take-off, enterprise surveys are unlikely to be revealing unless the questions are very carefully crafted to elicit relevant responses.

One of the lessons of recent economic history is that creative interventions can be remarkably effective even when the "investment climate," judged by standard criteria, is pretty lousy. South Korea's early reforms took place against the background of a political leadership that was initially quite hostile to the entrepreneurial class.[28] China's TVEs have been stunningly successful despite the absence of private property rights and an effective judiciary. Conversely, the Latin American experience of the 1990s indicates that the standard criteria do not guarantee an appropriate investment climate. Governments can certainly deter entrepreneurship when they try to do too much; but they can also deter entrepreneurship when they do too little.

It is sometimes argued that heterodoxy requires greater institutional strength and therefore lies out of reach of most developing countries. But the evidence does not provide much support for this view. It is true that the selective interventions I have discussed in the case of South Korea and Taiwan were successful in part due to unusual and favorable circumstances. But elsewhere, heterodoxy served to make virtue out of institutional weakness. This is the case with China's TVEs, Mauritius' export processing zone, and India's gradualism. In these countries, it was precisely institutional weakness that rendered the standard remedies impractical. It is in part because the standard reform agenda is institutionally so highly demanding—a fact now recognized through the addition of so-called "second generation reforms"—that successful growth strategies are so often based on unconventional elements (in their early stages at least).

It is nonetheless true that the implementation of the market failure approach requires a reasonably competent and non-corrupt government. For every South Korea, there are many Zaires where policy activism is an excuse for politicians to steal and plunder. Finely-tuned policy interventions can hardly be expected to produce desirable outcomes in setting such as the latter. And to the extent that Washington Consensus policies are more conducive to honest behavior on the part of politicians, they may well be preferable on this account. However, the evidence is ambiguous on this. Most

[28] One month after taking power in a military coup in 1961, President Park arrested some of the leading businessmen in Korea under the newly passed Law for Dealing with Illicit Wealth Accumulation. These businessmen were subsequently set free under the condition that they establish new industrial firms and give up the shares to the government (Amsden 1989, 72).

policies, including those of the Washington Consensus type, are corruptible if the underlying political economy permits or encourages it. Consider for example Russia's experiment with mass privatization. It is widely accepted that this process was distorted and de-legitimized by asset grabs on the part of politically well-connected insiders. Washington Consensus policies themselves cannot legislate powerful rent-seekers out of existence. Rank ordering different policy regimes requires a more fully specified model of political economy than the reduced-form view that automatically associates governmental restraint with less rent-seeking.[29]

I close this section with the usual refrain: the range of strategies that have worked in the past is quite diverse. Traditional import-substituting industrialization (ISI) model was quite effective in stimulating growth in a large number of developing countries (e.g., Brazil, Mexico, Turkey). So was East Asian style outward orientation, which combined heavy-handed interventionism at home with single-minded focus on exports (South Korea, Taiwan). Chile's post-1983 strategy was based on quite a different style of outward orientation, relying on large real depreciation, absence of explicit industrial policies (but quite a bit of support for non-traditional exports in agro-industry), saving mobilization through pension privatization, and discouragement of short-term capital inflows. The experience of countries such as China and Mauritius is best described as two-track reform. India comes as close to genuine gradualism as one can imagine. Hong Kong represents probably the only case where growth has taken place without an active policy of crowding in private investment and entrepreneurship, but here too special and favorable preconditions (mentioned earlier) limit its relevance to other settings. In view of this diversity, any statement on what ignites growth has to be cast at a sufficiently high level of generality.

2. An institution building strategy to sustain growth

In the long run, the main thing that ensures convergence with the living standards of advanced countries is the acquisition of high-quality institutions. The growth-spurring strategies described above have to be complemented over time with a cumulative process of institution building to ensure that growth does not run out of steam and that the economy remains resilient to shocks. This point has now been amply demonstrated both by historical accounts (North and Thomas 1973, Engerman and Sokoloff 1994) and by econometric studies (Hall and Jones 1999, Acemoglu et al. 2001, Rodrik et al., 2002, Easterly and Levine, 2002). However, these studies tend to remain at a very aggregate level of generality and do not provide much policy guidance (a point that is also made in Besley and Burgess 2002b).

[29] In Rodrik (1995) I compared export subsidy regimes in six countries, and found that the regimes that were least likely to be open to rent-seeking ex ante—those with clear-cut rules, uniform schedules, and no arms' length relationships between firms and bureaucrats—were in fact less effective ex post. Where bureaucrats were professional and well-monitored, discretion was not harmful. Where they were not, the rules did not help.

The empirical research on national institutions has generally focused on the protection of property rights and the rule of law. But one should think of institutions along a much wider spectrum. In its broadest definition, institutions are the prevailing rules of the game in society (North 1990). High quality institutions are those that induce socially desirable behavior on the part of economic agents. Such institutions can be both informal (e.g., moral codes, self-enforcing agreements) and formal (legal rules enforced through third parties). It is widely recognized that the relative importance of formal institutions increases as the scope of market exchange broadens and deepens. One reason is that setting up formal institutions requires high fixed costs but low marginal costs, whereas informal institutions have high marginal costs (Li 1999; Dixit 2004, chap. 3). I will focus here on formal institutions.

What kind of institutions matter and why? Table 11 provides a taxonomy of market-sustaining institutions, associating each type of institutions with a particular need. The starting point is the recognition that markets need not be self-creating, self-regulating, self-stabilizing, and self-legitimizing. Hence, the very existence of market exchange presupposes property rights and some form of contract enforcement. This is the aspect of institutions that has received the most scrutiny in empirical work. The central dilemma here is that a political entity that is strong enough to establish property rights and enforce contracts is also strong enough, by definition, to violate these same rules for its own purpose (Djankov et al., 2003). The relevant institutions must strike the right balance between disorder and dictatorship.

As Table 11 makes clear, there are other needs as well. Every advanced economy has discovered that markets require extensive regulation to minimize abuse of market power, internalize externalities, deal with information asymmetries, establish product and safety standards, and so on. They also need monetary, fiscal, and other arrangements to deal with the business cycle and the problems of unemployment/inflation that are at the center of macroeconomists' analyses since Keynes. Finally, market outcomes need to be legitimized through social protection, social insurance, and democratic governance most broadly (Rodrik 2000).

Institutional choices made in dealing with these challenges often have to strike a balance between competing objectives. The regulatory regime governing the employment relationship must trade off the gains from "flexibility" against the benefits of stability and predictability. The corporate governance regime must delineate the interests and prerogatives of shareholders and stakeholders. The financial system must be free to take risks, but not so much so that it becomes an implicit public liability. There must be enough competition to ensure static allocative efficiency, but also adequate prospect of rents to spur innovation.

The last two centuries of economic history in today's rich countries can be interpreted as an ongoing process of learning how render capitalism more productive by supplying the institutional ingredients of a self-sustaining market economy: meritocratic public bureaucracies, independent judiciaries, central banking, stabilizing fiscal policy, antitrust and regulation, financial supervision, social insurance, political democracy. Just

as it is silly to think of these as the prerequisites of economic growth in poor countries, it is equally silly not to recognize that such institutions eventually become necessary to achieve full economic convergence. In this connection, one may want to place special emphasis on democratic institutions and civil liberties, not only because they are important in and of themselves, but also because they can be viewed as meta-institutions that help society make appropriate selections from the available menu of economic institutions.

However, the earlier warning not to confuse institutional function and institutional form becomes once again relevant here. Appropriate regulation, social insurance, macroeoconomic stability and the like can be provided through diverse institutional arrangements. While one can be sure that some types of arrangements are far worse than others, it is also the case that many well-performing arrangements are functional equivalents. Function does not map uniquely into form. It would be hard to explain otherwise how social systems that are so different in their institutional details as those of the United States, Japan, and Europe have managed to generate roughly similar levels of wealth for their citizens. All these societies protect property rights, regulate product, labor, and financial markets, have sound money, and provide for social insurance. But the rules of the game that prevail in the American style of capitalism are very different from those in the Japanese style of capitalism. Both differ from the European style. And even within Europe, there are large differences between the institutional arrangements in, say, Sweden and Germany. There has been only modest convergence among these arrangements in recent years, with the greatest amount of convergence taking place probably in financial market practices and the least in labor market institutions (Freeman 2000).

There are a number of reasons for institutional non-convergence. First, differences in social preferences, say over the tradeoff between equity and opportunity, may result in different institutional choices. If Europeans have a much greater preference for stability and equity than Americans, their labor market and welfare-state arrangements will reflect that preference. Second, complementarities among different parts of the institutional landscape can generate hysteresis and path dependence. An example of this would be the complementarity between corporate governance and financial market practices of the Japanese "model," as discussed previously. Third, the institutional arrangements that are required to promote economic development can differ significantly, both between rich and poor countries and among poor countries. This too has been discussed previously.

There is increasing recognition in the economics literature that high-quality institutions can take a multitude of forms and that economic convergence need not necessarily entail convergence in institutional forms (North 1994, Freeman 2000, Pistor 2000, Mukand and Rodrik forthcoming, Berkowitz et al. 2003, Djankov et al. 2003, Dixit 2004).[30] North (1994, 8) writes: "economies that adopt the formal rules of another

[30] Furthermore, as Roberto Unger (1998) has argued, there is no reason to suppose that today's advanced economies have already exhausted all the useful institutional variations that could underpin healthy and vibrant economies.

economy will have very different performance characteristics than the first economy because of different informal norms and enforcement [with the implication that] transferring the formal political and economic rules of successful Western economies to third-world and Eastern European economies is not a sufficient condition for good economic performance." Freeman (2000) discusses the variety of labor market institutions that prevail among the advanced countries and argues that differences in these practices have first-order distributional effects, but only second-order efficiency effects. Pistor (2000) provides a general treatment of the issue of legal transplantation, and shows how importation of laws can backfire. In related work, Berkowitz et al. (2003) find that countries that developed their formal legal orders internally, adapted imported codes to local conditions, or had familiarity with foreign codes ended up with much better legal institutions than those that simply transplanted formal legal orders from abroad. Djankov et al. (2003) base their discussion on an "institutional possibility frontier" that describes the tradeoff between private disorder and dictatorship, and argue that different circumstances may call for different choices along this frontier. And Dixit (2004, 4) summarizes the lessons for developing countries thus: "it is not always necessary to create replicas of western style state legal institutions from scratch; it may be possible to work with such alternative institutions as are available, and build on them."

Mukand and Rodrik (forthcoming) develop a formal model to examine the costs and benefits of institutional "experimentation" versus "copycatting" when formulas that have proved successful elsewhere may be unsuitable at home. A key idea is that institutional arrangements that prove successful in one country create both positive and negative spillovers for other countries. On the positive side, countries whose underlying conditions are sufficiently similar to those of the successful "leaders" can imitate the arrangements prevailing there and forego the costs of experimentation. This is one interpretation of the relative success that transition economies in the immediate vicinity of the European Union have experienced. Countries such as Poland, the Czech Republic or the Baltic republics share a similar historical trajectory with the rest of Europe, have previous experience with capitalist market institutions, and envisaged full EU membership within a reasonable period (de Menil 2003). The wholesale adoption of EU's acquis communautaire may have been the appropriate institution-building strategy for these countries. On the other hand, countries may be tempted or forced to imitate institutional arrangements for political or other reasons, even when their underlying conditions are too dissimilar for the strategy to make sense.[31] Institutional copycatting may have been useful for Poland, but it is much less clear that it was relevant or practical for Ukraine or Kyrgyzstan. The negative gradient in the economic performance of transition economies as one moves away from Western Europe provides some support for this idea (see Mukand and Rodrik forthcoming).

---

[31] In Mukand and Rodrik (forthcoming) it is domestic politics that generates inefficient imitation. Political leaders may want to signal their type (and increase the probability of remaining in power) by imitating standard policies even when they know these will not work as well as alternative arrangements. But one can also appeal to the role of IMF and World Bank conditionality in producing this kind of outcome.

Even though it is recent, this literature opens up a new and exciting way of looking at institutional reform. In particular, it promises an approach that is less focused on so-called best practices or the superiority of any particular model of capitalism, and more cognizant of the context-specificity of desirable institutional arrangements. Dixit's (2004) monograph outlines a range of theoretical models that help structure our thinking along these lines.

VI. Concluding remarks

Richard Feynman, the irreverent physicist who won the Nobel Prize in 1965 for his work on quantum electrodynamics, relates the following story. Following the award ceremony and the dinner in Stockholm, he wanders into a room where a Scandinavian princess is holding court. The princess recognizes him as one of the awardees and asks him what he got the prize for. When Feynman replies that his field is physics, the princess says that this is too bad. Since no one at the table knows anything about physics, she says, they cannot talk about it. Feynman disagrees:

> "On the contrary," I answered. "It's because somebody knows *something* about it that we can't talk about physics. It's the things that nobody knows anything about that we *can* discuss. We can talk about the weather; we can talk about social problems; we can talk about psychology; we can talk about international finance … so it's the subject that nobody knows anything about that we can all talk about!" (Feynman 1985)

This is not the place to defend international finance (circa 1965) against the charge Feynman levels at it. But suppose Feynman had picked on economic growth instead of international finance. Would growth economists have a plausible riposte? Is the reason we all talk so much about growth that we understand so little about it?

It is certainly the case that growth theory is now a much more powerful tool than it was before Solow put pencil to paper. And cross-country regressions have surely thrown out some useful correlations and stylized facts. But at least at the more practical end of things—how do we make growth happen? —things have turned out to be somewhat disappointing. By the mid-1980s, policy oriented economists had converged on a new consensus regarding the policy framework for growth. We thought we knew a lot about what governments needed to do. But as my Martian thought experiment at the beginning of the paper underscores, reality has been unkind to our expectations. If Latin America was booming today and China and India were stagnating, we would have an easier time fitting the world to our policy framework. Instead, we are straining to explain why unorthodox, two-track, gradualist reform paths have done so much better than sure-fire adoption of the standard package.

Very few policy analysts think that the answer is to go back to old-style ISI, even though its record was certainly respectable for a very large number of countries. Certainly no-one one believes that central planning is a credible alternative. But by the

same token, few are now convinced that liberalization, deregulation, and privatization on their own hold the key to unleashing economic growth. Maybe the right approach is to give up looking for "big ideas" altogether (as argued explicitly by Lindauer and Pritchett 2002, and implicitly by Easterly 2001). But that would be overshooting too. Economics is full of big ideas on the importance of incentives, markets, budget constraints, and property rights. It offers powerful ways of analyzing the allocative and distributional consequences of proposed policy changes. The key is to realize that these principles do not translate directly into specific policy recommendations. That translation requires the analyst to supply many additional ingredients that are contingent on the economic and political context, and cannot be done a priori. Local conditions matter not because economic principles change from place to place, but because those principles come institution free and filling them out requires local knowledge.

Therefore, the real lesson for the architects of growth strategies is to take economics more seriously, not less seriously. But the relevant economics is that of the seminar room, with its refusal to make unconditional generalizations and its careful examination of the contingent relation between the economic environment and policy implications. Rule-of-thumb economics, which has long dominated thinking on growth policies, can be safely discarded.

Acknowledgements

I gratefully acknowledge financial support from the Carnegie Corporation of New York. I also thank, without implicating, Philippe Aghion, Richard Freeman, Steph Haggard, Ricardo Hausmann, Murat Iyigun, Sharun Mukand, José Antonio Ocampo, Andrei Shleifer, and Arvind Subramanian for comments that substantially improved this paper.

Table 2: Rules of good behavior for promoting economic growth

Original Washington Consensus:	"Augmented" Washington Consensus: … the previous 10 items, plus:
1. Fiscal discipline 2. Reorientation of public expenditures 3. Tax reform 4. Interest rate liberalization 5. Unified and competitive exchange rates 6. Trade liberalization 7. Openness to DFI 8. Privatization 9. Deregulation 10. Secure Property Rights	11. Corporate governance 12. Anti-corruption 13. Flexible labor markets 14. Adherence to WTO disciplines 15. Adherence to international financial codes and standards 16. "Prudent" capital-account opening 17. Non-intermediate exchange rate regimes 18. Independent central banks/inflation targeting 19. Social safety nets 20. Targeted poverty reduction

Table 3: East Asian anomalies

Institutional domain	**Standard ideal**	**"East Asian" pattern**
Property rights	Private, enforced by the rule of law	Private, but govt authority occasionally overrides the law (esp. in Korea).
Corporate governance	Shareholder ("outsider") control, protection of shareholder rights	Insider control
Business-government relations	Arms' length, rule based	Close interactions
Industrial organization	Decentralized, competitive markets, with tough anti-trust enforcement	Horizontal and vertical integration in production (chaebol); government-mandated "cartels"
Financial system	Deregulated, securities based, with free entry. Prudential supervision through regulatory oversight.	Bank based, restricted entry, heavily controlled by government, directed lending, weak formal regulation.
Labor markets	Decentralized, de-institutionalized, "flexible" labor markets	Lifetime employment in core enterprises (Japan)
International capital flows	"prudently" free	Restricted (until the 1990s)
Public ownership	None in productive sectors	Plenty in upstream industries.

Table 4: The logic of the Washington Consensus and a Chinese counterfactual

Problem		Solution
Low agricultural productivity	→	Price liberalization
Production incentives	→	Land privatization
Loss of fiscal revenues	→	Tax reform
Urban wages	→	Corporatization
Monopoly	→	Trade liberalization
Enterprise restructuring	→	Financial sector reform
Unemployment	→	Social safety nets
… and so on		

Table 5: How to understand/rationalize institutional anomalies: four illustrations

Objective	**What is problem?**	**Institutional response**	**Prerequisites**	**Institutional complements**
Financial deepening (saving mobilization and efficient intermediation)	Asymmetric information (investors know more about their projects than lenders do) and limited liability	"Financial restraint" (Hellmann et al. 1997): controlled deposit rates and restricted entry —creation of rents to induce better portfolio risk management, better monitoring of firms, and increased deposit mobilization by banks.	Ability to maintain restraint at <u>moderate</u> levels; Positive real interest rates; Macroeconomic stability; Avoid state capture by financial interests.	<u>Finance</u>: Highly regulated financial markets (absence of security markets and closed capital accounts to prevent cherry picking and rent dissipation); <u>Politics</u>: State "autonomy" to prevent capture and decay into "crony capitalism."

Table 5: How to understand/rationalize institutional anomalies: four illustrations (cont.)

Objective	**What is problem?**	**Institutional response**	**Prerequisites**	**Institutional complements**
Spurring investment and entrepreneurship in non-traditional activities	Economies of scale together with inter-industry linkages depress private return to entrepreneurship/investment below social return.	"Industrial policy as a coordination device" (Rodrik 1995) --credit subsidies (Korea) and tax incentives (Taiwan) for selected sectors; --protection of home market coupled with export subsidies; --public enterprise creation for upstream products; --arm-twisting and cajoling by political leadership; --socialization of investment risk through implicit investment guarantees.	A high level of human capital relative to physical capital. A relatively competent bureaucracy to select investment projects.	Trade: Need to combine import protection (in selected sectors) with exposure to competition in export markets to distinguish high-productivity firms from low-productivity ones; Business-government relations: "Embedded autonomy" (Evans) to enable close interactions and information exchange while preventing state capture and decay into "crony capitalism."

Table 5: How to understand/rationalize institutional anomalies: four illustrations (cont.)

Objective	**What is problem?**	**Institutional response**	**Prerequisites**	**Institutional complements**
Productive organization of the workplace	Tradeoff between information sharing (working together) and economies of specialization (specialized tasks)	"horizontal hierarchy" (Aoki 1997)	(unintended) fit with prewar arrangements of military resource mobilization in Japan	Corporate governance: insider control to provide incentive for accumulating long-term managerial skills; Labor markets: lifetime employment and enterprise unionism to generate long-term collaborative teamwork; Financial markets: main bank system to discipline firms and reduce the moral hazard consequences of insider control; Politics: "bureau-pluralism" (regulation, protection) to redistribute benefits to less productive, traditional sectors.

Table 5: How to understand/rationalize institutional anomalies: four illustrations (cont.)

Objective	**What is problem?**	**Institutional response**	**Prerequisites**	**Institutional complements**
Reduce anti-export bias	Import-competing interests are politically powerful and opposed to trade liberalization	export processing zone (Rodrik 1999)	saving boom; elastic supply of foreign investment; preferential market access in EU	Dual labor markets: segmentation between male and female labor force, so that increase female employment in the EPZ does not drive wages up in the rest of the economy.

Table 6: Sound economics and institutional counterparts: microeconomics

OBJECTIVE	**UNIVERSAL PRINCIPLES**	**PLAUSIBLE DIVERSITY IN INSTITUTIONAL ARRANGEMENTS**
Productive efficiency (static and dynamic)	Property rights: Ensure potential and current investors can retain the returns to their investments Incentives: Align producer incentives with social costs and benefits. Rule of law: Provide a transparent, stable and predictable set of rules.	What type of property rights? Private, public, cooperative? What type of legal regime? Common law? Civil law? Adopt or innovate? What is the right balance between decentralized market competition and public intervention? Which types of financial institutions/corporate governance are most appropriate for mobilizing domestic savings? Is there a public role to stimulate technology absorption and generation? (e.g. IPR "protection")

Table 7: Sound economics and institutional counterparts: macroeconomics

OBJECTIVE	**UNIVERSAL PRINCIPLES**	**PLAUSIBLE DIVERSITY IN INSTITUTIONAL ARRANGEMENTS**
Macroeconomic and Financial Stability	Sound money: Do not generate liquidity beyond the increase in nominal money demand at reasonable inflation. Fiscal sustainability: Ensure public debt remains "reasonable" and stable in relation to national aggregates. Prudential regulation: Prevent financial system from taking excessive risk.	How independent should the central bank be? What is the appropriate exchange-rate regime? (dollarization, currency board, adjustable peg, controlled float, pure float) Should fiscal policy be rule-bound, and if so what are the appropriate rules? Size of the public economy. What is the appropriate regulatory apparatus for the financial system? What is the appropriate regulatory treatment of capital account transactions?

Table 8: Sound economics and institutional counterparts: social policy

OBJECTIVE	**UNIVERSAL PRINCIPLES**	**PLAUSIBLE DIVERSITY IN INSTITUTIONAL ARRANGEMENTS**
Distributive justice and poverty alleviation	Targeting: Redistributive programs should be targeted as closely as possible to the intended beneficiaries. Incentive compatibility: Redistributive programs should minimize incentive distortions.	How progressive should the tax system be? Should pension systems be public or private? What are the appropriate points of intervention: educational system? access to health? access to credit? labor markets? tax system? What is the role of "social funds"? Redistribution of endowments? (land reform, endowments-at-birth) Organization of labor markets: decentralized or institutionalized? Modes of service delivery: NGOs, participatory arrangements., etc.

Handbook of Economic Growth, Volume 1A. Edited by Philippe Aghion and Steven N. Durlauf

DOI: 10.1016/S1574-0684(05)01015-4

Abstract

The new growth literature, using both endogenous growth and neoclassical models, has generated strong claims for the effect of national policies on economic growth. Empirical work on policies and growth has tended to confirm these claims. This paper casts doubt on this claim for strong effects of national policies, pointing out that such effects are inconsistent with several stylized facts and seem to depend on extreme observations in growth regressions. More modest effects of policy are consistent with theoretical models that feature substitutability between the formal and informal sector, have a large share for the informal sector, or stress technological change rather than factor accumulation.

Keywords

economic growth, macroeconomic policies, international trade, economic reform, economic development

JEL classification: O1, O4, E6, F4

An influential study by World Bank researchers Paul Collier and David Dollar (2001) finds that policy reform in developing countries would accelerate their growth and cut world poverty rates in half. They conclude that

> Poverty reduction – in the world or in a particular region or country – depends primarily on the quality of economic policy. Where we find in the developing world good environments for households and firms to save and invest, we generally observe poverty reduction.

I find the audacious claim that policy reform can cut world poverty in half a little daunting – even more so since Collier and Dollar base their results on an unpublished growth regression by me! (Like firearms, it is dangerous to leave growth regressions lying around.)

The International Monetary Fund (2000) also claims that "Where {sound macroeconomic} policies have been sustained, they have raised growth and reduced poverty." These claims are often held out as hope to economically troubled continents like Africa: "Policy action and foreign assistance ... will surely work together to build a continent that shows real gains in both development and income in the near future." Unfortunately, this claim was made in World Bank (1981) and the "real gains" in Africa have yet to arrive as of 2003.

Do the ambitious claims for the power of policy reform find support in the data? Are they consistent with theoretical views of how policy would affect growth?

The large literature on the determinants of economic growth, beginning with Romer (1986), has intensively studied national economic policies as key factors influencing long run growth. In this chapter, I take a look the state of this literature today, both theoretical and empirical. I do not claim to comprehensively survey the literature. I focus the chapter on the question of how strong is the case that national economic policies (by which I mean mainly macroeconomic and trade policies) have economically large effects on the growth rate of economies.

I am in the end skeptical that national policies have the large effects that the early growth literature claimed, or that the international agencies claim today. Although extremely bad policy can probably destroy any chance of growth, it does not follow that good macroeconomic or trade policy alone can create the conditions for high steady state growth.

Theoretical models that predict strong policy effects

The simplest theoretical model of endogenous growth is the *AK* mode of Rebelo (1991). Rebelo postulated that output could be proportional to a broad concept of capital (K) that included both physical and human capital:

$$Y = AK. \tag{1}$$

In principle, K could also include any kind of stock of knowledge, technology, or organizational technique that can be built up over time by sacrificing some of today's

consumption to accumulate such a stock. For example, technological knowledge could be accumulated by diverting some of today's output into lab equipment or other machines that help make new discoveries feasible. Or knowledge or human capital itself could be used to create further knowledge or human capital rather than producing today's output.[1] However, unlike many other endogenous growth models that explicitly address knowledge or technology [e.g. Aghion and Howitt (1998)], K is treated in this model as a purely private good – both excludable and rival. I will address below what happens when we relax this assumption.[2]

Constant returns to the factors that can be accumulated is also a key assumption in this model's prediction of a constant steady state rate of growth for given parameters and policies. This would rule out fixed costs in implementing a new technology, or increasing returns to accumulation at low levels of K, both of which feature in other growth models.

Since K is purely a private good, there is no role for government in this model. The market equilibrium yields the first best solution, and any government intervention in the form of taxes or price distortions must worsen welfare.

In this model, policies like tax rates have large effects on steady state growth. Consider first a tax (τ) on the purchase of investment goods (I). Consumption (C) is given by output less investment spending and taxes:

$$C = Y - (1+\tau)I. \tag{2}$$

Suppose the population size is constant and each (identical) household-dynasty maximizes welfare over an infinite horizon:

$$\max \int_0^\infty \mathrm{e}^{-\rho t} \frac{C^{1-\sigma}}{1-\sigma}\,\mathrm{d}t, \tag{3}$$

$$\dot{K} = I - \delta K. \tag{4}$$

[1] Rebelo (1991) showed that as long as the capital formation function itself has constant returns to accumulated factors, endogenous growth is possible even if final production has diminishing returns to capital.

[2] Since K in my models can always represent either technology or factor accumulation, I do not address the hot debate on how much factor accumulation matters for growth. On education, Benhabib and Spiegel (1994) and Pritchett (1997) show that cross-country data on economic growth rates show that increases in human capital resulting from improvements in the educational attainment of the work force have *not* positively affected the growth rate of output per worker. It may be that, on average, education does not effectively provide useful skills to workers engaged in activities that generate social returns. There is disagreement, however, Krueger and Lindahl (1999) argue that measurement error accounts for the lack of a relationship between growth per capita and human capital accumulation. Hanushek and Kimko (2000) find that the quality of education is very strongly linked with economic growth. However, Klenow (1998) demonstrates that models that highlight the role of ideas and productivity growth do a much better job of matching the data than models that focus on the accumulation of human capital. More work is clearly needed on the relationship between education and economic development. On physical capital accumulation, there is the debate between the "neoclassical" school stressing factor accumulation [Mankiw, Romer and Weil (1992), Mankiw (1995), Young (1995)] and the school stressing technology or the residual [Klenow and Rodriguez-Clare (1997a, 1997b), Hall and Jones (1999), Easterly and Levine (2001)].

Then the consumer–producer would invest at a rate that results in steady-state growth of

$$\frac{\dot{C}}{C} = \frac{(A/(1+\tau)) - \delta - \rho}{\sigma}. \tag{5}$$

Here policy has large effects on steady state growth. If $A = 0.15$ and $\sigma = 1$, then an increase from a tax rate of 0 to one of 30% would lower growth by 3.5 percentage points. Such a policy pursued over 30 years would leave income at the end 65 percent lower than it would have been in the absence of a tax. This is a strong claim for the effects of policy on economic development! It offers a possible explanation for the poverty of a poor nation – bad government policies (high τ) – which can be remedied easily enough by changing to good policies (low τ). It is clear why this has been a seductive theory for aid agencies and policymakers that seek to promote economic development.

The effects on accumulation are even more dramatic. Solving for the broad concept of investment that includes physical capital, human capital, technology, and knowledge accumulation, we get:

$$\frac{I}{Y} = \frac{(A/(1+\tau)) - \delta(1-\sigma) - \rho}{\sigma A}. \tag{6}$$

The effect of taxation on investment does not depend on A. If $\sigma = 1$, the derivative of I/Y with respect to the tax factor $1/(1+\tau)$ is unity. An increase of the tax rate from 0 to 30 percent would reduce investment by 23 percentage points of GDP!

Before examining this claim in more detail, note that the tax rate on investment goods does not have to be an explicit tax on capital goods. First of all, there is an equivalent income tax that would have had the same effect on growth (given by $t = 1 - 1/(1+\tau)$), so policies here could be any government action that diverts income away from the original investor in production. (Note using the result above, that every one percentage point increase in the income tax rate reduces investment by one percentage point of GDP.) Second, note that this result applies to the *marginal* effective tax rate on investment goods or income. While movements from 0 to 30 percent would be dramatic for average tax rates, a movement of 30 percentage points in marginal effective tax rates could easily come from a tax reform. Second, the tax on capital goods could stand for any policy that alters the price of investment goods relative to consumption.[3] For example, suppose that a populist government controls output prices for consumers but the investor must buy goods for investment on the black market. Then the premium of the black market price over the official price would act much like a tax on investment goods. If the one good in this model is tradeable, then the black market premium on foreign

[3] Chari, McGrattan and Kehoe (1996) and McGrattan and Schmitz (1998) present models and empirical work emphasizing the measured high relative price of capital goods as a policy factor inhibiting economic development. Hsieh and Klenow (2003) have an alternative story that stresses high capital prices and low income as the joint outcome of a technological disadvantage in producing tradeable goods (including capital goods) in poor countries.

exchange might be a good proxy for the wedge between official output prices and black market investment good prices (assuming that consumer goods can be imported at the official exchange rate, or at least that official output prices are controlled as if they could be). If we suppose that the purchaser of investment goods must hold cash in advance of a purchase of investment goods, then inflation would be indirectly be a tax on investment goods. One could also get similar results with institutional variables – a probability of expropriation of part or all of the capital good by the government or government officials demanding a bribe every time a new unit of capital is installed would act much like a tax on investment.

The claims for large policy effects become even stronger in growth models with increasing returns to capital and externalities. Suppose that there is a group of large but fixed size where the capital held by each member of the group has non-pecuniary externalities for the rest of the group. For example, a high human capital individual in a residential neighborhood might benefit the rest of the neighborhood with whom she socially interacts. The knowledge and connections that this individual brings might raise the productive potential of others (this is loosely what is called "social capital" in the literature). If this is true for all social interactions in the neighborhood, and these interactions are identical, costless, and exogenous for all members, then there will be a spillover from the average human capital of the neighborhood to each inhabitant of the neighborhood. The production function for an individual member would look like this:

$$y = Ak^{\alpha}\bar{k}^{\beta}. \tag{7}$$

One can think of other similar examples of spillovers. If k includes knowledge or technology, it is plausible that these goods are non-rival and partially non-excludable. For example, firms may benefit by example from new technology installed by other firms in the same trade. People in almost every human activity engage in "shop talk" that is incomprehensible to outsiders, but which apparently conveys productive knowledge to those involved in the activity.[4]

Assuming the same maximization problem as above (Equations (2) through (4)), then the individual will invest in k taking everyone else's investment as given (because the group is too large for her to influence its average). The optimal path of consumption is now given by

$$\frac{\dot{C}}{C} = \frac{(A\alpha k^{\alpha-1}\bar{k}^{\beta}/(1+\tau)) - \delta - \rho}{\sigma}. \tag{8}$$

However, since all members of the group are assumed to be identical, then $k = \bar{k}$ ex-post, and the growth rate for each individual will be

$$\frac{\dot{C}}{C} = \frac{(A\alpha \bar{k}^{\alpha+\beta-1}/(1+\tau)) - \delta - \rho}{\sigma}. \tag{9}$$

[4] The emphasis on the special properties of knowledge and technology was highlighted by Romer (1995) and Aghion and Howitt (1998). The idea of social capital has been stressed by authors such as Putnam (1993, 2000), Glaeser (2000), Narayan and Pritchett (1997), Woolcock and Narayan (2000).

There are multiple equilibria if $\alpha + \beta - 1 > 0$, i.e. if both the original importance of broad capital to production is large plus there are strong spillovers. If we have the special case of $\alpha+\beta = 1$, then we are back to the AK model, albeit one with suboptimal market outcomes because of the externality. If $\alpha+\beta-1 < 0$, then the model will feature similar prediction as the neoclassical model with a high capital share (discussed below).

In the multiple equilibria case, the return to capital increases the more initial capital there is, the opposite of the usual diminishing returns to capital. Figure 1 illustrates the possible outcomes. If the tax rate is low, the after tax rate of return to capital is the upper upward-sloping line. Any initial capital stock to the left of point A (where the after tax return is less than $\delta + \rho$) will go into a vicious circle of negative growth of consumption and decumulation of capital. Any point to the right of A (such as B) will go into a virtuous circle of positive and accelerating growth of consumption and positive capital accumulation.[5] Now suppose that tax rates are increased, shifting the rate of return to the lower upward-sloping line in Figure 1. Now any point to the left of C will go into a vicious circle of decline. An economy with capital stock B, which was in the expanding region under low taxes, is now in the declining region under high taxes. A policy shift now has an even more dramatic impact on national prosperity – it could spell the difference between subsistence consumption (say Mali) and industrialization (say Singapore). Policy spells the difference in the long run between per capita income of $300 and $30,000 – rather a dramatic effect. As in all multiple equilibria models, initial conditions matter and small things (like policy) can have large consequences. If the first endogenous growth model was seductive to policymakers, this is even more so – one government official at the stroke of a pen could change a nation's prospects from destitution to prosperity.

This increasing returns model is much like poverty trap models like those of Azariadis and Drazen (1990), Becker, Murphy and Tamura (1990), Kremer (1993), and Murphy, Shleifer and Vishny (1989). It is also consistent with models of in-group ethnic and neighborhood externalities [Borjas (1992, 1995, 1999), Benabou (1993, 1996)] and geographic externalities [Krugman (1991, 1995, 1998), Fujita, Krugman and Venables (1999)]. Ades and Glaeser (1999) present evidence for increasing returns in closed economies.

A story like that told in Figure 1 would also predict instability of growth rates if an economy is in the middle region B and is subject to continuous fluctuations in policies. The economy would keep shifting from positive to negative growth and back again as policies change. This is a possible story for some of the spectacular reversals in output growth that we have seen in countries like Cote d'Ivoire, Jamaica, Guyana, and Nigeria (see Figure 2).

It is often assumed that these strong claims for policy effects on growth are only a feature of endogenous growth models. However, the other innovation in the growth

[5] The feature of ever accelerating growth in this model leads to nonsensical predictions in the long run – the model would have to be modified at higher incomes with some feature that puts a ceiling on the rate of return to capital.

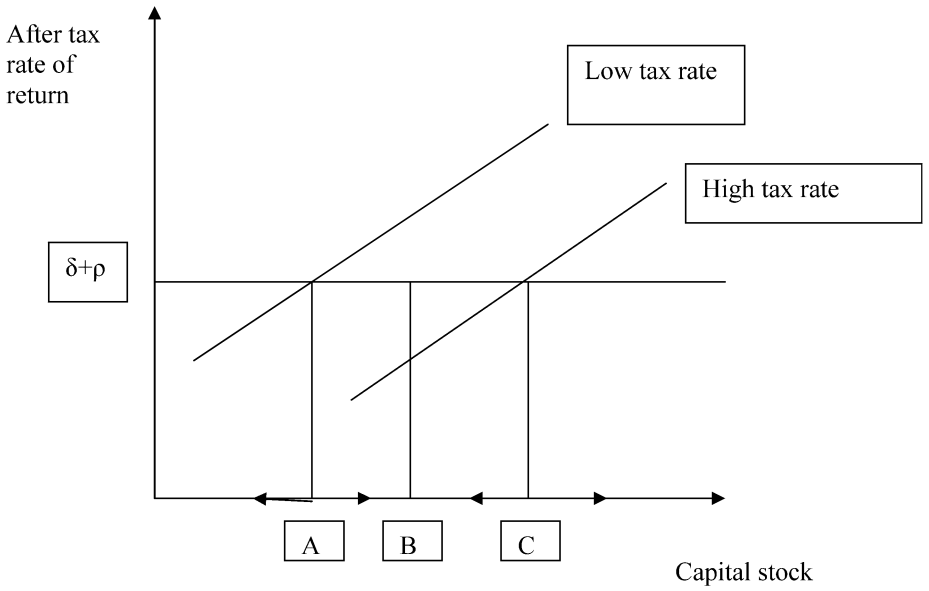

Figure 1. Multiple equilibria with increasing returns to capital, alternative tax regimes.

literature of the last two decades has been to put a much higher weight on capital even in the neoclassical exogenous growth model. Again, the justification is that capital is a broader concept than just physical equipment and buildings. It should include at least human capital, if not the more technology and knowledge forms of capital discussed above. Attributing part of the labor income in the national accounts to human capital, this would raise the share of capital in output from around 1/3 (if the only form of capital was physical) to something like 2/3.[6] The high capital share is also necessary to avoid counterfactual predictions about very high returns to capital in capital-scarce countries, and the same in the initial years of a transition from capital-scarcity to capital-abundance.

The neoclassical production function with labor-augmenting technological change is:

$$Y = K^{\alpha}(AL)^{1-\alpha}. \tag{10}$$

In per capita terms, we have:

$$y = k^{\alpha}A^{1-\alpha}. \tag{11}$$

The consumer–producer's maximization problem is the same as before, using Equations (2) through (4). Technological progress (the percent growth in A) is assumed to

[6] Mankiw, Romer and Weil (1992) and Mankiw (1995).

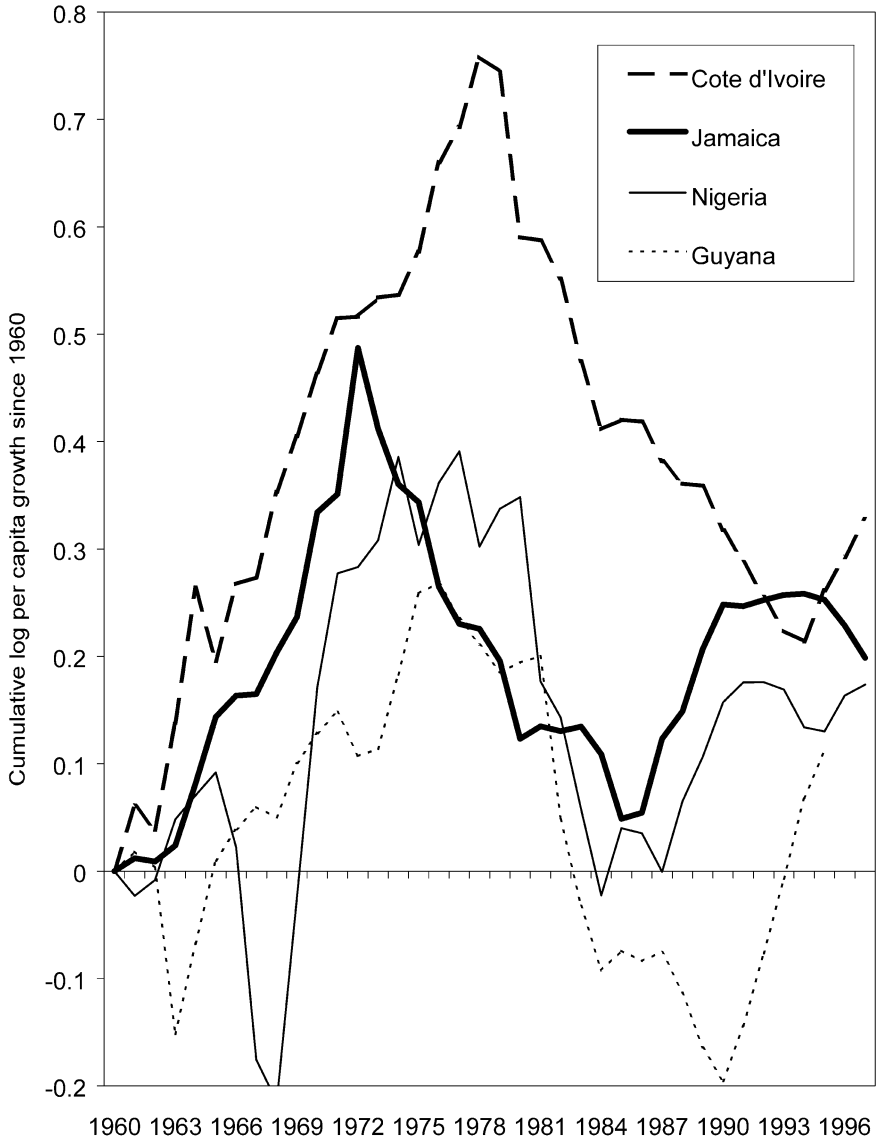

Figure 2. Examples of variable per capita income over time.

take place at an exogenous rate x. As is well known, accumulation of physical and human capital cannot sustain growth in the long run in the absence of technological progress. Since policy affects the outcome only through the incentive to accumulate capital, it follows that policy by itself cannot foster sustained growth in this model.

With growth in A of x, the long-run steady state will have per capita output y, capital per worker k, and per capita consumption all growing at the same (exogenous) rate x. The tax rate on capital goods has no effect on the steady-state growth rate. However, policy does have potentially large effects on the level of per capita income. To see this, it is convenient to write both capital per worker and per capita income relative to the technological level A. The optimal growth of per capita consumption is now:

$$\frac{\dot{C}}{C} = \frac{(\alpha(k/A)^{\alpha-1}/(1+\tau)) - \delta - \rho}{\sigma}. \tag{12}$$

Since (12) must equal x in steady state, an increase in the tax rate τ must always be offset by a decrease in the relative capital stock (raising the pre-tax rate of return to capital because of diminishing returns, i.e. because $\alpha < 1$). Setting (12) equal to x determines the k/A ratio in the steady state, which in turn gives the following for per capita income relative to technology:

$$\frac{y}{A} = \left[\frac{\alpha}{(1+\tau)(\sigma x + \delta + \rho)}\right]^{\frac{\alpha}{1-\alpha}}. \tag{13}$$

A high tax on investment inhibits capital accumulation and thus lowers the level of income relative to the technology level. High taxes are still a possible explanation of relative poverty in the neoclassical model. With a capital share of 2/3 (including both human and physical capital), a tax rate decrease from 50 percent to zero raises income by a factor of $(1.5)^2$, or 2.25 times. If the capital share were 0.8 (as writers like Barro and Mankiw have suggested), then the tax reduction would raise income by a factor of $(1.5)^4$ or 5 times.

Although there is no effect of the tax change on steady state growth, there will be a dramatic change in growth in the transition from one policy regime to another. There is one unique saddle path to the new steady state; consumption will jump to that saddle path after the change in policy (in a world of perfect certainty of course). To solve for the transition involves solving for the saddle-path of consumption in transition to the new steady state. Figure 3 shows a simulation of a decrease in the tax rate on investment from 50 percent to zero, with the following parameter values:

$\alpha = 0.6666$,
$\delta = 0.07$,
$\rho = 0.05$,
$\sigma = 0.9$,
$x = 0.02$.

For comparison, I also show a simulation of an endogenous growth rate model with $A = 0.138$, which gives the same 2 percent per capita growth rate at zero tax as the exogenous growth neoclassical model. Both models show dramatic growth rate effects after the policy change, still large after 20 to 30 years. It is only in the very long run that the neoclassical growth effect wears off with diminishing returns. Investment rates would show similar jumps after the policy change as growth rates.

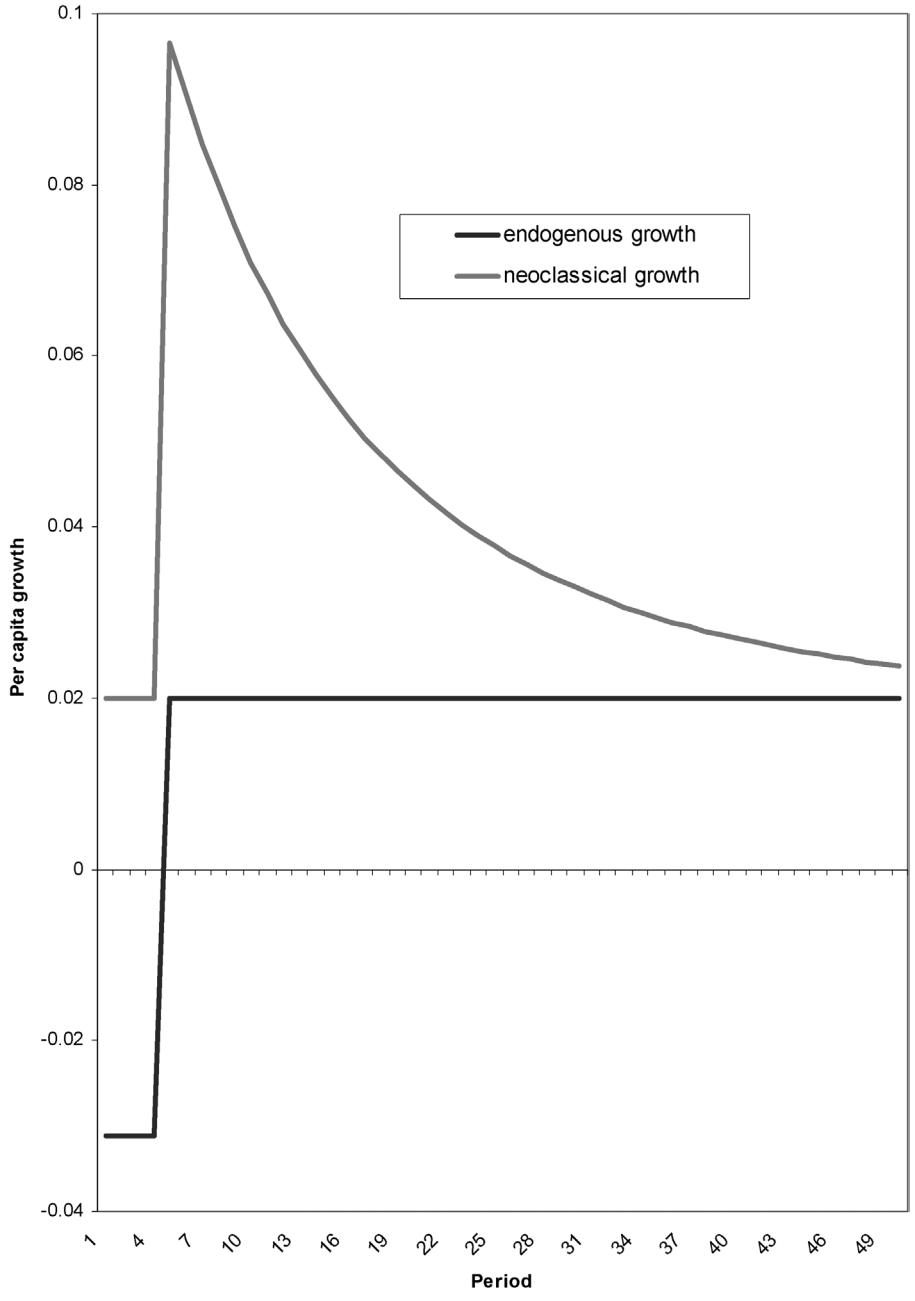

Figure 3. Endogenous growth and neoclassical growth with a reduction of tax rate on investment from 50 percent to zero.

What is different for the purposes of empirical work is that the predicted difference in growth rates in the endogenous growth model before and after the tax decrease could equally apply to cross-section differences in growth between high-tax and low-tax countries. In the neoclassical model, the predicted effect of policy change on growth is only for a cross-time effect within countries. However, this difference has been handled in practice by testing the effect of current policies on growth, controlling for initial income. Initial income can be thought of as representing policy regimes prior to the period under study. If current policy predicts a higher steady state level of income than initial income, then the transitional dynamics like those shown in Figure 3 will be set in motion. The neoclassical model would predict instability of growth rates over time if frequent policy changes shift the steady state level above or below the current income level, which is ironically similar to the increasing returns prediction of growth rate instability.

One big difference between the three models is that the neoclassical model predicts falling growth and investment after the initial policy-induced increase in growth, the increasing returns to capital model predict rising growth and investment afterwards, while the constant returns to capital model predict constant growth. I will examine some case studies of major policy reforms below to see which of these predictions appears to hold.

All of the three models predict large growth effects of policy changes. I will examine below the evidence for or against these claims, but here I will note how much these bold predictions are different from many other fields of economics, as well as from the pre-1986 growth literature. The literature on tax policy, for example, thinks that it is a big deal to identify a benefit of 0.1 percent of GDP from a major tax reform that lowers distortions. The notion that economic development of a whole society can be achieved a few stroke-of-the pen policy reforms seems simplistic in retrospect. If this is so, why haven't more countries successfully developed? Are large policy effects on growth an inevitable feature of new growth models?

Models that predict small policy effects on growth

To begin to understand some of the factors that might mitigate the large effects of policy on growth, suppose that there output is a function of two types of capital, only one of which can be taxed. For example, suppose that the first type of capital (K_1) is formal sector capital that must be transacted on markets in the open, while the second type of capital (K_2) is informal sector capital that can be accumulated away from the prying eyes of the tax man.

$$Y = A\left(\alpha K_1^{\gamma} + (1-\alpha)K_2^{\gamma}\right)^{\frac{1}{\gamma}}, \tag{14}$$

$$C = Y - (1+\tau)I_1 - I_2, \tag{15}$$

$$\dot{K}_1 = I_1 - \delta K_1, \tag{16}$$

$$\dot{K}_2 = I_2 - \delta K_2, \tag{17}$$

$$\frac{\dot{C}}{C} = \frac{(A\alpha[\alpha + (1-\alpha)(K_2/K_1)^{\gamma}]^{\frac{1-\gamma}{\gamma}}/(1+\tau)) - \delta - \rho}{\sigma}. \tag{18}$$

If these two capital goods are close to perfect substitutes, then the effects of taxes on growth go towards zero. Figure 4 shows the relationship between growth and tax rates at extreme values of γ. With γ close to 1 (close to perfect substitutability), there is only a minor effect of taxes and it is bounded from below no matter how high the tax rate. This is because with the elasticity of substitution greater than one, formal sector capital is not essential to production. The worst that high tax rates can do is drive formal capital use down to zero (which has only a small effect if the capital goods are close to perfect substitutes). After that, increases in tax rates have no further effect (explaining the flat segment of the curve in Figure 4). The effects of tax rates on growth continue to be strong if the elasticity of substitution between the two goods is less than one (the $\gamma = -1$ line in Figure 4).

The other parameter that plays an important role in how damaging are tax rates is the share (α) of formal sector capital (or more specifically, the share of the capital that is actually subject to taxation). Figure 5 shows how different are the effects of taxing investment in this factor when its share (α) is 0.1 compared to when its share is 0.8 (assuming an elasticity of substitution of unity). Of course, lowering the share of taxable capital would also limit the power of taxation in the neoclassical model.

Another factor that mitigates the effects of policies on growth is that many policies distort relative prices amongst different sectors or different types of goods, rather than penalizing all capital goods. With a distortion of relative prices, some capital goods are more expensive but others are cheaper. For example, with a black market premium on foreign exchange, those who receive licenses to import goods at the official exchange rate receive a subsidy, while those who must pay the black market rate for inputs pay an implicit tax.[7] Unanticipated high inflation is a tax on creditors but a subsidy to debtors. An overvalued real exchange rate penalizes producers of tradeables but subsidizes producers of nontradeables. Trade protection taxes imports but subsidizes production for the domestic market. The rate of subsidy is clearly related to the rate of taxation. One way to pin it down is to specify that the revenues from the tax on the first type of capital must just cover the subsidy expenditures on the second type of capital.

Here are the equations I have in mind. I revert to Cobb–Douglas for simplicity:

$$Y = AK_1^{\alpha}K_2^{1-\alpha}, \tag{19}$$

$$C = Y - (1+\tau)I_1 - (1-s)I_2. \tag{20}$$

(16) and (17) still represent the capital accumulation equations, and the consumer-producer maximizes (3) taking τ and s as given. Ex-post, the government must balance

[7] If black markets function efficiently, the opportunity cost of inputs is their black market value even for those who receive them at the subsidized price. However, the recipient of inputs at the official exchange rate still receives a subsidy per unit of input use.

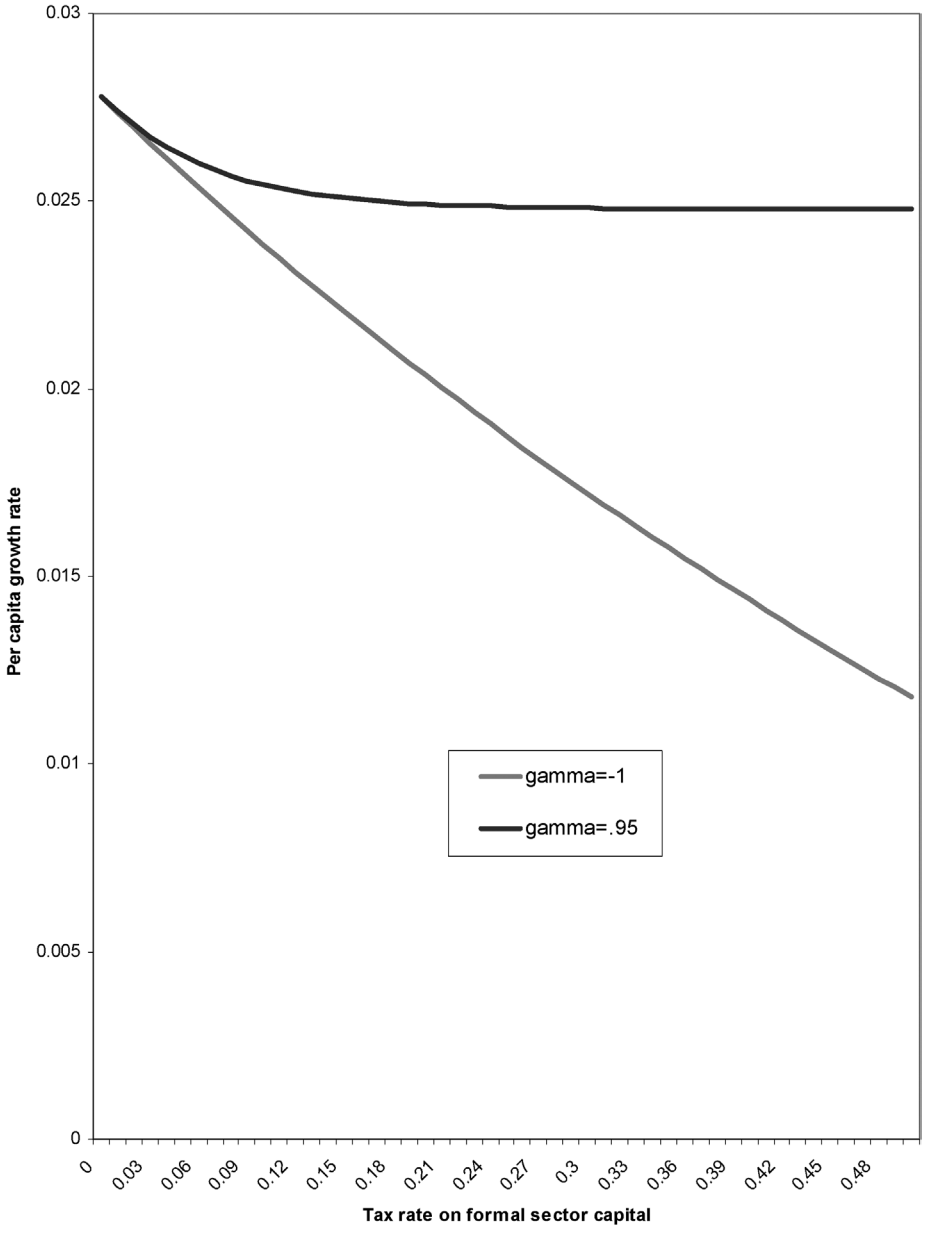

Figure 4. Growth rates with different assumptions about elasticity of substitution between capital good types.

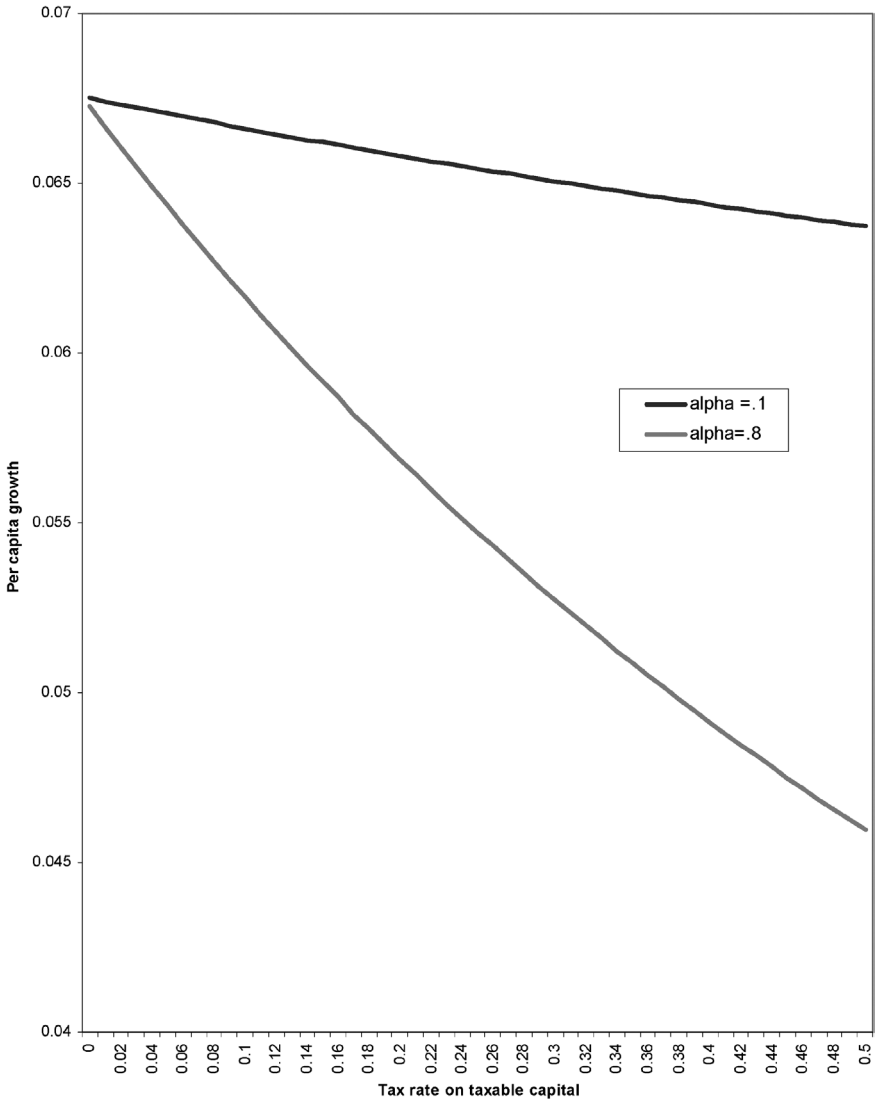

Figure 5. Tax rates and growth with different shares of taxable capital.

its budget so:

$$\tau I_1 = s I_2. \tag{21}$$

Because of the neat properties of Cobb–Douglas, the solution of the optimal capital ratio as a function of the subsidy rate (after taking into account the fiscal relation-

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 16
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

ship (21) between tax rates and subsidy rates) is very simple:

$$\frac{K_2}{K_1} = \frac{1-\alpha}{\alpha - s}. \tag{22}$$

The growth rate will display offsetting effects of the subsidy-cum-tax rate – on the one hand, it distorts the allocation of capital away from K_1 to K_2, lowering the pre-subsidy marginal product of K_2, while on the other hand, it of course subsidizes the rate of return to K_2.

$$\frac{\dot{C}}{C} = \frac{(A(1-\alpha)((\alpha - s)/(1-\alpha))^{\alpha}/(1-s)) - \delta - \rho}{\sigma}. \tag{23}$$

One can show that if (21) (the balanced budget requirement) is imposed, it is impossible for this kind of tax-cum-subsidy scheme to raise the rate of growth.[8] The tax-cum-subsidy will imply an efficiency loss from the distortion of resource allocation, and this efficiency loss will have a negative growth effect if all types of capital can be accumulated. However, the relationship between the distortion and the growth rate is highly nonlinear. As is well known in the literature on relative price distortions, the cost of the distortion increases more than proportionately with the size of the distortion.[9] In the traditional literature on "Harberger triangles", this was an output loss. In an endogenous growth model where all inputs can be accumulated, the distortion between relative prices of the inputs induces a reduction in growth. A small distortion introduces only a small wedge in between marginal products of the two inputs and does not cause a huge growth loss. Eventually, however, the distortion forces far too much accumulation of one type of capital relative to the other, severely lowering the marginal product of the excessive capital good due to diminishing returns. An increasing rate of subsidy also requires a more than one for one increase in the tax rate, as the tax base is shrinking with increased taxes while the capital goods being subsidized are increasing. The nonlinear relationship is shown in Figure 6. Note that distortions do not have much effect on growth at all up to subsidy rates of about 0.2 and then have increasingly catastrophic consequences after about 0.4.

There are other factors that mitigate the effects of policy on growth that I do not explicitly model here. One is policy uncertainty. The announcement of a new policy may not be credible, perhaps because high political opposition to it may imply a high probability of subsequent reversal. Many developing countries have a history of frequent reversals of incipient policy reforms, which makes any future reform less believable. For example, Argentina has been a chronic high inflation country for nearly half a century. Frequent stabilization attempts have subsequently come unwound; the fiasco of the Convertibility Plan in 2001 is only the latest example. In terms of the model above, the

[8] This applies to CES production functions more generally [see Easterly (1993) for a proof].

[9] One recent growth model emphasizing this nonlinearity is Gylfason (1999), where the cost e of a distortion c is amusingly expressed as $e = mc^2$.

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 17
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

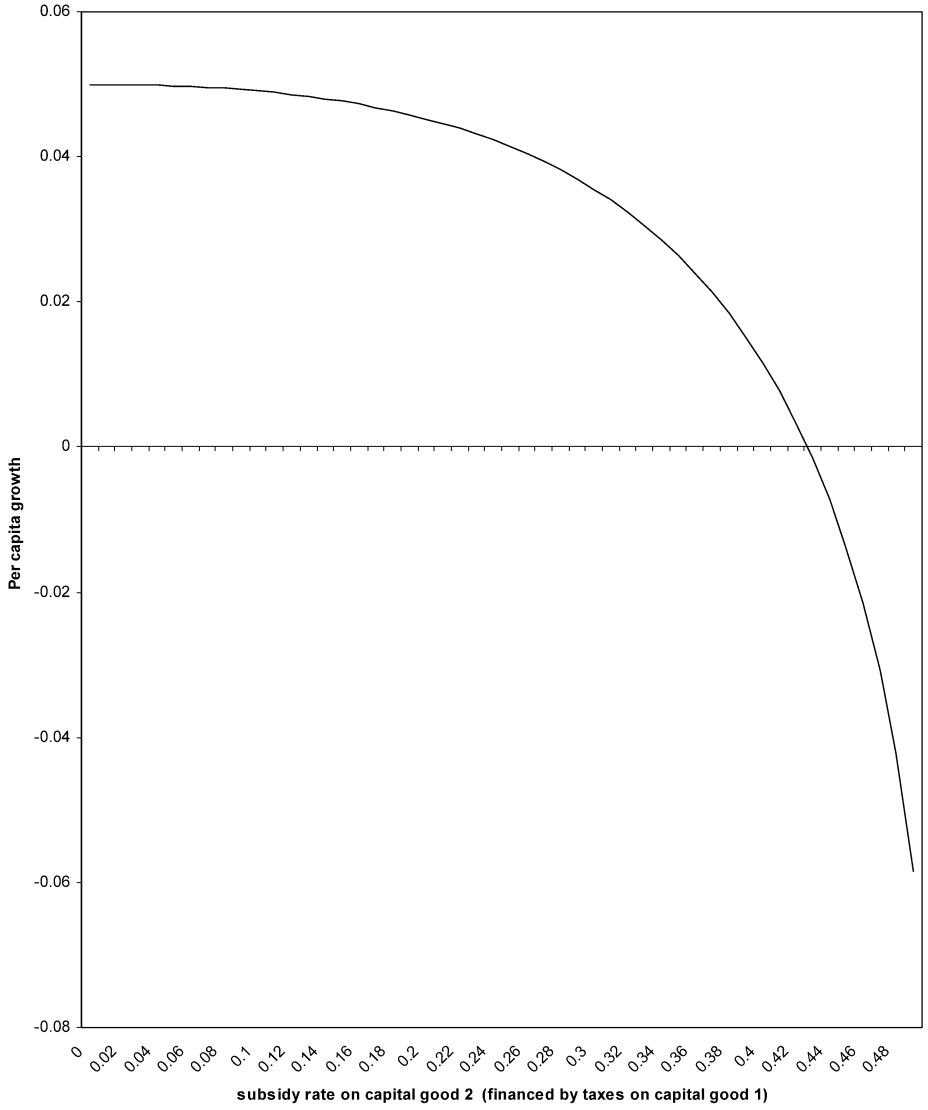

Figure 6. Growth rate and subsidy rate financed by taxes.

certainty equivalent of the after-tax return on capital may not increase much even after an announcement that taxes will be cut.

There is also the possibility that policies whose main purpose was to create rents for political patronage will be replaced with other policies that create new rents. For example, if the black market premium is abolished, the holders of import licenses at the

official exchange rate may seek new sources of income (for example, appointment as customs inspectors, where they can take bribes). There may be a law of conservation of political rents, akin to the second law of thermodynamics, if the factors inducing political rent seeking do not change.

Poor countries may be so close to subsistence consumption that they may not be able to take advantage of policy changes. Rebelo (1991) and Easterly (1994) show intertemporal utility functions with Stone–Geary preferences, in which consumers derive utility from consumption only above a certain floor of subsistence. This model predicts a very low intertemporal elasticity of substitution at levels of consumption close to subsistence. Intuitively, consumers close to subsistence have a limited ability to postpone consumption in order to take advantage of higher returns to saving. This model predicts a slow acceleration of growth even after a favorable policy change, as consumption must first rise well above subsistence.

Most importantly, policies may be offset or reinforced by more important factors that affect the growth and income. Achieving high output returns from a given set of inputs involves an incredibly complex set of institutions (such as enforcement of contracts and property rights), social norms, efficient sorting and matching of people and other inputs, advanced technological knowledge, full information on both sides of all transactions, low transaction costs, resolution of principal-agent problems, positive non-zero-sum game theoretic interactions among agents, resolution of public good problems, and so on. The development of institutions and social and political structures that address these issues successfully (from the standpoint of material production) is probably a long historical process.

The above models have a pale shadow of all this complexity in the parameter A. Note that the lower is A, the lower is the derivative of growth (or income in the neoclassical model) with respect to the policy parameter τ. Many authors have argued that differences in A explain a large part of income differences between countries [Hall and Jones (1999), Klenow and Rodriguez-Clare (1997a, 1997b), Easterly and Levine (2001)]. If a poor country is poor because of low A, then a change in policies may not do much to raise income or growth. Exogenous variation in A may also affect the political economy of policy – a high A country would be less likely to tolerate the costs of destructive policies, while bad policy may be tolerated in a low A country because it may not make much difference. Of course policy itself could influence A. However, if A really depends on all the complexities listed above, then the kind of macroeconomic policies I am considering in this paper may not have much effect on A.

Empirics

The literature tracing effects of economic policies on growth is abundant. I do not attempt to summarize it here, noting the summaries in Sala-i-Martin (2000), Temple (1997), Kenny (2001), and Easterly and Levine (2001). Some authors focus on openness to international trade [Frankel and Romer (1999)], others on fiscal policy [Easterly

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 19
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

and Rebelo (1993a, 1993b)], others on financial development [Levine, Loayza and Beck (2000)], and others on macroeconomic policies [Fischer (1993)]. Dollar (1992) stressed a measure of real exchange rate overvaluation as a proxy for outward orientation and thus a determinant of growth. These papers have at least one common feature: they all find that *some* indicator of national policy is strongly linked with economic growth, which confirms the argument made by Levine and Renelt (1992) – even though Levine and Renelt found that it was difficult to discern *which* policy matters for growth. The list of national economic policies that have received most extensive attention are fiscal policy, inflation, black market premiums on foreign exchange, financial repression vs. financial development, real overvaluation of the exchange rate, and openness to trade. The recommendation that countries pursue good policies on all these dimensions was labeled by Williamson (1985) as the "Washington Consensus".

I distinguish policies from "institutions", which have their own rich literature [see Acemoglu, Johnson and Robinson (2001, 2002), La Porta et al. (1999, 1998), Kaufmann, Kraay and Zoido-Lobatón (1999), Levine]. Institutions reflect deep-seated social arrangements like property rights, rule of law, legal traditions, trust between individuals, democratic accountability of governments, and human rights. Although governments can slowly reform institutions, they are not "stroke of the pen" reforms like changes in the macroeconomic policies listed above. I will consider at the end the relative role of policies and institutions in development.

Some empirical caveats

There are several things to note about the evidence on policies and growth before proceeding to new empirical analysis. The first is that the literature has devoted much effort to the most obvious candidate for a policy that influences growth – tax rates. Yet the literature has generally failed to find a link between income or output taxes and economic growth [Easterly and Rebelo (1993a, 1993b), Slemrod (1996)]. Nor are we likely to find that taxes have level effects, as rich countries have higher tax rates than poor countries. The outcome of natural experiments like the large tax increases in the US associated with the introduction of the income tax and the World Wars does not indicate income or level effects of taxes [Rebelo and Stokey (1995)]. Hence, the most obvious policy variable affecting growth is out of the running from the start.

Second, national economic policies are generally measured over the period 1960–2000, which is when data is available. This is also the period in which countries had independent governments making policy, as opposed to colonial regimes (on which we do not have data). Hence, if policies have an effect on the level or growth rate of income, this would have to show up in the period 1960–2000. However, history did not begin with a clean slate in 1960. The correlation of per capita income in 1960 with per capita income in 1999 is 0.87. Most of countries' relative performance is explained by the point they had already reached by 1960. It follows that the role of post-1960 policies

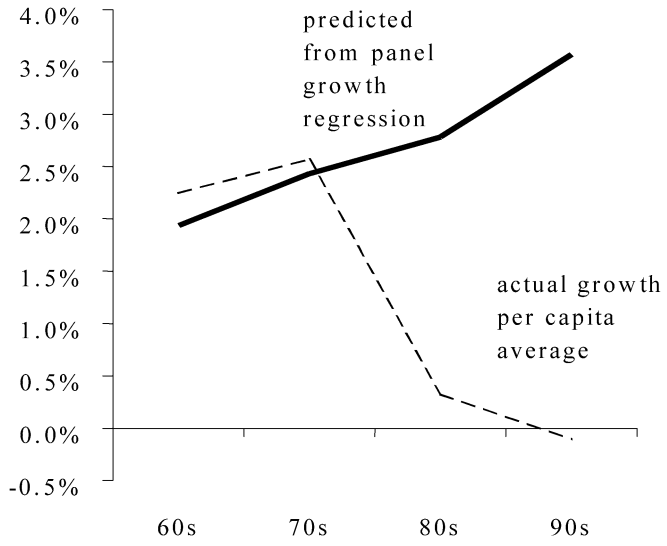

Figure 7. Predicted vs actual per capita growth for developing countries (assuming constant intercept across decades).

in determining development outcomes can only be limited. A view of economic development that puts all the weight on the 1960–2000 period is ahistorical, assuming away the complex histories of civilizations, conquests, and colonies.

Third, there is the general fact that developing countries had higher growth rates in the period 1960–1979 than in the period 1980–2000. Yet most of the "Washington Consensus" policies were adopted only after 1980. In the pre-1980 days, there was much more of an emphasis on state intervention and import-substituting industrialization, as opposed to the free trade, "get the prices right" approach after 1980. This big fact does not augur well for a strong positive effect of "good policies" on growth, although the growth slowdown after 1980 could have other causes. Easterly (2001a) showed the divergence between improving growth predicted by policies and actual growth outcomes across the 60s, 70s, 80s, and 90s (see Figure 7).

Fourth, there are many income differences within nations – between the sexes, between ethnic groups, and between regions – that cannot be explained by national economic policies. Easterly and Levine show that there are four ethnic–geographic clusters of counties with poverty rates above 35 percent in the US: (1) Counties in the West that have large proportions ($>$ 35%) of native Americans; (2) Counties along the Mexican border that have large proportions ($>$ 35%) of Hispanics; (3) Counties adjacent to the lower Mississippi river in Arkansas, Mississippi, and Louisiana and in the "black belt" of Alabama, all of which have large proportions of blacks ($>$ 35%); (4) Virtually all-white counties in the mountains of eastern Kentucky. The county data did not pick up the well-known inner-city form of poverty, mainly among blacks, be-

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 21
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

cause counties that include inner cities also include rich suburbs. An inner city zip code in DC, College Heights in Anacostia, has only one-fifth of the income of a rich zip code (20816) in Bethesda MD. This has an ethnic dimension again since College Heights is 96 percent black and the rich zip code in Bethesda is 96 percent white. The purely ethnic differentials in the US are well known. Blacks earn 41 percent less than whites; Native Americans earn 36 percent less; Hispanics earn 31 percent less; Asians earn 16 percent more.[10] There are also more subtle ethnic earnings differentials. Third-generation immigrants with Austrian grandparents had 20 percent higher wages in 1980 than third-generation immigrants with Belgian grandparents [Borjas (1992)]. Among Native Americans, the Iroquois earn almost twice the median household income of the Sioux. Other ethnic differentials appear by religion. Episcopalians earn 31% more income than Methodists [Kosmin and Lachman (1993), p. 260]. Twenty-three percent of the Forbes 400 richest Americans are Jewish, although only two percent of the US population is Jewish [Lipset (1997)].[11]

Poverty areas exist in many countries: northeast Brazil, southern Italy, Chiapas in Mexico, Balochistan in Pakistan, and the Atlantic provinces in Canada. Bouillon, Legovini and Lustig (1999) find that there is a negative Chiapas effect in Mexican household income data, and that this effect has gotten worse over time. Households in the poor region of Tangail/Jamalpur in Bangladesh earned less than identical households in the better off region of Dhaka [Ravallion and Wodon (1998)]. Ravallion and Jalan (1996) and Jalan and Ravallion (1997) likewise found that households in poor counties in southwest China earned less than households with identical human capital and other characteristics in rich Guangdong Province.

In Latin America, the main ethnic divide is between indigenous and non-indigenous populations and between white, mestizo, and black populations. In Mexico, 80.6 percent of the indigenous population is below the poverty line, while only 18 percent of the non-indigenous population is below the poverty line.[12] But even within indigenous groups in Latin America, there are ethnic differentials. There are 4 main language groups among Guatemala's indigenous population. Patrinos (1997) shows that the Quiche-speaking indigenous groups in Guatemala earn 22 percent less on average than Kekchi-speaking groups.

In Africa, there are widespread anecdotes about income differentials between ethnic groups, but little hard data. The one exception is South Africa. South African whites

[10] Tables 52 and 724, 1995 Statistical Abstract of US.

[11] Ethnic differentials are also common in other countries. The ethnic dimension of rich trading elites is well-known: the Lebanese in West Africa, the Indians in East Africa, and the overseas Chinese in Southeast Asia. Virtually every country has its own ethnographic group noted for their success. For example, in the Gambia a tiny indigenous ethnic group called the Serahule is reported to dominate business out of all proportion to their numbers – they are often called "Gambian Jews". In Zaire, Kasaians have been dominant in managerial and technical jobs since the days of colonial rule – they are often called "the Jews of Zaire" (New York Times, 9/18/1996).

[12] Source: [Psacharopoulos and Patrinos (1994, p. 6)].

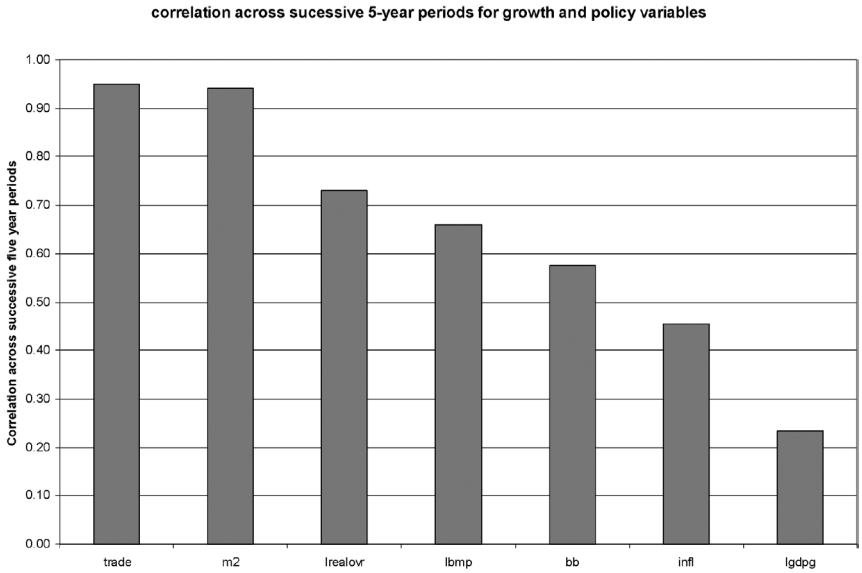

Figure 8. Persistence over time of policies and growth.

have 9.5 times the income of blacks. More surprisingly, among all-black traditional authorities (an administrative unit something like a village) in the state of KwaZulu-Natal, the ratio of the richest traditional authority to the poorest is 54 [Klitgaard and Fitschen (1997)]. While not ruling out national policy effects, these differences also highlight the importance of factors that do not operate at the national level.

Fifth, the role of policies in explaining post-1960 growth is bounded once we realize that policy variables are much more stable over time than are growth rates.[13] Figure 8 shows the correlation coefficient across successive 5-year periods between different kinds of policies and growth. As noted in the theoretical section, stability of policies over time and instability of growth rates is inconsistent with the AK model. It could be consistent with either the neoclassical model or the increasing returns growth model, assuming that policies are close to the steady state or critical point, respectively. Note that the non-persistence of growth rates and the high persistence of income levels is consistent, since persistent differences in growth rates would be required to scramble the income rankings from 1960 to 1999.

New empirical work

I here synthesize past results by running new regressions on an updated dataset for the years 1960–2000, using a panel of five year averages. Following the literature, I con-

[13] This was pointed out by Easterly et al. (1993).

Table 1
Variables used in analysis

Variable name	Definition	Source
LGDPG	Log per capita growth rate	World Bank 2002
INFL	Log (1 + inflation rate)	World Bank 2002

TRADE	(Exports+Imports)/GDP	World Bank 2002
GOVC	Government consumption/GDP	World Bank 2002
PRIV	Private sector credit/total credit	World Bank 2002
LNEWGDP	Log of per capita GDP	Summers–Heston 1991 updated using LGDPG
LTYR	Log of total schooling years	Barro–Lee 2000

centrate on the most common measures of macroeconomic policies, price distortions, financial development, and trade openness. My variables are listed in Table 1.

Table 2 shows the variables' summary statistics.

Table 3 shows the correlation coefficients between these variables and growth as well as between distinct policies. All of the bivariate correlations of policy variables with per capita growth are statistically significant at the 5 percent level. Most of the pairwise correlations between policy variables are also statistically significant, indicating the problem of collinearity that has plagued the literature. Bad policies tend to go together along a number of dimensions. M2 and PRIV have such a high correlation that it is clear they are measuring the same thing – the overall level of financial development.

I now concentrate on a core set of six variables that seem to capture distinct dimensions of policy: inflation, budget balance, real overvaluation, black market premium, financial depth, and trade openness. Initially, I will test the AK model's prediction that these policies will have growth rather than level effects, so I do not control for initial income (I will check this later on). I will use a variety of specifications and econometric methods to assess how robust are the statistical associations between policies and growth.

I start off with a figure emphasizing the bivariate association between growth and different policies (Figure 9). I divide the sample into two parts, picking out the minority part of the sample where policy is extremely bad and comparing it to the rest (for inflation, black market premium, real overvaluation, and budget balance). Inflation, black market premium, and budget balance all have a distribution featuring a long tail of extreme "bad policy", which seems like a real world experiment worth investigating. So I eyeball the distribution and pick a threshold that picks out this tail of bad policy.

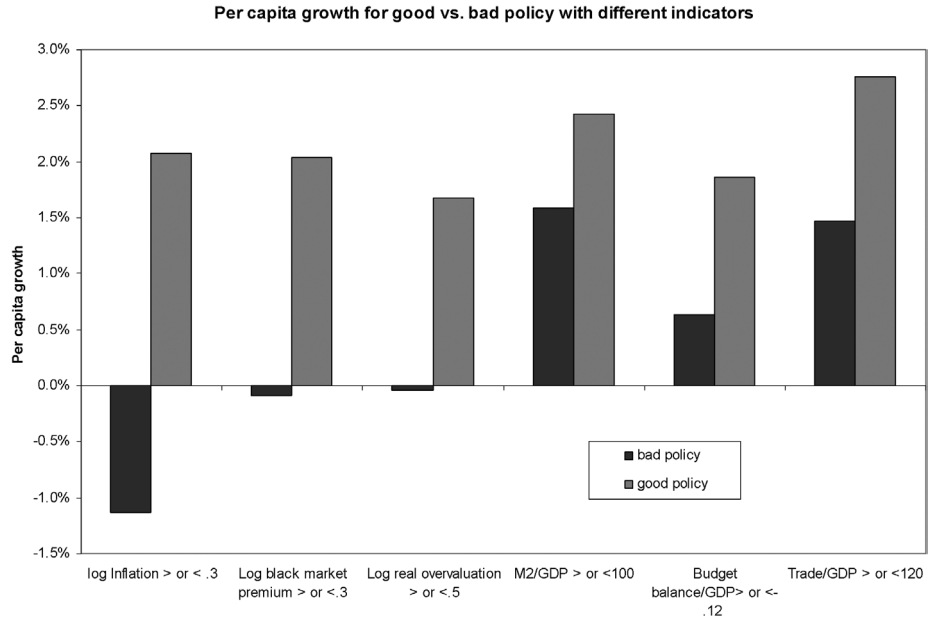

Figure 9. Bivariate effects of policy on growth.

Trade/GDP and M2/GDP have a long tail for extremely *good* policy, so I pick a threshold picking out the extremes of good policy (see Figures 10–15). Real overvaluation does not have a long tail in one direction or the other, but I follow the same practice as with inflation, black market premium, and budget balance in setting a threshold that picks out extremely bad policy. Figure 9 shows that these experiments of either extremely good or extremely bad policy are associated with important growth differences. All of the differences are statistically significant except for the results on M2/GDP. Such strong associations have contributed to the conventional wisdom that policy has strong growth effects.

In Table 4, I regress growth on all six policy variables, and then try dropping one at a time. In the base specification, four of the six policies are statistically significant at the 5 percent level, with trade openness just barely falling short. When I experiment with dropping one variable at a time, all of the six policy variables are significant at one time or another. The coefficients on the policy variables are fairly stable across different permutations of the variables.[14]

Table 5 shows the effect on growth of a one standard deviation improvement in each of the policy variables on growth. If all six variables were improved at the same time,

[14] The other policy variables that I tested: government consumption and private sector credit, were not significant when entered in addition to these variables (or substituting government consumption for budget deficits and private sector credit for M2).

the regression suggests a 3 percentage point improvement in per capita growth. These results also seem to support the assertion that policies have strong effects on per capita growth.

The promise of getting 3 additional percentage points of growth due to a moderate policy reform package is very seductive. However, there is something disquieting about

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 30
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

these results upon further reflection. The one standard deviation change in the policy variables is often very large: reduction of 0.32 in log inflation, 5 percentage point improvement in the budget balance as a ratio to GDP, 25 percentage point increase in M2/GDP, reduction of -0.39 in log real overvaluation, reduction of -0.56 in log black market premium, and increase of 45 percentage points in trade/GDP ratio. Such large changes are outside the experience of most countries with moderate inflation, budget deficits, real overvaluation, black market premiums, etc.

The large standard deviations are related to the long tails I mentioned above. Except for the real overvaluation index, all of the policy variables are highly skewed, with most of the sample concentrated at low values and a few very extreme observations. The outlying observations of inflation, budget deficits, and black market premium are realizations of extreme "bad policies". The outlying observations of trade/GDP and M2/GDP are realizations of extreme "good policies". It is econometric commonsense that extreme observations can be very influential in determining statistical significance of right-hand side variables. How do the above regressions do over more moderate ranges of policy variables?

Table 6 shows the effect of restricting the sample to observations where all six policy variables lie in the range of "moderate" policies. Moderate is defined rather arbitrarily by eye-balling the histograms above to determine where are the cutoffs containing the bulk of the sample (the same cutoffs as in Figure 9 above). Nevertheless, the cutoffs would fit a common-sense description of "extremes": inflation and black market premiums more than 0.3 in log terms (35 percent), real overvaluation more than 0.5 (68 percent), budget deficits greater than 12 percent of GDP, M2 to GDP ratios of more than 100 percent, and trade to GDP ratios of more than 120 percent. The results of excluding any observation where any of the six policy variables are "extreme" is striking: all six policy variables become insignificant, and the F-statistic for their joint effect also falls short of significance. This is not to dismiss the evidence for policy effects on growth (reducing the range of the right-hand side variables would be expected to diminish statistical significance). These extremes are far from irrelevant, as observations in which at least one of the six policies was "extreme" account for more than half the sample. However, these results highlight the dependence of the policy and growth evidence on extreme observations of the policy variables. (The significance of extreme values and the insignificance of moderate ones is also consistent with the prediction of the theoretical model on the nonlinear effects of tax-cum-subsidy policies on economic growth.) There is also the possible endogeneity of these extreme policies, which may reflect general institutional or political chaos. The results suggest that countries not undergoing extreme values of these variables do not have strong reasons to expect growth effects of moderate changes in policies.[15]

[15] The empirical literature on inflation has found that inflation only has a negative effect above some threshold level, although there are disagreements as to where that threshold is [Bruno and Easterly (1998), Barro (1995, 1998), Sarel (1996)].

Restrictions under moderate policies: INFL between −0.05 and 0.3, BB between −0.12 and 0.02, M2 < 1.0, LREALOVR between −0.5 and 0.5, Trade < 1.20, LBMP between −0.05 and 0.3.

These results are fairly intuitive if we think of destroying growth as a different process from creating growth. It is a lot easier to cut down a tree than to grow one.[16] Countries that pursue destructive policies like high inflation, high black market premium, chronically high budget deficits and other signs of macroeconomic instability are plausible candidates to miss out on growth. However, it doesn't follow that one can create growth with relative macroeconomic stability. The policies are inherently asymmetric – a leader can sow chaos by printing money and controlling the exchange until he gets a hyperinflation and an absurd black market premium. However, the best he can do in the other direction is zero inflation and zero black market premium. The results on policies and growth may simply reflect the potential for destruction from bad policies, not the potential for fostering long run development through good policy.

The only exception to this story is the trade/GDP variable, whose significance depended on "extremely good" policies. Whatever the source of the result on the extreme,

[16] Easterly (2001a) has a chapter "How governments can destroy growth".

Turning point for convergence is 2981.

this suggests that opening up for most economies – who likely would not reach this extreme even under complete free trade – would not be associated with growth effects.

The next thing to test is whether initial income belongs in the growth equation, as the neoclassical model would imply. It has also been common in the literature to add initial schooling as an indicator of whether the balance between physical and human capital is far from the optimal level. Table 7 shows the results on initial income and schooling.

The results are not very supportive of a conditional convergence result. Initial income and schooling do not enter significantly, although a nonlinear formulation of hump-shaped conditional convergence (including initial income squared) comes close to significance.[17] Since there is a large literature starting with Barro (1991) and Barro and Sala-i-Martin (1992) that does find conditional convergence, I do not claim this result

[17] Hump-shaped convergence is consistent with a neoclassical model in which there is some subsistence floor to consumption (the Stone–Geary utility function).

Table 8

is decisive. It does show the fragility of the results on both policies and initial conditions (note that three of the policy variables become insignificant when initial income is included). I will come back to the issue of conditional convergence when I examine effects of policy on growth with dynamic panel methods.

There is another robustness check that we should perform on the policies and growth results. Following common practice in the literature, I have been doing regressions on pooled time series cross-section observations. This implicitly assumes that the effects on growth of a policy change over time are the same as a policy difference between countries. It is straightforward to test this restriction by doing within and between regressions on the pooled sample. Table 8 shows the results. I also show the results of a random effects regression, which gives results similar to OLS on the pooled sample. The test of whether the random effects are orthogonal to the right-hand side variables is an indirect test of the equality of the coefficients from the between and within regressions. I strongly reject the hypothesis that the random effects are orthogonal. We can see from the between and within (fixed effects) regressions that the coefficients across time and across countries are indeed very different. Inflation is not significant in the be-

aghion v.2005/08/19 Prn:23/08/2005; 8:39 F:aghion1015.tex; VTEX/JK p. 34
aid: 1015 pii: S1574-0684(05)01015-4 docsubty: REV

tween regression but strongly significant in the within regression.[18] The budget balance is the reverse: strongly significant in the between regression but not in the fixed effects regression. The weak result that I found on M2/GDP in the pooled regression turns out to be because the between and within effects tend to cancel out: M2/GDP is strongly positively correlated with growth in the between regression and negatively correlated with growth in the within regressions. Real overvaluation and trade also show different results in the two different panel methods (real overvaluation is significant between countries and insignificant within countries, while trade is the reverse). This instability of growth effects is inconsistent with a simple AK view of growth with instantaneous transitional dynamics. It is also possible that five year averages are not long enough to wipe out cyclical fluctuations. The negative correlation between M2/GDP and growth could be seen as a cyclical pattern such as a loosening of monetary policy during recessions and tightening during booms. Likewise the correlation of trade/GDP with growth could indicate that international trade is pro-cyclical, as opposed to indicating any causal effect of openness on growth.

Also note that the r-squared of the between regression is much higher than the within regression. This is not surprising given that the between regression is on averages, but it does show that the growth effects of most concern to policy makers – the change over time within a given country of growth in response to policy changes – are very imprecisely estimated by the data. Fully 87 percent of the within country variance in growth rates is not explained by these six policy variables. This result is not surprising when we recall the persistence of policies over time and the non-persistence of growth rates.

Another panel method I apply to the data is the well-known dynamic panel estimator of Arellano and Bond (1991). This estimator uses first differences to remove the fixed effects. This method has several advantages: (1) it addresses reverse causality concerns by using twice-lagged values of the right-hand side variables as instruments for the first differences of RHS variables, (2) we can include initial income again, which is not possible with traditional panel methods because it would be correlated with the error term (Arellano and Bond address this by instrumenting for initial income with the twice-lagged value), and (3) we can also include the lagged growth rate to allow for partial adjustment of growth to policy changes, which is more plausible than instantaneous adjustment.

The results in Table 9 are notable in reinvigorating the conditional convergence hypothesis. This is consistent with previous work that shows a higher coefficient (in absolute value) on initial income with dynamic panel methods than with pooled or cross-section OLS [Caselli, Esquivel and Lefort (1995)]. The coefficient on lagged growth is not significant, failing to find support for the partial adjustment hypothesis. The results on policies are similar (not surprisingly) to the fixed effects estimator above. Inflation

[18] This is consistent with the Bruno and Easterly (1998) result that high inflation crises have a strong temporary negative effect on output but no permanent effects.

and trade are strongly significant with the right sign, while M2/GDP still has a significant but perverse sign. The results do not change much if I experiment with omitting one policy variable at a time. The estimates are consistent because I fail to reject that second order serial correlation is zero. The difference with the fixed effects result on policies is that these results have somewhat more claim to being causal. However, the Sargan test rejects the overidentifying restrictions, except in the last equation where I add time dummies. This highlights a weakness of the strong claims for causality made by the dynamic panel method – they depend on the rather dubious assumption that the lagged right-hand side variables do not themselves enter the growth equation. The same problem afflicts the cross-section or pooled regressions that use lagged values of policy

as instruments for current policies. Traditionalists who like intuitive arguments why instruments plausibly affect the independent but not the dependent variable are not very persuaded by lagged policies as instruments. As Mankiw (1995) noted sarcastically, if I instrument for the price of apples with the lagged price of apples in an equation for the quantity of apples, is it the supply or demand equation that I have identified?

Policy episodes and transition paths

A more informal approach to detecting the nature of policy effects on growth is to do episodic analysis – try to identify major policy reforms and simply examine what happened to growth and investment before and after. The shortcomings of this approach are that we do not control for other factors that affect growth and that it is somewhat arbitrary to define what are "major policy reforms". The advantage is that we can see the annual path of growth rates and thus get a better test of the different prediction for post-reform transitional dynamics made by the models in the theoretical section.

One ambitious attempt to identify major policy reform episodes was made by Sachs and Warner (1995). Sachs and Warner rate an economy as closed if any of the following hold: (1) a black market premium more than 20 percent, (2) the government has a purchasing monopoly at below-market prices on a major commodity export, (3) the country has a socialist economic system, (4) non-tariff barriers cover more than 40 percent of intermediate and capital goods imports, and (5) weighted average tariff of more than 40 percent on intermediate and capital goods. Note that only some of these criteria have anything to do with "trade openness" in the usual sense, as pointed out by Rodriguez and Rodrik (2001). The important thing for my purposes is that Sachs and Warner identify the dates of "reform" according to these criteria. I utilize an updated series of Sachs–Warner openness that goes through 1998.[19] I pick out countries with at least 13 years of growth data after opening. Since most openings happen towards the end of the sample period, this limits the sample of countries to only 13: Botswana, Chile, Colombia, Costa Rica, Ghana, Guinea, the Gambia, Guinea-Bissau, Israel, Mexico, Morocco, New Zealand, and Papua New Guinea. Figure 16 shows the path of growth and investment before and after opening, after first smoothing each country's series individually with an HP filter. The results do not support any of the above policies and growth models very convincingly. Investment is completely at variance with the predictions for its transitional path. Growth does show a steady acceleration after opening. This could be either a symptom of increasing returns or simply a process of increased credibility as the reforms take hold. Note however that growth was highest many years before the opening. Perhaps the story of closed and open economies is something more complex like temporary high growth under import substitution, which eventually crashed, followed by an opening of the economy and a partial recovery of growth.

[19] The source is Easterly, Levine and Roodman (2003).

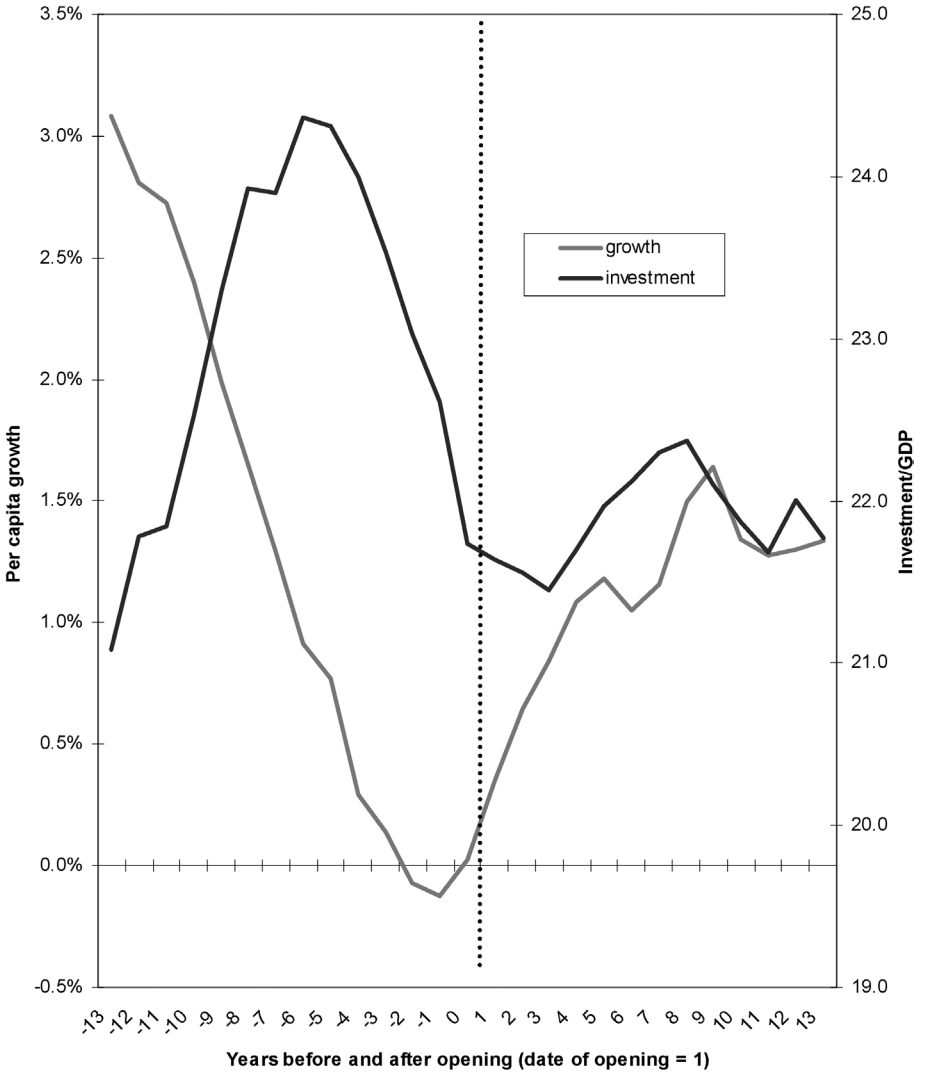

Figure 16. Growth and investment before and after opening economy in 13 countries.

One of the few cases to fit the predictions of growth models as to transitional dynamics is Ghana, where both investment and growth increase after opening. Both keep rising after the date of opening, again supporting either an increasing returns story or increasing credibility of reform (see Figure 17).

Another type of reform that lends itself to transition analysis is stabilization from high inflation. I record episodes of high inflation as following the above definition (log

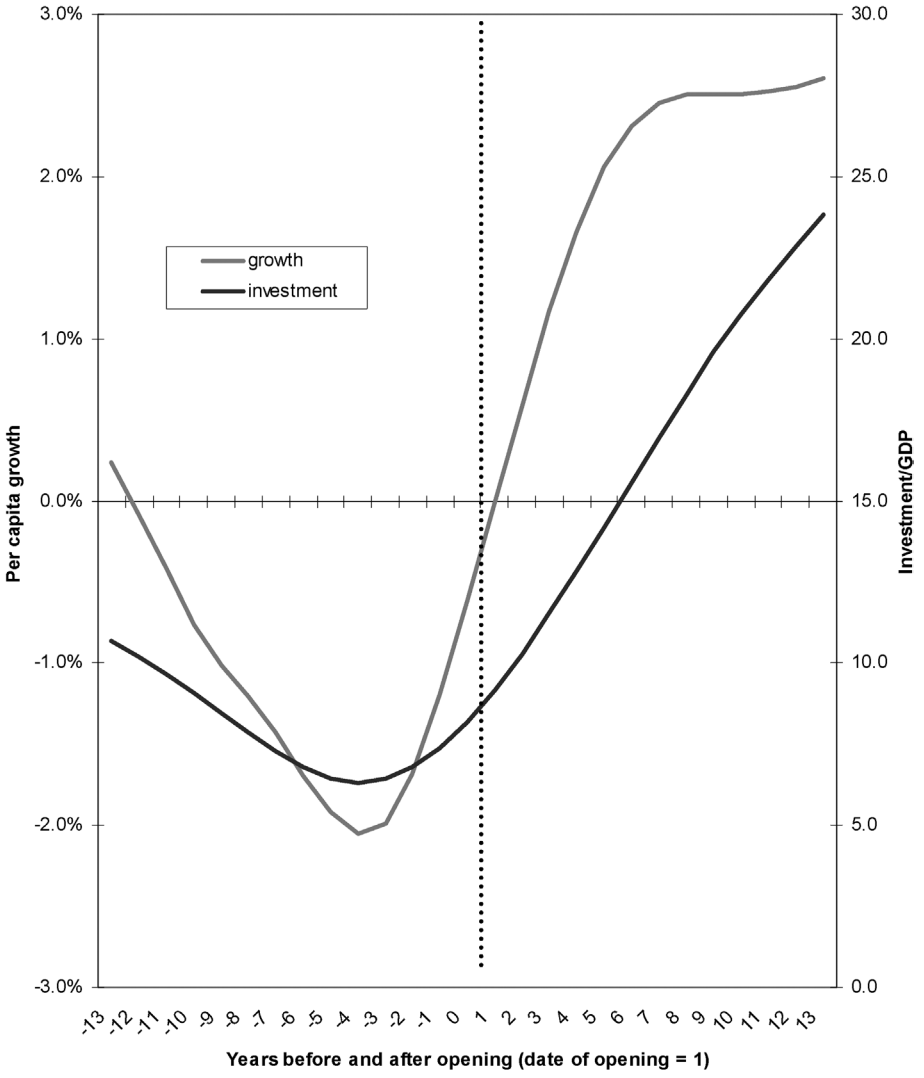

Figure 17. Growth and investment before and after opening economy in Ghana.

rate of inflation above 0.3). I measure years of high inflation prior to stabilization, and then years after stabilization when inflation remains below 0.3. I require that there be at least two years of high inflation to rule out one-time spikes in the price level. The first year after inflation comes down is recorded as year 1. Figure 18 shows the behavior of growth and investment before and after inflation comes down. Growth fits the prediction of theoretical models in jumping to a higher path immediately after inflation comes

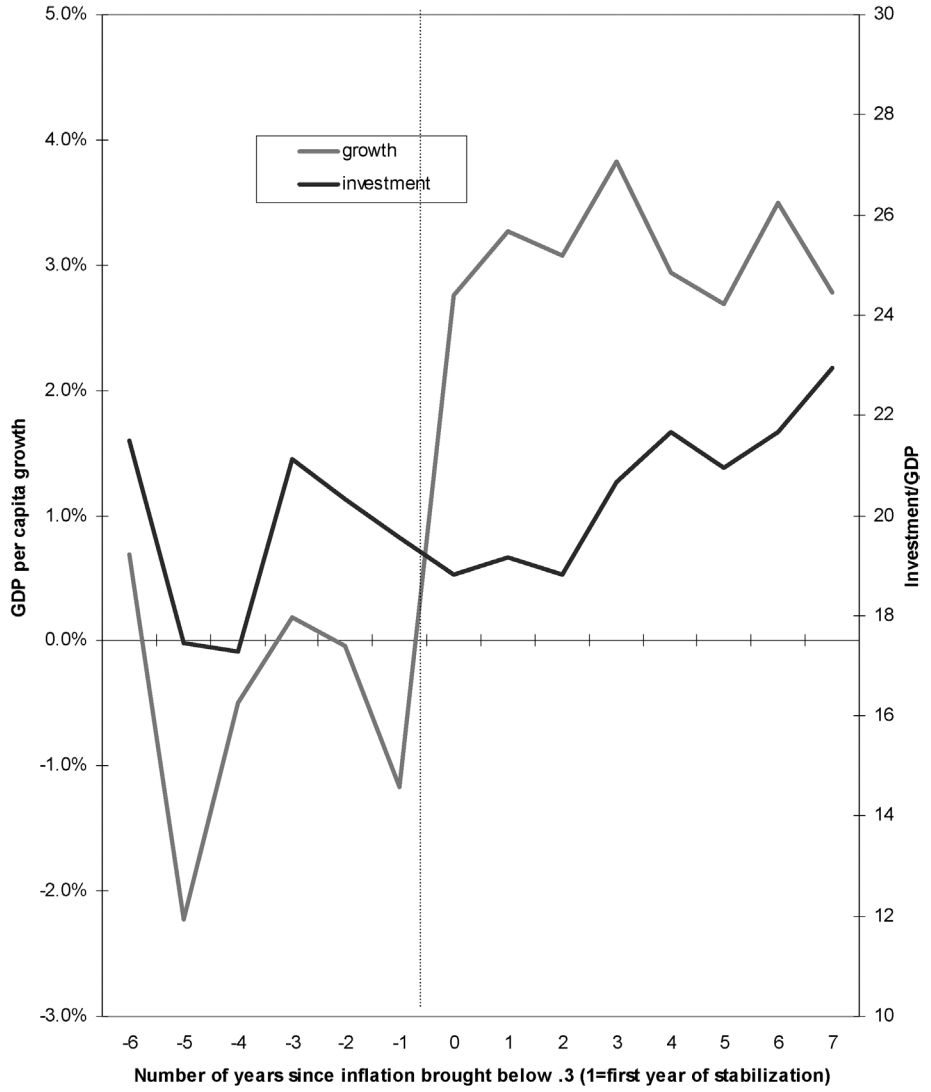

Figure 18. Investment and growth after inflation stabilization.

down. We only have a large enough sample for 7 years after inflation comes down, but growth seems to remain fairly constant post-stabilization. Investment fails to fit the transition predictions of any of the models.

We are left with a somewhat mixed picture. There is a fairly rapid growth effect after policy reform, either accelerating or constant. Investment in physical capital does not seem to respond to reforms in the way predicted by growth models. Of course,

causality is up for grabs. There is also still the extreme policies problem, as episodes in which the country was closed or inflation was very high reflect asymmetrically destructive policies; it is not surprising that growth rebounds after these policies are terminated.

Institutions versus policies

Recent research has examined the relative role of historical institutions and more recent government policy behavior. The *institutions view* holds that geographic and historical conditions produce long-lasting differences in institutions. For example, environments where crops are most effectively produced using large plantations will quickly develop political and legal institutions that protect the few landholders from the many peasants [Engermann and Sokoloff (1997)]. Even when agriculture recedes from the economic spotlight, enduring institutions will continue to thwart competition and hence economic development. Similarly, many countries' institutions were shaped during colonization, so that examining colonies is a natural experiment. European colonialists found different disease environments around the globe. In colonies with inhospitable germs and climates, the colonial powers established extractive institutions, so that a few colonialists could exploit natural resources. In colonies with hospitable climates and germs, colonial powers established settler institutions. According to this view, the institutional structures created by the colonialists in response to the environment endure even with the end of colonialism [Acemoglu, Johnson and Robinson (2001, 2002)]. A history of ethnolinguistic divisions may both prevent the development of good institutions and be more damaging when those institutions are absent [Mauro (1995), Easterly and Levine (1997), and Easterly (2001a)]. Thus, the institution view argues that economic development mainly depends on institutions that reflect deep-seated historical factors [North (1992)].

In contrast, the *policy* view – which is really a collection of many different approaches – questions the importance of history or geography in shaping economic development today. This view is embedded in the approach of multilateral development institutions. The policy view holds that economic policies and institutions reflect current knowledge and political forces. Thus, changes in either knowledge about which policies and institutions are best for development or changes in political incentives will produce rapid changes in institutions and economic policies. According to the policy view, while history and geography may have influenced production and institutions, understanding them is not crucial to understanding economic development today.

Easterly and Levine (2003) examine whether major macroeconomic policies – inflation, trade policies, and impediments to international transactions as reflected in real exchange rate overvaluation – help explain current levels of economic development, after controlling for institutions. They do this in two steps. First, they treat the macroeconomic policy indicators, which are averaged over the last four decades as exogenous.

Simultaneity bias may bias these results toward finding a significant statistical relationship between policies and economic development if economic success tends to produce better policies. Second, they treat the macroeconomic policy indicators as endogenous; they use instrumental variables (geographic variables and ethnolinguistic fractionalization) to control for potential simultaneity bias. Using these two methods, they assess whether macroeconomic policies explain cross-country differences in economic development. In both methods they instrument for institutions with the set of variables discussed above.

The evidence suggests that macroeconomic policies do not have a significant impact on economic development after accounting for the impact of institutions on the level of economic development. When the policy variables are treated as included exogenous variables, the Institutions Index enters all of the regression significantly. Furthermore, the coefficient size on the Institutions Index is essentially unchanged from regressions that did not include policy indicators. Thus, even after controlling for macroeconomic policies, institutions explain cross-country differences in economic development. Furthermore, the data never reject the OIR-test. The policy indicators never enter the regressions significantly. Inflation, Openness, and Real Exchange Rate Overvaluation never enter with a P-value below 0.10. Moreover, even when they are included together, the data do not reject the null hypothesis that the three policies all enter with coefficients equal to zero, which is shown using the F-test on the three policy variables.

When using instrumental variables for the policy indicators, they again find that macroeconomic policies do not explain economic development. Specifically, they fail to reject that hypothesis that macroeconomic policies have zero impact on economic development after accounting for the impact of institutions.

As noted earlier, the instrumental variables explain a significant amount of the cross-country variation in the Institutions Index. In the first-stage regressions for policy, Easterly and Levine (2003) find that the instruments explain a significant amount of the cross-country variation in Openness and Real Exchange Rate Overvaluation at the 0.01 significance level. However, the instruments do not do a very good job of explaining cross-country variation in inflation, i.e., they fail to find evidence that the instruments explain average inflation rates over the last four decades at the 0.01 significance level. The policy variables never enter significantly in either method. While the exogenous component of the Institutions Index (i.e., the component defined by endowments) continues to significantly account for international differences in the level of GDP per capita, the macroeconomic policy indicators do not add any additional explanatory power.

This raises the suspicion that adverse macroeconomic policies (and macroeconomic volatility in general) may have been proxying for poor institutions in growth regressions. Acemoglu et al. (2003) provide some evidence supporting this suspicion.

In sum, the long run effect of policies on development is difficult to discern once you also control for institutions.

Conclusions

The large literature on national policies and growth established some statistical association between national economic policies and growth. I confirm that association in this paper and I show how it could have reasonable theoretical foundations. However, I find that the associations seem to depend on extreme values of the policy variables, that the results are not very robust to different econometric methods or introducing initial income, and that a levels regression does not show any effect of policies after controlling for institutions (both instrumented for possible endogeneity). These results are consistent with other theoretical models that predict only modest effects of national policies, depending on model parameters, and show nonlinear effects of tax-cum-subsidy schemes. They are also consistent with the view that the residual A explains most of income and growth differences, and it likely reflects deep-seated institutions that are not very amenable to change in the short run.

Long-term Economic growth

and the History of Technology

Joel Mokyr
Departments of Economics and History
Northwestern University

Version of Oct. 2003

Prepared for the *Handbook of Economic growth,* edited by Philippe Aghion and Steven Durlauf.

Some of the material in this paper is adapted from my books *The Lever of Riches: Technological Creativity and Economic Change* New York: Oxford University Press, 1990; *The Gifts of Athena: Historical Origins of the Knowledge Economy*. Princeton: Princeton University Press, 2002 and *The Enlightened Economy: an Economic history of Britain, 1700-1850.* Harmondsworth: Penguin Press, 2004, as well as from a number of more detailed papers available upon request.

Introduction

As every economist knows, the modern era is the era of economic growth. In the past two centuries, measures of output per capita have increased dramatically and in a sustained manner, in a way they had never done before. It seems by now a consensus to term the start of this phenomenon "the Industrial Revolution," although it is somewhat in dispute what precisely is meant by that term (Mokyr, 1998b). In the past two decades an enormous literature has emerged to explain this phenomenon. A large number of "deep" questions have emerged which this literature has tried to answer. Below I list the most pertinent of these questions and in the subsequent pages, I shall make an attempt to answer them.

1. What explains the *location* of the Industrial Revolution (in Europe as opposed to the rest of the world, in Britain as opposed to the rest of Europe, in certain regions of Britain as opposed to others). What role did geography play in determining the main parameters of the Industrial Revolution?

2. What explains the *timing* of the Industrial Revolution in the last third of the eighteenth century (though the full swing of economic growth did not really start until after 1815)? Could it have started in the middle ages or in classical antiquity?

3. Is sustained economic growth and continuous change the "normal" state of the economy, unless it is blocked by specific "barriers to riches" or is the stationary state the normal condition, and the experience of the past 200 years is truly a revolutionary regime change?

4. What was the role of technology in the origins of the Industrial Revolution and the subsequent evolution of the more dynamic economies in which rapid growth became the norm?

5. What was the relation between demographic behavior (and specifically the fall in mortality after 1750 and the subsequent decline in fertility and shift toward fewer but higher-quality children) in bringing about and sustaining modern economic growth?

6. What was the role of institutions (in the widest sense of the word) in bringing about modern economic growth, and to what extent can we separate it from other factors such as technology and factor accumulation?

7. To what extent is modern growth due to "culture," that is, intellectual factors regarding beliefs, attitudes, and preferences? Does culture normally adapt to the economic environment, or can one discern autonomous cultural changes that shaped the economy?

8. Did the "Great Divergence" really start only in the eighteenth century, and until then the economic performance and potential of occident and the orient were comparable, or can signs of the divergence be dated to the renaissance or even the middle ages?

9. Was the Industrial Revolution "inevitable" in the sense that the economies a thousand years earlier already contained the seeds of modern economic growth that inexorably had to sprout and bring it about?

10. What was the exact role of human capital, through formal education or other forms, in bringing about modern economic growth?

Technology and Economic growth

Economists have become accustomed to associate long-term economic growth with technological progress; it is deeply embedded in the

main message of the Solow-inspired growth models, which treated technological change as exogenous, and even more so in the endogenous growth models.[1] Whether technology is a deus ex machina that somehow makes productivity grow a little each year, or produced within the system by the rational and purposeful application of research and development, the growth of human and physical capital that are strongly complementary with productivity growth, or even in the simple TFP computations that often equate the residual with technological progress — technology is central to the dynamic of the economy in the past two centuries. Many scholars believe that people are inherently innovative and that if only the circumstances are right (the exact nature of these conditions differs from scholar to scholar), technological progress is almost guaranteed. This somewhat heroic assumption is shared by scholars as diverse as Robert Lucas and Eric L. Jones, yet it seems at variance with the historical record. The record is that despite many significant, even path-breaking innovations in many societies since the start of written history, it has not really been a major factor in economic growth, such as it was, before the Industrial Revolution.

Instead, economic historians studying earlier periods have come to realize that technology was less important than institutional change in explaining pre-modern episodes of economic growth. It is an easy exercise to point to the many virtues of "Smithian Growth," the increase in economic output due to commercial progress (as opposed to technological progress). Better markets, in which agents could specialize according to their comparative advantage and take full advantage of economies of scale, and in which enhanced competition would stimulate efficiency and the adoption of best-practice technology could generate growth sustainable for decades and even centuries. Even with no changes whatsoever in technology, economies can grow in the presence of peace, law and order, improved communications and trust, the introduction of money and credit, enforceable and secure property rights, and similar institutional improvements (Greif, 2003). Similarly, better institutions can lead to improved

[1] The opening line of the standard textbook in the area states that the "most basic proposition of growth theory is that in order to sustain a positive growth rate of output per capita in the long run, there must be continual advances in technological knowledge" (Aghion and Howitt, 1998, p. 11).

allocation of resources: law and order and improved security can and will encourage productive investment, reduce the waste of talent on rent-seeking and the manipulation of power for the purposes of redistribution (North, 1990; Shleifer and Vishny, 1998; Baumol, 2002). Tolerance for productive "service minorities" who lubricated the wheels of commerce (Syrians, Jews and many others) played important roles in the emergence of commerce and credit. Economic history before 1750 is primarily about this kind of growth. The wealth of Imperial Rome and the flourishing of the medieval Italian and Flemish cities, to pick just a few examples, were based above all on commercial progress, sometimes referred to as "Smithian Growth."

It is usually assumed by economists that sustained economic growth is a recent phenomenon simply because if modern rates of growth had been sustained, a simple backward projection suggests that income in 1500 or in 1000 would have been absurdly low.[2] Clearly, growth at the rates we have gotten used to in the twentieth century are unthinkable in the long run. Yet it is equally implausible to think that just because growth was slower, there was *none* of it – after all, there is a lot of time in the long run. One does not have to fully subscribe to Graeme Snooks's use of Domesday book and Gregory King's numbers 600 years later to accept his view that by 1688 the British economy was very different indeed from what it had been at the time of William the Conqueror. Adam Smith had no doubt that "the annual produce of the land and labour of England... is certainly much greater than it was a little more than century ago at the restoration of Charles II (1660)... and [it] was certainly much greater at the restoration than we can suppose it to have been a hundred years before" (Smith, 1776-1976, pp. 365-66).[3] On the eve of the Industrial Revolution, large parts of

---

[2] For instance, income per capita in the UK in 1890 was about $4100 in 1990 international dollars. It grew in the subsequent years by an average of 1.4% per year. Had it been growing at that same rate in the previous 300 years, income percapita in 1590 would have been $ 61, which clearly seems absurdly low.

[3] Snooks's (1994) belief in pre-modern growth is based essentially on his comparison between the income per capita he has calculated from the Domesday book (1086) and the numbers provided by Gregory King for 1688. While such computations are of course always somewhat worrisome (what, exactly, does it mean to estimate the

Europe and some parts of Asia were enjoying a standard of living that had not been experienced ever before, in terms of the quantity, quality, and variety of consumption.[4] Pre-1750 growth was primarily based on Smithian and Northian effects: gains from trade and more efficient allocations due to institutional changes. The Industrial Revolution, then, can be regarded not as the beginnings of growth altogether but as the time at which technology assumed an ever-increasing weight in the generation of growth.[5] It should not be confused with the demographic transition, which came later and whose relationship with technological progress is complex and poorly understood.

This is not to say that before the Industrial Revolution technology was altogether unimportant in its impact on growth. Medieval Europe was an innovative society which invented many important things (including movable type, gunpowder, spectacles, the mechanical clock) and adopted many more inventions from other societies (paper, navigational instruments, Arabic numerals, the lateen sail, wind power). Yet, when all is said and done, it is hard to argue that the impact of these inventions on the growth of GDP or some other measure of aggregate output were all that large. The majority of the labor force was still employed in agriculture where progress was exceedingly slow (even if over the long centuries be-

---

nominal income of 1086 in the prices of 1688 given the many changes in consumption items?), the order of magnitude provided by Snooks (an increase of real income by 580 percent) may survive such concerns. Medievalists tend to agree with the occurrence of economic growth in Britain, though their figures indicate a much slower rate of growth, about a 111 percent growth rate between 1086 and 1470 (Britnell, 1996, p. 229), which would require more economic growth in the sixteenth and seventeenth centuries than can be justified to square with Snooks's numbers. Engerman (1994, p. 116) assesses that most observers will agree with Snooks's view that by 1700 England had a high level of per capita income and was in a good position to "seek the next stage of economic growth." Yet clearly he is correct in judging that "modern" economic growth (prolonged, continuous, rapid) did not begin until the early nineteenth century.

[4] Indeed, many historians speak of a "consumer revolution" *prior to* the Industrial Revolution, which would be inexplicable without rising income before 1750. Lorna Weatherill (1988) suggests that if there was a Consumer Revolution at all, it peaked in the period 1680-1720. Moreover, consumer revolutions were taking place elsewhere in Europe. Seventeenth century Holland was, of course, the most obvious example thereof, but Cissie Fairchilds (1992) has employed probate records to show that France, like England, experienced a consumer revolution, albeit fifty years later.

[5] It is in that sense that the view of modern economists (e.g. Galor and Weil, 2000, p. 809) that "the key event that separates Malthusian and Post-Malthusian regimes is the acceleration of the pace of technological progress" is a bit misleading, since it draws a link between technological progress and demographic change that thus far has not been closely examined.

tween 800 and 1300 the three-field system and the growing efficiency at which livestock was employed did produce considerable productivity gains).

Moreover, it is true for the pre-1750 era – as it was a fortiori after 1750 – that technology itself interacted with Smithian growth because on balance improved technology made the expansion of trade possible – above all maritime technology in all its many facets, but also better transport over land and rivers, better military technology to defeat pirates, better knowledge of remote lands, and the growing ability to communicate with strangers. A decomposition of growth into a technology component and a trade-and-institutions component must take into account such interactions.

All the same, the main reason why technological progress was at best an also-ran in the explanation of economic growth before 1750 is that even the best and brightest mechanics, farmers, and chemists — to pick three examples — knew relatively little of what could be known about the fields of knowledge they sought to apply. The pre-1750 world produced, and produced well. It made many pathbreaking inventions. But it was a world of engineering without mechanics, iron-making without metallurgy, farming without soil science, mining without geology, water-power without hydraulics, dye-making without organic chemistry, and medical practice without microbiology and immunology. Not enough was known to generate sustained economic growth based on technological change. Such statements are of course to some extent provocative and perhaps even irresponsible: how can we define "what could be known" in any meaningful sense? Who knew "that which was known" and how did they use it? In what follows I shall propose a simple framework to understand how and why new technology emerges and how it was limited before the eighteenth century and then liberated from its constraints. I will then argue that "technological modernity" means an economy in which *sustained* technological progress is the primary engine of growth and that it depended on the persistence of technological progress.

A Historical Theory of Technology

Technology is knowledge. Knowledge, as is well known, has always been a difficult concept for standard economics to handle. It is at the core of modern economic growth, but many characteristics make it slippery to handle. Knowledge is above all a non-rivalrous good, that is, sharing it with another person does not diminish the knowledge of the original owner. It is not quite non-excludable, but clearly excludability is costly and for many types of knowledge exclusion costs are infinite. It is produced in the system, but the motivation of its producers are rarely purely economic. Indeed, the producers of scientific knowledge almost never collect but a

tiny fraction of the surplus they produce for society. It is the mother of all spillover effects. A more fruitful approach than to view knowledge as an odd sort of good, pioneered by Olsson (2000, 2003), is to model knowledge as a set, and to analyze its growth in terms of the properties of existing knowledge rather than looking at the motivations of individual agents.

The basic unit of analysis of technology is the "technique." A technique is a set of instructions, much like a cookbook recipe, on how to produce goods and services. As such, it is better defined than the concept of a stock of "ideas" that some scholars prefer (e.g. Charles Jones, 2001). The entire set of feasible techniques that each society has at its disposal is bound by the isoquant. Each point on or above the isoquant in principle represents a set of instructions on how to combine various ingredients in some way to produce a good or service that society wants. While technology often depends on artifacts, the artifacts are not the same as the technique and what defines the technique is the content of the instructions. Thus, a piano is an artifact, but what is done with it depends on the technique used by the pianist, the tuner, or the movers. Society's production possibilities are bound by what society knows. This knowledge includes the knowledge of making artefacts and using them.

But who is "society"? The only sensible way of defining knowledge at a social level is as the *union* of all the sets of individual knowledge. This definition is consistent with our intuitive notion of the concept of an invention or a discovery – at first only *one* person has it, but once that happens society as a whole feels it has acquired it. Knowledge can be stored in external storage devices such as books, drawings, and artifacts but such knowledge is meaningless unless it can be transferred to an actual person. Such a definition immediately requires a further elaboration: if one person possesses a certain knowledge, how costly is it for others to acquire it? This question, indeed is at the heart of the idea of a "technological society." Knowledge is shared and distributed, and its transmission through learning is essential for such a society to make effective use of it. Between the two extremes of a society in which all knowledge acquired by one member is "episodic" and not communicated to any other member, and the other extreme in which all knowledge is shared through some monstrous network, there was a reality of partial and costly sharing and access. But these costs were not historically invariant, and their changes are one of the keys to technological change.

Progress in exploiting the existing stock of knowledge will depend first and foremost on the efficiency and cost of access to knowledge. Although knowledge is a public good in the sense that the consumption of one does not reduce that of others, the private costs of acquiring it are not negligible, in terms of time, effort, and often other real resources as well (Reiter, 1992, p. 3). Access costs include the costs of finding out whether an

answer to a question actually exists, if so, where it can be found, then paying the cost of acquiring it, and finally verifying the correctness of the knowledge. When the access costs become very high, it could be said in the limit that social knowledge has disappeared.[6] Language, mathematical symbols, diagrams, and physical models are all means of reducing access costs. Shared symbols may not always correspond with the things they signify, as postmodern critics believe, but as long as they are shared they reduce the costs of accessing knowledge held by another person or storage device.

The determinants of these access costs are both institutional and technological: "open knowledge" societies, in which new discoveries are published as soon as they are made and in which new inventions are placed in the public domain through the patenting system (even if their application may be legally restricted), are societies in which access costs will be lower than in societies in which the knowledge is kept secret or confined to a small and closed group of insiders whether they are priests, philosophers, or mandarins. Economies that enjoyed a high level of commerce and mobility were subject to knowledge through the migration of skilled workmen and the opportunities to imitate and reverse-engineer new techniques. As access costs fell in the early modern period, it became more difficult to maintain intellectual property rights through high access costs, and new institutions that provided incentives for innovators became necessary, above all the patent system emerging in the late fifteenth and sixteenth centuries. The printing press clearly was one of the most

---

[6] This cost function determines how costly it is for an individual to access information from a storage device or from another individual. The *average* access cost would be the average cost paid by all individuals who wish to acquire the knowledge. More relevant for most useful questions is the *marginal* access cost, that is, the *minimum* cost for an individual who does not yet have this information. A moment reflection will make clear why this is so: it is very expensive for the average member of a society to have access to the Schrödinger wave equations, yet it is "accessible" at low cost for advanced students of quantum mechanics. If someone "needs" to know something, he or she will go to an expert for whom this cost is as low as possible to find out. Much of the way knowledge has been used in recent times has relied on such experts. The cost of finding them experts and retrieving knowledge thus determines marginal access costs. Equally important, as we shall see, is the technology that provides access to storage devices.

significant access-cost-reducing inventions of the historical past.[7] The nature of the books printed, such as topic, language, and accessibility, played an equally central role in their reduction. People normally acquired knowledge and skills vertically, but also from one another through imitation. Postdoctoral students in laboratory settings full-well realize the differences between the acquisition of codifiable knowledge and the acquisition of tacit knowledge through imitation and a certain *je ne sais quoi* we call experience.[8]

Techniques constitute what I have called *prescriptive* knowledge – like any recipe they essentially comprise instructions that allow people to "produce," that is, to exploit natural phenomena and regularities in order to improve human material welfare.[9] The fundamental unit of set of prescriptive knowledge has the form of a set of do-loops (often of great complexity, with many if-then statements), describing the "hows" of what we call production.

There are two preliminary observations we need to point out in this context. One is that it is impossible to specify explicitly the entire

---

[7] Elizabeth Eisenstein (1979) has argued that the advent of printing created the background on which the progress of science and technology rests. In her view, printing created a "bridge over the gap between town and gown" as early as the sixteenth century, and while she concedes that "the effect of early printed technical literature on science and technology is open to question" she still contends that print made it possible to publicize "socially useful techniques" (pp. 558, 559).

[8] It should be obvious that in order to read such a set of instructions, readers need a "codebook" that explains the terms used in the technique (Cowan and Foray, 1997). Even when the techniques are explicit, the codebook may not be, and the codebook needed to decipher the first codebook and the next, and so on, eventually must be tacit. Sometimes instructions are "tacit" even when they could be made explicit but it is not cost-effective to do so.

[9] These instructions are essentially identical to the concept of "routines|" proposed by Nelson and Winter (1982). When these instructions are carried out in practice, we call it production, and then they are no longer knowledge but action. "Production" here should be taken to include household activities such as cooking, cleaning, childcare, and so forth, which equally require the manipulation of natural phenomena and regularities. It is comparable to DNA instructions being "expressed." Much like instructions in DNA, the lines in the technique can be either "obligate" (do X) or "facultative" (if Y, do X). For more complex techniques, nested instructions are the rule.

content of a set of instructions. Even a simple cooking recipe contains a great deal of assumptions that the person executing the technique is supposed to know: how much a cup is, when water is boiling, and so on. For that reason, the person executing a technique is supposed to have certain knowledge that I shall call *competence* to distinguish it from the knowledge involved in writing the instructions for the first time (that is, actually making the invention). Competence consists of the knowledge of how to read, interpret, and execute the instructions in the technique and the supplemental tacit knowledge that cannot be fully written down in the technique's codified instructions. There is a continuum between the implicit understandings and clever tricks that make a technique work we call tacit knowledge, and the minor improvements and refinements introduced subsequent to invention that involve actual adjustments in the explicit instructions. The latter would be more properly thought off as microinventions, but clearly any sharp distinction between them would be arbitrary. All the same, "competence" and "knowledge" are no less different than the differences in skills needed to play the Hammerklavier sonata and those needed to compose it. One of the most interesting variables to observe is the ratio between the knowledge that goes into the first formulation of the technique in question (invention) and the competence needed to actually carry out the technique. As we shall see, it is this ratio around which the importance of human capital in economic growth will pivot.

The second observation is the notion that every technique, because it involves the manipulation and harnessing of natural regularities, requires an *epistemic base,* that is, a knowledge of nature on which it is based. I will call this type of knowledge *propositional* knowledge, since it contains a set of propositions about the physical world. The distinction between propositional and prescriptive knowledge seems obvious: the planet Neptune and the structure of DNA were not "invented"; they were already there prior to discovery, whether we knew it or not. The same cannot be said about diesel engines or aspartame. Polanyi notes that the distinction is recognized by patent law, which permits the patenting of inventions (additions to prescriptive knowledge) but not of discoveries (additions to propositional knowledge). He points out that the difference boils down to observing that prescriptive knowledge can be "right or wrong" whereas "action can only be successful or unsuccessful."(1962, p. 175). Purists will object that "right" and "wrong" are judgments based on socially constructed criteria, and that

"successful" needs to be defined in a context, depending on the objective function that is being maximized.

The two sets of propositional and prescriptive knowledge together form the set of useful knowledge in society. These sets satisfy the conditions set out by Olsson (2000) for his "idea space." Specifically, the sets are infinite, closed, and bounded. They also are subsets of much larger sets, the sets of knoweable knowledge. At each point of time, the actual sets describe what a society knows and consequently what it can do. There also is a more complex set of characteristics that connect the knowledge at time t with that in the next period. Knowledge is mostly cumulative and evolutionary. The "mostly" is added because it is not wholly cumulative (knowledge *can* be lost, though this has become increasingly rare) and its evolutionary features are more complex than can be dealt with here (Mokyr, 2003a).

The actual relation between propositional and prescriptive knowledge can be summarized in the following 10 generalizations:

1. Every technique has a minimum epistemic base, which contains the least knowledge that society needs to possess for this technique to be invented. The epistemic base contains at the very least the trivial statement that technique i works.[10] There are and have been some techniques, invented accidentally or through trial and error, about whose modus operandi next to nothing was known except that they worked. We can call these techniques *singleton* techniques (since their domain is a singleton).

2. Some techniques require a minimum epistemic base larger than a singleton for a working technique to emerge. It is hard to imagine such techniques as nuclear resonance imaging or computer assisted design software as emerging in any society as the result of serendipitous finds or trial-and-error methods, without the designers having a clue of why and how they worked.

[10] This statement is true because the set of propositional knowledge contains as a subset the list (or catalog) of the techniques that work – since that statement can be defined as a natural regularity.

3. The actual epistemic base is equal to or larger than the minimum epistemic base. It is never bound from above in the sense that the amount that can be known about the natural phenomena that govern a technique is infinite. In a certain sense, we can view the epistemic base at any given time much like a fixed factor in a production function. As long as it does not change, it imposes concavity and possibly even an upper bound on innovation and improvement. On the other hand, beyond a certain point, the incremental effect of widening the actual epistemic base on the productivity growth of a given technique will run into diminishing returns and eventually be limited.

4. There is no requirement that the epistemic base be "true" or "correct" in any sense. In any event, the only significance of such a statement would be that it conforms to contemporary beliefs about nature (which may well be refuted by future generations). Thus the humoral theory of disease, now generally rejected, formed the epistemic base of medical techniques for many centuries. At the same time, some epistemic bases can be more effective than others in the sense that techniques based on them perform "better" by some agree-upon criterion. "Effective knowledge" does not mean "true" – many techniques were based on knowledge we no longer accept yet were deployed for long periods with considerable success.[11]

5. The wider the actual epistemic base supporting a technique relative to the minimum one, the more likely an invention is to occur, ceteris paribus. A wider epistemic base means that it is less likely for a researcher to enter a blind alley and to spend resources

[11] Here one can cite many examples. Two of them are the metallurgical writings and inventions of René Réaumur and Tobern Bergman, firmly based on phlogiston physics, and the draining of swamps based on the belief that the "bad air" they produced caused malaria.

in trying to create something that cannot work.[12] Thus, a wider epistemic base reduces the costs of research and development and increases the likelihood of success.

6. The wider the epistemic base, the more likely an existing technique is to be improved, adapted, and refined through subsequent microinventions. The more is known about the principles of a technique, the lower will be the costs of development and improvement. This is above all because the more is known *why* something works, the better the inventor can tweak its parameters to optimize and debug the technique. Furthermore, because invention so often consists of analogy with or the recombination of existing techniques, lower access cost to the catalog of existing techniques (which is part of propositional knowledge) stimulates and streamlines successful invention.

7. The epistemic bases in existence during the early stages of an invention are historically usually quite narrow at first, but are often enlarged following the appearance of the invention, and sometimes directly on account of the invention.

8. Both propositional and prescriptive knowledge can be "tight" or "untight." Tightness measures the degree of confidence and consensualness of a piece of knowledge: how sure are people that the knowledge is "true" or that the technique "works?" The tighter a piece of propositional knowledge, the lower are the costs of verification and the more likely the technique is to be adopted, and vice versa. Of course, tightness should be closely correlated with effectiveness: a laser printer works better than a dot matrix, and

---

[12] Alchemy – the attempt to turn base metals into gold by chemical means – was still a major occupation of the best minds of the scientific revolution above all Isaac Newton. By 1780 Alchemy was in sharp decline and in the nineteenth century chemists knew enough to realize that it was a misallocation of human capital to search for the stone of the wise as it was for the fountain of youth. The survival of astrology in our time demonstrates that the prediction of the future – always a technique based on a very narrow epistemic base – has not benefitted in a similar way from a widening of the prescriptive knowledge on which it was based.

there can be little dispute about the characteristics here. If two techniques are based on incompatible epistemic bases, the one that works better will be chosen and the knowledge on which it is based will be judged to be more effective. But for much of history, such testing turned out to be difficult to do and propositional knowledge was more often selected on the basis of authority and tradition that effectiveness. Even today, for many medical and farming techniques it is often difficult to observe what works and what does not work as well without careful statistical analysis or experimentation.

9. It is not essential that the person writing the instructions actually knows himself everything that is in the epistemic base. Even if very few individuals in a society know quantum mechanics, the practical fruits of the insights of this knowledge to technology may still be available just as if everyone had been taught advanced physics. It is a fortiori true that the people carrying out a set of instructions do not know how and why these instructions work, and what the support for them is in propositional knowledge. No doctor prescribing nor any patient taking an aspirin will need to study the biochemical properties of prostaglandins, though such knowledge may be essential for those people trying to design an analgesic with, say, fewer side effects. What counts is collective knowledge and the cost of access as discussed above. It is even less necessary for the people actually carrying out the technique to possess the knowledge on which it is based, and normally this is not the case.

10. The existence of a minimum epistemic base is a necessary but insufficient condition for a technique to emerge. A society may well accumulate a great deal of propositional knowledge that is never translated into new and improved techniques. Knowledge opens doors, but it does not force society to walk through them.

The significance of the Industrial Revolution.

Historians in the 1990s have tended to belittle the significance of the Industrial Revolution as a historical phenomenon, referring to it as the so-called Industrial Revolution, and pointing to the slowness and gradualness of economic change, as well as the many continuities that post 1760 Britain had with earlier times (for a critical survey, see Mokyr 1998b).

Before I get to the heart of the argument, two points need to be cleared away. The first is the myth that the Industrial Revolution was a purely British affair, and that without Britain's leadership Europe today would still be largely a subsistence economy. The historical reality was that many if not most of the technological elements of the Industrial Revolution were the result of a joint international effort in which French, German, Scandinavian, Italian, American and other "western" innovators collaborated, swapped knowledge, corresponded, met one another, and read each others' work.

It is of course true that in most cases the first successful economic *applications* of the new technology appeared in Britain. Clearly in 1789 Britain had an advantage in the execution of new techniques. Yet an overwhelming British advantage in *inventing* — especially in generating the crucial macroinventions that opened the doors to a sustained trajectory of continuing technological change — is much more doubtful, and their advantage in expanding the propositional knowledge that was eventually to widen the epistemic bases of the new techniques is even more questionable. Britain's technological precociousness in the era of the Industrial Revolution was a function of three factors.

First, it was at peace in a period when the Continent was engulfed in political and military upheaval. Not only that there was no fighting on British soil; the French revolution and the Napoleonic era was a massive distraction of talent and initiative that would otherwise have been available to technology and industry.[13] The attention of both decision makers and

---

[13] The great chemists Claude Berthollet and Jean-Antoine Chaptal, for instance, both directed their abilities to administration during the Empire. Their illustrious teacher, the great Lavoisier himself, was executed as a tax farmer. Another example is Nicolas de Barneville, who was active in introducing British spinning equipment into France. De Barneville repeatedly was called upon to serve in military positions and was "one of those unfortunate individuals whose lives have been marred by war and revolution ... clearly a victim of the troubled times" (McCloy, 1952, pp. 92-94).

inventors was directed elsewhere.[14] During the stormy years of the Revolution, French machine breakers found an opportunity to mount an effective campaign against British machine, thus delaying their adoption (Horn, 2003). Second, Britain's entrepreneurs proved uncannily willing and able to adopt new inventions regardless of where they were made, free from the "not made here" mentality of other societies. Some of the most remarkable inventions made on the Continent were first applied on a wide scale in Britain. Among those, the most remarkable were gas-lighting, chlorine bleaching, the Jacquard loom, the Robert continuous paper-making machine, and the Leblanc soda making process.[15] In smaller industries, too, the debt of the British Industrial Revolution to Continental technology demonstrates that in no sense did Britain monopolize the inventive process.[16] The British advantage in application must be chalked up largely

---

[14] The Frenchman Philippe LeBon, co-inventor of gaslighting in the 1790s, lost out in his race for priority with William Murdoch, the ingenious Boulton and Watt engineer whose work in the end led the introduction of this revolutionary technique in the illumination of the Soho works in 1802. As one French historian sighs, "during the terrors of the Revolution... no one thought of street lights. When the mob dreamed of lanterns, it was with a rather different object in view" (Cited by Griffiths, 1992, p. 242).

[15] Nicholas Leblanc, who developed the soda making process named after him. Leblanc reacted salt and sulphuric acid to produce sodium sulphate, which after heating with lime or charcoal yielded raw soda together with hydrochloric acid, a noxious by-product. The Leblanc process became the basis of the modern chemical industry and is regarded as one of the most important inventions of the time. In the adoption of soda, Britain was relatively slow, and only in the 1820s did it start to adopt Leblanc's process on a large scale. The explanation usually given for this delay is the high tax on salt, which made artificial soda more expensive than vegetable alkali. Once the salt tax was repealed, British soda production grew rapidly and by the 1850s exceeded French output by a factor of three (Haber, 1958, pp. 10-14).

[16] The most important breakthrough in the glass industry was made in 1798 by Pierre Louis Guinand, a Swiss, who invented the stirring process in which he stirred the molten glass in the crucible using a hollow cylinder of burnt fireclay, dispersing the air bubbles in the glass more evenly. The technique produced optical glass of unprecedented quality. Guinand kept his process secret, but his son sold the technique to a French manufacturer in 1827, who in turn sold it to the Chance Brothers Glass Company in Birmingham, which soon became one of the premier glassmakers in Europe. The idea of preserving food by cooking followed by vacuum sealing was hit upon by the Frenchman Nicolas Appert in 1795. Appert originally used glassware to store preserved foods, but in 1812 an Englishman named Peter Durand suggested using

to its comparative advantage in microinventions and in the supply of the human capital that could carry out the new techniques.[17] To employ the terminology proposed earlier: Britain may not have more propositional knowledge available for its invention and innovation process, but if it workers possessed higher levels of competence, then the new techniques that had emerged would find their first applications there. Its system of informal technical training, through master-apprentice relationships, created workers of uncommon skill and mechanical ability. This system produced, of course, inventors: the most famous of these such as the clockmakers John Harrison and Benjamin Huntsman, the engineer John Smeaton, the instrument maker Jesse Ramsden, the wondrously versatile inventor Richard Roberts, the chemists James Keir and Joseph Black, and of course the great Watt himself were only the first row of a veritable army of people, who in addition to possessing formal knowledge, were blessed by a technical intuition and dexterity reaching into the deeps of tacit knowledge.

Third, by the middle of the eighteenth century Britain had developed an institutional strength and agility that provided it with a considerable if temporary advantage over its Continental competitors: it had a healthier public finance system, weaker guilds, no internal tariff barriers, a superior internal transportation system, fairly well-defined and enforced property rights on land (enhanced by Parliamentary acts when necessary), and a power structure that favored the rich and the propertied classes. Moreover, it had that most elusive yet decisive institutional feature that makes for economic success: the flexibility to adapt its economic and legal institutions without political violence and disruptions. Britain's great asset was not so much that she had "better" government but rather that its

---

tin-plated cans, which were soon found to be superior. By 1814, Bryan Donkin was supplying canned soups and meats to the Royal Navy.

[17] This was already pointed by Daniel Defoe, who pointed out in 1726 that "the English ... are justly fam'd for improving Arts rather than inventing" and elsewhere in his Plan of English Commerce that "our great Advances in Arts, in Trade, in Government and in almost all the great Things we are now Masters of and in which we so much exceed all our Neighbouring Nations, are really founded upon the inventions of others." The great engineer John Farey, who wrote an important treatise on steam power, testified a century later that "the prevailing talent of English and Scotch people is to apply new ideas to use, and to bring such applications to perfection, but they do not imagine as much as foreigners."

political institutions were nimbler, and that they could be changed at low social cost by a body assigned to changing the rules and laws by which the economic game was played. Many of the rules still on the books in the eighteenth century were not enforced, and rent seeking arrangements, by comparison, were costly to attain and uncertain in their yield. British mercantilist policy was already in decline on the eve of the Industrial Revolution. Yet as the Industrial Revolution unfolded, it required further change in the institutional basis of business. The Hanoverian governments in Britain were venal and nepotist, and much of the business of government was intended to enrich politicians. But with the growing notion that rent seeking was harmful, this kind of corruption weakened. As Porter (1990, p. 119) put it, with the rise of the laissez faire lobby, Westminster abandoned its long-standing mercantilist paternalism, repealing one regulation after another. Abuses may have been deep rooted, and rent-seekers resisted all they could, but form the last third of the eighteenth century on rent-seeking was on the defensive, and by 1835 many of the old institutions had vanished, and the British state, for a few decades, gave up on redistributing income as a main policy objective. Following North (1990, p. 80) we might call this adaptive efficiency, meaning not only the adaptation of the allocation of resources but of the institutions themselves. To bring this about, what was needed was a meta-institution such as parliament that was authorized to change the rules in a consensual manner.

Compared to Britain, the Continental countries had to make a greater effort to cleanse their economic institutions from medieval debris and the fiscal ravages of absolutism, undo a more complex and pervasive system of rent seeking and regulation, and while extensive reforms were carried out in France, Germany, and the Low Countries after the French Revolution, by 1815 the work was still far from complete and had already incurred enormous social costs. It took another full generation for the Continent to pull even. None of the British advantages was especially deep or permanent. They explain Britain's position as the lead car in the Occident Express that gathered steam in the nineteenth century and drove away from the rest of the world, but it does not tell us much about the source of power. Was Britain the engine that pulled the other European cars behind it, or was Western Europe on an electric train deriving its motive power from a shared source of motive energy?

One useful mental experiment is to ask whether there would have been an Industrial Revolution in the absence of Britain. A counterfactual industrial revolution led by Continental economies would have been delayed by a few decades and differed in some important details. It might have relied less on "British" steam and more on "French" water power and "Dutch" wind power technology, less on cotton and possibly more on wool and linen. It would have more of an *étatist* flavor, with a bigger emphasis on military engineering and public projects. But in view of the capabilities of French engineers and German chemists, the entrepreneurial instincts of Swiss and Belgian industrialists, and the removal of many institutions that had hampered their effective deployment before 1789, a technological revolution not all that different from what actually transpired would have happened. Even without Britain, by the twentieth century the gap between Europe and the rest of the world would have been there (Mokyr, 2000).

The second point to note is that the pivotal element of the Industrial Revolution took place later than is usually thought. The difference between the Industrial Revolution of the eighteenth century and other episodes of a clustering of macroinventions was not just in the celebrated inventions in the period 1765-1790. While the impact of the technological breakthroughs of these years of *sturm und drang* on a number of critical industries stands undiminished, the critical difference between this Industrial Revolution and previous clusters of macroinventions is not that these breakthroughs occurred at all, but that their momentum did not level off and peter out after 1800 or so. In other words, what made the Industrial Revolution into the "great divergence" was the *persistence* of technological change after the first wave. We might well imagine a counterfactual technological steady state of throstles, wrought iron, and stationary steam engines, in which there was a one-off shift from wool to cotton, from animate power to stationary engines, and of cheap wrought iron. It is easy to envisage the economies of the West settling into these techniques without taking them much further, as had happened in the wave of inventions of the fifteenth century.

But this is not what happened. The "first wave" of innovations was followed after 1820 by a secondary ripple of inventions that may have been less spectacular, but these were the microinventions that provided the muscle to the downward trend in production costs. The second stage of the Industrial Revolution adapted novel ideas and tricks to be applied in new

and more industries and sectors, improved and refined the earlier and eventually showed up in the productivity statistics. Among those we may list the perfection of mechanical weaving after 1820; the invention of Roberts's self-acting mule in spinning (1825); the extension and adaptation of the techniques first used in cotton to carded wool and linen; the continuing improvement in the iron industry through Neilson's hot blast (1829) and other inventions; the continuing improvement in steampower, raising the efficiency and capabilities of the low pressure stationary engines, while perfecting the high pressure engines of Trevithick, Woolf, and Stephenson and adapting them to transportation; the advances in chemicals before the advent of organic chemistry (such as the breakthroughs in candle-making and soap manufacturing thanks to the work of Eugène-Michel Chevreul on fatty acids); the introduction and perfection of gas-lighting; the breakthroughs in engineering and high-precision tools by Maudslay, Whitworth, Nasmyth, Rennie, the Brunels, the Stephensons, and the other great engineers of the "second generation"; the growing interest in electrical phenomena leading to electroplating and the work by Hans Oersted and Joseph Henry establishing the connection between electricity and magnetism, leading to the telegraph in the late 1830s; the continuous improvement in crucible steelmaking through coordinated crucibles (as practiced for example by Krupp in Essen); the pre-Bessemer improvements in steel thanks to the work of Scottish steelmakers such as David Mushet (father of Robert Mushet, celebrated in one of Samuel Smiles's *Industrial Biographies*), and the addition of manganese to crucible steel known as Heath's process (1839).

The second wave of inventions was the critical period in the sense that it shows up clearly in the total income statistics. Income per capita growth after 1830 accelerates to around 1.1 percent, even though recent calculations confirm that only about a third of that growth to total factor productivity growth (Antras and Voth, 2003, p. 63; Mokyr, 2003c). Income growth in Britain during the "classical" Industrial Revolution was modest. This fact is less difficult to explain than some scholars make it out to be, and any dismissal of the Industrial Revolution as a historical watershed for that reason seems unwarranted. After all, the disruptions of international commerce during the quarter century of the French Wars coincided with bad harvests and unprecedented population growth. Yet the main reason is simply that in the early decades the proportion of the British economy

affected by technological progress and that can be viewed as a "modern sector" was simply small, even if its exact dimensions remain in dispute. From 1830 this sector expands rapidly as the new technology is applied more broadly (especially to transportation), growth accelerates, and by the mid 1840's there is clear-cut evidence that the standard of living in Britain is rising even for the working class. It also serves as a bridge between the first Industrial Revolution and the more intense and equally dramatic changes of the second Industrial Revolution I will discuss below.

To sum up, then, the period 1760-1830 Western Europe witnessed a growing importance of invention, the emergence of new techniques that in the longer run were to have an enormous impact on productivity and growth. Without belittling the other elements that made the Industrial Revolution possible, the technological breakthroughs of the period prepared the ground for the economic transformation that made the difference between the West and the Rest, between technological modernity and the much slower and often-reversed economic growth episodes of the previous millennia. In order to come up with a reasonable explanation of the technological roots of economic growth in this period, we must turn to the intellectual foundations of the explosion of technical knowledge.

The Intellectual Roots of the Industrial Revolution

Economic historians like to explain economic phenomena with other economic phenomena. The Industrial Revolution, it was felt for many decades should be explained by economic factors. Relative prices, better property rights, endowments, changes in fiscal and monetary institutions, investment, savings, exports, and changes in labor supply have all been put forward as possible explanations (for a full survey, see Mokyr, 1998). Yet the essence of the Industrial Revolution was technological, and technology is knowledge. How, then, should we explain not just the famous inventions of the Industrial Revolution but also the equally portentous fact that these inventions did not peter out fairly quickly after they emerged, as had happened so often in the past?

The answer has to be sought in the intellectual changes that occurred in Europe *before* the Industrial Revolution. These changes affected the sphere of propositional knowledge. The problem, as economic historians have known for many years, is that it is very difficult to argue that the

scientific revolution of the seventeenth century we associate with Galileo, Descartes, Newton, and many other giants, had a direct impact on the Industrial Revolution (McKendrick, 1973). Few important inventions, both before and after 1800, can be directly attributed to great scientific discoveries or were dependent in any direct way on scientific expertise. The advances in physics, chemistry, biology, medicine, and other areas occurred too late to have the desired effect. The scientific advances of the seventeenth century, crucial as they were to the understanding of nature, had more to do with the movement of heavenly bodies, optics, magnetism, and the classification of plants than with the motions of machines. To say that therefore it had no economic significance is an exaggeration: many of the great scientists wrote about mechanics and the properties of materials.[18] Yet it is hard to see many examples of eighteenth-century inventions that owed their existence to a prior scientific discovery.[19] After 1800 the

---

[18] From the viewpoint of the history of technology, Galileo is particularly important because his theory of mechanics and concept of force lies at the basis of all machines. Until Galileo, the idea that general laws governed all machines was not recognized; each machine was described as if it were unique. Galileo realized that all machines transmitted and applied force as special cases of the lever and fulcrum principle. As Cardwell points out, Galileo's theory of mechanics is interesting to the economist because the concept governing it is one of efficiency: "The function of a machine is to deploy and use the powers that nature makes available in the best possible way for man's purposes... the criterion is the amount of work done --- however that is evaluated --- and not a subjective assessment of the effort put into accomplishing it" (Cardwell, 1972, pp. 38-39). In the writings of Galileo, the leading scientist of his time, economic efficiency is linked with science. In his *Motion and Mechanics* he wrote that the advantage of machines was to harness cheap sources of energy because "the fall of a river costs little or nothing." In this he differed radically from his inspiration, Archimedes, and this difference between the two scientific giants who established the science of mechanics epitomizes the difference between classical and early modern society. The great French physicist René Réaumur (1683-1757) studied in great detail the properties of Chinese porcelain and the physics of iron and steel.

[19] Unlike the technologies that developed in Europe and the United States in the second half of the nineteenth century, science, in this view, had little direct guidance to offer to the Industrial Revolution (Hall, 1974, p. 151). Shapin notes that "it appears unlikely that the 'high theory' of the Scientific Revolution had any substantial direct effect on economically useful technology either in the seventeenth century or in the eighteenth.... historians have had great difficulty in establishing that any of these spheres of technologically or economically inspired science bore

connection becomes gradually tighter, yet the influence of science proper on some branches of production (and by no means all at that) does not become decisive until after 1870.

All the same, the success of the Industrial Revolution must be found in the developments in the area of useful knowledge that occurred in Europe before and around 1750. What mattered was not so much scientific knowledge itself but the method and culture involving the generation and diffusion of propositional knowledge. The Industrial Revolution and its aftermath were based on a set of propositional knowledge that was not only increasing in size, but which was becoming increasingly accessible, and in which segments that were more effective were becoming tighter. Propositional knowledge was increasingly tested by whether the techniques that were based on it could be verified, either by experiment or by virtue of the performance of the techniques based on them.

The Scientific Method that evolved in the seventeenth century meant that observation and experience were placed in the public domain. Betty Jo Dobbs (1990), William Eamon (1990, 1994), and more recently Paul David (1997) have pointed to the scientific revolution of the seventeenth century as the period in which "open science" emerged, when knowledge about the natural world became increasingly nonproprietary and scientific advances and discoveries were freely shared with the public at large. Thus scientific knowledge became a public good, communicated freely rather than confined to a secretive exclusive few as had been the custom in medieval Europe. The sharing of knowledge within "open science" required systematic reporting of methods and materials using a common vocabulary and consensus standards, and should be regarded as an exogenous decline in access costs, which made the propositional knowledge, such as it was, available to those who might find a use for it. Those who added to useful knowledge would be rewarded by honor, peer recognition, and fame – not a monetary reward that was in any fashion proportional to their contribution. Even those who discovered matters of significant insight to industry, such as Claude Berthollet, Joseph Priestly, and Humphry Davy, wanted credit, not profit.

Scientific Method here also should be taken to include the changes in the rhetorical conventions that emerged in the seventeenth century,

---

substantial fruits" (1996, pp. 140–41, emphasis added).

during which persuasive weight continued to shift away from "authority" toward empirics, but which also increasingly set the rules by which empirical knowledge was to be tested so that useful knowledge could be both accessible and trusted.[20] Verification meant that a deliberate effort was made to make useful knowledge tighter and thus more likely to be used. It meant a willingness, rarely observed before, to discard old and venerable interpretations and theories when they could be shown to be in conflict with the evidence. Scientific method meant that a class of experts evolved who often would decide which technique worked best.[21]

The other crucial transformation that the Industrial Revolution inherited from the seventeenth century was the growing change in the very purpose and objective of propositional knowledge. Rather than proving some religious point, such as illustrating the wisdom of the creator, or the satisfaction of that most creative of human characteristics, curiosity, natural philosophers in the eighteenth century increasingly came under the influence of the idea that the main purpose of knowledge was to improve mankind's material condition – that is, find technological applications. Bacon in 1620 had famously defined technology by declaring that the control of humans over things depended on the accumulated knowledge about how nature works, since "she was only to be commanded by obeying her." This idea was of course not entirely new, and traces of it can be found in medieval thought and even in Plato's *Timaeus*, which proposed a rationalist view of the universe and was widely read by twelfth-century intellectuals. In the seventeenth century, however, the practice of science

---

[20] Shapin (1994) has outlined the changes in trust and expertise in Britain during the seventeenth century associating expertise, for better or for worse, with social class and locality. While the approach to science was ostensibly based on a "question authority" principle (the Royal Society's motto was *nullius in verba*—on no one's word), in fact no system of useful (or any kind of) knowledge can exist without some mechanism that generates trust. The apparent skepticism with which scientists treated the knowledge created by others increased the trust that others had in the findings, because outsiders could then assume —as is still true today—that these findings had been scrutinized and checked by other "experts."

[21] As Hilaire-Pérez (2000, p. 60) put it, "the value of inventions was too important an economic stake to be left to be dissipated among the many forms of recognition and amateurs: the establishment of truth became the professional responsibility of academic science."

became increasingly permeated by the Baconian motive of material progress and constant improvement, attained by the accumulation of knowledge.[22] The founding members of the Royal Society justified their activities by their putative usefulness to the realm. There was a self-serving element to this, of course, much as with National Science Foundation grant proposals today. Practical objectives in the seventeenth century were rarely the primary objective of the growth of formal science. But part of the changing culture implied a gradual change in the agenda of research.

A central intellectual change in Europe before the Industrial Revolution, oddly neglected by economic historians, was the Enlightenment. Definitions of this amorphous and often contradictory historical phenomenon are many, but for the purposes of explaining the Industrial Revolution we only to examine a slice of it, which I have termed the *Industrial Enlightenment*. To be sure, some historians have noted the importance of the Enlightenment as a culture of rationality, progress, and growth through knowledge.[23] Perhaps the most widely diffused Enlightenment view involved the notion that long-term social improvement was possible. It surely is true that not all Enlightenment philosophers believed that progress was either desirable or inevitable. And yet their work created the attitudes, the institutions, and the mechanisms by which new useful knowledge was created, spread, and put to good use. Above all was the pervasive belief in the Baconian notion that we can attain material progress (that is, economic growth) through controlling nature and that we can only

---

[22] Robert K. Merton ([1938] 1970, pp. ix, 87) asked rhetorically how "a cultural emphasis upon social utility as a prime, let alone an exclusive criterion for scientific work affects the rate and direction of advance in science" and noted that "science was to be fostered and nurtured as leading to the improvement of man's lot by facilitating technological invention." He might have added that non-epistemic goals for useful knowledge and science, that is to say, goals that transcend knowledge for its own sake and look for some application, affected not only the rate of growth of the knowledge set but even more the chances that existing knowledge will be translated into techniques that actually increase economic capabilities and welfare.

[23] One of the most cogent statements is in McNeil (1987, pp. 24-25) who notes the importance of a "faith in science that brought the legacy of the Scientific Revolution to bear on industrial society ... it is imperative to look at the interaction between culture *and* industry, between the Enlightenment and the Industrial Revolution."

harness nature by understanding her. Francis Bacon, indeed, is a pivotal figure in understanding the Industrial Enlightenment and its impact. Modern scholars seem agreed: Bacon was the first to regard knowledge as subject to constant growth, an entity that continuously expands and adds to itself rather than concerned with retrieving, preserving and interpreting old knowledge (Vickers, 1992, esp. pp. 496-97).[24] The understanding of nature was a social project in which the division of knowledge was similar to Adam Smith's idea of the division of labor, another enlightenment notion.[25] Bacon's idea of bringing this about was through what he called a "House of Salomon" – a research academy in which teams of specialists collect data and experiment, and a higher level of scientists tty to distill these into general regularities and laws. Such an institution was the Royal Society, whose initial objectives were inspired by Lord Bacon.[26]

Nothing of the sort, I submit, can be detected in the Ottoman Empire, India, Africa, or China. It touched only ever so lightly (and with a substantial delay) upon Iberia, Russia, and South America but in many of these areas it encountered powerful resistance and retreated. Invention, as many scholars have rightly stressed, was never a European monopoly, and much of its technological creativity started with adopting ideas and tech-

---

[24] Bacon was pivotal in inspiring the Industrial Enlightenment. His influence on the Industrial Enlightenment can be readily ascertained by the deep admiration the encyclopédistes felt toward him, including a long article on Baconisme written by the Abbé Pestre and the credit given him by Diderot himself in his entries on *Art* and *Encyclopédie*. The *Journal Encyclopédique* wrote in 1756 "If this society owes everything to Chancellor Bacon, the philosopher doe not owe less to the authors of the *Encyclopédie*" (cited by Kronick, 1962, p. 42). The great Scottish Enlightenment philosophers Dugald Stewart and Francis Jeffrey agreed on Baconian method and goals, even if they differed on some of the interpretation (Chitnis, 1976, pp. 214-15).

[25] A typical passage in this spirit was written by the British chemist and philosopher Joseph Priestley (1768, p. 7): "If, by this means, one art or science should grow too large for an easy comprehension in a moderate space of time, a commodious subdivision will be made. Thus all knowledge will be subdivided and exteded, and *knowledge* as Lord Bacon observes, being *power*, the human powers will be increased ... men will make their situation in this world abundantly more easy and comfortable."

[26] McClellan (1985), p. 52. It should be added that strictu sensu the Royal Society soon allowed in amateurs and dilettantes and thus became less of a pure "Baconian" institution than the French Académie Royale.

niques the Europeans had observed from others (Mokyr, 1990). The difference was the ability to break out of the circle of concavity and negative feedback and smash the upper bound on income that the limitations of knowledge and institutions had set on practically all economies until then. The stationary state was replaced by the steady state. It is this phenomenon rather than coal or the ghost acreage of colonies that answers Pomeranz's query (2000, p. 48) why Chinese science and technology – which did not "stagnate" – "did not revolutionize the Chinese economy."

The Industrial Enlightenment can be viewed in part as a movement that insisted on asking not just "which techniques work" but also "why" – realizing that such questions held the key to continuing progress. In that sense, the intellectuals at its center felt intuitively that constructing and widening an epistemic base for the techniques in use would lead to continuing technological progress. Scientists, engineers, chemists, medical doctors, and agricultural improvers made sincere efforts to generalize from the observations they made, to connect observed facts and regularities (including successful techniques) to the formal propositional knowledge of the time, and thus provide the techniques with wider epistemic bases. The bewildering complexity and diversity of the world of techniques in use was to be reduced to a finite set of general principles governing them.[27] These insights would lead to extensions, refinements, and improvements, as well as speed up and streamline the process of invention.[28] Asking such questions was of course much easier than answering them. In the longer term, however, asking such questions and developing the tools to get to the answers were essential if technical progress was not to fizzle out.[29] The

---

[27] Thus Erasmus Darwin, grandfather of the biologist and himself a charter member of the Lunar Society and an archtypical member of the British Industrial Enlightenment, complained in 1800 that Agriculture and Gardening had remained only Arts without a true theory to connect them (Porter, 2000, p. 428). For details about Darwin, see especially McNeil (1987) and Uglow (2002).

[28] Somewhat similar views have been expressed recently by other scholars such as John Graham Smith (2001) and Picon (2001).

[29] George Campbell, an important representative of the Scottish Enlightenment noted that "All art [including mechanical art or technology] is founded in science and practical skills lack complete beauty and utility when they do not originate in knowledge" (cited by Spadafora, 1990, p. 31).

typical enlightenment inventor did more than tinkering and trial-and-error fiddling with existing techniques, he tried to relate puzzles and challenges to whatever general principles could be found, and if necessary to formulate such principles anew. To do so, each inventor needed some mode of communication that would allow him to tap the knowledge of others. The paradigmatic example of such an inventor remains the great James Watt, whose knowledge of mathematics and physics were matched by his tight connections to the best scientific minds of his time, above all Joseph Black and Joseph Priestley. The list of slightly less famous pioneers of technology can be made arbitrarily long.

The other side of the Industrial Enlightenment had to do with the diffusion of and the access to existing knowledge. The *philosophes* fully realized that knowledge should not be confined to a select few but should be disseminated as widely as possible. Some Enlightenment thinkers believed this was already happening: the philosopher and psychologist David Hartley believed that "the diffusion of knowledge to all ranks and orders of men, to all nations, kindred and tongues and peoples... cannot be stopped but proceeds with an ever accelerating velocity."[30] Diffusion needed help, however, and much of the Industrial Enlightenment was dedicated to making access to useful knowledge easier and cheaper.[31] From the widely felt need to rationalize and standardize weights and measures, the insistence on writing in vernacular language, to the launching of scientific societies and academies (functioning as de facto clearing houses of useful knowledge), to that most paradigmatic Enlightenment triumph, the *Grande Encyclopédie*, the notion of diffusion found itself at the center of attention among intellectuals.[32] Precisely because the Industrial Enlightenment was

---

[30] Cited by Porter (2000, p. 426).

[31] The best summary of this aspect of the Industrial Enlightenment was given by Diderot in his widely-quoted article on "Arts" in the *Encyclopédie*: "We need a man to rise in the academies and go down to the workshops and gather material about the [mechanical] arts to be set out in a book that will persuade the artisans to read, philosophers to think along useful lines, and the great to make at least some worthwhile use of their authority and wealth."

[32] Roche (1998, pp. 574-75) notes that "if the *Encyclopédie* was able to reach nearly all of society (although ... peasants and most of the urban poor had access to the work only indirectly), it was because the project was broadly conceived as a work of

not a national or local phenomenon, it became increasingly felt that differences in language and standards became an impediment and increased access costs. Watt, James Keir, the Derby clockmaker John Whitehurst, all worked on a system of universal terms and standards, that would make French and British experiments "speak the same language" (Uglow, 2002, p. 357). Books on science and technology were translated rather quickly, even when ostensibly Britain and France were at war with one another.

Access costs depended in great measure on knowing what was known, and for that search engines were needed. The ultimate search engine of the eighteenth century was the encyclopedia. Diderot and d'Alembert's *Encyclopédie* did not augur the Industrial Revolution, it did not predict factories, and had nothing to say about mechanical cotton spinning equipment or steam engines. It catered primarily to the landowning elite and the bourgeoisie of the *ancien régime* (notaries, lawyers, local officials) rather than specifically to an innovative industrial bourgeoisie, such as it was. It was, in many ways, a conservative document (Darnton, 1979, p. 286). But the Industrial Enlightenment, as embodied in the *Encyclopédie* and similar works that were published in the eighteenth century did propose a very different way of looking at technological knowledge: instead of intuition came systematic analysis, instead of mere dexterity an attempt to attain an understanding of the principles at work, instead of secrets learned from a master, an open and accessible system of training and learning. It was also a comparatively user-friendly compilation, arranged in an accessible way, and while its subscribers may not have been mostly artisans and small manufacturers, the knowledge contained in it dripped down through a variety of leaks to those who could make use of it.[33]

---

popularization, of useful diffusion of knowledge." The cheaper versions of the Diderot-d'Alembert masterpiece, printed in Switzerland, sold extremely well: the Geneva (quarto) editions sold around 8000 copies and the Lausanne (octavo) editions as many as 6000.

[33] Pannabecker points out that the plates in the *Encyclopédie* were designed by the highly skilled Louis-Jacques Goussier who eventually became a machine designer at the Conservatoire des arts et métiers in Paris (Pannabecker, 1996). They were meant to popularize the rational systematization of the mechanical arts to facilitate technological progress.

Encyclopedias and "dictionaries" were supplemented by a variety of textbooks, manuals, and compilations of techniques and devices that were somewhere in use. The biggest one was probably the massive *Descriptions des arts et métiers* produced by the French Académie Royale des Sciences.[34] Specialist compilations of technical and engineering data appeared, such as the detailed descriptions of windmills (*Groot Volkomen Moolenboek*) published in the Netherlands as early as 1734. A copy was purchased by Thomas Jefferson (Davids, 2001). Jacques-François Demachy's *l'Art du distillateur d'eaux fortes* (1773) (published as a volume in the *Descriptions*) is a "recipe book full of detailed descriptions of the construction of furnaces and the conduct of distillation" (John Graham Smith, 2001, p. 6). In agriculture, meticulously compiled data collections looking at such topics as yields, crops, and cultivation methods were common.[35]

The Industrial Enlightenment realized instinctively that one of the great sources of technological stagnation was a social divide between those who knew things ("*savants*") and those who made things ("*fabricants*"). To construct pipelines through which those two groups could communicate was at the very heart of the movement.[36] The relationship between those who possessed useful knowledge and those who might find a use for it was

---

[34] The set included 13,500 pages of text and over 1,800 plates describing virtually every handicraft practiced in France at the time, and every effort was made to render the descriptions "realistic and practical" (Cole and Watts, 1952, p. 3).

[35] William Ellis's *Modern Husbandman or Practice of Farming* published in 1731 gave a mont-by-month set of suggestions, much like Arthur Young's most successful book, *The Farmer's Kalendar* (1770). Most of these writings were empirical or instructional in nature, but a few actually tried to provide the readers with some systematic analysis of the principles at work. One of those was Francis Home's *Principles of Agriculture and Vegetation* (1757). One of the great private data collection projects of the time were Arthur Young's famed *Tours* of various parts of England and William Marshall's series on *Rural Economy* (Goddard, 1989). They collected hundreds of observations on farm practice in Britain and the continent. although at times Young's conclusions were contrary to what his own data indicated (see Allen and Ó Gráda, 1988).

[36] This point was first made by Zilsel(1942) who placed the beginning of this movement in the middle of the sixteenth century. While this may be too early for the movement to have much economic effect, the insight that technological progress occurs when intellectuals communicate with producers is central to its historical explanation.

changing in eighteenth-century Europe and points to a reduction in access costs. They also served as a mechanism through which practical people with specific technical problems to solve could air their needs and thus influence the agenda of the scientists, while at the same time absorbing what best-practice knowledge had to offer. The movement of knowledge was thus bi-directional, as perhaps seems natural to us in the twenty-first century. In eighteenth-century Europe, however, such exchanges were still quite novel.

An interesting illustration can be found in the chemical industry. Pre-Lavoisier chemistry, despite its limitations, is an excellent example of how *some* knowledge, no matter how partial or erroneous, was believed to be of use in mapping into new techniques. The pre-eminent figure in this field was probably William Cullen, a Scottish physician and chemist. Cullen lectured (in English) to his medical students, but many outsiders connected with the chemical industry audited his lectures. Cullen believed that as a philosophical chemist he had the knowledge needed to rationalize the processes of production (Donovan, 1975, p. 78). He argued that pharmacy, agriculture, and metallurgy were all "illuminated by the principles of philosophical chemistry" and added that "wherever any art [that is, technology] requires a matter endued with any peculiar physical properties, it is chemical philosophy which informs us of the natural bodies possessed of these bodies" (cited by Brock, 1992, pp. 272–73).[37] He and his colleagues worked, among others, on the problem of purifying salt (needed for the Scottish fish-preservation industry), and that of bleaching with lime, a common if problematic technique in the days before chlorine. This kind of work "exemplifies all the virtues that eighteenth-century chemists believed would flow from the marriage of philosophy and practice" (Donovan, 1975, p. 84).

Ironically, this marriage remained barren for many decades. In chemistry the expansion of the epistemic base and the flurry of new techniques it generated did not occur fully until the mid-nineteenth century (Fox, 1998). Cullen's prediction that chemical theory would yield the principles that would direct innovations in the practical arts remained, in the words of the leading expert on eighteenth-century chemistry, "more

---

[37] Very similar sentiments were expressed by the author of the article on chemistry, Gabriel-François Venel, in the *Encyclopédie.* He regarded advances in arts and chemical science as reciprocal, bound together on a common trunk (Keyser, 1990, p. 228).

in the nature of a promissory note than a cashed-in achievement" (Golinski, 1992, p. 29). Manufacturers needed to know why colors faded, why certain fabrics took dyes more readily than others, and so on, but as late as 1790 best-practice chemistry was incapable of helping them much (Keyser, 1990, p. 222). Before the Lavoisier revolution in chemistry, it just could not be done, no matter how suitable the social climate: the epistemic base simply did not exist. All the same, Cullen personifies a social movement that increasingly sought to increase its propositional knowledge for economic purposes, a personification of scientific culture. Whether or not he could deliver, his patrons and audience in the culture of the Scottish Enlightenment believed that there was a chance he could (Golinski, 1988) and put their money behind their beliefs.

To dwell on one more example, consider the development of steam power. The ambiguities of the relations between James Watt and his mentor, the Scottish scientist Joseph Black are well-known. Whether or not Watt's crucial insight of the separate condenser was due to Black's theory of latent heat, there can be little doubt that the give-and-take between the scientific community in Glasgow and the creativity of men like Watt was essential in smoothing the path of technological progress. Richard Trevithick, the Cornish inventor of the high pressure engine, posed sharp questions to his scientist acquaintance Davies Gilbert (later President of the Royal Society), and received answers that supported and encouraged his work (Burton, 2000, pp. 59-60). Decades later, the work of Joule and Rankine on thermodynamics led to the development of the two cylinder compound marine steam engine.[38]

As might be expected, in some cases the bridge between propositional and prescriptive knowledge occurred within the same mind: the very same people who also were contributing to science made some critical inventions (even if the exact connection between their science and their ingenuity is not always clear). The importance of such dual or "hybrid" careers, as Eda Kranakis (1992) has termed them, is that access to the propositional knowledge that could underlie an invention is immediate, as is the feedback to propositional knowledge. In most cases the technology

---

[38] In other areas, too, the discourse between those who controlled S-knowledge and those who built new techniques was fruitful. Henry Cort, whose invention of the puddling and rolling process was no less central than Watt's separate consenser, also consulted Joseph Black during his work.

shaped the propositional research as much as the other way around. The idea that those contributing to propositional knowledge should specialize in research and leave its "mapping" into technology to others had not yet ripened. Among the inventions made by people whose main fame rests on their scientific accomplishments were the chlorine bleaching process invented by the chemist Claude Berthollet, the invention of carbonated (sparkling) water and rubber erasers by Joseph Priestley, and the mining safety lamp invented by the leading scientist of his age, Humphry Davy (who also, incidentally, wrote a textbook on agricultural chemistry and discovered that a tropical plant named *catechu* was a useful additive to tanning).[39]

Typical of the "dual career" phenomenon was Benjamin Thompson (later Count Rumford, 1753-1814), an American-born mechanical genius who was on the loyalist side during the War of Independence and later lived in exile in Bavaria, London, and Paris; he is most famous for the scientific proof that heat is not a liquid (known at the time as *caloric*) that flows in and out of substances. Yet Rumford was deeply interested in technology, helped establish the first steam engines in Bavaria, and invented (among other things) the drip percolator coffeemaker, a smokeless-chimney Rumford stove, and an improved oil lamp. He developed a photometer designed to measure light intensity and wrote about science's ability to improve cooking and nutrition (G. I. Brown, 1999, pp. 95–110). Rumford is as good a personification of the Industrial Enlightenment as one can find. Indifferent to national identity and culture, Rumford was a "Westerner" whose world spanned the entire northern Atlantic area (despite being an exile from the United States, he left much of his estate to establish a professorship at Harvard). In that respect he resembled his older compatriot inventor Benjamin Franklin, who was as celebrated in Britain and France as he was in his native Philadelphia. Rumford could, within the same mind, map from his knowledge of natural phenomena and regularities to create

[39] It is unclear how much of the best-practice science was required for the safety lamp, and how much was already implied by the empirical propositional knowledge accumulated in the decades before 1815. It is significant that George Stephenson, of railway fame, designed a similar device at about the same time.

things he deemed useful for mankind (Sparrow, 1964, p. 162).[40] Like Franklin and Davy, he refused to take out a patent on any of his inventions — as a true child of the Enlightenment he was committed to the concept of open and free knowledge.[41] Instead, he felt that honor and prestige were often a sufficient incentive for people to contribute to useful knowledge. He established the Rumford medal, to be awarded by the Royal Society "in recognition of an outstandingly important recent discovery in the field of thermal or optical properties of matter made by a scientist working in Europe, noting that Rumford was concerned to see recognised discoveries that tended to promote the good of mankind." Not all scientists eschewed such profits: the brilliant Scottish noblemen Archibald Cochrane (Earl of Dundonald) made a huge effort to render the coal tar process he patented profitable, but failed and ended up losing his fortune.

The other institutional mechanism emerging during the Industrial Enlightenment to connect between those who possessed prescriptive knowledge and those who wanted to apply it was the emergence of meeting places where men of industry interacted with natural philosophers. So-called scientific societies, often known confusingly as literary and philosophical societies, sprung up everywhere in Europe. They organized lectures, symposia, public experiments, and discussion groups, in which the topics of choice were the best pumps to drain mines, or the advantages of growing clover and grass.[42] Most of them published some form of "proceedings," as often meant to popularize and diffuse existing knowledge as it was to dispay new discoveries. Before 1780 most of these societies were

---

[40] It is telling that Rumford helped found the London Royal Institute in 1799. This institute was explicitly aimed at the diffusion of useful knowledge to wider audiences through lectures. In it the great Humphry Davy and his illustrious pupil Michael Faraday gave public lectures and did their research.

[41] The most extreme case of a scientist insisting on open and free access to the propositional knowledge he discovered was Claude Berthollet, who readily shared his knowledge with James Watt, and declined an offer by Watt to secure a patent in Britain for the exploitation of the bleaching process (J. G. Smith, 1979, p. 119).

[42] The most famous of these societies were the Manchester Literary and Philosophical Society (founded in 1781) and the Birmingham Lunar Society, where some of the great entrepreneurs and engineers of the time mingled with leading chemists, physicists, and medical doctors. But in many provincial cities such as Liverpool, Hull, and Bradford, a great deal of activity took place.

informal and ad hoc, but they eventually became more formal. The British Society of Arts, founded in 1754, was a classic example of an organization that embodied many of the ideals of the Industrial Enlightenment. Its purpose was "to embolden enterprise, to enlarge science, to refine art, to improve manufacture and to extend our commerce." Its activities included an active program of awards and prizes for successful inventors: over 6,200 prizes were granted between 1754 and 1784.[43] The society took the view that patents were a monopoly, and that no one should be excluded from useful knowledge. It therefore ruled out (until 1845) all persons who had taken out a patent from being considered for a prize and even toyed with the idea of requiring every prize-winner to commit to never take out a patent.[44] It served as a clearing house for technological information, reflecting the feverish growth of supply and demand for useful knowledge.

What was true for Britain was equally true for Continental countries affected by the Enlightenment. In the Netherlands, rich but increasingly technologically backward, heroic efforts were established to infuse the economy with more innovativeness.[45] In Germany, provincial academies were founded in all the significant German states in the eighteenth century. The Berlin Academy, in its early years directed by the great Leibniz, and among its achievements wa sthe discovery that sugar could be extracted from beets. In France, great institutions were created

[43] For details see, Wood (1913), Hudson and Luckhurst (1954).

[44] Hilaire-Pérez (2000), p. 197. Wood (1913), pp. 243-45.

[45] The first of these was established in Haarlem in 1752, and within a few decades the phenomenon spread much like in England to the provincial towns. The Scientific Society of Rotterdam known oddly as the *Batavic Association for Experimental Philosophy* was the most applied of all, and advocated the use of steam engines (which were purchased in the 1770s but without success). The Amsterdam Society was known as *Felix Meritis* and carried out experiments in physics and chemistry. These societies stimulated interest in physical and experimental sciences in the Netherlands, and they organized prize-essay contests on useful applications of natural philosophy. A physicist named Benjamin Bosma for decades gave lectures on mathematics, geography, and applied physics in Amsterdam. A Dutch Society of Chemistry founded in the early 1790s helped to convert the Dutch to the new chemistry proposed by Lavoisier (Snelders, 1992). The Dutch high schools, known as *Athenea* taught mathematics, physics, astronomy, and at times counted distinguished scientists among their staff.

under royal patronage, above all the Académie Royale des Sciences, created by Colbert and Louis XIV in 1666 to disseminate information and resources.[46] Yet the phenomenon was nationwide: 33 official learned societies were functioning in the French provinces during the eighteenth century counting over 6,400 members. Overall, McClellan (1981, p. 547) estimates that during the century perhaps between 10,000 and 12,000 men belonged to learned societies that dealt at least in part with science. Between 1692 and 1792, 11 towns in Italy formed scientific societies (Inkster, 1991, p. 35). At the level of the creation of propositional knowledge, at least, there is little evidence that the *ancien régime* was incapable of generating sustained progress.

The *Académie Royale* exercised a fair amount of control over the direction of French scientific development and acted as technical advisor to the monarchy. By determining what was published and exercising control over patents, the *Académie* became a powerful administrative body, providing scientific and technical advice to government bureaus. France, of course, had a somewhat different objective than Britain: it is often argued that the *Académie* linked the aspirations of the scientific community to the utilitarian concerns of the government creating not a Baconian society open to all comers and all disciplines but a closed academy limited primarily to Parisian scholars (McClellan, 1981). Yet the difference between France and Britain was one of emphasis and nuance, not of essence: they shared a utilitarian optimism of man's ability to create wealth. In Germany, too, learned academies and private societies were founded to promote industrial, agricultural, and political progress through science. Around 200 societies appeared during the half-century spanning from the Seven Years War to the climax of the Napoleonic occupation of Germany, such as the Patriotic Society founded at Hamburg in 1765 (Lowood, 1991, pp. 26-27). These societies, too, emphasized the welfare of the population at large and the

---

[46] It was one of the oldest and financially best supported scientific societies of the eighteenth century, with a membership which included d'Alembert, Buffon, Clairaut, Condorcet, Fontenelle, Laplace, Lavoisier, and Reaumur. It published the most prestigious and substantive scientific series of the century in its annual proceedings Histoire et Memoires and sponsored scientific prize contests such as the Meslay prizes. It recognized achievement and rewarded success for individual discoveries and enhanced the social status of scientists, granting salaries and pensions. A broad range of scientific disciplines were covered, with mathematics and astronomy particularly well represented, as well as botany and medicine.

country over private profit. Local societies supplemented and expanded the work of learned national academies, which were first founded in Berlin in 1700.[47] Publishing played an important role in the work of societies bent on the encouragement of invention, innovation and improvement. This reflected the emergence of open knowledge, a recognition that knowledge was a non-rivalrous good the diffusion of which was constrained by access costs.

To summarize, then, the Industrial Revolution had intellectual roots that needed to be met if sustained economic growth could take place just as it had to satisfy economic and social conditions. The importance of property rights, incentives, factor markets, natural resources, law and order, market integration, and many other economic elements is not in question. But we need to realize that without understanding the growth of useful knowledge, the technological elements will remain inside a black box.

The emergence of technological modernity.

The essence of technological modernity is non-stationarity: many scholars have observed that technological change has become self-propelled and autocatalytic, in which change feeds on change. Unlike other forms of growth, spiraling technological progress does not appear to be bounded from above. Predictions in the vein of "everything that can be invented already has been" have been falsified time and again. The period that followed the Industrial Revolution was one in which innovation intensified, and while we can distinguish a certain ebb and flow, in which major breakthroughs and a cluster of macroinventions were followed by waves of

---

[47] The German local societies were private institutions, unlike state-controlled academies, which enabled them to be more open, with few conditions of entry, unlike the selective, elitist academies. They broke down social barriers, for the established structures of Old Regime society might impede useful work requiring a mixed contribution from the membership of practical experience, scientific knowledge, and political power. Unlike the more scientifically-inclined academies, they invited anyone to join, such as farmers, peasants, artisans, craftsmen, foresters, and gardeners, and attempted to improve the productivity of these occupations and solve the economic problems of all classes. Prizes rewarded tangible accomplishments, primarily in the agricultural or technical spheres. Their goal was not to advance learning like earlier academies, but to apply useful results of human knowledge, discovery and invention to practical and civic life (Lowood, 1991).

microinventions and secondary extensions and applications, it is clear that the modern era is one in which rapid and perhaps accelerating change has become the norm. In the premodern past, whether in Europe or elsewhere in the world, invention had remained the exception, if perhaps not an uncommon one. In the second half of the nineteenth century and even more so in the twentieth century, change has become the norm, and even in areas previously untouched by technological innovation, mechanization, automation, and novelty have become inevitable. There is no evidence to date that technology in its widest sense converges to anything.

To oversimplify, the Industrial Revolution could be reinterpreted in light of the changes in the characteristics and structure of propositional knowledge in the eighteenth century and the techniques that rested on it. Before 1750 the human race, as a collective, did not know enough to generate the kind of sustained technological progress that could account for the growth rates we observe. In the absence of such knowledge, no set of institutions, no matter how benevolent, could have substituted for useful knowledge. The dynamics of knowledge itself were critical to the historical process. Useful knowledge after the Industrial Revolution increased by feeding on itself, spinning out of control as it were, whereas before it had always been limited by its epistemic base and suppressed by economic and social factors, creating what physicists call a "phase transition."[48]

How do we explain this change in technological dynamic? In economics, phase transitions can be said to occur when a dynamic system has multiple steady states such as an economy that has a "poverty trap" (low-income equilibrium) and a high income (or rapid growth steady state). A phase transition occurs when the system switches from one equilibrium or regime to another. A simple model in which this can be illustrated is one in which capital and skills are highly complementary. In such models one equilibrium is characterized by rapid investment, which raises the demand for skills; the positive feedback occurs because the increase in the rate of return to human capital induces parents to invest more in their children, have fewer children (since they become more expensive), which raises the rate of return on physical capital even more and encourages investment. A regime change may occur when an exogenous shock is violent enough to

---

[48] For a definition of phase transitions, see for instance Ruelle (1991), pp. 122-23.

bump the system off one basin of attraction and move it to another one. The difficulty is to identify a historical shock that was sufficiently powerful to "bump" the system to a rapid growth trajectory. The alternative is to presume that historical processes cause the underlying parameters to change slowly but cumulatively, until one day what was a slow-growth steady state is no longer an equilibrium at all and the system, without a discernible shock, moves rather suddenly into a very different steady state. These models, pioneered by Galor and Weil (2000), move from comparative statics with respect to a parameter determining the dynamic structure, to a dynamical system in which this parameter is a latent state variable that evolves and ultimately can generate a phase transition.[49]

Recent work in growth theory have produced a class of models that reproduce this feature in one form or another. Three models of interest have this characteristic, even if they include additional elements. Cervellati and Sunde (2002) model the relationship between mortality and human capital investment. This is a little explored aspect of modernization, but one that must have been of some importance. All other things equal, longer life expectancy would encourage investment in human capital, although it is important to emphasize that a reduction in infant mortality would not directly bring this about, because decisions about human capital are made later in life. Increases in life expectancy at age 10 or so are more relevant here. The other important idea in the Cervellati and Sunde paper is that human capital comes in two forms, a "theoretical" form and a "practical" form, corresponding roughly to "scientific" and "artisanal" knowledge or the categories of useful knowledge proposed above. They assume that human abilities are heterogeneous but that the threshold a at which people start to invest in "theoretical" knowledge as opposed to "crafts" is endogenously determined by life expectancy. This threshold level depends on the costs of acquiring the two types of human capital, their rates of return, and the life expectancy over which they are amortized. Given their

[49] Another example of this type of "phase transition" has been proposed recently by David (1998). He envisages the community of "scientists" to consist of local networks or "invisible colleges" in the business of communicating with each other. Such transmission between connected units can be modeled using percolation models in which information is diffused through a network with a certain level of connectivity. David notes that these models imply that there is a minimum level of persistently communicative behavior that a network must maintain for knowledge to diffuse through and that once this level is achieved the system becomes self-sustaining.

assumptions, the locus of points in the life-expectancy-ability space that define an intra-generational equilibrium is S-shaped. A second relationship in this model is that life expectancy itself depends on the level of education of the previous generation: better educated parents will be better situated to help their children survive. The model is closed by postulating a relationship between the high quality human capital and total productivity. Under these conditions, the dynamic evolution of human capital formation and life expectancy *for any level of technology* can be shown in the following diagram (see fig. 1, adapted from Cervellati and Sunde). This model reproduces a sophisticated version of a poverty "trap" at the attractor point Z (where life expectancy T is low and the threshold level of *a* is close to unity, so that few people choose the high-quality education) and the highly-developed equilibrium point Y in which life expectancy is higher and more people get the high quality education. The neat aspect of the Cervellati-Sunde model is that if for some reason the productivity of the high-quality human capital rises, the curve HH rotates counter-clockwise and becomes less S-shaped. This produces the kind of observed phase transition when the old poverty trap is no longer an equilibrium and the system abruptly starts to move to point Y [see fig. 2].

In their model, the shift is built-in, because if only a few people are receiving the "theoretical" education, they will expand productivity. But any exogenous disturbance that raises the marginal productivity of "scientific activity" will have the same effect, including an exogenous increase in the stock of propositional knowledge and an ideologically-induced change in the agenda of research. Clearly, then, the Industrial Enlightenment, much like an endogenous growth in productivity, can produce a sequence as in fig. 2 and generate an "Industrial Revolution" of this type. While under the assumptions of this paper an Industrial Revolution is "inevitable," they recognize that if technological progress has stochastic elements, this could imply a different prediction (p. 23). Either way, however, the emergence of technologically-based "modern growth" can be understood without the need for a sudden violent shock.

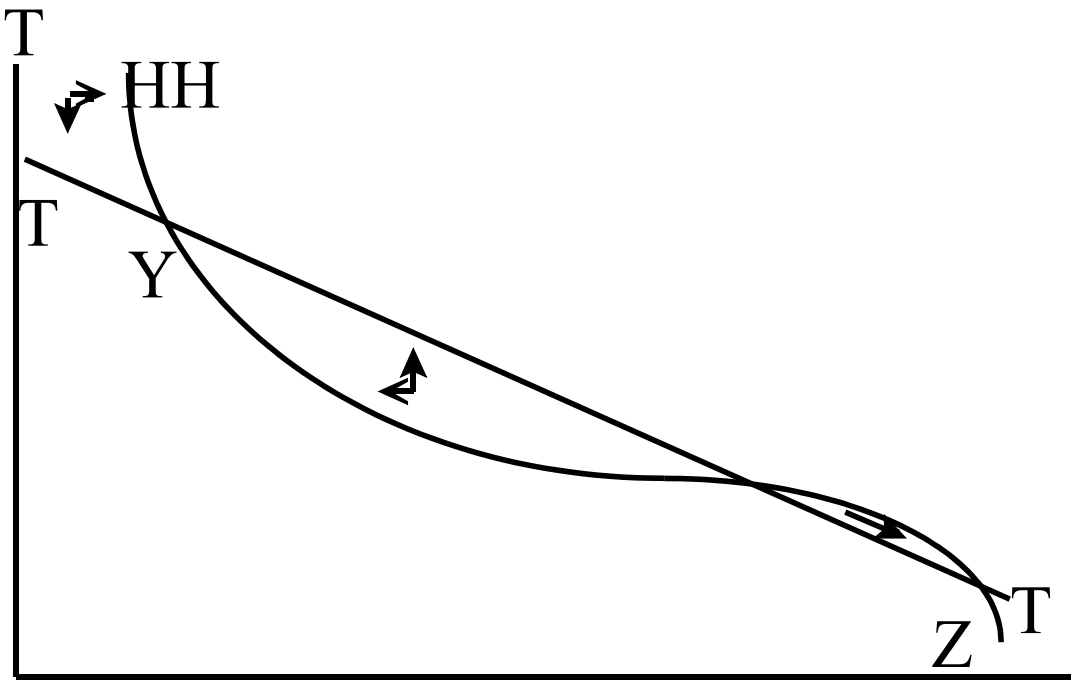

Fig. 1: Poverty trap in a traditional society society a
Source: Cervellati and Sunde (2003)

A second model that generates a sudden transition of this nature is that by Galor and Weil (2000). The Galor-Weil model purports to explain both the Industrial Revolution (post-1750 technological progress) *and* the demographic transition (post-1850 fertility decline). The basic idea is that technological progress itself (rather than the higher income it creates) raises the rate of return on human capital. One interesting idea in this paper is that technological progress is actually costly because it devalues the skills that parents can impart on their children, and instead needs a more institutionalized form of education in which new technology can be "taught." In this they follow an important idea originally proposed by T.W. Schultz (1975), that one of the main functions of human capital is to help

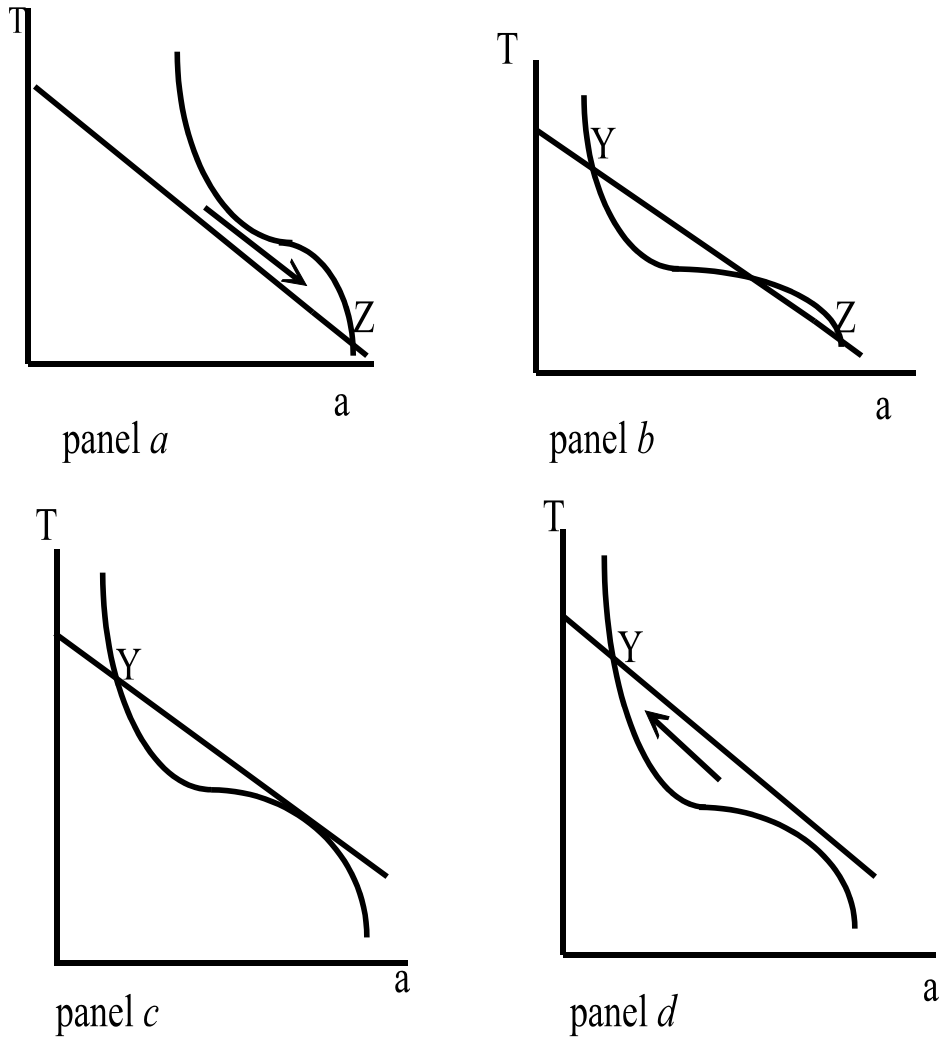

Fig. 2: Transition from traditional to modern society

Source: Cervellati and Sunde (2003)

individuals cope with disequilibria. The positive feedback effect occurs because investment in human capital generates more technological progress. In the Galor-Weil model, the economic *ancien régime* is not really a steady state but a "pseudo steady state" despite its long history: within a seeming stability the seeds for the phase transition are germinating invisibly. The way this works is that technological progress in the pre-modern economy is invariably translated into more children, but technology itself depends on the size of population so that at some point the population reaches a "take-off" point where the phase transition can take place. To assure this result, the model postulates that the traditional economy is at "subsistence" at which all increases in income are translated into more children, an extreme version of a Malthusian equilibrium. Once consumption exceeds a threshold, parents start investing in child quality instead of quantity, and the improved education of the next generation then generates more technological change. The idea is conveyed in fig. 3. In panel (a), depicting a "small population" economy, the only equilibrium is at the origin, with no education and no sustained technological progress. As population increases, however, the growth curve g_{t+1} shifts up to create a situation like panel (b) in which there are two stable equilibria (beside the unstable one at $<e_u,g_u>$). They are the low-education ("bad") equilibrium at g_l where education is zero and technological progress is low. It might seem that only a powerful shock can "bump" the economy to the right of the unstable equilibrium to move to the high equilibrium, but keep in mind that if population is growing, the curve g_{t+1} keeps moving up until the economy ends up in a situation like panel (c) where the old "bad equilibrium" is no longer viable and the economy converges to an equilibrium of high education and rapid technological progress.

A third model, in which technology plays a "behind the scenes" role, is the highly original and provocative model by Galor and Moav (2002). In that model, the phase transition is generated by evolutionary forces and natural selection. The idea is that there are two classes of people, those who have many children (r-strategists) and others (K-strategists) who have relatively few but "high-quality" offspring and who invest more in education. Much like Galor and Weil (2000), Lucas (2002), and others, this paper assumes that the world before 1750 was "Malthusian," but it, too, was not entirely static. Because fertility (plus survival) rates were associated with income in the Malthusian economy, the system provided an advantage to K-strategists and their proportion in the population edges up slowly.

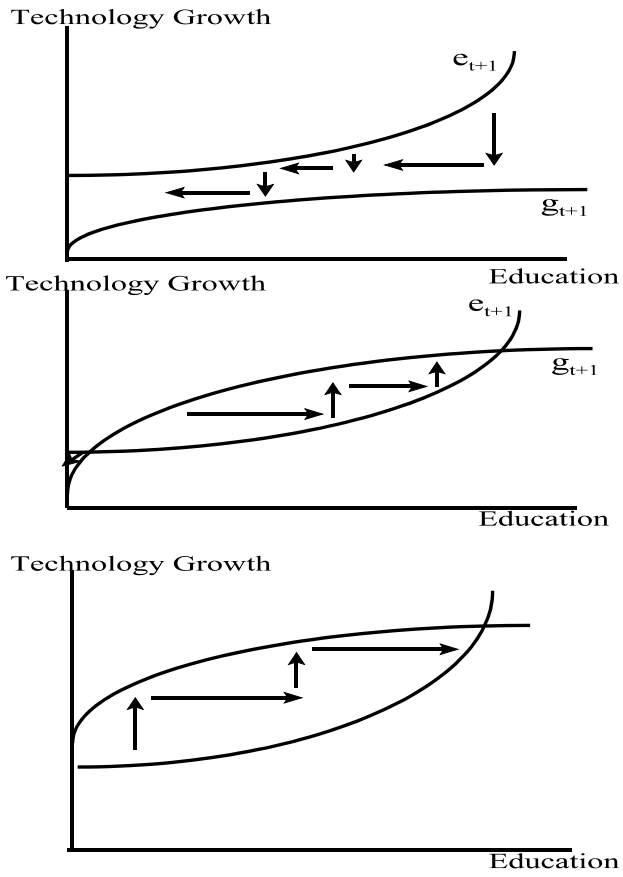

Fig. 3: Transition to a Modern Economy

Source: Galor and Weil, 2000

When "quality types" are selected for, more smart and creative people are added and technology advances. Technological progress increases the rate of return to human capital, induces more people to have more "high quality" (educated) children which provides the positive feedback loop. Moreover, as income advances, households have more resources to spend on education, which add to further expansion. Again, technology in this model is wholly endogenous to education and investment in human capital, and an autonomous development in human knowledge and the interplay between propositional and prescriptive knowledge is not really modeled.

The way the Galor-Moav model reproduces a phase transition is depicted below in fig.4. The diagrams represent a locus of equilibrium points between education at time t (e_t) and growth the next period (g_{t+1}). In panel a, the economy is at an equilibrium at the origin, in the absence of K-strategists who invest in the education of their children. The economy is poor and static, the very picture of a Malthusian state. However, if there are any k-strategists in this economy, their number will steadily grow, causing the e locus to shift to the left, producing an intermediate economy with multiple equilibria. Much like in the Galor-Weil model, this system has a low- and a high-level equilibrium, but because of the changing composition of the economy, the e_{t+1} curve keeps shifting up until the low level steady state $<e_L,g_L>$ is no longer an equilibrium as in panel c. From then on, the economy moves into a steady state with constant growth and a high level of education. An ironic twist of this model that in the end the K-strategists, who are responsible for the transitional dynamics, will be outbred by the r-strategists and vanish. Despite the somewhat limiting assumptions of this model (the "type" is purely inherited and not a choice variable), this paper presents an innovative way of looking at the problem of human capital formation and economic growth in the historical context of the Industrial Revolution.

Fig. 4: Education and Technology in an Evolutionary Model.
Source: Galor and Moav (2002), pp. 1163-65

In some sense Galor and Moav's reliance on evolutionary logic to explain technological progress is ironic. In recent years it has been realized increasingly that knowledge *itself* is subject to evolutionary dynamics, in that new ideas and knowledge emerge and are selected for (or not), and that knowledge systems follow a highly path-dependent trajectory governed by Darwinian forces (Ziman, 2000; Mokyr 2003). Yet this insight still awaits to be incorporated in the "take-off" models of growth theorists. Evolutionary models predict that sudden accelerations or "explosions" of evolutionary change (known oddly as "adaptive radiation") occur when conditions are ripe, such as the so-called Cambrian explosion which has been compared to the Industrial Revolution (Kauffman, 1995, p. 205). Another example of rapid evolutionary innovation is the spectacular proliferation of mammals at the beginning of the Cenozoic after the disappearance of the giant reptiles. The idea that evolution proceeds in the highly non-linear rhythm known as "punctuated equilibrium" has been suggested as a possible insight that economic historians can adapt from evolutionary biology (Mokyr, 1990).

Some of these (and other, similar) models may be more realistic than others, and economic historians may have to sort them out. A phase transition model without any reliance on the quality of children and human capital is proposed by Charles Jones (2001) relying on earlier work by Michael Kremer (1993). In Jones's model, what matters is the size rather than the quality of the labor force. In very small populations, the few new ideas that occur lead in straightforward Malthusian fashion to higher populations and not to higher income per capita. As the population gets larger and larger, however, new ideas become more and more frequent, and productivity pulls ahead. The model assumes increasing returns in population and thus generates a classic multiple equilibria kind of story. The positive feedback thus works through fertility behavior responding to higher productivity, and through an increasing returns to population model. As per capita consumption increases, parents substitute away from children to consume other goods, and fertility declines. In this fashion these models succeed in generating both a sudden and discontinuous growth of income per capita or consumption and the fertility transition. Jones shows that for reasonable parameter values he can simulate a world economy that reproduces the broad outlines of modern economic history (including an initial rise in fertility in the early stages of the Industrial Revolution, followed by a decline). Yet the exact connection between the demographic changes and the economic changes in the post 1750 period are far from

understood, and much of the new growth literature pays scant attention to many variables that surely must have affected the demand for children and fertility behavior. These include technological changes in contraceptive technology, a decline in infant- and child mortality, and the changing role of children in the household economy due to the rise in modern technology. It is also open to question whether and to what extent "numbers matter," that is, technology is driven by the flow of "new ideas" and the more people are around, the more likely — all other things equal — new ideas are to emerge.[50] The real question is whether the ideas that count are really a monotonic function of population size (Jones assumes a positive elasticity of .75 to generate his results), or whether they are generated by a minority so small that they are a negligible fraction of the population.[51] The historical record on that is subject to serious debate. It might be added that population growth in Britain was almost nil in the first half of the eighteenth century, and while it took off during the post 1750 era, the same was true for Ireland, where no Industrial Revolution of any kind can be detected.

Most endogenous growth historical models, however, depend on the notion that investment in human capital is critical to the process of "take-off" or phase transition.[52] Historically, however, such a view is not unproblematic either. The idea that the fertility reduction due to changing rates of return on human capital, especially advanced by Lucas (2002), runs into the Fertility Paradox: the first nation to clearly reduce its fertility rate through a decline in marital fertility (that is, intentional and conscious behavior) was *not* the country in which advanced technological techniques were adopted in manufacturing, but France. In Britain fertility rates come down eventually, but the decline does not start until the mid 1870s, a century after the beginning of the Industrial Revolution (e.g., Tranter, 1985, chapter 4).

---

[50] The pedigree of this idea clearly goes back to the work of Julian Simon (1977, 2000).

[51] This sensitivity is reflected in Jones's simulations: the proportion inventors in the population in 1700 in his computations (set to match the demographic data) is 0.875%, but it *declines* in1800 to less than half that number. By constraining the twentieth century data to stay at that level, Jones shows that the Industrial Revolution would be delayed by 300 years.

[52] For a similar view advanced by an economic historian before the new growth economics, see Easterlin (1981).

To argue, therefore, that technological progress was rooted in demographic behavior (through smaller families) seems at variance with the facts. It may well be that in the twentieth century this nexus held, but given the decline in wage premia it is hard to see the rate of return on human capital to be the driving factor.

Moreover, Britain, the most advanced industrial nation in 1850, was far from being the best educated, the most literate, or in some other way the best-endowed in traditional human capital. Increases in male literacy in Britain during the Industrial Revolution were in fact modest and its educational system as a whole lagging behind (Mitch, 1998). The Lutheran nations of the Continent — Germany and the Scandinavian nations — were far more literate and, in one formulation, "impoverished sophisticates."[53] Jewish minorities throughout European history were unusually well-endowed in human capital (Botticini and Eckstein, 2003) yet contributed little or nothing to the Industrial Revolution before 1850. Clearly human capital as a concept is indispensable, but we need to be far more specific as to what *kind* of human capital was produced, for and by whom, what was the source of the demand for it, and how it was distributed over the population. In his recent survey, the social historian Peter Kirby (2003, p. 118) concludes that the idea that nineteenth century education and literacy emerged as a response to a need for a trained labor force is misleading. There was a significant gap between formal 'education' and 'occupational training, the latter remaining embedded in the workplace in the form of apprenticeships and trainee positions. Before 1870, at least, the rate of return on formal education in his view was so low that its benefits did not outweigh the costs. That is not to say that being literate did not convey advantages in terms of social and occupational mobility, but many of the skills that we associate with schooling could be attained informally.

The historical role of human capital in economic growth must be re-examined with some care. In terms of the framework delineated here its importance was first in reducing access costs: literate and educated innovators could and did read articles, books and personal letters from scientists, as well as familiarize themselves with techniques used elsewhere. By knowing more, the cost of verification fell: some obviously bogus and ineffective pieces of propositional knowledge could be rejected offhand.

---

[53] This is a term used by Lars Sandberg in a pathbreaking paper (1979).

Secondly, a more literate and educated labor force could be assumed to be more competent, that is, be able to execute instructions contained in more and more complex techniques. Yet because the process could be divided up more and more, thanks to better access, the actual amount of such knowledge that a *single* worker had to control may not have increased, it may have just changed. Human capital may have been more important in learning new instructions, than in executing more complex and difficult techniques. Above all, human capital made the prepared minds that, as Pasteur famously said, are favored by Fortune. Much technological progress consisted of fumbling and stumbling into some lucky find – but only systematic training allowed inventors to recognize what they found and how to apply it most fruitfully. Yet it is a fair question to ask of all economists who draw links between demographic behavior — whether through the quality-quantity trade-off or otherwise—how many inventors and technically truly able people were needed to generate sustained technological progress.

Eighteenth century Britain did have a cadre of highly skilled technicians and mechanics, most of them trained in the apprenticeship system rather than in formal academies, and these contributed materially to its technological development. But the process of training apprentices did not always correspond to the neoclassical depiction of human capital formation. In addition to imparting skills, it was a selection process in which naturally gifted mechanics would teach themselves from whatever source was available as much as learn from their masters. In the eighteenth century the publishing industry supplied a large flow of popular science books, encyclopedias, technical dictionaries and similar "teach-yourself" kind of books.[54] These mechanics and technicians were the ones that made the Industrial Revolution possible by generating a stream of microinventions that accounted for the actual productivity gains when the great breakthroughs or macroinventions created the opportunities to do so and by providing the competence to carry out the new instructions, that is, to build and construct the new devices according to blueprints and specifications.

Technological change in the era of the Industrial Revolution, based on invention, innovation, and implementation, did not necessarily require

---

[54] Among the many eminent self-educated scientists was Michael Faraday, whose interests in electricity were first stimulated by reading an article in the *Encyclopedia Britannica*.

that the entire labor force or most of it, much less the population at large, be highly educated; that depended entirely on whether the relation between innovation and the growth of competence was strong and positive. An economy that is growing technologically more sophisticated and more productive may end up using techniques that are more difficult to invent and artefacts that are more complex in design and construction, but may be easier to actually use and run on the shop floor. Production techniques became more modular and standardized, meaning that labor might become more specialized and that each worker had to know less rather than more. If much of the new technology introduced after 1825 was like the self-actor—simpler to use if more complex to build— it may well be that the best model to explain technological progress (in the sense of inventing new techniques rather than implementing existing ones) is not the *mean* level of human capital (or, as model-builders have it, the level of human capital of a representative agent), but just the density in the upper tail of the distribution, that is, the level of education and sophistication of a small and pivotal elite of engineers, mechanics, and chemists, dexterous, motivated, imaginative, well-trained technically, with some understanding of some of the science involved. What knowledge the firms could not supply from its own workforce, it purchased from the outside in the form of consulting engineers.[55] Arguably, the system also depended on the increased skills of lower-level technicians, supervisors, foremen, and skilled artisans that the factories needed to introduce new techniques on the shop floor and to make the necessary adjustments to specific tasks and usages. But the bulk of the labor force consisted of rank-and file workers who were in a different category, and thus any model that relates human capital to demographic behavior runs into a serious dilemma. It stands to reason that the ratio of competence to knowledge is higher in agriculture than in manufacturing and in services, since a great deal of competence concerns uncodified knowledge about very local conditions of soil and weather. As the share of agriculture in the labor force and total output declined, this may be one reason why the

[55] Such outside professional consultants included the famous British "coal-viewers" who advised coal mine owners not only on the optimal location and structure of coal mines but also on the use of the Newcomen steam pumps employed in mines in the eighteenth century (Pollard, 1968, pp. 152–53). "Civil engineers" was a term coined by the great engineer John Smeaton, who spent much of his life "consulting" to a large number of customers in need of technical advice.

relative importance of this form of human capital has declined in the twentieth century.

The human capital argument can be tested, at a rudimentary level, by looking at the ratio between skilled and unskilled wages (or wage premium). The problem is of course that without estimating a complete model of the market for skills, the historical course of that ratio cannot be assigned to demand or supply factors. If, however, we assume that technology is the prime mover in this market and we keep in mind that the supply of skills will lag considerably behind a rise in wages (since the acquisition of skills takes time), it would stand to reason that we should observe some increase in the skill premium during the Industrial Revolution. No such change can be observed. Indeed, one of the most surprising facts is that in the twentieth century this skill ratio declined precipitously (Knowles and Robertson, 1951). This could be caused by an (otherwise unexplained) increase in supply, but it is at least consistent with a story that stresses the ability of unskilled labor to operate effectively in a sophisticated technology environment.

The argument I propose, that technological progress is driven by a relatively small number of pivotal people, is not a call for a return to the long-defunct "heroic inventor" interpretation of the Industrial Revolution. The great British inventors stood on the shoulders of those who provided them with the wherewithal of tools and workmanship. John Wilkinson, it is often remarked, was indispensable for the success of James Watt, because his Bradley works had the skilled workers and equipment to bore the cylinders exactly according to specification. Mechanics and instrument makers such as Jesse Ramsden, Edward Nairn, Joseph Bramah, and Henry Maudslay; clock makers such as Henry Hindley, Benjamin Huntsman (the inventor of the crucible technique in making high quality steel), John Whitehurst (a member of the Lunar Society), and John Kay of Warrington (not to be confused with his namesake, the inventor of the flying shuttle, who was trained as a reed and comb maker), engineers such as John Smeaton, Richard Roberts, and Marc I. Brunel; ironmasters such as the Darbys, the Crowleys, and the Crawshays; steam engine specialists such as William Murdoch and Richard Trevithick; chemists such as John Roebuck, Alexander Chisholm, and James Keir were as much part of the story as the "superstars" Arkwright, Cort, Crompton, Hargreaves, Cartwright, Trevithick, and Watt. More often than not, these were men for whom Griffiths's judgment of William Murdoch (the gifted and ingenious Watt and Boulton

employee, credited with the invention of the famous Sun-and-Planets gear) holds: “his inventiveness was instinctive, not analytical. He had an innate sense of mechanical propriety, of the *chose juste*, which led him to simple, robust and highly original solutions” (Griffiths, 1992, p. 209). These were obviously men who could squeeze a great deal out of a narrow epistemic base who could recognize more effective useful knowledge and base better techniques on them. In the end, however, there was no escaping a more formal and analytical approach, in which a widening reliance on physics and mathematics was inevitable. Oddly enough, this approach originated in France more than in Britain.[56]

Below the great engineers came a much larger contingent of skilled artisans and mechanics, upon whose dexterity and adroitness the top inventors and thus Britain's technological success relied. These were the craftsmen who could accurately produce the parts, using the correct dimensions and materials, who could read blueprints and compute velocities, understood tolerance, resistance, and the interdependence of mechanical parts. These were the applied chemists who could manipulate laboratory equipment and acids, the doctors whose advice sometimes saved lives even if nobody quite yet understood why, agricultural specialists who experimented with new breeds of animals, fertilizers, drainage systems, and fodder crops. These anonymous but capable workers produced a cumulative stream of small, incremental, but cumulatively indispensable microinventions without which Britain would not have become the "workshop of the world." It is perhaps premature to speak of an "invention industry" by this period, but technical knowledge at a level beyond the reach of the run-of-the-mill artisan became increasingly essential to create the inventions associated with the Industrial Revolution.[57]

---

[56] The “Big Three polytechnicien” engineers of the early nineteenth century, Gustave-Gaspard Coriolis, Jean-Victor Poncelet, and Louis Navier, placed mechanical and civil engineering on a formal base, and supported practical ideas with more formal theory than their more pragmatic British colleagues

[57] A number of high-skill sectors that had developed in Britain since 1650 played important roles in them. Among those instrument- and clock making, mining, and ship yards are of central importance. Cardwell (1972, p. 74) points out that a number of basic technologies converge on mining (chemistry, civil engineering, metallurgy) and that mining sets the hard, "man-sized" problems, controlling powerful forces of nature and transforming materials on a large scale. In addition, however,

The average "quality" of the rest of the labor force – in terms of their technical training – may have mattered to the development and adoption of the new techniques less than is commonly believed. A venerable tradition in economic history, in fact, has argued that technological progress in the first stages of the Industrial Revolution was "deskilling," requiring workers who were able to carry out repetitive routine actions instead of the skilled labor of skilled craftsmen.[58] The "factory system" required workers to be supervised and assisted by skilled mechanics, and hence the variance of the skill level may have increased even if we cannot be sure whether *average* skills had to go up or down. Moreover, the term "skill" may be too confining. Human capital was in part produced in schools, but what future workers were taught in schools may have had as much to do with behavior as with competence. Docility and punctuality were important characteristics that factory owners expected from their workers. "The concept of industrial discipline was new, and called for as much innovation as the technical inventions of the age," writes Pollard ([1965] 1968, p. 217). Early factories designed incentives to bring about the discipline, but they also preferred to hire women and children, who were believed to be more docile. Some of the literature by economists on human capital acquisition may have to be reinterpreted in this fashion. Beyond that, however, human capital was instrumental in creating competence rather than knowledge itself. Yet given that much of competence consisted of tacit knowledge and experience, and given that much of the competence could be front-loaded into the equipment by a small number of brilliant designers, the role of either the size of the population or their "mean" level of human capital should be questioned. It seems plausible that the degree of networking and the level of access costs *within* the relatively small community of highly trained engineers and scientists may have been of greater importance.

British millwrights were technologically sophisticated: the engineer John Fairbairn, a millwright himself, noted that eighteenth century British millwrights were "men of superior attainments and intellectual power," and that the typical millwright would have been "a fair arithmetician, knew something of geometry, levelling and mensuration and possessed a very competent knowledge of practical mechanics" (cited in Musson and Robinson, 1969, p. 73).

[58] On the eve of the Industrial Revolution, much of the manufacturing sector in Europe had already been de-skilled to a considerable extent, with much of the production carried out in the homes of unskilled rural workers.

To understand the "phase transition" in the dynamic of useful knowledge, we need to look again at the relationship between propositional and prescriptive knowledge. As the two forms of knowledge co-evolved, they increasingly enriched one another, eventually tipping the balance of the feedback mechanism from negative to positive and creating the phase transition. During the early stages of the Industrial Revolution propositional knowledge mapped into new techniques creating what we call "inventions." This mapping should not be confused with the linear models of science and technology, popular in the mid-twentieth century, which depicted a neat flow from theory to applied science to engineering and from there to technology. Much of the propositional knowledge that led to invention in eighteenth century was artisanal: pragmatic, informal, intuitive, and empirical. Only very gradually did it the kind of formal and consensual knowledge we think of today as "science"become a large component of it. It was, in all cases, a small fraction of what is known today. What matters is that it was subject to endogenous expansion: prescriptive knowledge in its turn enhanced propositional knowledge, and thus provided positive feedback between the two types of knowledge, leading to continuous mutual reinforcement. When powerful enough, this mechanism can account for the change in stability of the entire system. The positive feedback from prescriptive to propositional knowledge took a variety of forms.

One of those forms is what Rosenberg has called "focusing devices:" technology posed certain riddles that science was unable to solve, such as "why (and how) does this technique work." The most celebrated example of such a loop is the connection between steam power and thermodynamics, exemplified in the well–known tale of Sadi Carnot's early formulation, in 1824, of the Second Law of Thermodynamics by watching the difference in fuel economy between a high pressure (Woolf) steam engine and a low pressure one of the Watt type.[59] The next big step was made by an Englishman, James P. Joule, who showed the conversion rates from work to

[59] It is interesting to note that Carnot's now famous *Reflexions sur la puissance motrice du feu* (1824) was initially ignored in France and eventually found its way second hand and through translation into Britain, where there was considerably more interest in his work because of the growing demand by builders of gigantic steam engines such as William Fairbairn in Manchester and Robert Napier in Glasgow for theoretical insights that would help in making better engines.

heat and back.[60] Joule's work and that of Carnot were then reconciled by a German, R. J. E. Clausius (the discoverer of entropy), and by 1850 a new branch of science dubbed "thermodynamics" by William Thomson (later Lord Kelvin) had emerged (Cardwell, 1971, 1994).[61] Power technology and classical energy physics subsequently developed hand-in-hand, culminating in the career of the Scottish physicist and engineer William Rankine whose *Manual of the Steam Engine* (1859) made thermodynamics accessible to engineers and led to a host of improvements in actual engines. In steam power, then, the positive feedback can be clearly traced: the first engines had emerged in the practical world of skilled blacksmiths, millwrights, and instrument makers with only a minimum of theoretical understanding. These machines then inspired theorists to come to grips with the natural regularities at work and to widen the epistemic base. The insights generated were in turn fed back to engineers to construct more efficient engines. This kind of mutually reinforcing process can be identified, in a growing number of activities, throughout the nineteenth century. They required the kind of intellectual environment that the Industrial Enlightenment had created: a world in which technical knowledge was accessible and communicable in an international elite community, a technological invisible college that encompassed much of the Western world.

A less well known example of this feedback mechanism, but equally important to economic welfare, is the interaction between the techniques of food-canning and the evolution of bacteriology. As noted earlier, the canning

---

[60] The ways in which the growth of practical knowledge can influence the emergence of propositional knowledge are well illustrated by Joule's career: he was a child of industrial Lancashire (his father owned a brewery) and in the words of one historian, "with his hard-headed upbringing in industrial Manchester, was unambiguously concerned with the *economic* efficiency of electromagnetic engines...he quite explicitly adopted the language and concerns of the economist and the engineer" (Morus, 1998, p. 187, emphasis in original). As Ziman remarks (1976, p. 26), the first law of thermodynamics could easily have been derived from Newton's dynamics by mathematicians such as Laplace or Lagrange, but it took the cost accountancy of engineers to bring it to light.

[61] Research combining experiment and theory in thermodynamics continued for many decades after that, especially in Scotland and in Mulhouse, France, where Gustave Adolphe Hirn, a textile manufacturer, led a group of scientists in tests on the steam engines in his factory and was able to demonstrate the law of conservation of energy.

of food was invented in 1795, by Nicolas Appert. He discovered that when he placed food in champagne bottles, corked them loosely, immersed them in boiling water, and then hammered the corks tight, the food was preserved for extended periods. Neither Appert nor his English emulators who perfected the preservation of food in tin-plated canisters in 1810 really understood why and how this technique worked, because the definitive demonstration of the notion that microorganisms were responsible for putrefaction of food was still in the future. It is therefore a typical example of a technique with a narrow epistemic base. The canning of food led to a prolonged scientific debate about what caused food to spoil. The debate was not put to rest until Pasteur's work in the early 1860s. Pasteur knew of Appert's work, and eventually admitted that his own work on the preservation of wine was only a new application of Appert's method. Be that as it may, his work on the impossibility of spontaneous generation clearly settled the question of why the technique worked and provided the epistemic base for the technique in use. When the epistemic base of food-canning became wider, techniques improved: the optimal temperatures for the preservation of various foods with minimal damage to flavor and texture were worked out by two MIT scientists, Samuel Prescott and William Underwood.[62]

A different feedback mechanism from prescriptive to propositional knowledge was described by Derek Price as "Artificial Revelation." The idea is fairly simple: our senses limit us to a fairly narrow slice of the universe that has been called a "mesocosm": we cannot see things that are too far away, too small, or not in the visible light spectrum (Wuketits, 1990, pp. 92, 105). The same is true for our other senses, for the ability to make very accurate measurements, for overcoming optical and other sensory illusions, and — perhaps most important in our own time — the computational ability of our brains. Technology consists in part in helping us overcome these limitations that evolution has placed on us and learn of natural phenomena we were not meant to see or hear.[63] The period of the Industrial

---

[62] A University of Wisconsin scientist, H. L. Russell, proposed to increase the temperature of processing peas from 232° to 242°, thus reducing the percentage spoiled can from 5 percent to 0.07 percent (Thorne, 1986, p. 145).

[63] Derek Price notes that Galileo's discovery of the moons of Jupiter was the first time in history that somebody made a discovery that had been totally unavailable to others by a process that did not involve a deep and clever thought (1984b, p. 54).

Revolution witnessed a great deal of improvement in techniques whose purpose it was to enhance propositional knowledge. Lavoisier and his circle designed and used better laboratory equipment that allowed them to carry out more sophisticated experiments.[64] Alessandro Volta invented a pile of alternating silver and zinc disks that could generate an electric current in 1800. Volta's battery was soon produced in industrial quantities by William Cruickshank. Through the new tool of electrolysis, pioneered by Humphry Davy, chemists were able to isolate element after element and fill in much of the detail in the maps whose rough contours had been sketched by Lavoisier and Dalton. Volta's pile, as Davy put it, acted as an "alarm bell to experimenters in every part of Europe" (cited by Brock, 1992, p. 147).Or consider the development of the technique of in vitro culture of micro-organisms (the Petri dish was invented in 1887 by R. J. Petri, an assistant of Koch's). Price feels that such advances in knowledge are "adventitious"(1984a, p. 112). Travis (1989) has documented in detail the connection between the tools developed in the organic chemical industry and advances in cell biology. These connections between prescriptive and propositional knowledge are just a few examples of advances in scientific techniques that can be seen as adaptations of ideas originally meant to serve an entirely different purpose, and they reinforce the contingent and accidental nature of much technological progress (Rosenberg, 1994, pp. 251–52).

The invention of the modern compound microscope attributed to Joseph J. Lister (father of the famous surgeon) in 1830 serves as another good example. Lister was an amateur optician, whose revolutionary method of grinding lenses greatly improved image resolution by eliminating spherical aberrations.[65] His invention and the work of, among others, Pierre Guinand

---

[64] The famous mathematician Pierre-Simon de Laplace was also a skilled designer of equipment and helped to build the calorimeter that resulted in the celebrated "Memoir on Heat" jointly written by Laplace and Lavoisier (in 1783), in which respiration was identified as analogous to burning. Much of the late eighteenth-century chemical revolution was made possible by new instruments such as Volta's eudiometer, a glass container with two electrodes intended to measure the content of air, used by Cavendish to show the nature of water as a compound.

[65] The invention was based on a mathematical optimization for combining lenses to minimize spherical aberration and reduced average image distortion by a huge proportion, from 19 to 3 percent. Lister is reputed to have been the first human being ever to see a red blood cell.

and Samuel Klingenstierna changed microscopy from an amusing diversion to a serious scientific endeavor and eventually allowed Pasteur, Koch, and their disciples to refute spontaneous generation and to establish the germ theory, a topic I return to below. The germ theory was one of the most revolutionary changes in useful knowledge in human history and mapped into a large number of new techniques in medicine, both preventive and clinical. Indeed, the widespread use of glass in lenses and instruments in the West was itself something coincidental, a "giant accident," possibly a by-product of demand for wine and different construction technology (Macfarlane and Martin, 2002). It seems plausible that without access to this rather unique material, the development of propositional knowledge in the West would have taken a different course.[66]

A third mechanism of technology feeding back into prescriptive knowledge is through what might be called the "rhetoric of knowledge." This harks back to the idea of "tightness" introduced earlier. Techniques are not "true" or "false." Either they work as expected or they do not, and thus they can be interpreted to confirm or refute the propositional knowledge that serves as their epistemic base. Prescriptive knowledge has varying degrees of tightness, depending on the degree to which the available evidence squares with the rhetorical conventions for acceptance. Laboratory technology transforms conjecture and hypothesis into an accepted fact, ready to go into textbooks and to be utilized by engineers, physicians, or farmers. But a piece of propositional knowledge in the past was often tested simply by verifying that the techniques based on it actually worked. The earthenware manufacturer Josiah Wedgwood felt that his experiments in pottery actually tested the theories of his friend Joseph Priestley, and professional chemists, including Lavoisier, asked him for advice. Similarly, once biologists discovered that insects could be the vectors of pathogenic microparasites, insect-fighting techniques gained wide acceptance. The success of these techniques in eradicating yellow fever and malaria was the best confirmation of the hypotheses about the transmission mechanisms of the disease and helped earn them wide support.

---

[66] MacFarlane and Martin (2002, pp. 81-82) note that glass lenses not only made possible specific discoveries but led to a growing confidence in a world of deeper truths to be discovered, destabilizing conventional views. "The obvious was no longer true. Hidden connections and buried forces could be analyzed."

Or consider the question of heavier-than-air flight. Much of the knowledge in aeronautics in the early days was experimental rather than theoretical, such as attempts to tabulate coefficients of lift and drag for each wing shape at each angle. It might be added that the epistemic base supporting the first experiments of the Wright brothers was quite untight: in 1901 the astronomer and mathematician Simon Newcomb (the first American since Benjamin Franklin to be elected to the Institute of France) opined that flight carrying anything more than "an insect" would be impossible.[67] The success at Kitty Hawk persuaded all but the most stubborn doubting Thomases that human flight in heavier-than-air fixed wing machines was possible. Clearly their success subsequently inspired a great deal of research on aerodynamics. In 1918 Ludwig Prandtl published his magisterial work on how wings could be scientifically rather than empirically designed and the lift and drag precisely calculated (Constant, 1980, p. 105; Vincenti, 1990, pp. 120–25). Even after Prandtl, not all advances in airplane design were neatly derived from first principles in an epistemic base in aerodynamic theory, and the ancient method of trial and error was still widely used in the search for the best use of flush riveting in holding together the body of the plane or the best way to design landing gear (Vincenti, 1990, pp. 170–99; Vincenti, 2000).

It is important not to exaggerate the speed and abruptness of the transition. Thomas Edison, a paradigmatic inventor of the 2nd Industrial Revolution barely knew any science, and in many ways should be regarded an old-fashioned inventor who invented by trial-and-error through intuition, dexterity and luck. Yet he knew enough to know what he did not know, and that there were others who knew what he needed. Among those who supplied him with the propositonal knowledge necessary for his research were the mathematical physicist Francis Upton, the trained electrical engineer Hermann Claudius, the inventor and engineer Nikola Tesla, the physicist Arthur E. Kennelly (later professor of electrical engineering at Harvard), and the chemist Jonas W. Aylsworth. Yet by that time access costs had declined enough so that he could learn for instance of

---

[67] He was joined in that verdict by the Navy's chief engineer, Admiral George Melville (Kelly, 1943, pp. 116–17; Crouch, 1989, p. 137). Nor were the inventors themselves all that certain: in a widely quoted remark, Wilbur Wright in a despondent mood remarked to his brother that "not within a thousand years would men ever fly" (Kelly, 1943, p. 72).

the work of the great German physicist Hermann von Helmholtz through a translated copy of the latter's work on acoustics.

The positive feedback from technology to prescriptive knowledge entered a new era with development of the computer. In the past, the practical difficulty of solving differential equations limited the application of theoretical models to engineering. A clever physicist, it has been said, is somebody who can rearrange the parameters of an insoluble equation so that it does not have to be solved. Computer simulation can evade that difficulty and help us see relations in the absence of exact closed-form solutions and may represent the ultimate example of Bacon's "vexing" of nature. In recent years simulation models have been extended to include the effects of chemical compounds on human bodies. Combinatorial chemistry and molecular biology are both equally unimaginable without fast computers. It is easy to see how the mutual reinforcement of computers and their epistemic base can produce a virtuous circle that spirals uncontrollably away from its basin of attraction. Such instability is the hallmark of Kuznets's vision of the role of "useful knowledge" in economic growth.

In addition to the positive feedback within the two types of knowledge, one might add the obvious observation that *access costs* were themselves a function of improving techniques, through better communications, storage, and travel techniques. In this fashion, expansions in prescriptive knowledge not only expanded the underlying supporting knowledge but made it more accessible and thus more likely to be used. As already noted, this is particularly important because so much technological progress consists of combinations and applications of existing techniques in novel ways, or parallels from other techniques in use. Precisely for this reason, cheap and reliable access to the monster catalog of all feasible techniques is an important element in technological progress. As the total body of useful knowledge is expanding dramatically in our own time, it is only with the help of increasingly sophisticated search engines that needles of useful knowledge can be retrieved from a haystack of cosmic magnitude.

Technological modernity is created when the positive feedback from the two types of knowledge becomes self-reinforcing and autocatalytic. We could think of this as a phase transition in economic history, in which the old parameters no longer hold, and in which the system's dynamics have been unalterably changed. There is no necessity for this to be true even in the presence of positive feedback; but for certain levels of the parameters, the system as a whole becomes unstable. It may well that this instability in the

knowledge-producing system are what is behind what we think of as "technological modernity." Kuznets, of course, felt that the essence of modern growth was the increasing reliance of technology on modern science. This view, as I have argued above needs clarification and amplification. Inside the black box of technology is a smaller black box called "research and development" which translates inputs into the output of knowledge. This black box itself contains an even smaller black box which models the available knowledge in society, and it is this last box I have tried to pry open. Yet all this is only part of the story: knowledge creates opportunities, but it does not guarantee action. Knowledge is an abstract concept, it glosses over the human agents who possess it and decide to act upon it. What motivates them, and why did some societies seem to be so much more inclined to generate new knowledge and to exploit the knowledge it had? To understand why during the past two centuries the "West" has been able to take advantage of these opportunities we need to examine the institutional context of innovation.

Institutions and Technological progress

Beyond the interaction of different kinds of knowledge was the further level of interaction and feedback between human knowledge and the institutional environment in which it operates. Before 1750, economic progress of any kind had tended to run into what could best be called negative institutional feedback. One of the few reliable regularities of the premodern world was that whenever a society managed, through thrift, enterprise, or ingenuity to raise its standard of living, a variety of opportunistic parasites and predators were always ready to use power, influence, and violence to appropriate this wealth. Such rent-seekers, who redistributed wealth rather than created it, came either from within the economy in the form of tax-collectors, exclusive coalitions, and thugs, or they came from outside as alien pillagers, mercenaries, and plunderers. The most obvious and costly form of negative institutional feedback before 1815 was, of course, war. Rent-seeking and war often went in hand in hand. Britain, France, the United Provinces and most other Continental powers fought one another constantly in hugely costly attempts to redistribute taxable real estate, citizens and activities from one to the other, a typical "mercantilist" kind of

policy.[68] Economic growth indirectly helped instigate these conflicts. Wealth accumulation, precisely because it was mostly the result of "Smithian Growth," was usually confined to a region or city and thus created an incentive to greedy and well-armed neighbors to engage in armed rent-seeking. It surely is no accident that the only areas that had been able to thwart off such marauders with some success were those with natural defenses such as Britain and the Netherlands. Yet the Dutch United Provinces were weakened by the relentless aggressive mercantilist policies of powerful neighbors.[69] The riches of the Southern Netherlands – unfortunately easier to invade – were repeatedly laid to waste by invading mercenary soldiers after 1570. More subtle forms of rent-seeking came from local monopolists (whose claims to a right to exclude others were often purchased from strongmen), guilds with exclusionary rights, or nobles with traditional rights such as *banalités*. A particularly harmful form of rent-seeking were price controls on grain that redistributed resources from the countryside to the city by keeping grain prices at below equilibrium levels (Root, 1994).

Had institutional feedback remained negative, as it had been before 1750, the economic benefits of technological progress would have remained limited. Mercantilism, as Ekelund and Tollison (1981, 1997) have emphasized, was largely a system of rent seeking, in which powerful political institutions redistributed wealth from foreigners to themselves as well between different groups and individuals within the society. The Industrial Enlightenment meant that the old rent-seeking traditions of exclusionary privileges were increasingly viewed as both unfair and inefficient.

---

[68] O'Brien (2003, p. 5) notes that between the nine-years war (starting in 1688) and the Congress of Vienna in 1815, Britain and France were at or on the brink of war for more than half the period, justifying the term "Second Hundred Years War."

[69] The standard argument is that national defense was so costly that high indirect taxes led to high nominal wages, which rendered much of Dutch manufacturing uncompetitive. See for example Charles Wilson (1969). De Vries and Van Der Woude (1997, p. 680) point out that in 1688 the Dutch committed huge resources to an invasion of England because the future economic well-being on the Republic depended on the destruction of French mercantilism and the establishment of an international order in which the Dutch economy could prosper, yet it "proved to be a profitless investment." More recently, Ormrod (2003) has confirmed the view that the decline of the Dutch Republic was a direct consequence of the mercantilist policies of its neighbors, especially Britain.

Mercantilism had been a game of international competition between rival political entities. To defeat an opponent, a nation had to outcompete it, which it often did by subsidizing exports and raw materials imports, and imposing a tariff on finished goods. As it dawned upon people that higher productivity could equally outcompete other producers, they switched to a different policy regime, one that economists certainly would recognize as more enlightened.[70] In the century before 1750, mercantilism had begun to decline in certain key regions in Western Europe, above all in Britain, where many redistributive arrangements such as guilds, monopolies, and grain price regulations were gradually weakening, though their formal disappearance was still largely in the future. The Age of Enlightenment led to some pre-1789 reforms on the Continent thanks to a few enlightened despots, but it seems beyond doubt that the French Revolution and the ensuing political turmoil did more than anything else to transform Enlightenment ideas into institutional changes that paved the road for economic growth (Mokyr, 2003b). The Enlightenment also advocated more harmonious and cosmopolitan altitudes in international relations and its influence may have contributed to the relative calm that settled upon Europe after the Congress of Vienna. Political reforms that weakened privileges and permitted the emergence of freer and more competitive markets had an important effect on economic performance. The institutional changes in the years between 1770 and 1815 saw to it that the Industrial Revolution was not followed by a surge in rent-seeking and violence that eventually could have reversed the process.

The feedback between technological and institutional change is central to the process of historical change. The co-evolution of technological knowledge and institutions during the second Industrial Revolution has been noticed before.[71] Above all, three kind of institutions were important in

---

[70] In 1773, the steam engine manufacturer Matthew Boulton told Lord Harwich that mechanization and specialization made it possible for Birmingham manufacturers to defeat their Continental competitors (cited by Uglow, 2002, p. 212).

[71] Nelson (1994) has pointed to a classic example, namely the growth of the large American business corporation in the closing decades of the nineteenth century, which evolved jointly with the high-throughput technology of mass production and continuous flow. In their pathbreaking book, Fox and Guagnini (1999) have pointed to the growth of practically-minded research laboratories in academic communities, which increasingly cooperated and interacted successfully with industrial establishments to

facilitating the sustained technological progress central to economic growth: those that provided for connections between the people concerned mostly with propositional knowledge and those on the production side; those that set the agenda of research to generate new propositional knowledge that could be mapped into new techniques; and those institutions that created *incentives* for innovative people to actually spend resources in order to map this knowledge into actual techniques and specifically that weakened the effective social and political resistance against new techniques. As noted above, even some of the formal endogenous growth models require a growing proportion of labor in the "invention sector," a condition that clearly demands that their profits not be expropriated altogether.

The institutions that created the bridges between prescriptive and propositional knowledge in late eighteenth and nineteenth century Europe are well understood: universities, polytechnic schools, publicly funded research institutes, museums, agricultural research stations, research departments in large financial institutions. Improved access to useful knowledge took many forms: cheap and widely diffused publications disseminated it. Technical subjects penetrated school curricula in every country in the West (although Britain, the leader in the first Industrial Revolution, lost its momentum in the last decades of the Victorian era). All over the Western world, textbooks of applied science (or "experimental philosophy" in the odd terminology of the time), professional journals, technical encyclopedias, and engineering manuals appeared in every field and made it easier to "look things up." The professionalization of expertise meant increasingly that anyone who needed some piece of useful knowledge could find someone who knew, or who knew who knew. The learned journal first appeared in the 1660s and by the late eighteenth century had become one of the main vehicles by which prescriptive knowledge was diffused. In the eighteenth century, most scientific journals were in fact deliberately made accessible, because they more often than not catered to a lay audience and thus were media of education and dissemination rather than repositories of original contributions (Kronick, 1962, p. 104). Review articles and book

---

create an ever-growing stream of technological adaptations and microinventions. Many other examples can be cited, such as the miraculous expansion of the British capital market which emerged jointly with the capital-hungry early railroads and the changes in municipal management resulting from the growing realization of the impact of sanitation on public health (Cain and Rotella, 2001).

reviews that summarized and abstracted books and learned papers (especially those published overseas and were less accessible), another obvious example of an access-cost reduction, were popular.[72] In the nineteenth century, specialized scientific journals became increasingly common and further reduced access costs, if perhaps more and more requiring the intermediation of experts who could decode the jargon.

To be sure, co-evolution did not always quickly produce the desired results. British engineering found it difficult to train engineers using best-practice knowledge, and the connections between science and engineering remained looser and weaker than elsewhere. In 1870 a panel appointed by the Institute of Civil Engineers concluded that "the education of an Engineer is effected by...a simple course of apprenticeship to a practicing engineer...it is not the custom in England to consider *theoretical* knowledge as absolutely essential" (cited by Buchanan, 1985, p. 225). A few individuals, above all William Rankine at Glasgow, argued forcefully for more bridges between theory and practice, but significantly he dropped his membership in the Institute of Civil Engineers. Only in the late nineteenth century did engineering become a respected discipline in British universities.

Elsewhere in Europe, the emergence of universities and technical colleges that combined research and teaching, thus simultaneously expanding propositional knowledge and reducing access costs, advanced rapidly. An especially good and persuasive example is provided by Murmann (1998), who describes the co-evolution of technology and institutions in the chemical industry in imperial Germany, where the new technology of dyes, explosives, and fertilizers emerged in constant interaction with the growth of research and development facilities, institutes of higher education, and large industrial corporations with a knack for industrial research.[73] Institutions remained a major determinant of access costs. To understand the

---

[72] This aspect of the Industrial Enlightenment was personified by the Scottish writer and mathematician John Playfair (1748-1819) whose textbooks and review essays in the *Edinburgh Review* made a special effort to incorporate the work of Continental mathematicians, as witnessed by the essays in 1807 on the work of Mechain and Delambre on the earth's meridian, and his 1808 review of LaPlace's *Traité de Mécanique Celeste* (Chitnis, 1976, pp. 176-77, 222).

[73] Most famous, perhaps, was the invention of alizarin in 1869, a result of the collaboration between the research director at BASF, Caro, with the two academics Graebe and Liebermann.

evolution of knowledge, we need to ask who talked to whom and who read what. Yet the German example illustrates that progress in this area was halting and complex; it needs to be treated with caution as a causal factor in explaining systematic differences between nations. The famed *technische Hochschulen*, the German equivalent of the French *polytechniques,* had lower social prestige than the universities and were not allowed to award engineering diplomas and doctorates till 1899. The same is true for the practical, technically oriented *Realschulen* which had lower standing than the more classically inclined *Gymnasien*. Universities conducted a great deal of research, but it goes too far to state that what they did was a *deliberate* application of science to business problems.[74] Universities and businesses co-evolved, collaborating through intense communications, overlapping personnel, and revolving doors. The second Industrial Revolution rested as much on industry-based science as on the more common concept of science-based industry (König, 1996).

Designing institutions that create the correct ex ante motivations to encourage invention is not an easy task. Economists typically believe that agents respond to economic incentives. A system of relatively secure property rights, such as emerged in Britain in the seventeenth century, clearly was prerequisite. Without it, even if useful knowledge would expand, the investment and entrepreneurship required for a large scale implementation of the new knowledge would not have been forthcoming. On a more specific level, the question of intellectual property rights and rewards for those who add to the stock of useful knowledge is paramount. Some of the best recent work in the economic history of technological change focuses on the working of the patent system as a way of preserving property rights for inventors. In a series of ingenious papers, Kenneth Sokoloff and Zorina Khan have shown how the American patent system exhibited many of the characteristics of a market system: inventors responded to demand conditions, did all they could to secure the gains from

---

[74] James (1990, p. 111) argues that Germany's "staggering supremacy" was not due to scientists looking for applicable results but came about "because her scientists experimented widely without any end in mind and then discovered that they could apply their new information." This seems a little overstated, but all the same we should be cautious in attributing too much intent and directionality in the growth of knowledge. Much of it was in part random or the unintended consequence of a different activity, and it was the selection process that gave it its technological significance. In that respect, the evolutionary nature of the growth in useful knowledge is reaffirmed.

their invention and bought and sold licenses in what appears to be a rational fashion. It was far more accessible, open, and cheaper to use than the British system, and attracted ordinary artisans and farmer as much as it did professional inventors and eccentrics (Khan and Sokoloff, 1993, 1998, 2001; Khan, 2002).

Whether this difference demonstrates that a well-functioning system of intellectual property rights is truly essential to the growth of useful knowledge remains an open question. For one thing, the American system was far more user-friendly than the British patent system prior to its reform in 1852. Yet despite the obvious superiority of the U.S. system and the consequent higher propensity of Americans to patent, there can be little doubt that the period between 1791 and 1850 coincides roughly with the apex of British superiority in invention. The period of growing American technological leadership, after 1900, witnessed a stagnation and then a decline in the American per capita patenting rate. Other means of appropriating the returns on R&D became relatively more attractive. In Britain, MacLeod (1988) has shown that the patent system provided only weak and erratic protection to inventors and that large areas of innovation were not patentable. Patenting was associated with commercialization and the rise of a profit-oriented spirit, but its exact relation to technological progress is still obscure.[75] What is sometimes overlooked is that patents placed technical information in the public realm and thus reduced access costs. Inventors, by observing what had been done, saw what was possible and were inspired to apply the knowledge thus acquired to other areas not covered by the patent. In the United States, *Scientific American* published lists of new patents from 1845, and these lists were widely consulted. Despite the limitations that patents imposed on applications, they reduced access costs to the knowledge

[75] In fact, economists have argued that for countries that are technologically relatively backward, strict patent systems may be on balance detrimental to economic welfare (for a summary, see Lerner, 2000). In a different context, Hilaire-Pérez (2000) has shown how different systems of invention encouragement in eighteenth-century Europe were consistent with inventive activity: whereas in France the state played an active role of awarding "privileges" and pensions to inventors deemed worthy by the French Academy, in Britain the state was more passive and allowed the market to determine the rewards of a successful inventor. These systems were not consistently enforced (some British inventors whose patents for one reason or another failed to pay off were compensated by special dispensation) and, as Hilaire-Pérez shows, influenced one another.

embodied in them. This function of the patent system apparently was fully realized in the 1770s. The full specification of patents was meant to inform the public. In Britain this was laid out in a decision by chief justice Lord Mansfield, who decreed in 1778 that the specifications should be sufficiently precise and detailed so as to fully explain it to a technically educated person. In the Netherlands, where patenting had existed from the 1580s, the practice of specification was abandoned in the mid-1630s but revived in the 1770s (Davids, 2000, p. 267).

In at least two countries, the Netherlands and Switzerland, the complete absence of a patent system in the second half of the nineteenth century does not seem to have affected the rate of technological advance (Schiff, 1971). Of course, being small, such countries could and did free- ride on technological advances made elsewhere, and it would be a fallacy to infer from the Dutch and Swiss experience that patents did not matter. It also seems plausible that reverse causation explains part of what association there was between the propensity to patent and the generation of new techniques: countries in which there were strong and accessible bridges between the *savants* and the *fabricants* would feel relatively more need to protect the offspring of these contacts. Lerner (2000) has shown that rich and democratic economies, on the whole, provided more extensive patent protection. The causal chain could thus run from technological success to income and from there to institutional change rather than from the institutions to technological success, as Khan and Sokoloff believe. It may well be true, as Abraham Lincoln said, that what the patent system did was "to add the fuel of interest to the fire of genius" (cited by Khan and Sokoloff, 2001, p. 12), but that reinforces the idea that we need to be able to say something about how the fire got started in the first place.

Other institutions have been widely recognized as aiding in the generation of new techniques. Among those are relatively easy entry and exit from industries, the availability of venture capital in some form, the reduction of uncertainty by a large source of assured demand for a new product or technique (such as military procurement), the existence of agencies that coordinate and standardize the networked components of new techniques, and revolving doors between industry and organizations that specialize in the generation of propositional knowledge such as universities and research institutes.

Before these institutions and the inventions they stimulated, however, had to be the propositional knowledge on which the inventions

rested. Augmenting this knowledge opened the door that economic incentives and markets pushed societies through. Had the doors remained closed, however, improved incentives for innovation wold have been useless. Commercial, entrepreneurial, and even sophisticated capitalist societies have existed that made few important technical advances, simply because the techniques they employed rested on narrow epistemic base and the propositional knowledge from which these bases were drawn was not expanding. The reasons for this could be many: the agendas of intellectual activity may not have placed a high priority on useful knowledge, or a dominant conservative religious philosophy might have stifled a rebellious attitude toward existing propositional knowledge. Above all, there has to be a belief that such knowledge will eventually be socially useful even if the gains are likely to be reaped mostly by persons others than the ones who generate the novel propositional knowledge. Given that increasing this knowledge was costly and often regarded as socially disruptive, the political will by agents who controlled resources to support this endeavor,whether they were rich aristocratic patrons or middle-class taxpayers, was not invariably there. The amounts of resources expended on R&D, however, are not more important than questions about how they are spent, on what, and what kind of access potential users have to this knowledge.

One specific example of an area in which technological innovation and institutional change interacted in this fashion was in the resistance of vested interests to new technology (Mokyr, 1994, 2002). Here institutions are particularly important, because by definitions such resistance has to operate outside of the market mechanism. If left to markets to decide, it seems likely that superior techniques and products will inexorably drive out existing ones. For the technological status quo to fight back thus meant to use non-market mechanisms. These could be legal, through the manipulation of the existing power structure, or extralegal, through machine-breaking, riots, and the use of personal violence against inventors and the entrepreneurs who tried to adopt their inventions.

At one level, eighteenth-century Enlightenment thinking viewed technological change as "progress" and implicitly felt that social resistance to it was socially undesirable. Yet there was a strand of thought, associated with Rousseau and with later elements of romanticism such as Cobbett and Carlyle continuing with the Frankfurt school in the twentieth century, that viewed industrialization and modern technology sincerely as evil and destructive. Such ideological qualm often found themselves allied with those

whose human and physical capital was jeopardized by new techniques. The ensuing battle came to a crashing crescendo during the Industrial Revolution. The Luddite rebellion — a complex set of events that involved a variety of grievances, not all of which were related to rent-seeking – was mercilessly suppressed. It would be a stretch to associate the harsh actions of the British army in the midlands with anything like the Enlightenment. All the same, it appears that rent-seeking inspired resistance against new technology had been driven into a corner by that time by people who believed that "freedom" included the freedom to innovate.

The British example is quite telling.[76] In the textile industries, by far the most resistance occurred in the woolen industries. Cotton was a relatively small industry on the eve of the Industrial Revolution and had weakly entrenched power groups. There were some riots in Lancashire in 1779 and 1792, and a Manchester firm that pioneered a powerloom was burnt down. Yet cotton was unstoppable and must have seemed that way to contemporaries. Wool, however, was initially far larger and had an ancient tradition of professional organization and regulation. Laborers in the wool trades tried to use the political establishment for the purposes of stopping the new machines. In 1776 workers petitioned the House of Commons to suppress the jennies that threatened the livelihood of the industrious poor, as they put it. After 1789, Parliament passed sets of repressive laws (most famously the Combination Act of 1799), which in Horn's (2002) view were not only intended to save the regime from French-inspired revolutionary turmoil, but also to protect the Industrial Revolution from resistance "from below." Time and again, groups and lobbies turned to Parliament requesting the enforcement of old regulations or the introduction of new legislation that would hinder the machinery. Parliament refused. The old laws regulating the employment practices in the woollen industry were repealed in 1809, and the 250 year old Statute of Artificers was repealed in 1814. Lacking political support in London, the woolworkers tried extralegal means. As Randall has shown, in the West of England the new machines were met in most places by violent crowds, protesting against jennies, flying shuttles, gig mills, and scribbling machines (Randall, 1986; 1989). Moreover, in these areas magistrates were persuaded by fear or propaganda that the machine breakers were in the right. The tradition of violence in the West of England,

[76] Some of the following is based on Mokyr (1994).

writes Randall, deterred all but the most determined innovators. Worker resistance was responsible for the slow growth and depression of the industry rather than the reverse (Randall, 1989). The West of England, as a result, lost its supremacy to Yorkshire. Resistance in Yorkshire was not negligible either, but it was unable to stop mechanization. Violent protests, such as the Luddite riots, were forcefully suppressed by soldiers. As Paul Mantoux put it well many years ago, "Whether [the] resistance was instinctive or considered, peaceful or violent, it obviously had no chance of success" (Mantoux, 1928, p. 408).Had that not been the case, sustained progress in Britainwould have been severely hampered and possibly brought to an end.[77]

In other industries, too, resistance appeared, sometimes from unexpected corners. When Samuel Clegg and Frederick Windsor proposed a central gas distribution plan for London, they were attacked by a coalition that included the eminent scientist Humphry Davy, the novelist Walter Scott, the cartoonist George Cruickshank, insurance companies, and the aging James Watt (Stern, 1937). The steam engine was resisted in urban areas by fear of "smoky nuisances," and resistance to railroads was rampant in the first years of their incipience. Mechanical sawmills, widely used on the Continent, were virtually absent from Britain until the nineteenth century.[78] Even in medical technology, where the social benefits were most widely diffused, the status quo tried to resist. When Edward Jenner applied to the Royal Society to present his findings, he was told "not to risk his reputation by presenting to this learned body anything which appeared so much at variance with established knowledge and withal so incredible" (Keele, 1961,

---

[77] As Randall has shown, in the West of England the new machines were met by violent crowds, protesting against jennies, flying shuttles, gig mills, and scribbling machines (Randall, 1986; 1989). Moreover, in these areas magistrates were persuaded by fear or propaganda that the machine breakers were in the right. The tradition of violence in the West of England, writes Randall, deterred all but the most determined innovators. Worker resistance was responsible for the slow growth and depression of the industry rather than the reverse (Randall, 1989). The West of England, as a result, lost its supremacy in the wool industry to Yorkshire.

[78] The resistance against sawmills is a good example of attempts to use both legal and illegal means. It was widely believed in the eighteenth century that sawmills, like gigmills, were illegal although there is no evidence to demonstrate this. When a wind-powered sawmill was constructed at Limehouse (on the Thames, near London) in 1768, it was damaged by a mob of sawyers "on the pretence that it deprived many workmen of employment" (Cooney, 1991).

p. 94).[79] In medical technology, in general, resistance tended to be particularly fierce because many of the breakthroughs after 1750 were inconsistent with accepted doctrine, and rendered everything that medical professionals had laboriously learned null and void. It also tended, more than most other techniques, to incur the wrath of ethical purists who felt that some techniques in some way contradicted religious principles, not unlike the resistance to cloning and stem-cell research in our own time. Even such a seemingly enormously beneficial and harmless invention as anesthesia was objected on a host of philosophical grounds (Youngson, 1979, pp. 95-105; 190-98).

The two most famous cases of technology-related rioting in Britain are the Luddite riots between 1811 and 1816, and the Captain Swing riots of 1830-32. In both cases the riots were partially caused by technological innovation. To be sure, in Nottingham, where the Luddite troubles started, to be sure, there had been no technological change in the stocking frames and the anger of workmen was directed against low wages, work practices and similar issues. When the riots spread to Yorkshire, however, the finishers ("croppers") in the wool trade were directly motivated by the introduction of gig mills, shearing machines, and other machinery used in the finishing trades. The Yorkshire croppers were well-organized, and their main organization, "the Institution," was small and highly effective in organizing its members (Thomis, 1972 pp. 48-57). Their abortive attack on an advanced and mechanized mill at Rawfolds has become famous in the literature through its depiction in Charlotte Brontë's *Shirley* (Thomis, 1972; Thompson, 1963, pp. 559-65). In Lancashire, on the other hand, machine breaking during the Luddite riots occurred largely because they were a convenient target, not because of any deeply-felt anti-technological feeling. The history of machine breaking and violence against innovators is of course

---

[79] Jenner's famous discovery of the smallpox vaccine ran into the opposition of the inoculators concerned about losing their lucrative trade (Hopkins, 1983, p. 83). The source of the vaccine, infected animals, was a novelty and led to resistance in and of itself: Clergy objected to the technique because of the "iniquity of transferring disease from the beasts of the field to Man" (Cartwright, 1977, p. 86). Cartoonists depicted people acquiring bovine traits, and one woman complained that after he daughter was vaccinated she coughed like a cow and grew hairy (Hopkins, 1983, p. 84). Despite all this, of course, the smallpox vaccine was one of the most successful macroinventions of the period of the Industrial Revolution and its inventor became an international celebrity.

a complex story and not all cases of rioting were necessarily a response to technological change (Bohstedt, 1983, pp. 210-221). Moreover, machine breaking and rioting was just one of the ways in which resistance to technological change could manifest itself.

The Captain Swing riots were aimed, as is well-known, against the steam threshers. They bore in some ways a resemblance to the Luddite riots a decade and a half earlier, in that the resentment against machinery was aggravated by short-run fluctuations in the economy, and that the anger against new machinery was compounded by other grievances. The Swing riots were at least in part aimed against Irish migrant workers (Stevenson, 1979, p. 243). Yet the Captain Swing riots stand out because they were the only antitechnological movement in Britain, legal or extralegal, that was successful in slowing down the adoption of the technology altogether. The steam thresher against which they were aimed vanished from the South of England until the 1850s. As Hobsbawm and Rudé point out, the resistance against the machines was shared by some farmers and gentry. It was the first major successful act of "Luddism" in Britain in the nineteenth century, and it is perhaps symbolic that it occurred in the year typically (and arbitrarily) designed as the last year of the period known as the Industrial Revolution (Hobsbawm and Rudé, 1973, pp. 256-59, 317-23).

With the rise in the factory and the strengthening of the bargaining power of capitalists, authority and discipline might have reduced, at least for a while, the ability of labor to resist technological progress. The factory, however, did not solve the problem of resistance altogether; unions eventually tried to undermine the ability of the capitalist to exploit the most advanced techniques. Collective action by workers imposed an effective limit on the "authority" exercised by capitalists. Workers' associations tried to ban some new techniques altogether or tried to appropriate the entire productivity gains in terms of higher piece wages, thus weakening the incentive to innovate. On the other hand, such strikes often led to technological advances aimed specifically at crippling strikes (Bruland, 1982; Rosenberg, 1976, pp. 118-119).[80]

---

[80] The most famous example of an invention triggered by a strike was that of the self-acting mule, invented in 1825 by Richard Roberts at the prompting of Manchester manufacturers plagued by a strike of mule operators.

Conclusions: Technology, Growth, and the Rise of the Occident

In economic history, more so perhaps than in other disciplines, everything is a matter of degree, and there are no absolutes. The arguments made in this survey represent an interpretation that is by no means generally accepted. Many scholars have argued eloquently and persuasively for continuity rather than the view that something radical and deep changed in western society between 1760 and 1830. Almost every element we associate with the Industrial Revolution can be seen to have precedent and precursor. Some of these are quite valid (episodes of growth and "modernity" can be found in earlier periods, the use of coal and non-animate energy was expanding already in the centuries before the Industrial Revolution; agricultural productivity may have been as high in 1290 as it was in 1700; factory-like settings can be found in earlier periods). Others are based on misapprehensions (the aeolipiles built by Hero of Alexandria were *not* atmospheric steam engines). In the end, the debate on continuity can only be settled if we accept a criterion by which to judge the degree of continuity. If the criterion is economic growth, the continuity faction in the end will have to concede defeat, even if the loss is one in overtime. The Industrial Revolution *itself* was not a period of rapid economic growth, but it is clear beyond question that it set into motion an economic process that by the middle of the nineteenth century created a material world that followed a dynamic not hitherto experienced.

Not only that growth was faster and more geographically dispersed (covering by 1914 most of Europe, North America, other European offshoots, and Japan) than had been experienced by any economy before, it was sustainable. Unlike previous episodes, it kept rolling through the twentieth century. A moment of reflection will underline the enormity of this achievement. The twentieth century was in many ways a very bad century for the Western world: two horrid World Wars, a hugely costly depression, the collapse of international trade after 1914, the disastrous collectivist experiment in Russia extended to all of Eastern Europe in 1945, and the loss of its Colonial Empire — all of these should have pointed to catastrophe, misery, and a return to economic barbarism for the *Abendland*. Something similar may have happened in the fourteenth century, the disasters of which in some views set Europe's economy back for a century or more.

Yet by the 1990s, the gap between rich and poor nations is bigger than ever and Danny Quah's "twin peaks" are getting further and further

apart. Despite the huge setbacks, the engine that drove the Occident express had become so immensely powerful that it easily overwhelmed the twentieth century roadblocks that bad luck and human stupidity placed on its tracks. The Great Divergence train stormed on, undaunted.

Social scientists and historians discussing this issue are often accused of "triumphalism" which is paired with "Eurocentricity" or "Western-centricity." Whether the scholars who make such accusations actually mean to argue that gap in income and living standards is imaginary (or ephemeral), or whether they just feel that it is unjust and unfair, is sometimes hard to tell.[81] Yet if the rest of the world is to eventually enjoy the material comforts available to most people in the west or not, we should not give up on our attempt to understand "how the West did it."

To make some headway, if we want to understand why the West did what it did we should ask questions about the *when*. The consensus is that by 1750, the gap between the twin peaks was much smaller than it was today. If Europe was richer than the rest of the world, it was so by a margin that looks thin compared to what it is today. The so-called "California School" has been arguing indeed that living standards and measurable indicators of economic performance between China and Europe were not all that different by 1750.[82] If this is accepted, and if we are willing to take the Yang-Zhi delta as indicative of economic conditions of the non-European world, the current gap between rich and poor is largely the result of the Industrial Revolution and the events that followed it. Be that as it may, underneath its surface the European soil in 1500 already contained the seeds of the future divergence in 1750. There was, however, nothing inexorable about what happened after: the seeds need not have sprouted, they could have been washed away by the flood of wars, pulled out by rapacious tax collectors, or the young sprouts of future growth might have been burned by intolerant religious authorities. There could have been a Great *Convergence* after 1800 instead of what actually took place, in which Europe would have reverted back to the kind of economic performance prevalent in 1500. In the end, the economic history of technology — like all evolutionary sequences

---

[81] Such confusions mark especially the literature associated with Gunder Frank (1998) and Blaut (1993).

[82] See especially Wong (1997); Pomeranz (2000); Goldstone (2002).

— contains a deep and irreducible element of contingency. Not all that was had to be.

The question of "when" is important because it makes geographical explanations that explain Europe's success by its milder climate or conveniently located coal reserves less powerful, because these differences are time-invariant. Something had changed in Europe before the Industrial Revolution that destabilized the economic dynamic in the West, but not elsewhere. The question of "where" is also important. Britain was not "Europe" and even today there are some European regions that clearly are not part of the Western economic development pattern or very recent arrivals. On the other hand, a number of non-European nations have been able to join the "convergence club."

There are two alternative scenarios of the emergence of the gap. One is that, regardless of living standards and income in 1750, Europe was already deeply different in 1750 in many respects. In their different ways, David Landes (1998), Eric Jones (1981, 1988), Avner Greif (2003),and Angus Maddison (1998) subscribe to this view. By 1750 Europe had already had Calvin and Newton, Spinoza and Galileo, Bacon and Descartes. It had a commercial capitalism thriving especially in Atlantic Ports, a well-functioning monetary system, and the ability of rulers to tax their subjects had been constrained in complex but comparatively effective ways. It had universities, representative parliamentary bodies, embryonic financial institutions, powerful navies and armies, microscopes and printing presses. Its agriculture was gradually switching to more productive rotations, adopting new crops, and experimenting with animal breeding. Its manufacturing system was market-oriented and competitive. It had established the beginning of a public health system that had conquered the plague (still rampant elsewhere) and was making inroads against smallpox. Its ships, aided by sophisticated navigational instruments and maps, had subjugated and colonized already some parts of the non-European world and neither the Mongols nor the Ottoman Turks were a threat anymore. It drank tea, ate sugar, smoked tobacco, wore silk and cotton, and ate from better plates in coal- or peat heated homes. Its income per capita, as well as we can measure it, may have been little different from what it had been in the late middle ages (though Adam Smith disagreed), yet it was already ahead.

The alternative school emphasizes that many of these European features could be found in other societies, especially in China and Japan, and that when Europe and the Orient differed, the difference was not always

necessarily conducive to economic growth. Ch'ing China may not have been an open economy, but it had law and order, internal, a meritocratic bureaucracy peace and a great deal of medium- and long-distance trade within its borders. We need to be wary from the logical fallacy that all initial differences between Europe and China contributed to the outcome. Some of the initial difference may have actually worked the other way, so that the Great Divergence took place despite them. Others were ambiguous in their effect.[83] In order to understand what triggered Europe's economic miracle, we need to identify one more event that happened before the Industrial Revolution, happened in the right areas, and which can be connected logically to subsequent growth.

I have referred to this event as "the Industrial Enlightenment" and have attempted to show how it affected the two central elements of the Industrial Revolution, technology and institutions, and how these two elements then affected one another. The concept of Enlightenment I employ is somewhat different than what is customary. Not everything that is normally included in the historians' idea of the Enlightenment mattered, and not everything that mattered could be attributed to the Industrial Enlightenment. The emphasis on the Enlightenment illustrates how economists should think about culture and cultural beliefs as discussed in great length by Greif (2003). Culture mattered to economic development — how could it not? But we have to show the exact ways in which it mattered and through which channels it operated. I have argued that cultural beliefs changed in the eighteenth century, but beyond Greif's notion of cultural beliefs, I would include the metaphysical beliefs that people held about their environment and nature, and their attitudes toward the relationship between production and useful knowledge. It should also include their cultural beliefs about the possibility and desirability of progress and their notions of economic freedom, property, and novelty.

In that sense, at least, the Enlightenment may have been the missing link that economic historians have hitherto missed. Greif (XIII-17) points out that many of the institutional elements of modern Europe were already in

---

[83] An example is the European States System, often hailed as the element of competition which constrained and disciplined European governments into a more rational behavior, lest they weaken their military power. Yet the costs of wars may well have exceeded the gains, and the mercantilist policies that the States System triggered in the seventeenth century had doubtful effects on economic performance.

place in the late Middle Ages: individualism, man-made formal law, corporatism, self governance, and rules that were determined through an institutionalized process in which those are subject to them can be heard and have an input. Yet these elements did not trigger modern growth at that time, and it bears reflecting why not. The technological constraints were too confining, and the negative feedbacks too strong. The Baconian belief that nature is logical and understandable, that the understanding of nature leads to its control, and that control of nature is the surest route to increased wealth, was the background of a movement that, although it affected but a minute percentage of Europe's population, played a pivotal role in the emergence of modern growth. If culture can be said to matter, it did so because the prevailing ideology of knowledge among those who mattered started to change in a way it did not elsewhere. The eighteenth century Enlightenment, moreover, brought back many of the institutional elements of an orderly and civil society, together with the growing realization, most eloquently expressed by Adam Smith, that economic activity was not a zero-sum game and that redistributive institutions and rent-seeking are costly to society.

All the same, ideological changes and cultural developments are not the entire story. A desire for improvement and even the "right" kind of institutions by themselves do not produce *sustained* growth unless society produces new useful knowledge and unless the growth of knowledge can be sustained over time. Useful knowledge grows because in each society there are people who are creative and original, and motivated by some combination of greed, ambition, curiosity, and altruism. All four of those motives can be seen to be operating among the people who helped make the Industrial Revolution, often in the same people. Yet in order to be translated from personal predilections to facts on the ground and from there to economic growth, an environment that produced the correct incentives and the proper access to knowledge had to be there. The uniqueness of the European Enlightenment was that it created that kind of environment.

I have argued here that the experience of the past two centuries support the view that the production and utilization of knowledge are consistent with an interpretation that useful knowledge went through a phase transition in which it entered a critical region in which equilibrium concepts may no longer apply. This means that as far as future technological progress and economic growth are concerned, not even the sky is the limit. Science Fiction writers have known this all along.

General Purpose Technologies

Boyan Jovanovic and Peter L. Rousseau*

January 2003

Abstract

Electricity and IT are perhaps the two most important GPTs to date. We analyze how the U.S. economy reacted to them. The Electricity and IT eras are similar, but they also different in important ways. Electrification was more broadly adopted, whereas IT seems to be technologically more revolutionary. The productivity slowdown is stronger in the IT era but the ongoing spread of IT and its continuing precipitous price decline are reasons for optimism about growth in the coming decades.

1 Introduction

The term "general-purpose technology," or GPT, has seen extensive use in recent treatments of the role of technology in economic growth, and is usually reserved for changes that transform both household life and the ways in which firms conduct business. Steam, electricity, and information technology (IT) are often classified as GPTs for this reason. They affected the whole economy.

As David (1991) pointed out some years ago, a GPT does not deliver productivity gains immediately upon arrival. Figure 1 shows the evolution of the growth in output per man hour in the U.S. economy over the past 130 years, with periods of rapid diffusion of the two major GPTs shaded and the dashed line representing long-term trends as generated with the Hodrick-Prescott (H-P) filter.[1] Productivity growth was apparently quite rapid during the heyday of steam power (circa. 1870), but fell as electrification arrived in the 1890s, with the defining moment probably being the

*NYU and the University of Chicago, and Vanderbilt University. We thank the National Science Foundation for support, and J. Cummins, B. Hobijn, J. Lerner and G. Violante for providing us with data. This is a proposed chapter in the forthcoming Handbook of Economic Growth.

[1] Output per man-hour in the business, non-farm sector is from John Kendrick [U.S. Bureau of the Census (1975, Series D684, p. 162)] for 1889-1947, and from the Bureau of Labor Statistics (2002) for 1948-2001. For 1874-1889, we use Kendrick's decadal averages for 1869-79 and 1879-89, and assume a constant growth rate from 1874-84 and 1885-89.

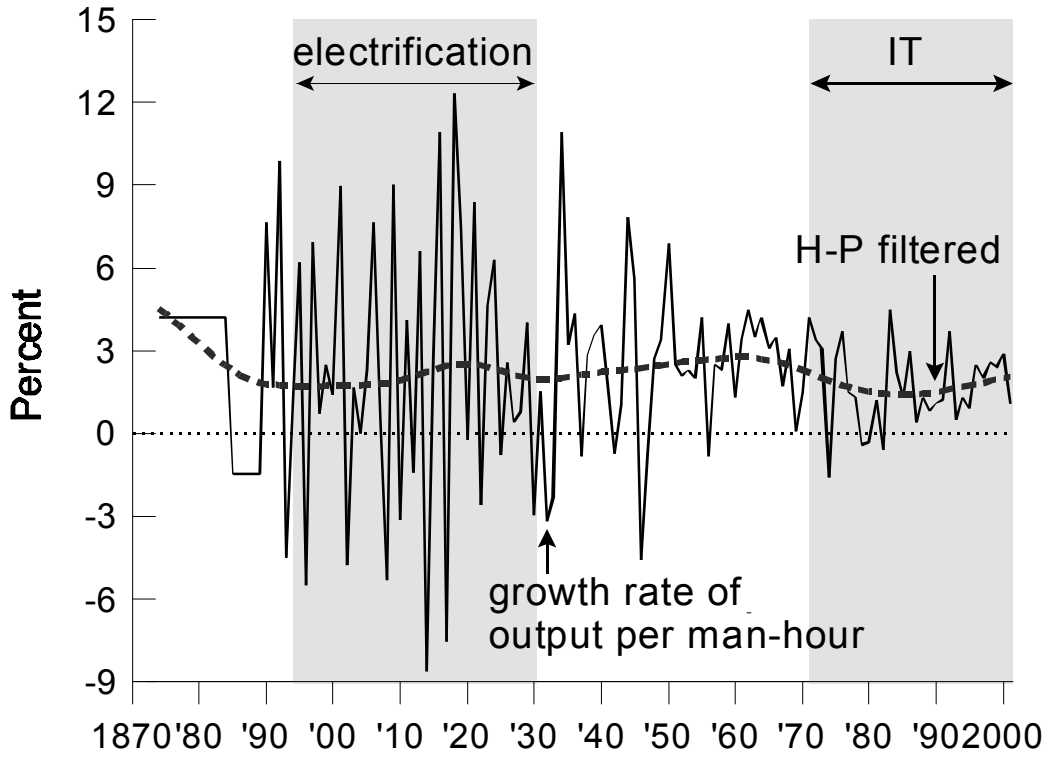

Figure 1: Annual growth in output per man-hour.

startup of the first hydro-electric facility at Niagara Falls in 1894. It was only in the period after 1915, which saw the diffusion of secondary motors and the widespread establishment of centralized power grids, that electricity finally pervaded businesses and households more generally and the productivity numbers began to rise. Figure 1 also shows that the arrival of IT, which we date with Intel's invention in 1971 of the "4004 computer chip" (the key component of the personal computer), did not reverse the decline in productivity growth that had begun more than a decade earlier. To some extent it seems that we are still waiting for computers to show up in the productivity figures.

But it is not obvious that the startup of the Niagara Falls dam in 1894 and Intel's invention of the 4004 chip in 1971 should define the birth of the two GPTs. Indeed, the reader may wonder how we choose the dating for the two GPT eras. In fact, the dates do coincide with periods of adoption: Net adoption of the two GPTs picks up about where the shading begins and, in the case of electrification, adoption reaches a plateau in 1929, whereas new adoption of IT is still rising today so that, on that criterion, the IT era still continues.

1.1 What is a GPT?

Each shaded area in Figure 1 contains a growth slowdown. Will the growth slowdown of the current IT era be followed by a rise in growth in the first half of the 21st century? If the second shaded area in Figure 1 is in some "fundamental" respects like the first shaded area, then we can expect growth to pick up over the next several decades. In Jovanovic and Rousseau (2002a) we have argued that the first half of the 21st century will have higher growth than, say, the 1950s and 1960s. Gordon (2000), on the other hand, is pessimistic, arguing that IT does not measure up to electricity and that it will not have such positive results. This chapter will conclude that the two eras are indeed similar.

So, what are these "fundamental" features of the two GPTs that we may attempt to compare? More generally, what criteria can one use to distinguish a GPT from other technologies? Bresnahan and Trajtenberg (1995) argue that a GPT should have the following three characteristics:

1. *Pervasiveness*: The GPT should spread to most sectors.

2. *Improvement*: The GPT should get better over time and, hence, should keep lowering the costs of its users.

3. *Innovation spawning*: The GPT should make it easier to invent and produce new products or processes.

Most technologies possess each of these characteristics to some degree, and therefore a GPT cannot differ qualitatively from these other technologies. Moreover, this is a short list which we shall later broaden. Nevertheless, we shall begin with measures of these three characteristics in the next section. But first, we summarize our findings:

1.2 Summary of findings

The evidence shows similarities and differences between the electrification and the IT eras. Electrification was more pervasive (#1), whereas IT has a clear lead in terms of improvement (#2) and innovation spawning (#3). Let us list the similarities and differences in more detail.

1.2.1 Similarities between the electrification and IT eras

1. In both of the GPT eras growth is below rates attained in the decades immediately preceding.

2. Measures of reallocation and invention – startups, exits, patents, trademarks, and investment by new firms relative to incumbents – are all higher during the GPT eras.

3. Private consumption rose gradually during each GPT era.

4. Real interest rates are about the same during the two GPT eras, and about three percentage points higher than in the middle 40 years of the 20th century.

1.2.2 Differences between the electrification and IT eras

1. Innovation measures are growing much faster for IT than for Electrification – patents and trademarks surge much more strongly during the IT era, and the price of IT is falling 100 times faster, at least, than did the price of electricity.

2. IT is spreading more slowly than did electrification, and its net adoption still continues to rise in the United States.

3. The productivity slowdown is stronger in the IT era.

4. No comparable sudden collapse of the stock markey occured early on in the Electrification era.

5. The Electrification era saw a surplus in the U.S. trade balance, in part surely because Europe had to finance a string of wars, whereas the IT era finds the United States in a trade deficit

The differences seem to outnumber the similarities. Yet the overall evidence clearly supports the view that technological progress is uneven, that it does entail the episodic arrival of GPTs, that these GPTs bring on turbulence and lower growth early on and higher growth and prosperity later.

2 Measuring the three characteristics of a GPT

As suggested in Figure 1, we shall choose electricity and IT as our candidate GPTs, and the measures that we provide will pertain mostly to these two technologies. In passing, we shall also touch upon steam and internal combustion. The three subsections below report, in turn, various measures of each characteristic – pervasiveness, improvement, and innovation – for the two GPTs at hand.

2.1 Pervasiveness of the GPT

The first characteristic is the technology's pervasiveness. We begin with the aggregates and then look in more detail at industrial sectors.

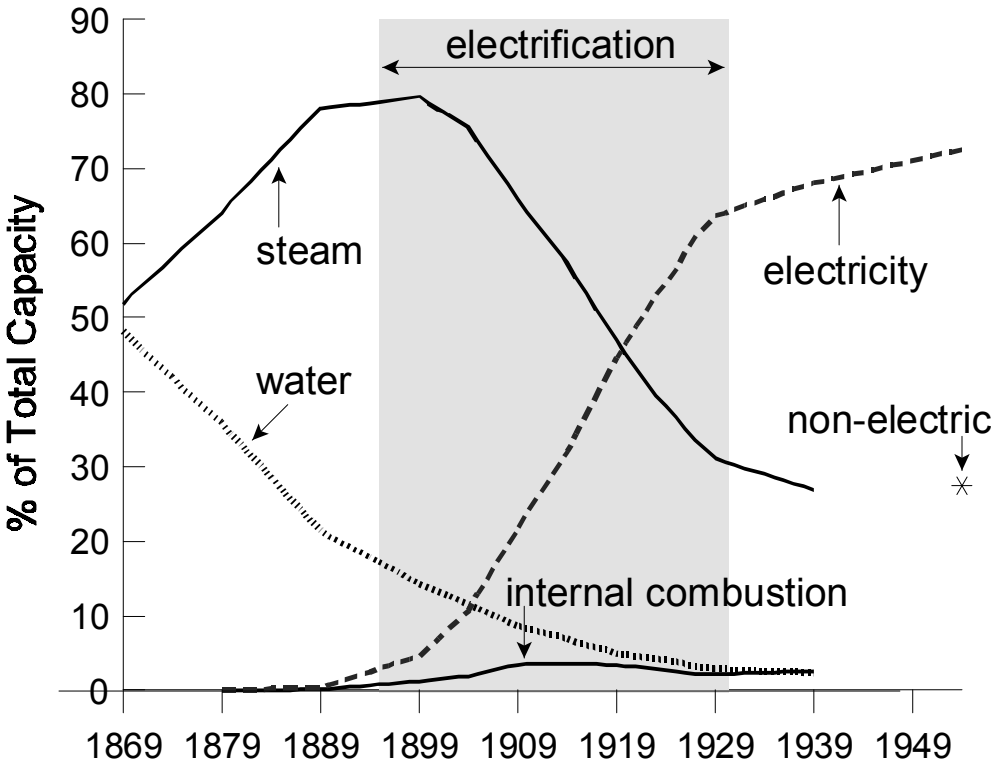

Figure 2: Shares of total horsepower generated by the main sources in U.S. manufacturing, 1869-1954.

2.1.1 Pervasiveness in the aggregate

We would like to track the evolution of GPTs using continuous time series from about 1850 to the present, but we do not have data that consistently cover the entire stretch of time, and thus will need to break this period into two overlapping segments: 1869-1954 and 1947-2001.

Figure 2 shows the shares of total horsepower in manufacturing by power source from 1869 to 1954.[2] The period covers the fall of water wheels and turbines, the rise and fall of steam engines and turbines, the rise and gradual flattening out of the internal combustion engine, and the sharp rise in the use of primary and secondary electric motors. The symmetry of the plot is striking in that, with the exception

[2]We construct the shares of total horsepower capacity in manufacturing as ratios of each power source (DuBoff ,1964, table 14, p. 59) to the total (table 13, p. 58). DuBoff estimates these quantities in 1869, 1879, 1889, 1899, 1904, 1909, 1914, 1919, 1923, 1925, 1927, 1929, 1939, and 1954, and we linearly interpolate between these years. This source does not include a breakdown of non-electrical capacity (i.e., water, internal combustion, and steam) after 1939, and so we mark the broader-defined "non-electrical" share for 1954 with an asterisk.

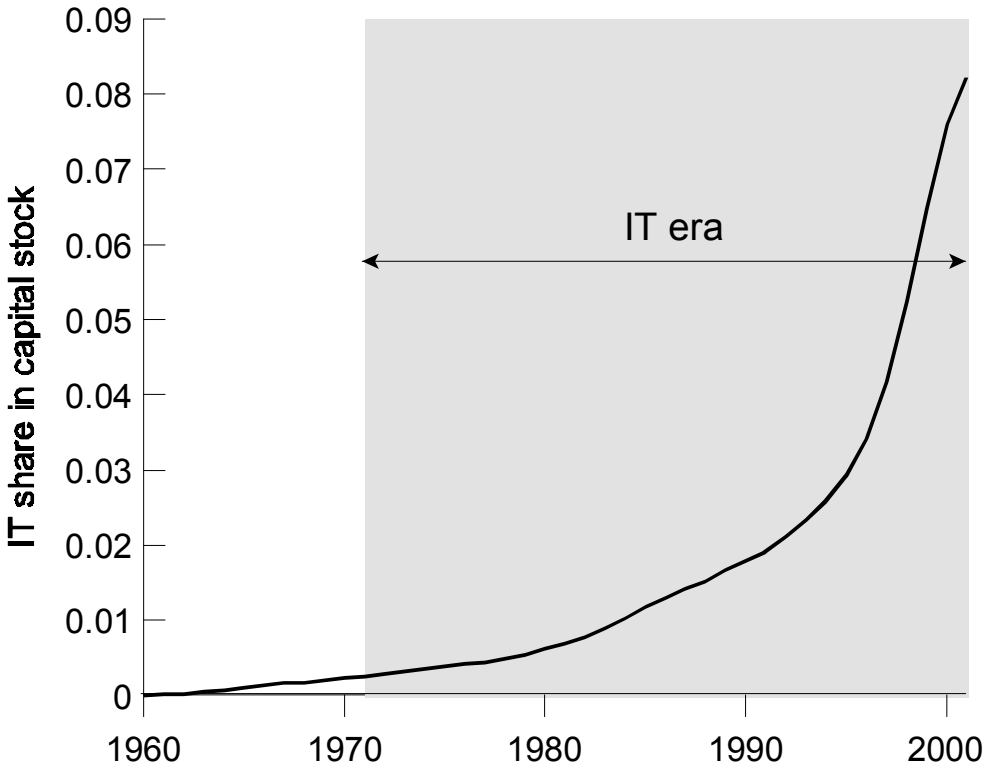

Figure 3: Shares of computer equipment and software in the aggregate capital stock, 1960-2001.

of internal combustion, power-generating technologies seem to have led for the most part sequential existences. The relative brevity of the entire steam cycle, which rises and falls within a period of 50-60 years, suggests that the technology that replaced it, Electricity, was important enough to force change quickly among manufacturers. In contrast, the decline of water power was more gradual. Moreover, if we could continue the graph to the present, electricity would surely still command a very high share of manufacturing power as a new source (e.g., solar power?) has not yet emerged to replace it. The persistence of electricity as the primary power source, even though its diffusion throughout the manufacturing sector was complete decades ago, helps to identify it as one of the breakthrough technologies of the modern era.

Figure 3 shows the diffusion of computers in the U.S. industrial sector as measured by the real share of IT equipment and software in the real aggregate capital stock.[3]

[3] We build the ratio plotted in Figure 3 by summing the capital stocks of 62 industrial sectors from the detailed non-residential fixed asset tables in fixed 1996 dollars made available by the Bureau of Economic Analysis (2002). IT capital includes mainframe and personal computers, storage devices, printers, terminals, integrated systems, and pre-packaged, custom, and own-account software. The total capital stock is the sum of all fixed asset types.

Computer and software purchases appear to have reached the first inflection point in their "S-curve" more slowly than Electrification in the early years of its GPT-era, but it is striking how much faster the IT share has risen over the past few years. Moreover, while the diffusion of electricity had slowed down by 1930, the year which we mark as the end of the Electrification "era," yet computer and software sales continue their rapid rise to this day.

The scaling of the vertical axes in Figure 2 and Figures 3 is different. The vertical axis in Figure 2 measures the shares of total horsepower in manufacturing, whereas the vertical axis in Figures 3 is the real share of IT equipment and software in the real aggregate capital stock. But scaling aside, the diffusion process appears to be much more protracted for IT than for Electrification insofar as a comparison of the shape of the diffusions in the two figures suggests that the IT era will last longer than the 35 years of Electrification. The acceleration in adoption, which was over by about 1905 for Electrification, did not end until about 1997 for IT.

Why did electricity spread faster than IT seems to be doing? We do not know if this is because it was more profitable, or because the rapid price decline of computers and peripherals makes it optimal to wait and adopt later, or still for some other reson.

2.1.2 Pervasiveness among sectors

Cummins and Violante (2002, p. 245) classify a technology as a GPT when the share of new capital associated with it reaches a critical level, and that adoption is widespread across industries. Electrification seems to fit this description. Figure 4 shows the shares of total horsepower electrified in manufacturing sectors at ten-year intervals from 1889 to 1954.[4] Electrical adoption was very rapid between 1899 and 1919 but slowed considerably thereafter, with the dispersion in the adoption rates largest around 1919.

The main message in Figure 4 is that electrical technology affected individual manufacturing sectors with a striking degree of uniformity. Moreover, Table 1, which shows the rank correlations of electricity shares across sectors and time, indicates that there was little change in the relative ordering of the manufacturing sectors either. This means that the sectors that were the heaviest users of electricity in 1890 remained among the leaders as adoption slowed down in the 1930s. Indeed, the adoption of electricity was sweeping and widespread.

It was not practical to set up the wiring required to electrify households early on. This is apparent from the peculiar two-stage adoption process that many factories chose in adopting electricity: Located to a large extent in New England factory towns, textile firms around the turn of the century readily adapted the new technology by using an electric motor rather than steam to drive the shafts which powered looms,

[4]The shares of electrified horsepower include primary and secondary electric motors, and are computed using data from DuBoff (1964, tables E-11 and E-12a through E-12e, pp. 228-235).

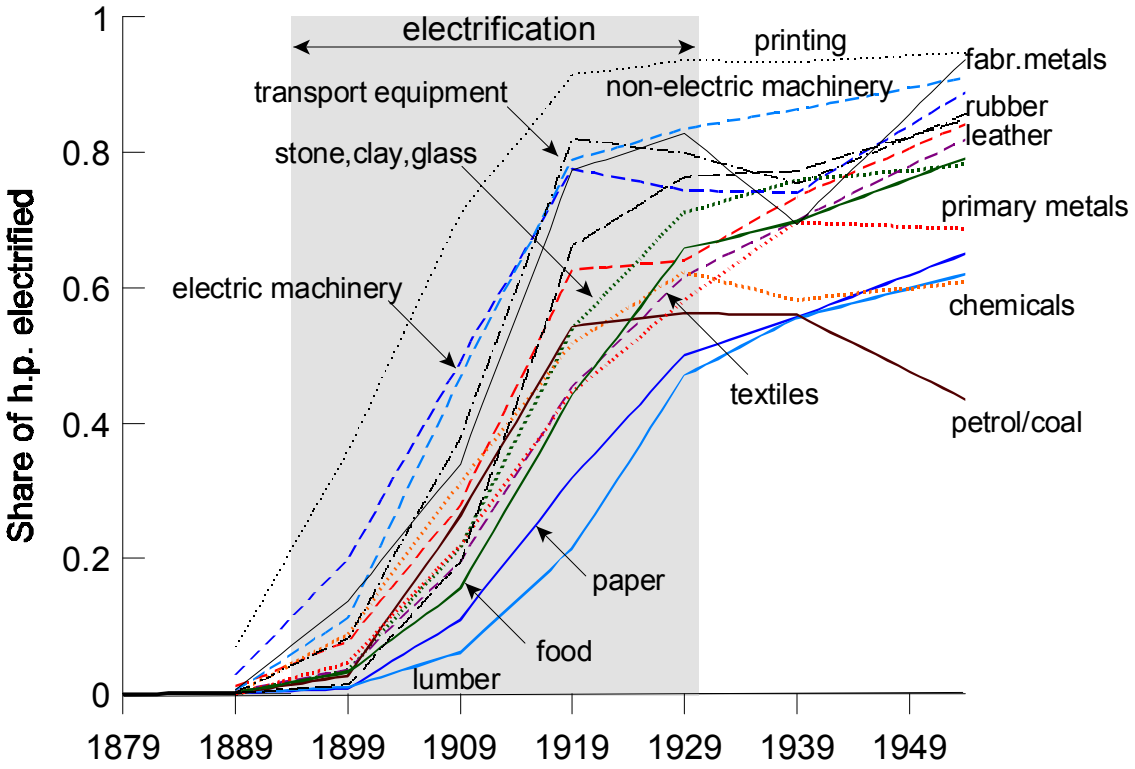

Figure 4: Shares of electrified horsepower by manufacturing sector, 1890-1954.

spinning machines and other equipment [see Devine (1983)]. Further delays in the distribution of electricity made it more costly to electrify a new industrial plant fully.

Table 1
Rank correlations of electricity shares in total horsepower
by manufacturing sector, 1889-1954

	1889	1899	1909	1919	1929	1939	1954
1889	1.000						
1899	0.707	1.000					
1909	0.643	0.918	1.000				
1919	0.686	0.746	0.893	1.000			
1929	0.639	0.718	0.739	0.871	1.000		
1939	0.486	0.507	0.571	0.750	0.807	1.000	
1954	0.804	0.696	0.650	0.789	0.893	0.729	1.000

Figure 5 shows the same data as Figure 4, but now in percentile form. We build them by sorting the electricity shares in each year and, given that only 15 sectors

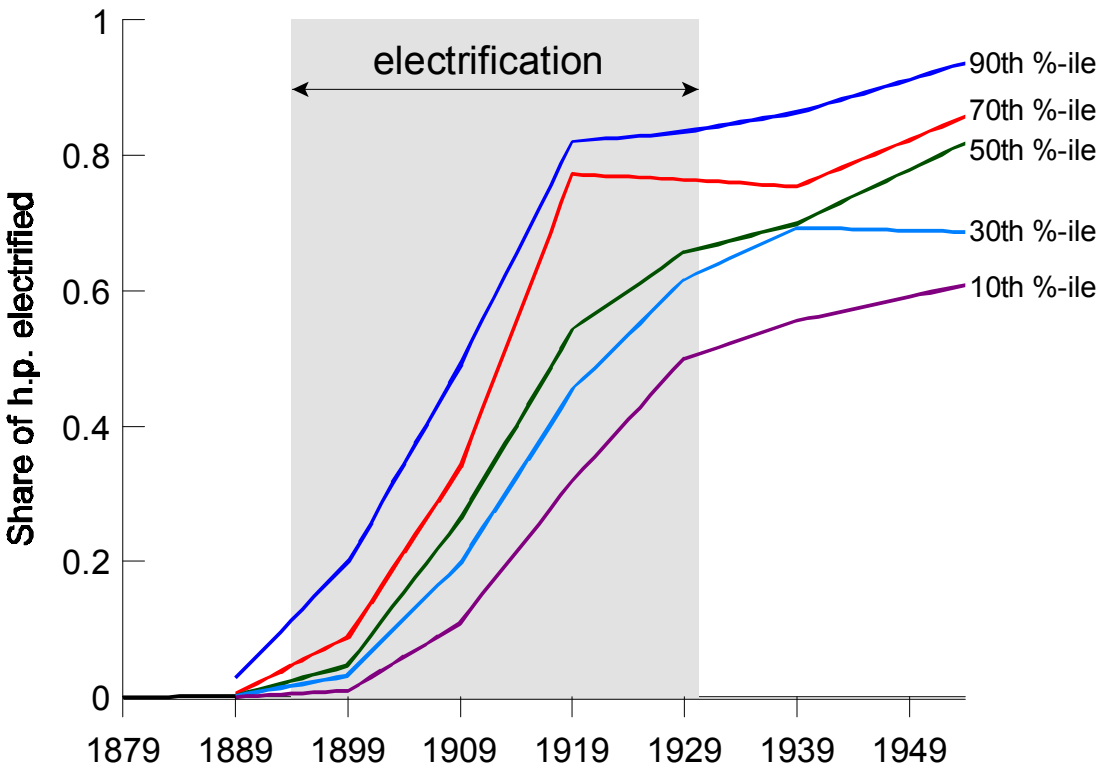

Figure 5: Shares of electrified horsepower by manufacturing sector in percentiles, 1890-1954.

are represented, plotting the 2nd, 5th, 8th, 11th and 14th largest shares in each year. The percentile diffusion curves will be useful when drawing comparisons with the IT era. They also help us in dating electricity as a GPT. Linear extrapolation between the years 1890 and 1900 suggests that in 1894, about one percent of horsepower equivalents in the median industry was provided by electricity. Whether or not this is the right percentage for dating the start of the Electrification era, we shall use the same percentage for the median industry to date the beginning of the IT era, thereby using a common standard for choosing the left-end points of the two shaded areas.

In the century before the Electricity revolution, the technology that primarily drove manufacturing was steam. Figure 6 shows just how slowly steam was replaced between 1899 and 1939.[5] It is natural that industries such as rubber, primary metals, non-electric machinery, and stone, clay, and glass, which saw such rapid increases in electricity use over the same period, would withdraw from steam most rapidly.

[5]The sectoral shares of manufacturing horsepower driven by steam were computed from DuBoff (1964, tables E-12a through E-12e, pp. 229-233), and include steam engines and turbines. These shares are available on a decade basis from 1899 until 1939 only, which is why the time coverage in Figure 6 is shorter than that in Figure 4.

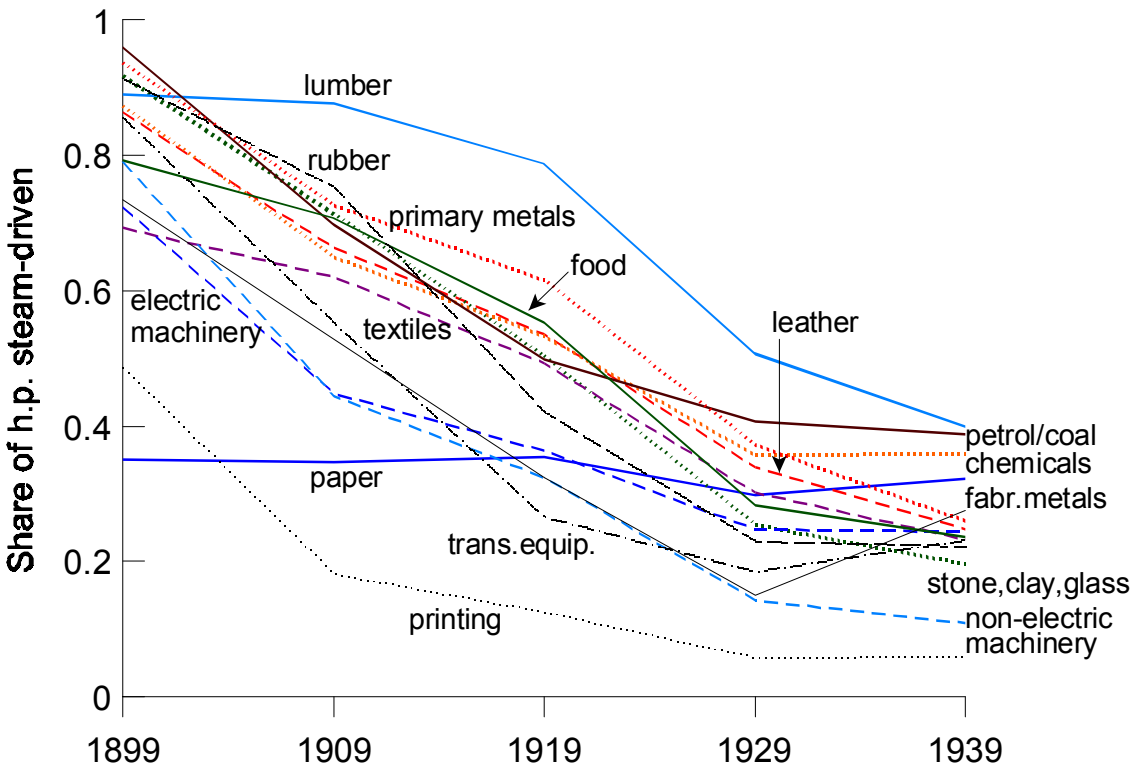

Figure 6: Shares of steam-driven horsepower by manufacturing sector, 1899-1939.

Indeed, most of the industries that quickly switched over to electricity had been heavy users of steam. This is clear from Figure 4 and Figure 6, taken together, and from the rank correlations presented in Table 2 which decay quickly and suggest a non-uniformity in the destruction of steam technology across sectors.

Table 2
Rank correlations of steam shares in total horsepower
by manufacturing sector, 1889-1954

	1899	1909	1919	1929	1939
1899	1.000				
1909	0.825	1.000			
1919	0.604	0.800	1.000		
1929	0.525	0.604	0.832	1.000	
1939	0.261	0.282	0.496	0.775	1.000

The spread of information technology was also rapid, but does not appear to have been as widespread as electricity. Figure 7 shows the share of real IT equipment and software in the real net capital stocks of 62 sectors from 1960 to 2001 plotted as

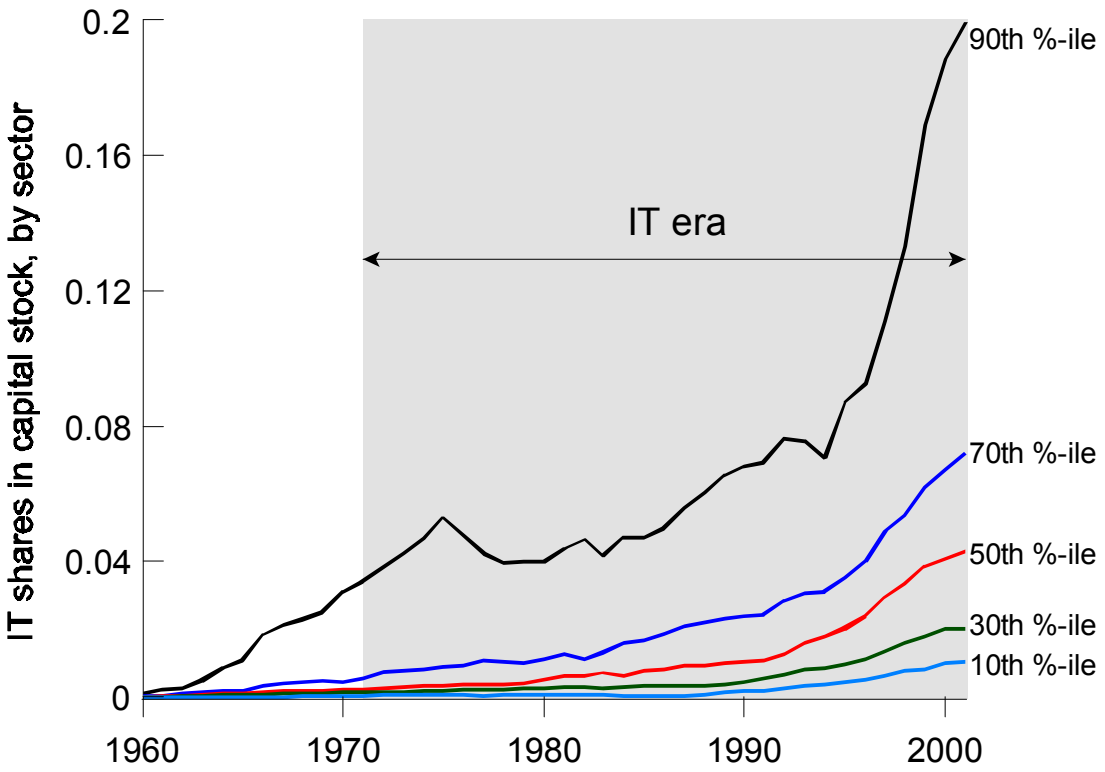

Figure 7: Shares of IT equipment and software in the capital stock by sector in percentiles, 1960-2001.

annual percentiles.[6] In the case of IT, some sectors adopted very rapidly, and by 1975 six of them (the 90th percentile) had already achieved IT equipment and software shares of more than 5 percent. Other sectors lagged behind, and some did not adopt IT in a substantive way until after 1985.

On the other hand, the rank correlations of the IT shares across sectors, shown in Table 3, are even higher than those obtained for Electrification. On the face of it then, Electrification would appear to have been the more sweeping GPT-type event because it diffused more rapidly in the U.S. economy and all sectors adopted it pretty much at the same time, whereas IT diffused rapidly in some sectors and not-so-rapidly in others. Nonetheless, the recent gains in IT shares show that the diffusion of this GPT has yet to slow down in the way that Electrification did after 1929.

[6]The sectoral capital stocks are from the detailed non-residential fixed asset tables in fixed 1996 dollars made available by the Bureau of Economic Analysis (2002). We present the sectoral shares for the IT epoch in percentile form because the number of sectors covered is much larger than was possible for electrification and steam.

Table 3
Rank correlations of IT shares in capital stocks
by sector, 1961-2001

	1961	1971	1981	1991	2001
1961	1.000				
1971	0.650	1.000			
1981	0.531	0.806	1.000		
1991	0.576	0.746	0.847	1.000	
2001	0.559	0.682	0.734	0.909	1.000

So far we have discussed adoption by firms, and it determines the dating of the two GPT epochs. We turn to households next.

2.1.3 Adoption by households

Households also underwent electrification and the purchase of personal computers for home use during the respective GPT-eras. Figure 8 shows the cumulative percentage of households that obtained electric service and that owned a personal computer in each year following the "arrival" of the GPT.[7] If we continue to date Electricity as arriving in 1894 and the personal computer in 1971, Figure 8 shows that households adopted electricity about as rapidly as they are adopting the personal computer. By the time the technology is officially 35 years old (in 1929), nearly seventy percent of households had electricity. A comparison with Figure 5 shows that this is just a little higher than the 1929 penetration of electrified horsepower share by the median manufacturing sector. As in the case of firms, the Electrification of households reaches a plateau in 1929, although it resumed its rise a few years later. On the other hand, there is no sign yet that the diffusion of the computer among either households or firms is slowing down.

With households, as with firms, diffusion lags seem to arise for different reasons for the two technologies. Rural areas were difficult to reach for Electricity, but not so for the PC, for which the main barrier is probably the cost of learning how to use it. This barrier seems to have more to do with human capital than was the case with Electricity.

In some ways it is puzzling that the diffusion of the PC has not been much faster than that of Electrification. The price of computing is falling much faster than the price of Electricity did. Affordable PCs came out in the 1980s, when the technology was some 15 years old. On the other hand, households had to wait longer for affordable electrical appliances. Only after 1915, when secondary motors begin to spread widely,

[7]Data on the spread of electricity use by consumers are approximations derived from U.S. Bureau of the Census (1975) *Historical Statistics of the United States* (series S108 and S120). Statistics on computer ownership for 1975 through 1998 are from Gates (1999, p. 118), and from the Census Bureau's *Current Population Survey* thereafter.

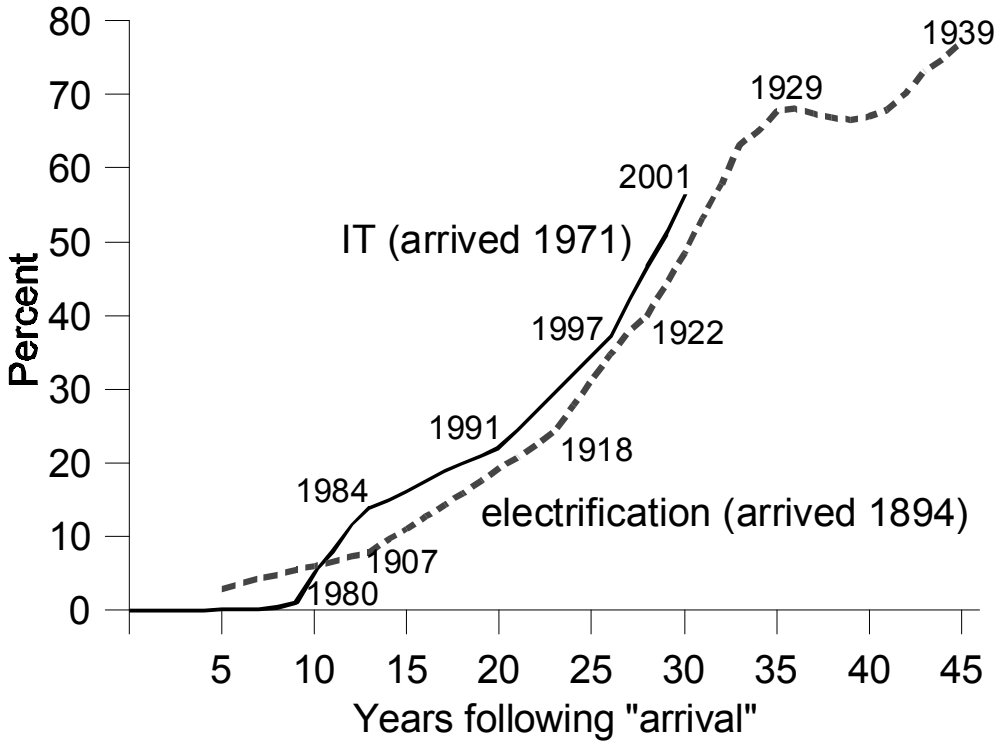

Figure 8: Percent of households with electric service and personal computers during the two technological epochs.

and electrical appliances began to be invented, did the benefits of Electrification outweigh the costs for a majority of households. Greenwood, Shesadri and Yorukoglu (2001) document the spread of electrically powered household appliances and argue that their diffusion helped raise female labor-force participation by freeing up their time from housework.

2.1.4 On dating the endpoints of the era of a GPT

Our dating procedure reflects net adoption rates by firms, but the dates would not change much if we had instead used net adoption by households. The shaded areas are periods when the S-shaped adoption curves are, for the most part, rising. Whether or not they start to fall later should not affect the designated adoption eras. For instance, electricity has not yet been replaced in the same way that steam was phased out in the first half of the twentieth century, but the "Electrification era" still ends in 1930 because adoption as measured in Figures 2, 4, and 5 flattens out. Figures 2 and 6 show that the steam era must have ended sometime around 1899 because net adoption is already negative.

Net adoption is endogenous and it should reflect the profitability of the technology at hand compared to that of other technologies. The Niagara Falls dam in 1894 and the development of alternating current made it possible to produce and distribute electricity more cheaply at greater distances. Figures 4 and 5 show that at the outset, some sectors (like printing) raced ahead of others in terms of how quickly they adopted. Later on, as the technology matures, its adoption becomes more universal. Eventually, the lagging sectors tend to catch up a bit, in relative terms, but not completely. Inequality of adoption is highest in the middle of the adoption era. We also see such a temporary rise in inequality in Figure 6 about the same time.

2.2 Improvement of the GPT

The second characteristic that Bresnahan and Trajtenberg suggested is an improvement in the efficiency of the GPT as it ages. Presumably this would show up in a decline in prices, an increase in quality, or both. How much a GPT improves can be therefore measured by how much cheaper a unit of quality gets over time. If technology is embodied in capital, then presumably, capital as a whole should be getting cheaper faster during a GPT era, but especially capital that is tied to the new technology.

To answer these questions, we first look at the prices of capital as a whole and then at the prices of its components. Figure 9 is a quality-adjusted series for the relative price of equipment as a whole, p_k/p_c (i.e., relative to the consumption price index), since 1885, constructed from a number of sources, with a linear time trend included.[8] The figure shows that equipment prices declined most sharply between 1905 and 1920, and again after 1975. The 1905-1920 period is also the one that showed the most rapid growth of electricity in manufacturing (see Figure 4) and in the home (see Figure 8). The post-1975 period follows the introduction of the PC.

Figure 10 aims to look at the components of the aggregate capital stock; specifically, the components tied to the two GPTs. Because deflators for electrically powered capital are not available in the first half of the twentieth century, Figure 10 compares the declines in relative prices associated with three GPT's – electricity, internal com-

[8] Krusell et al. (2000) build such a series from 1963 using the consumer price index to deflate the quality-adjusted estimates of producer equipment prices from Gordon (1990, table 12.4, col. 2, p. 541). Since Gordon's series ends in 1983, they use VAR forecasts to extend it through 1992. We start with Krusell et al. and work backward, deflating Gordon's remaining estimates (1947-62) with an index for non-durable consumption goods prices that we derive from the National Income Accounts. Since we are not aware of a quality-adjusted series for equipment prices prior to 1947, we use the average price of electricity as a proxy for 1902-46, and an average of Brady's (1966) deflators for the main classes of equipment for 1885-1902. We deflate the pre-1947 composite using the Bureau of Labor Statistics (BLS) consumer prices index of all items [U.S. Bureau of the Census (1975, series E135)] for 1913-46 and the Burgess cost of living index [U.S. Bureau of the Census (1975, series E184)], which has greater precision than the BLS series, for 1885-1912.

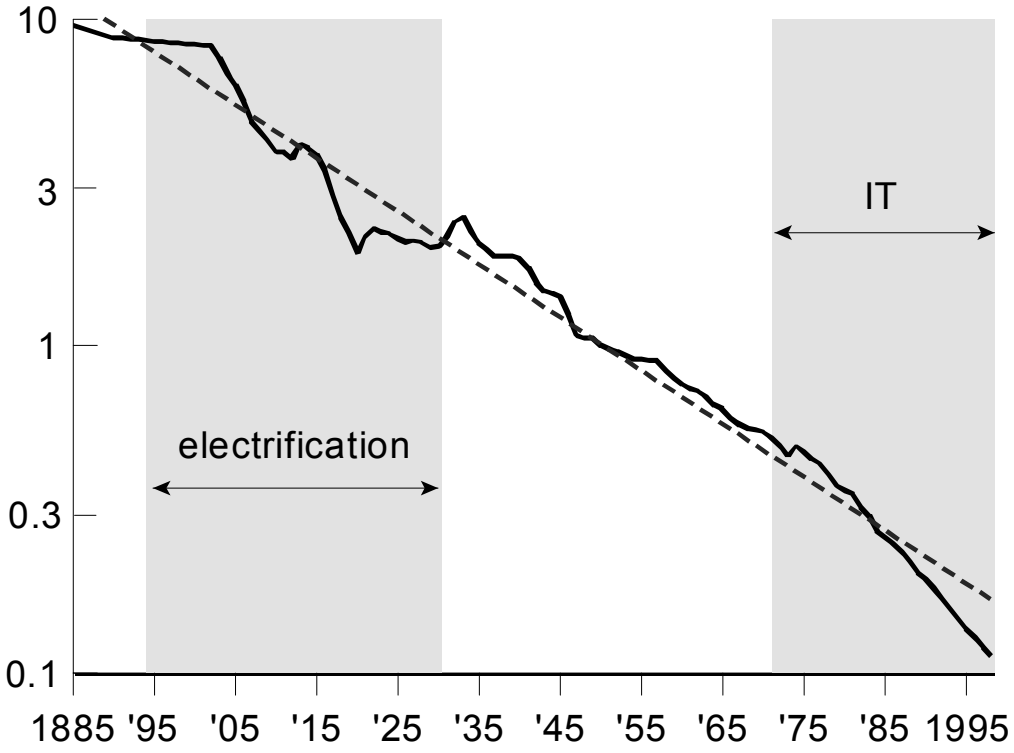

Figure 9: The relative price of equipment.

bustion, and computers – once again relative to the consumption price index.[9] The

[9]To construct a quality-adjusted price index, we join the "final" price index for computer systems from Gordon (1990, table 6.10, col. 5, p. 226) for 1960-78 with the pooled index developed for desktop and mobile personal computers by Berndt, Dulberger, and Rappaport (2000, table 2, col. 1, p. 22) for 1979-99. Since Gordon's index includes mainframe computers, minicomputers, and PCs while the Berndt et al. index includes only PCs, the two segments used to build our price measure are themselves not directly comparable, but a joining of them should still reflect quality-adjusted prices trends in the computer industry reasonably well. We set the index to 1000 in the first year of the sample (i.e., 1960).

Electricity prices are averages of all electric energy services in cents per kilowatt hour from the *Historical Statistics of the United States* (U.S. Bureau of the Census, 1975, series S119, p. 827) for 1903, 1907, 1917, 1922, and 1926-70, and from the *Statistical Abstract of the United States* for 1971-89. We interpolate under a constant growth assumption between the missing years in the early part of the sample. For 1990-2000, prices are U.S. city averages (June figures) from the Bureau of Labor Statistics (*http:www.bls.gov*). We then set the index to equal 1000 in the first year of the sample (i.e., 1903).

Motor vehicle prices for 1913-40 are annual averages of monthly wholesale prices of passenger vehicles from the National Bureau of Economic Research (Macrohistory Database, series m04180a for 1913-27, series m04180b for 1928-40, *http://www.nber.org*). From 1941-47, they are wholesale prices of motor vehicles and equipment from *Historical Statistics* (series E38, p. 199), and from 1948-2000 they are producer prices of motor vehicles from the Bureau of Labor Statistics (*http://www.bls.gov*).

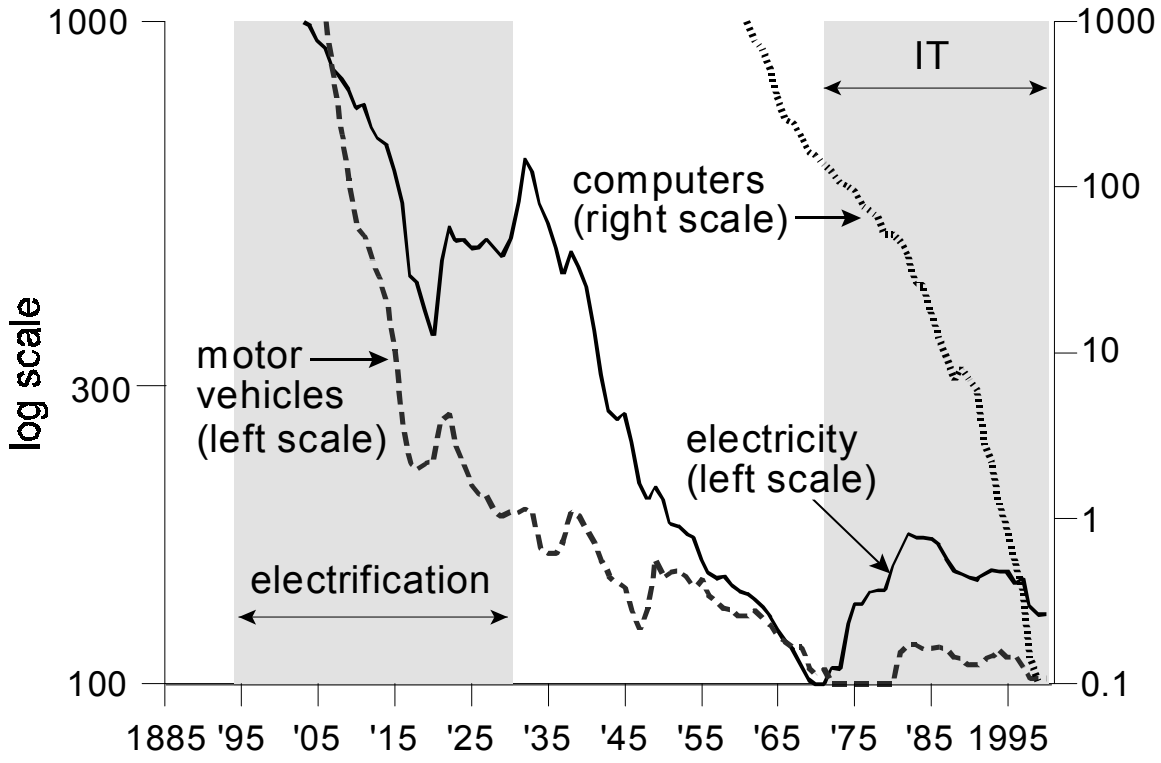

Figure 10: Price indexes for products of two technological revolutions.

use of the left-hand scale for electricity and motor vehicles and the right-hand scale for computers underscores the extraordinary decline in computer prices since 1960 compared to the earlier technologies. While the electricity and the automobile indexes fall by a factor of 10, the computer index falls by a factor of 10,000.

The more important question, however, is how the general decline in equipment prices compares to the declines associated more directly with the GPTs of each epoch. Figure 11 makes this comparison by plotting the relative prices of all three GPT's along with the general equipment index on the same logarithmic scale, with the starting point for each of the GPTs normalized to the level of the general equipment price index in that year. By this measure, it is clear that electricity and motor vehicle prices declined at about the same pace as that of equipment generally until the start of the IT price data, though it is also interesting that motor vehicle prices appear to have declined faster than electricity prices. After 1960, declining computer prices and rising shares of computers in equipment stocks seem to have drawn the general index downward, while computing prices fell thousands of times faster than the general

To approximate prices from 1901-1913, we extrapolate assuming constant growth and the average annual growth rate observed from 1913-24. We then join the various components to form an overall price index, and set it to equal 1000 in the first year of the sample (i.e., 1901).

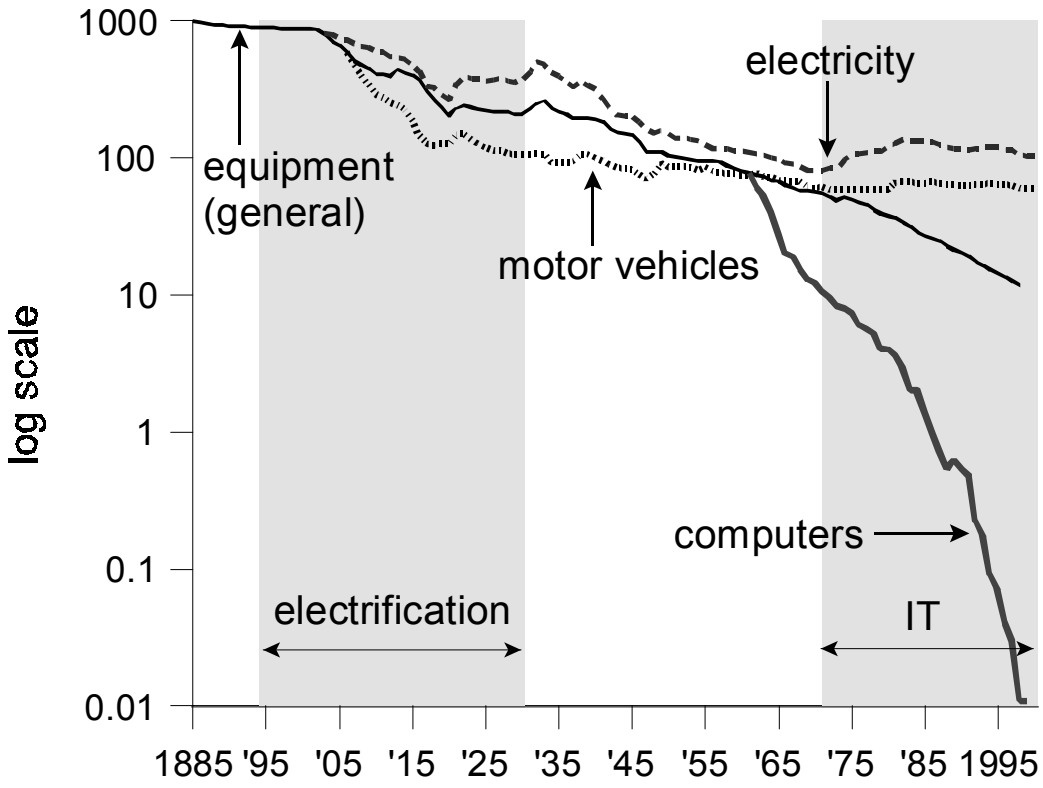

Figure 11: Comparison of the decline in general and GPT-specific equipment prices.

equipment index.

It can be said that the electricity index, being the price of a kilowatt hour, understates the accompanying technological change because it does not account for improvements in electrical equipment, and especially improvements in the efficiency of electrical motors. Such improvements may be contained in the price series for capital generally. Yet based on the price evidence in figures 10 and 11, electricity, motor vehicles, and computers might all qualify as GPTs, but computers are clearly the most revolutionary of the three.

2.3 Ability of the GPT to spawn innovation

The third characteristic that Bresnahan and Trajtenberg suggested was the technology's ability to generate innovation. Any GPT will affect all sorts of production processes, including those for invention and innovation. Some GPTs will be biased towards helping to produce existing products, others towards inventing and implementing new ones. An example of a more specific technology that was heavily skewed towards future products was hybrid corn. Griliches (1957, p. 502) explains why hy-

brid corn was not an invention immediately adaptable everywhere, but, rather, that it was the invention of a method of inventing, a method of breeding superior corn for specific localities.

Electricity and IT have both helped reduce costs of making existing products, and they both spawn innovation, but IT is more skewed towards the latter. The 1920s especially saw a wave a new products powered by electricity, and the computer is now embodied in many new products as well. But as the patenting evidence will bear out, IT seems to have more of a skew towards contributing to further innovation – the role of the computer in simulation should be known to many of us writing research papers. Feder (1988) describes how computers play a similar role in the invention of new drugs.

2.3.1 Patenting

Patenting should be more intense after a GPT arrives and while it is spreading due to the introduction of related new products. Figure 12, which shows the per capita numbers of patents issued on inventions annually from 1790 to 2000 and trademarks registered from 1870 to 2000, shows two surges in activity – between 1900 and 1930, and again after 1977.[10] Is it mere chance that patenting activity was most intense during our technological revolutions? Moreover, it appears that patenting activity picks up after the end of the U.S. Civil War in 1865, and again at the conclusion of World War II in 1945. The slowdown in patenting during the wars and acceleration immediately thereafter suggest that there is some degree of intertemporal substitution in the release of new ideas away from times when it might be more difficult to popularize them and towards times better suited for the entry of new products.

Does the surge in patenting reflect a rise in the number of actual inventions, or was the surge prompted by changes in the law that raised the propensity to patent? This question is important because, over longer periods of time, patents may reflect policy rather than invention: Figure 13 analyzes data described in detail in Lerner (2002) and shows that worldwide, changes in patent policy changes are correlated with the patent series in Figure 12. It is possible, therefore, that the U.S. series reflects court-enforcement attitudes. Kortum and Lerner (1998) analyze this question and found that the surge of the 1990s was worldwide, but not systematically related to country-specific policy changes, and they conclude that technology was the cause for the surge.

[10] We use the total number "utility" (i.e., invention) patents from the U.S. Patent and Trademark Office for 1963-2000, and from the U.S. Bureau of the Census (1975, series W-96, pp. 957-959) for 1790-1962. The number of registered trademarks are from the U.S. Bureau of the Census (1975, series W-107, p. 959) for 1870-1969, and from various issues of the *Statistical Abstract of the United States* for later years. Population figures, which are for the total resident population and measured at mid-year, are from U.S. Bureau of the Census (1975, series A-7, p. 8) for 1790-1970, and from the Bureau of Economic Analysis thereafter.

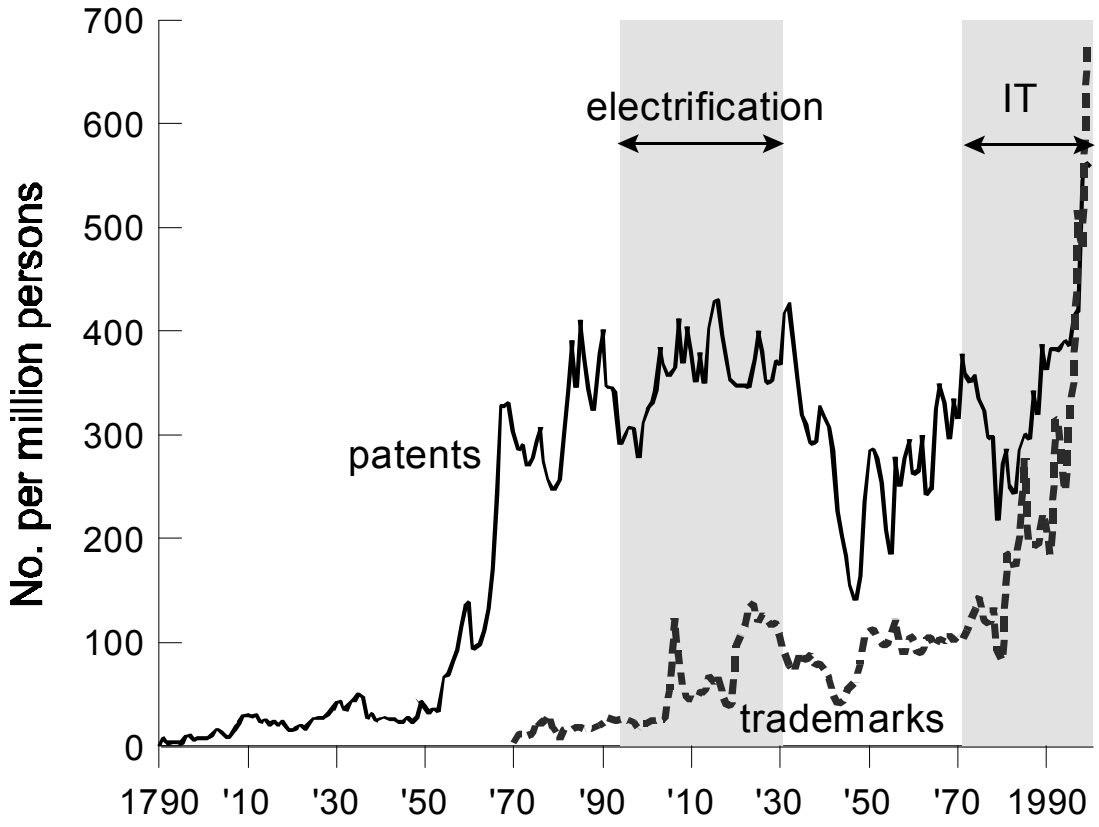

Figure 12: Patents issued on inventions and trademarks registered in the United States per million persons, 1790-2000.

Further support for this view comes from the behavior of trademarks per head, which we also plot in figure 12. Trademarks behave more or less the same as patents do, except for their higher trend. Trademarks are easier to obtain than patents and are not governed by legal developments concerning patents. But with trademarks we have a different concern: Do trademarks proxy for the number of products, or do they just measure duplicative activity and the amount of competition? The answer may depend on what market one looks at. In the market for bananas, for example, Wiggins and Raboy (1996) find that brand names are correlated with measures of quality that do explain price variation, suggesting, therefore, that brand names do signify product differentiation.

2.3.2 Investment in new firms vs. investment by incumbents

If new technologies are more easily embraced by new firms that do not bear the burden of costs sunk in old technologies and the rigid and firm-specific organization capital required to operate them, we should expect to see waves of new listings on

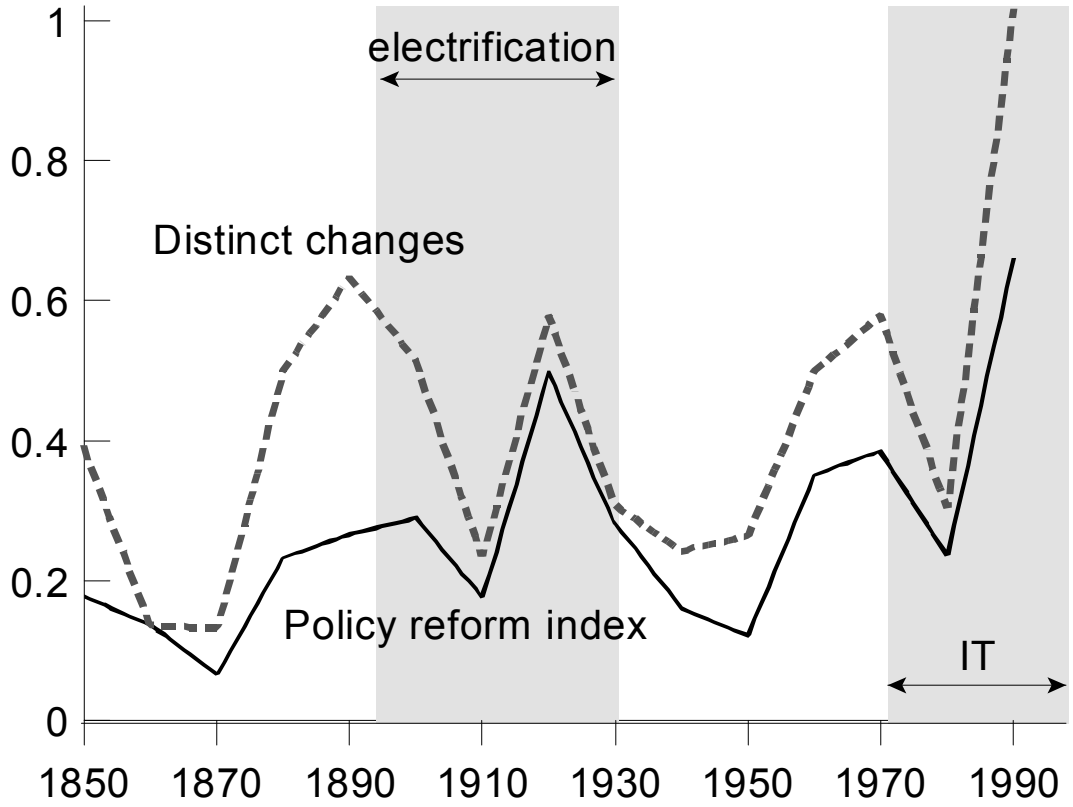

Figure 13: Indexes of worldwide changes in patent laws.

the stock exchange during GPT eras. Figure 14 shows the value of firms entering the New York Stock Exchange (NYSE), the American Stock Exchange (AMEX), and NASDAQ in each year from 1885 through 2001 as percentages of total stock market value.[11] As predicted by Trajtenberg and Helpman, IPOs surge between 1895 and 1929, and then after 1977, which again closely matches the dating of our two technological revolutions.

[11]The data used to construct Fig. 14 and others in this chapter that use stock market valuations are from the University of Chicago's Center for Research in Securities Prices (CRSP) files for 1925-2001. NYSE firms are available in CRSP continuously, AMEX firms after 1961, and NASDAQ firms after 1971. We extended the CRSP stock files backward from their 1925 starting year by collecting year-end observations from 1885 to 1925 for all common stocks traded on the NYSE. Prices and par values are from the *The Commercial and Financial Chronicle,* which is also the source of firm-level data for the price indexes reported in the well-known study by Cowles et al. (1939). We obtained firm book capitalizations from *Bradstreet's*, *The New York Times*, and *The Annalist*. The resulting dataset, which includes 24,475 firms, though limited to annual observations, actually includes more common stocks than the CRSP files in 1925. As such, the dataset complements others that have begun to build a more complete view of securities prices in other markets for the pre-CRSP period [see, for example, Rousseau (1999) on Boston's 19th century equity market.

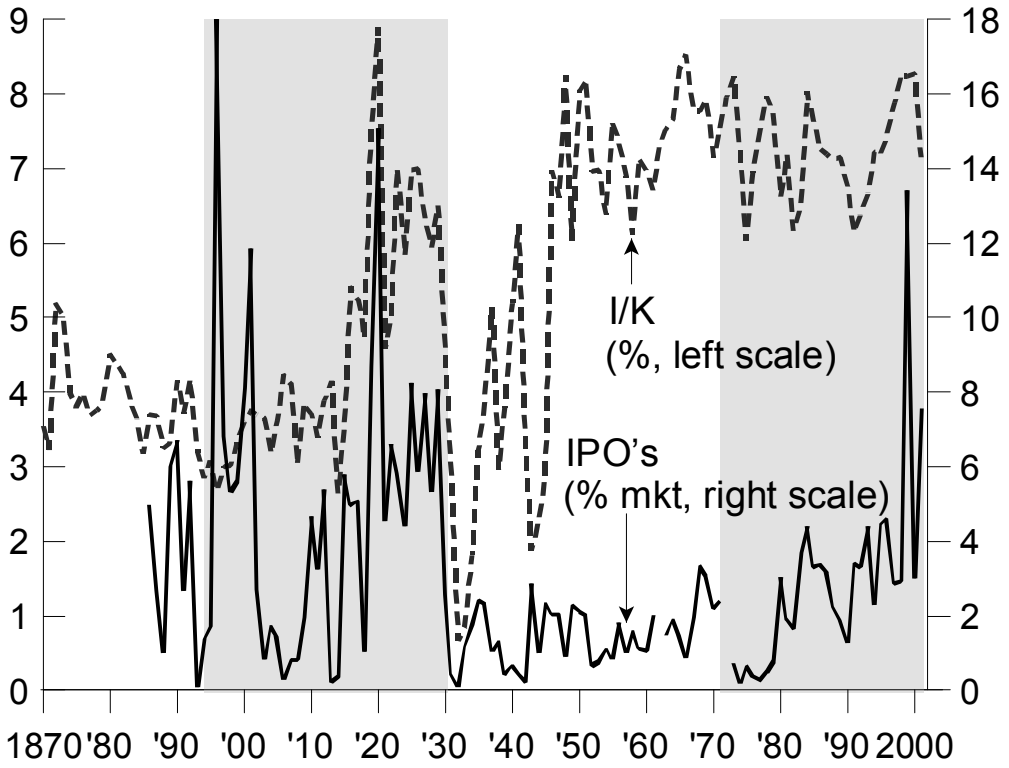

Figure 14: Annual IPOs as a percent of stock market value, and investment as a percent of the net capital stock, 1870-2001.

The dashed line in Figure 14 is private investment since 1870 as a percent of the net stock of private capital for the U.S. economy as a whole, and as such is the aggregate analog of the solid line that covers only the stock market.[12] The solid line in Figure 15 shows the ratio of the solid and dashed lines in Figure 14. In both figures it is clear that, during Electrification, investment by stock market entrants accounted for a larger portion of stock market value than overall new investment in

[12]To build the investment rate series, we start with gross private domestic investment in current dollars from the Bureau of Economic Analysis (2002, Table 1, pp. 123-4) for 1929-2001 and then ratio splice the gross capital formation series in current dollars, excluding military expenditures, from Kuznets (1961b, Tables T-8 and T-8a) for 1870-1929. We construct the net capital stock using the private fixed assets tables of the Bureau of Economic Analysis (2002) for 1925-2001. Then, using the estimates of the net stock of non-military capital from Kuznets (1961a, Table 3, pp. 64-5) in 1869, 1879, 1889, 1909, 1919, and 1929 as benchmarks, we use the percent changes in a synthetic series for the capital stock formed by starting with the 1869 Kuznets (1961a) estimate of $27 billion and adding net capital formation in each year through 1929 from Kuznets (1961b) to create an annual series that runs through the benchmark points. Finally, we ratio-splice the resulting series for 1870-1925 to the later BEA series. The investment rate that appears in Figure 14 is the ratio of our final investment to the capital stock series, expressed as a percentage.

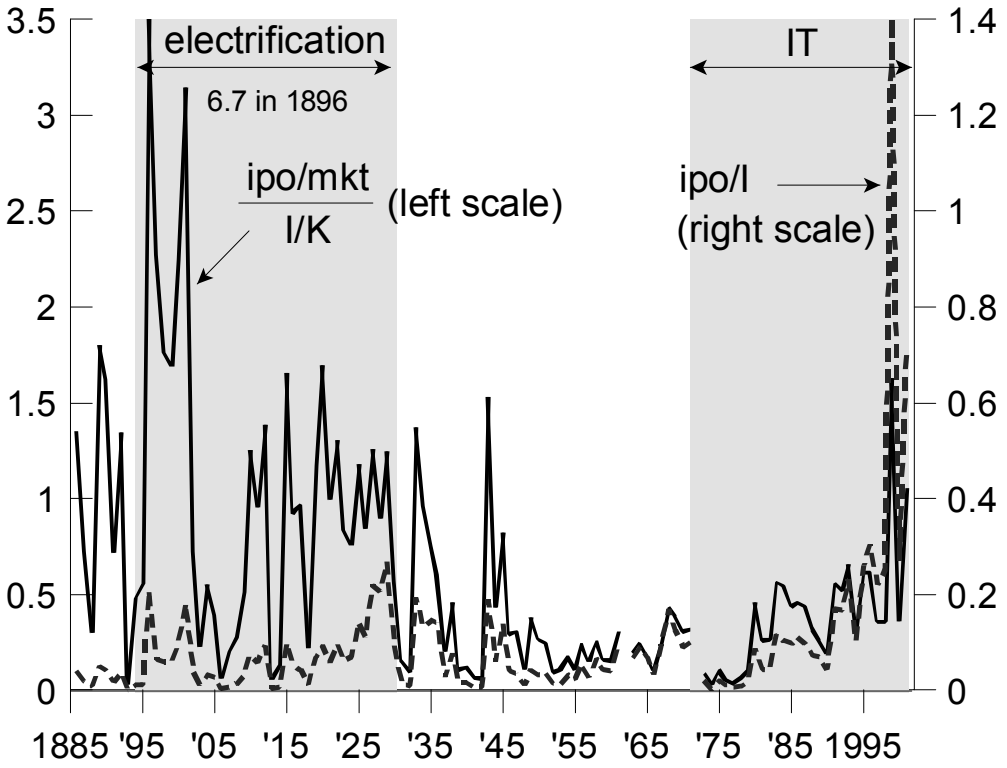

Figure 15: Ratio of IPOs as a percent of the stock market to investment as a percent of the net capital stock, 1885-2001.

the U.S. economy contributed to the aggregate capital stock. This is consistent with the adoption of electricity favoring the unencumbered entrant over the incumbent, who may have incurred large adjustment costs in using the new technology. We say this because aggregate investment, while indeed including new firms, has an even larger component attributable to incumbents. Moreover, the ratio of IPO to aggregate investment activity was highest in the early years of Electrification, which is when these adjustment costs would have been greatest. Although the ratio given by the solid line in Figure 15 has so far stayed below unity for most of the IT-era, it has been rising rapidly in recent years. This could be because IT adoption involved very large adjustment costs for both incumbents and entrants in the early years until the price of equipment and software fell enough to promote adoption among new firms.

The solid line in Figure 15 shows a downward trend mainly because the stock market gained importance as a model of financing in the early part of the 20th century. IPOs are normalized by the stock market which was small early on, and has since become larger. The dotted line in Figure 15 shows the ratio of the un-normalized series of IPOs and aggregate investment. This has a positive trend for

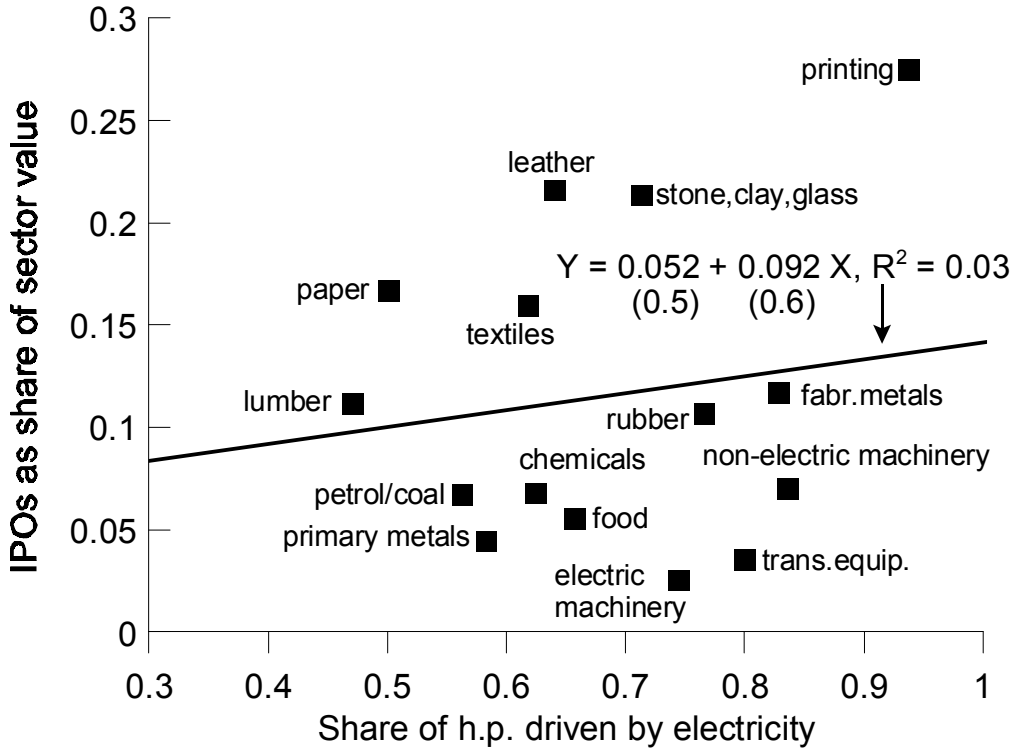

Figure 16: IPOs as shares of sector value 1890-1930 vs. shares of electricity-driven horsepower in 1929.

the same reason that the previous figure showed a negative one: IPOs were not that important early on because the stock market was small. After 1970, IPOs capture a much larger share of the investment by new entrants than they did before the first World War, for example, and even a larger fraction than in the 1920s. When we consider both lines together, we do get the impression that new firms invest more during the GPT eras than at other times.

Does the distribution of entries across sectors shed light on the role of technological factors in the entry waves? Perhaps so. Figure 16 is a scatterplot of the share of IPOs in the market capitalization of 15 manufacturing sectors between 1890 and 1930 vs. their respective shares of horsepower driven by electricity in 1929.[13] In other words, we ask whether sectors with more IPOs ended up embracing the new technology more vigorously than sectors with less entry. The regression line plotted in Fig. 16

[13]We compute the IPO shares by sector by summing year-end IPO values by sector for 1890 through 1930, converting each year's total into real terms using the implicit price deflator for gross domestic product, and then summing across years. We do the same for all listed firms by sector, and use the quotient of sector IPO values and total sector values to compute the shares shown in Fig. 16.

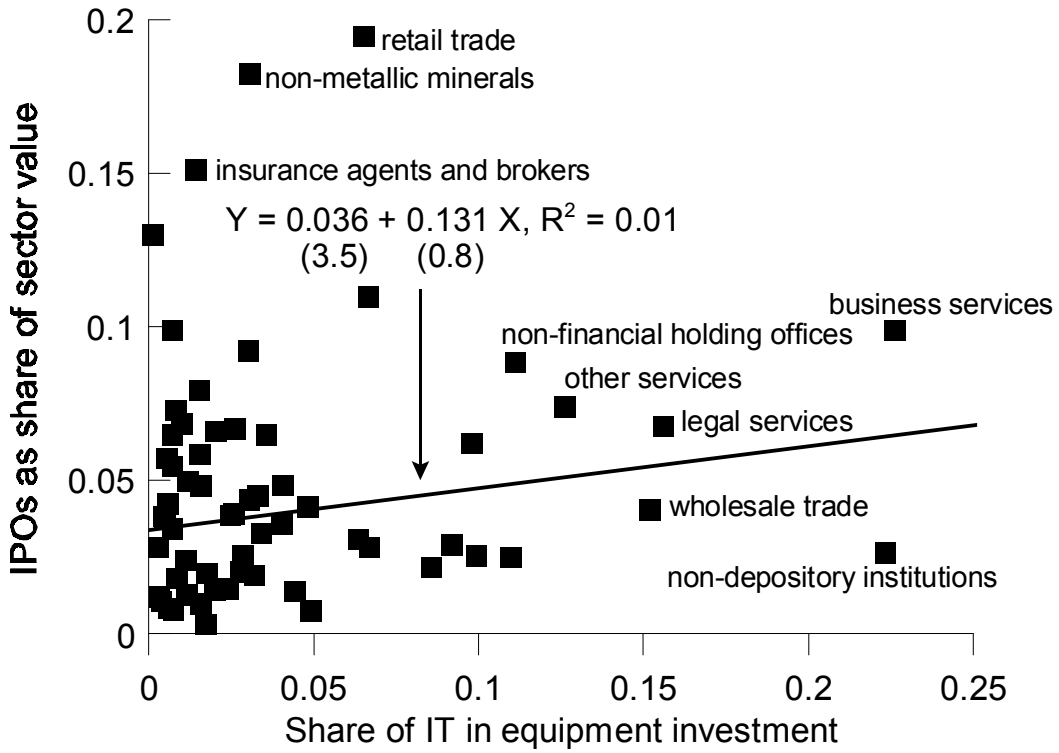

Figure 17: IPOs as shares of sector value 1971-2001 vs. shares of IT in equipment investment in 2000.

indicates that this relationship is indeed positive, though with only 15 observations the slope coefficient is not statistically significant at conventional levels.

In Figure 17, we consider IPOs over the 1971-2001 IT-epoch against shares of computers and peripherals in equipment investment in 2000, we once again obtain a sectoral scatter with a positive slope, though like Electrification, the slope coefficient is not statistically significant.

3 Other symptoms of GPT

So far we have provided some measures of the three qualities of a GPT – its pervasiveness, its rate of improvement, and its innovation-spawning tendency. Now we turn to less direct measures, as are suggested by various theoretical models that deal with GPTs and that predict the following symptoms:

1. *Productivity should slow down.*—The new technology may not be user friendly at first, and output may fall for a while as the economy adjusts.

2. *The skill premium should rise.*—If the GPT is at first user unfriendly, skilled people will be in greater demand when a new technology arrives, and their earnings should rise compared to those of the unskilled.

3. *Entry, exit and mergers should rise.*—These are alternative modes of reallocation of assets.

4. *Stock prices should initially fall.*—The value of old capital should fall; how fast it does so depends on the way that the market learns of the GPT's arrival.

5. *Young and small firms should do better.*—The ideas and products associated with the GPT will often be brought in by new firms. The market share and market value of young firms should rise relative to old firms

6. *Interest rates and the trade deficit.*—The rise in desired consumption relative to output should cause interest rates to rise or the trade balance to worsen.

These are not propositions but hypotheses that one can find in much of the work on GPTs. Now we give evidence on each one in turn. Each gets its own subsection.

3.1 Productivity slowdown

Even in routine activities, learning seems to cause delays of several years before plant productivity peaks [Bahk and Gort (1993)]. It is far from settled whether IT is the reason for the productivity slowdown – Bessen (2002) finds that IT did cause a big part of the slowdown, whereas Comin (2002) argues the opposite. It also is not yet definitely known from the work of Caballero and Hammour (1994) and others whether recessions at business-cycle frequencies are episodes of heightened reallocation. At any rate, the theoretical models of Atkeson and Kehoe (1993), Hornstein and Krusell (1996), Jovanovic and Nyarko (1996), Greenwood and Yorukoglu (1997) and Jovanovic and Rousseau (2002a) emphasize various adjustment costs and learning delays that may cause output to fall at first when a GPT arrives. David (1991) argues that the speed with which a new technology diffuses depends on the pool of investment opportunities that are available when it arrives, and remarks that the quality of this pool in the late 1960s was low because the large backlog of the post-war period had just and finally been eliminated. He also points out that there can often be "slippage" between the technology frontier and implementation due to high input costs and the slow introduction of complementary products.

Figure 1 shows that productivity does not rise quickly in the early phases of the two GPTs, though there is some evidence of greater productivity between 1918 and 1929. This could be taken as further evidence that IT did not do as much as did electricity to raise the productivity on existing processes and products. Productivity was high in the early years of Electrification but fell rapidly as the technology matured. It

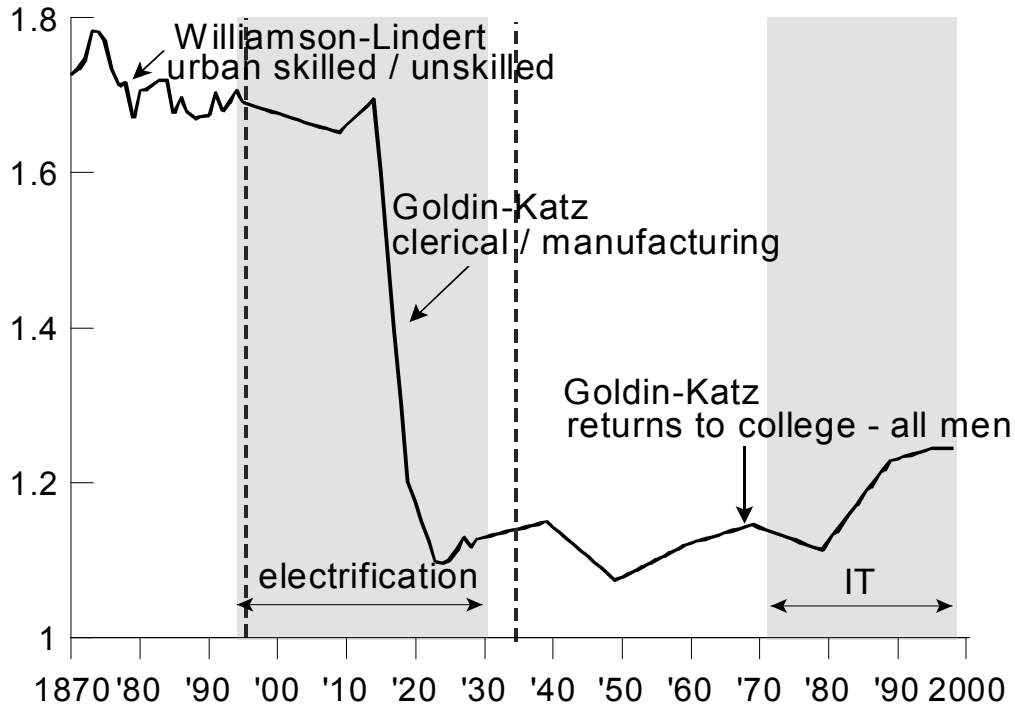

Figure 18: The skill premium.

stayed low through the Depression and 1940s, and then rose rapidly before the IT-age arrived. This pattern is consistent with David's model of exhausted investment opportunities. And while it is interesting to consider the productivity slowdown after 1971, it is also important to recognize that productivity is considerably higher today than it was before IT's arrival.

3.2 The skill premium

As Nelson and Phelps (1966) and Griliches (1969) argued, and Bartel and Lichtenberg (1987) and Krusell et al. (2000) have confirmed, new technology should raise the relative earnings of the skilled. Figure 18 presents a series for the earnings of skilled relative to unskilled labor. We construct the series by combining Williamson's and Lindert's (1980, p. 307) estimates of the wage ratio for urban skilled and unskilled workers for 1870-1894 with estimates from Goldin and Katz (1999) of the ratio of clerical to manufacturing production wages for 1895-1938 and the returns to 16 versus 12 years of schooling for men for 1939-1995.[14] Despite the need to merge data from

[14]Combining several very different series into a continuous "skill premium" is necessary due to sectoral shifts in the skilled and unskilled labor forces that render some measures of skill more applicable to certain periods than others. For example, a college education appears to have become

disparate sources to form a continuous series, a U-shape still emerges, with the skill premium high in the early stages of Electrification (i.e., 1890 to 1918), and then rising rapidly during the post-1978 part of the IT epoch. We suspect that the fall in the skill premium from 1918-1924 would be less deep, and thus the overall U-shape of Figure 18 more apparent, had it not been for the rapid rise of the public higher-education system after the end of the first World War [see Goldin and Katz (1998, p. 10)].

3.3 Entry, exit, and mergers should rise

Gort (1969) argued that technological change will generate merger waves. Evidence since then has shown that mergers and takeovers play a reallocative role. Lichtenberg and Siegel (1987), McGuckin and Ngyen (1995) and Schoar (2000) find that the productivity of a target firm rises following a takeover. The trade-off between exits and acquisitions margins is studied by Jovanovic and Rousseau (2002b,c). This last pair of papers shows that firms will tend to place themselves on the merger market rather than disassemble and sell their assets at times when the value of organization capital is high. Further, reallocation of assets among firms either by merger, consolidation, or purchases of unbundled used capital are more likely to occur than purchases of new capital when firms need to make large adjustments to their capital stocks because of the fixed costs associated with entering the merger market. We believe that both of these conditions are likely to hold during times of sweeping technological change.

The U-shaped top line of Figure 19 is our estimate of the total amount of capital that has been reallocated on the U.S. stock market over the past 112 years. Its components are the stock market capitalization of entering and exiting firms divided by two, and the value of merger targets.[15] Entries and exits divided by two, given

a more important determinant of income in the postwar period than it was in earlier years. Since the Goldin and Katz observations are generally decadal, we interpolate between them to obtain an annual series for 1895 to 1995. The vertical dotted lines in Figure 18 mark the points where we need to change data sources.

[15] We identify targets for 1926-2001 using the CRSP stock files and various supplementary sources. CRSP itself identifies more than 8,000 firms that exited the database by merger between 1926 and 2001, but links less than half of them of them to acquirers. Our examination of the 2000 Edition of Financial Information Inc.'s *Directory of Obsolete Securities* and every issue of Predicasts Inc.'s *F&S Index of Corporate Change* between 1969 and 1989 uncovered the acquirers for 3,646 of these unlinked mergers, 1803 of which turned out to be CRSP firms. We also recorded all mergers from 1895 to 1930 in the manufacturing and mining sectors from the original worksheets underlying Nelson (1959) and collected information on mergers from 1885 to 1894 from the financial news section of weekly issues of the *Commercial and Financial Chronicle.* For 1890-1930, we use worksheets for the manufacturing and mining sectors that underlie Nelson (1959). The resulting target series includes the market values of exchange-listed firms in the year prior to their acquisition, and reflects 9,030 mergers. Stock market capitalizations are from our extension of CRSP backward to 1885 (see footnote 11). Before assigning a firm that no longer carries a price in our database as an "exit," we check the list of hostile takeovers from Schwert (2000) for 1975-1996 and individual issues of the *Wall Street Journal* from 1997-2001 to ensure that we record firms taken private under a hostile tender offers as mergers.

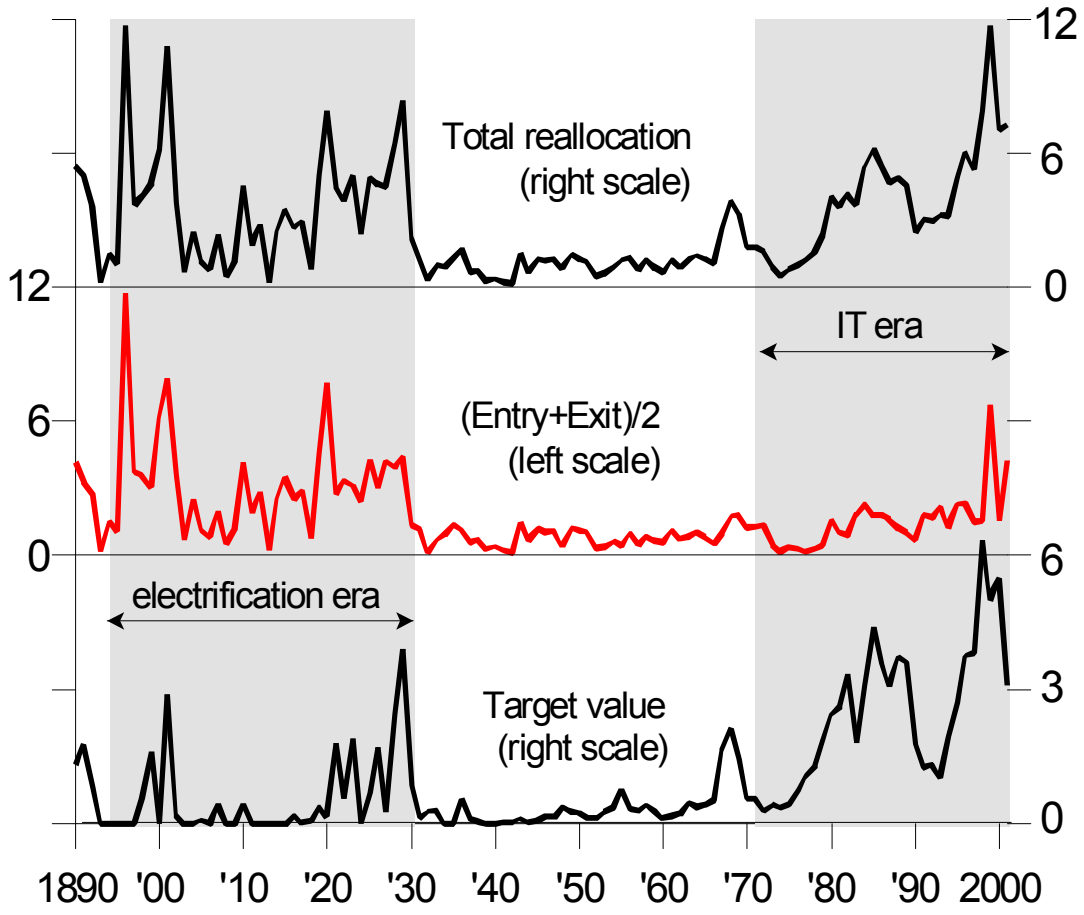

Figure 19: Reallocated capital and components as percentages of stock market value, 1890-2001.

by the center line, is a rough measure of how much capital exits from the stock market and comes back in under different ownership, or at least under a different name. The lower line is the stock-market value of merger targets. Regardless of whether reallocation occurs through mergers or through entry and exit, it is much more prevalent during the periods that we associate with Electrification and IT.

3.4 Stock prices should fall

The value of old capital should fall suddenly if the arrival of the GPT is a surprise, as in Greenwood and Jovanovic (1999) Hobijn and Jovanovic (2001), Jovanovic and Rousseau (2002a) and Laitner and Stolyarov (2002), or more gradually as in Trajtenberg and Helpman (1998). Figure 20 shows that the stock market declined in 1973-74. No such sudden drop is visible for stock prices in the early 1890's. Why not? Maybe

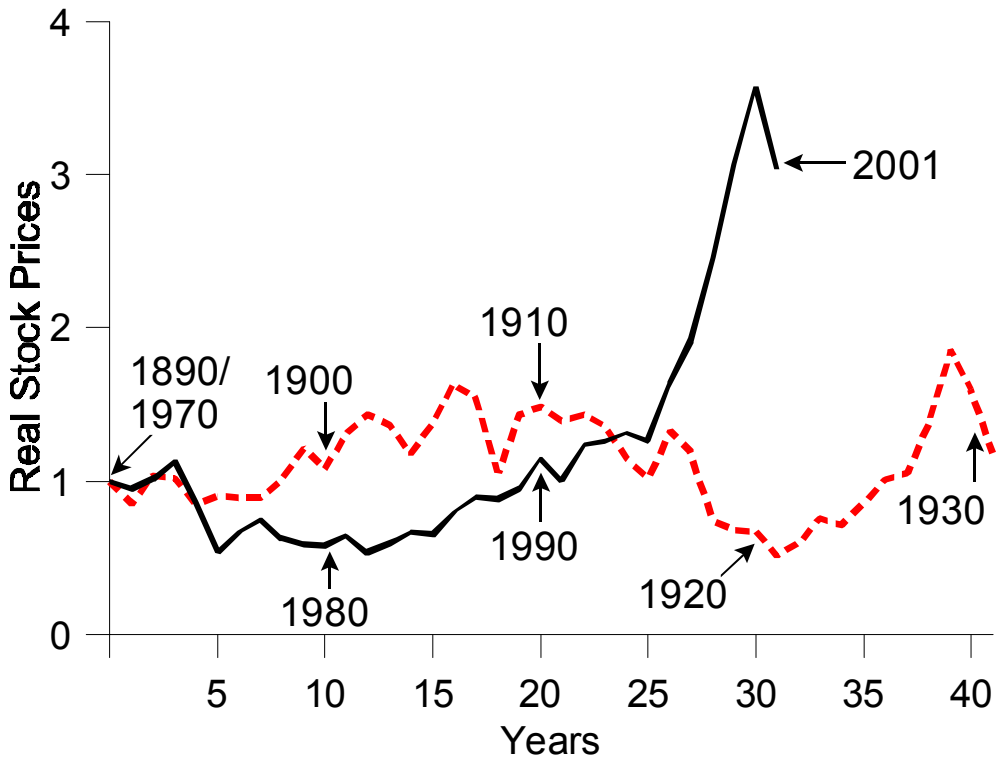

Figure 20: The real Cowles/S&P stock price index across the transition periods.

because the market was thin and unrepresentative in those days, with railway stocks absorbing a large chunk of market capitalization. More likely, the realization that the new technology would work well was more gradual and was not prompted by any single event like the completion of the Niagara Falls dam in 1894.[16]

In other words, that it does not happen for the first period could be that the events of the early 1890's were foreseen, as would be the case in Helpman and Trajtenberg (1998a) where stock prices are predicted to fall earlier and more gradually. It also could be, as Boldrin and Levine (2001) would claim, that old capital is essential in the production of new capital and that its value may not fall in quite the way that it would when capital can be produced from consumption goods alone as is the case in many growth models, including that of Jovanovic and Rousseau (2002a).

If stock-price declines were caused by the threat of IT to incumbents, this should relate especially to those sectors that later invested heavily in IT. Hobijn and Jovanovic (2001, p. 1218) confirm this using regression analysis.

[16] We obtain the composite stock price index from Wilson and Jones (2002), and deflate using the CPI.

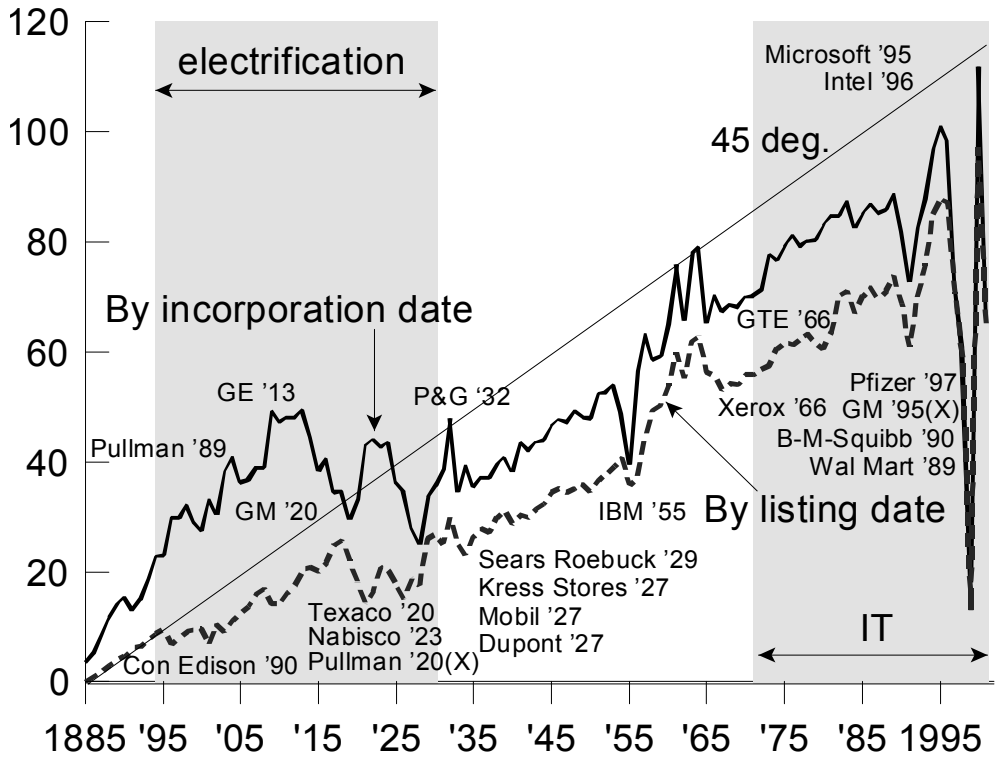

Figure 21: Average age (in years) of the largest firms whose market values sum to 5 percent of GDP.

3.5 Young firms should do better

The evidence on this hypothesis is mixed, but positive overall.

3.5.1 The age of the leadership

As a GPT takes hold, we should not only expect to see firms coming to market more quickly, but the market leaders getting younger as well. In other words, every stage in the lifetime of the firm should be shorter. This stands in contrast to Hopenhayn (1982), in which the age distribution of an industry's leadership is invariant when an industry is in a long-run stochastic equilibrium. That is, the average age of, say, the top 5% or top 10% of the firms is fixed. Some leaders hold on to their positions and this tends to make the leading group older, but others are replaced by younger firms, and this has the opposite effect. In equilibrium the two forces offset one another and the age of the leadership stays the same. Keeping the age of the leaders flat requires, in other words, constant replacement.

Figures 21 and 22 show that, overall, the age of the leaders is anything *but* flat. It sometimes rises faster than the 45^0 line, indicating that the age of the leaders is

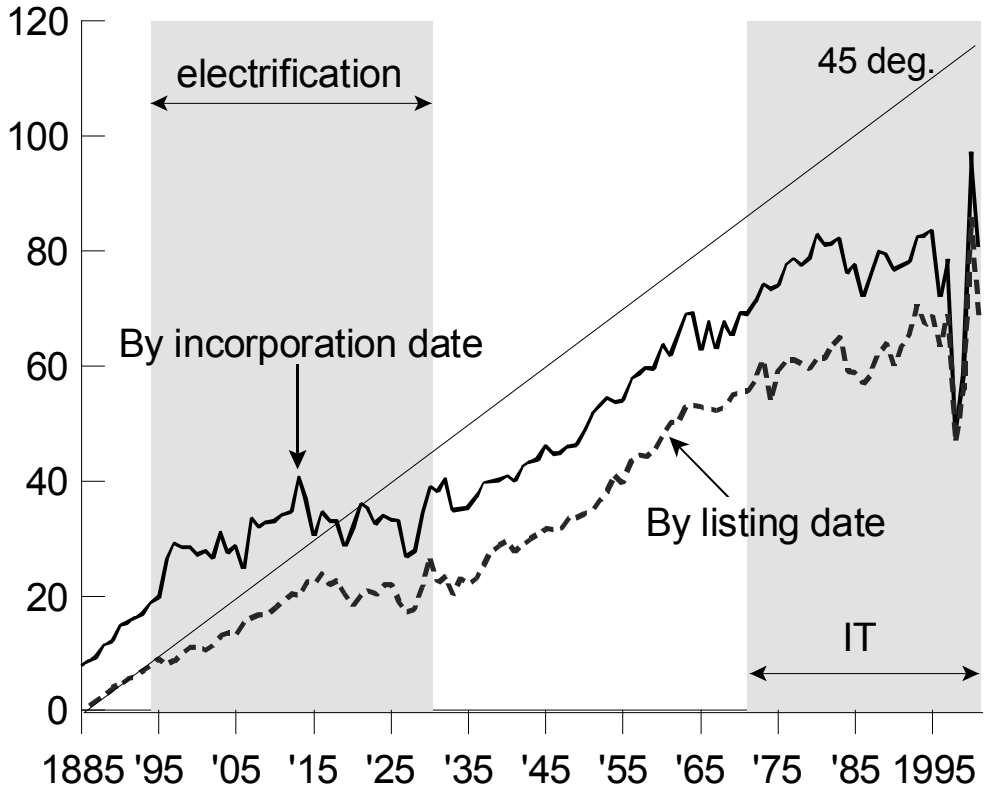

Figure 22: Average age (in years) of the largest firms whose market values sum to 10 percent of GDP.

rising faster than the passage of time. At other times it is flat or falling, indicating replacement. Both figures show, however, that during the Electricity and the IT revolutions, the lines are flat or falling, so that replacement was then high. This is best seen in Figure 22.

Figure 21 plots the value-weighted average age of the largest firms whose market values sum to 5 percent of GDP. "Age" is from incorporation and from exchange listing. We label some important entries and exits from this group (with exits denoted by "X"). Based upon years from incorporation, the leading firms were being replaced by *older* firms over the first 30 years of our sample, because the solid line is then steeper than the 45° line. In the two decades after the Great Depression the leaders held their relative positions as the 45° slope of the average age lines shows. The leaders got younger in the '90s, and their average ages now lie well below the 45° line. The shake-out of 1999-2001 comes from Microsoft's huge rise in 1999, when it was worth more than 5 percent of GDP on its own, and its rapid decline in 2000, which transferred the full 5 percent share to GE. The two firms split the 5 percent share in 2001. The slopes of regression lines in Figure 21 (estimated with constant and

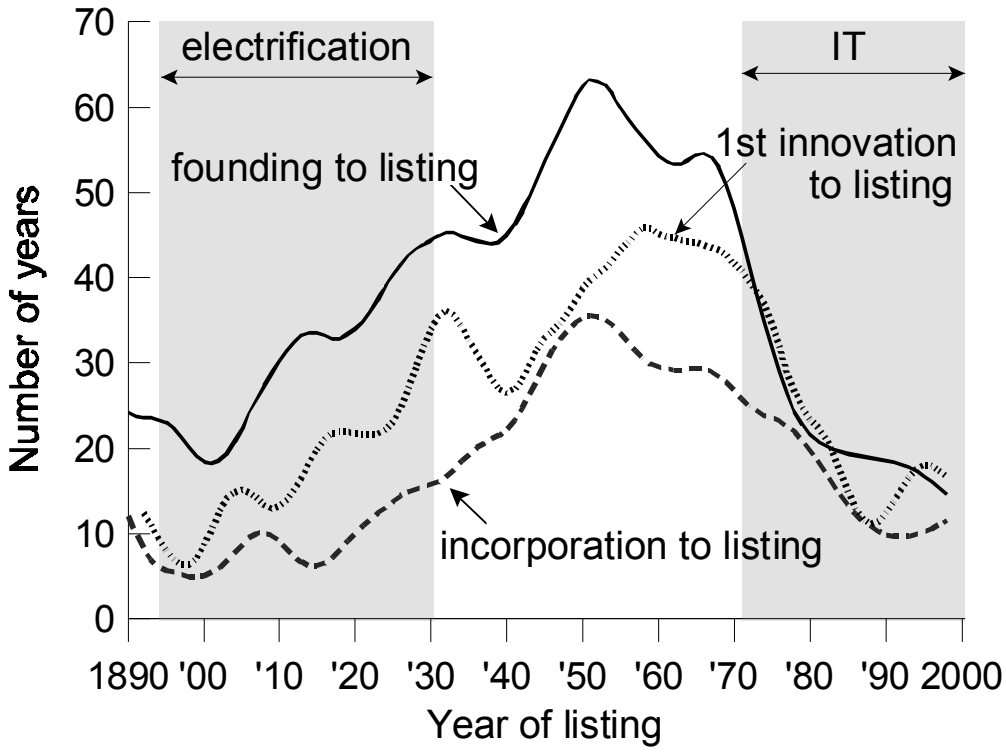

Figure 23: Waiting times to exchange listing.

time trend) are 0.62 for years since incorporation and 0.67 for years since exchange listing.

3.5.2 The age of firms at their IPO

According to its third "innovation-spawning" characteristic, when a GPT arrives it gives rise to new projects that are unusually profitable. When such projects arrive, firms will be more impatient to implement them. When it is the new firms that come upon such projects (rather than the incumbents), they will feel the pressure to list sooner. The argument is developed and tested in Jovanovic and Rousseau (2001b). We argue there that the Electricity-era and the IT-era firms came in younger because the technologies that they brought in were too productive to be kept out of the market for very long.

Figure 23 shows HP-filtered average waiting times from founding, first product or process innovation, and incorporation to exchange listing based upon individual company histories and our extended CRSP database.[17] The vertical distance between

[17]Listing years after 1925 are those for which firms enter CRSP. For 1885-1924, they are years in which prices first appear in the NYSE listings of *The Annalist, Bradstreet's*, *The Commercial*

the solid and dotted lines shows that firms often have their first innovation soon after founding, but that it then takes years, even decades, to list on a stock exchange. We interpret this delay as a period during which the firm and possibly its lenders learn about what the firm's optimal investment should be. But when the technology is highly innovative, the incentive to wait is reduced, and the firm lists earlier, which is what the evidence shows.

When firms gather less information before investing, the investments that they undertake will be riskier. One may conjecture that if new entrants waited less before investing, then incumbents also undertook projects earlier than they would normally. In all these cases, the resulting investments would be riskier than if more time were allowed to plan them. Moreover, the newness of the GPT would add further risk. On all these grounds, we expect higher interest rate differentials on the average investment.

Figure 24, which portrays the spread between interest rates on riskier and safe investments since 1885, shows that this has been for the most part the case.[18] It is important to note that we formed the series in Figure 24 by ratio-splicing three different spreads together, and that the "safe" asset after 1920 is the short-term treasury bill while for earlier years it is a long-term government bond, yet the fluctuations in this series should still reflect fluctuations in risk perceptions reasonably well, at least to the extent that term premia rather than riskiness are the main factors that lead to yield differentials among the various government securities.

During the Electrification era, spreads rose between 1894 and 1907, which is when uncertainty about the usefulness and possibilities for adoption of the new technology were greatest. Spreads fell after that as the future of electricity became more clear. In the IT-era, spreads have an upward trend from 1970 through the 1990s, and only seem to have fallen recently. This may well reflect the lag in the widespread adoption of the IT technology. The rise of the spread in 1930 and its very slow decline in the subsequent 15 years through 1945 probably has to do with the macroeconomic instability induced by the events prior and during the Great Depression, and then

and Financial Chronicle, or *The New York Times*. The 6,238 incorporation dates used to construct Figure 23 are from *Moody's Industrial Manual* (1920, 1928, 1955, 1980), Standard and Poor's *Stock Market Encyclopedia* (1981, 1988, 2000), and various editions of Standard and Poor's *Stock Reports*. The 3,827 foundings are from Dun and Bradstreet's *Million Dollar Directory* (2000), Moody's, Etna M. Kelley (1954), and individual company websites. The 482 first innovations were obtained by reading company histories in *Hoover's Online* (2000) and company websites. We linearly interpolate the series between missing points before applying the HP-filter to the time series in the figure.

[18] In Figure 24, we use the spread between the interest rates on Baa rated corporate bonds (from Moody's Investors Service) and three-month T-bills [from the FRED database for 1934-2001 and the Board of Governors (1976) for 1920-34] for the period from 1920 to the present. For 1900-20, we ratio splice the spread between the interest rate on prime commercial paper with 60-90 days until maturity [Homer and Sylla (1991, table 49, p. 358)] and the redemption yields on the U.S. government consol 2s of 1930 [Homer and Sylla (1991, table 46, p. 343] onto the Baa - T-bill spread. Finally, for 1885-99, we splice the spread between the commercial paper rate [Homer and Sylla (1991, table 44, p. 320] and the redemption yields on U.S. government refunding 4s of 1907 [Homer and Sylla (1991, table 43, p. 316] onto the previous result.

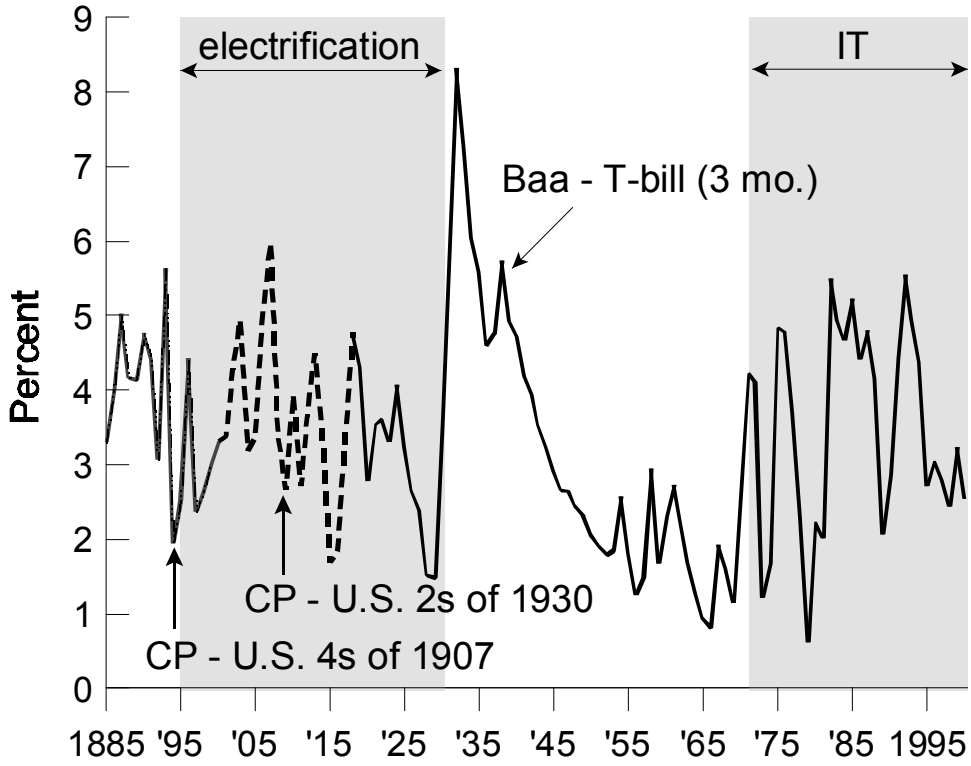

Figure 24: Nominal interest rate spreads between riskier and safer bonds, 1885-2000.

the heavy borrowing by the U.S. government to to finance the second World War, which lowered rates on T-bills.

3.5.3 The stock market performance of young vs. old after entry

Young firms are smaller. If "creative destruction" does indeed mean that old firms give way to young firms, then we should see signs of it in Figure 25, which depicts the relative appreciation of *total* market value of small versus large firms since 1885.[19] We define "small" firms as those in the lowest quintile of CRSP, and "large" firms as those in the upper quintile. The figure shows that small firms outperform large ones in the long run and that the growth premium is about 7.5 percent per year. But the two technological epochs do not show a faster rise than the other epochs, and this is puzzling. The IT era shows, in particular, that the large firms regrouped after 1983. Surprisingly, recessions do not seem to hurt the long-term prospects of small firms: The relative index rises in 10 of the 23 NBER recessions.

[19] Being a total value index, this differs from the relative stock price index that is plotted in Figure 8 of Hobijn and Jovanovic (2001). For the post-1925 period for which they overlap, the qualitative behavior of the two series is essentially the same.

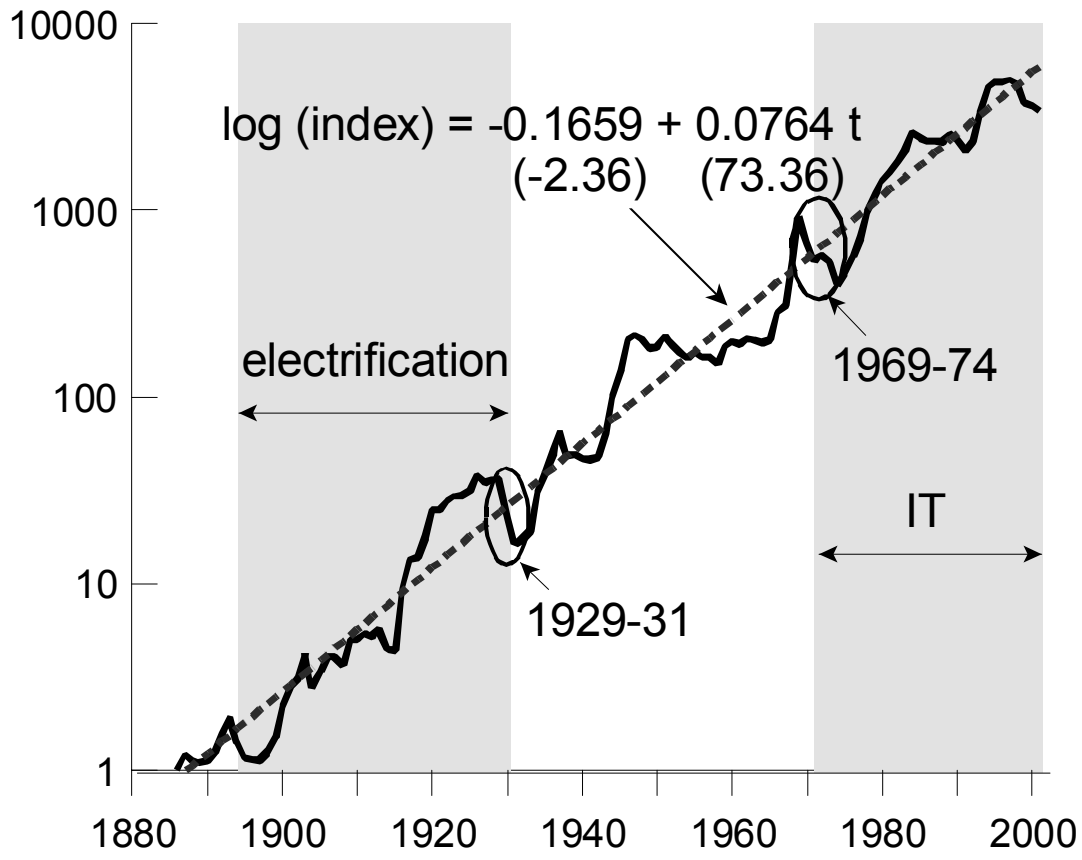

Figure 25: The relative capital appreciations of small vs. large firms.

The two periods that we wish to focus on are 1929-31 and the early 1970s. In both periods, the small-cap firms lost out relative to the large-cap firms. The first period comes at the end of the Electrification era and the relative decline of small cap firms is what one would have expected. But the early 1970's come at the beginning of a new GPT, and small-cap firms should have outperformed the large-cap firms during that time. Yet the opposite happened. It is only after 1974 that the small-cap firms start to perform better.

Regression evidence on age and stock-market performance.—If the GPT is brought in by young firms, then the capital loss imposed by the GPT's arrival should fall more heavily on old firms. To test this using data on individual firms, let

A_i = age since listing of firm i in 1970.
S_i = share (in firm i's sector) of IT capital in the capital stock in 2001.

This measures firm's exposure to the impact of the new technology of the sector. For the measure of expected performance we take the change in a firm's stock price over intervals that start in 1971 and end in 1975, 1980, 1985, 1990, and 1995. These should

reflect the market's expectation of how well the firm will handle the consequences of the GPT. We regressions take the form:

$$\ln\left(\frac{P_{i,1975}}{P_{i,1970}}\right) = c_0 + c_1 A_i + c_2 S_i - c_3 A_i S_i. :$$

We summarize the firm-level results in Table 4.

Table 4
Age and stock market performance

	Dependent variable: $\ln(P_{t+i}/P_t)$				
	1971-75	1971-80	1971-85	1971-90	1971-95
constant	-0.737	-0.143	0.152	-0.057	0.577
	(-24.3)	(-2.96)	(2.58)	(-0.59)	(6.06)
A	0.007	-0.001	-0.001	0.003	-.002
	(6.40)	(-0.46)	(-0.55)	(0.97)	(-0.51)
S	-3.497	-2.266	-1.035	-0.602	2.719
	(-7.60)	(-3.37)	(-1.20)	(-0.46)	(1.88)
$A * S$	0.047	0.043	-0.016	-0.122	-0.106
	(2.22)	(1.14)	(-0.39)	(-2.09)	(-1.76)
R^2	.089	.009	.003	.006	.012
N	2218	1814	1367	981	843

Note: The table presents coefficient estimates for the subperiods included in column headings with T-statistics in parentheses. The R^2 and number of observations (N) for each regression appear in the final two rows.

The interaction between the firm's age (A) and its exposure to (S) is negative and significant only when the period during which we measure price appreciation extends to 1990 and 1995. We would have expected this coefficient to be negative always since older firms in sectors in which IT would become important would be less able to adjust to the new technology than newer ones. Over the 1971-75, 1971-80, and 1971-85 periods, the interaction term comes in positive, but statistically significant only in the first subperiod. It thus seems that IT firms took a long time to realize gains in the market after the technology's arrival. We do not have a lot of firms with continuous price data prior to 1900, but have enough observations to at least attempt the same regression for the Electrification era. In this case, we got

$$\ln\left(\frac{P_{i,1899}}{P_{i,1894}}\right) = \underset{(1.09)}{2.111} - \underset{(-0.46)}{0.129} A_i - \underset{(-0.88)}{2.307} S_i + \underset{(0.55)}{0.213}\, A_i S_i$$

(T-stats in parenthesis) $R^2 = .015$, $N = 56$. In this very small sample, we do not see a direct effect of age on capital depreciation as the Electrification era got underway, and the interaction term is not statistically significant.

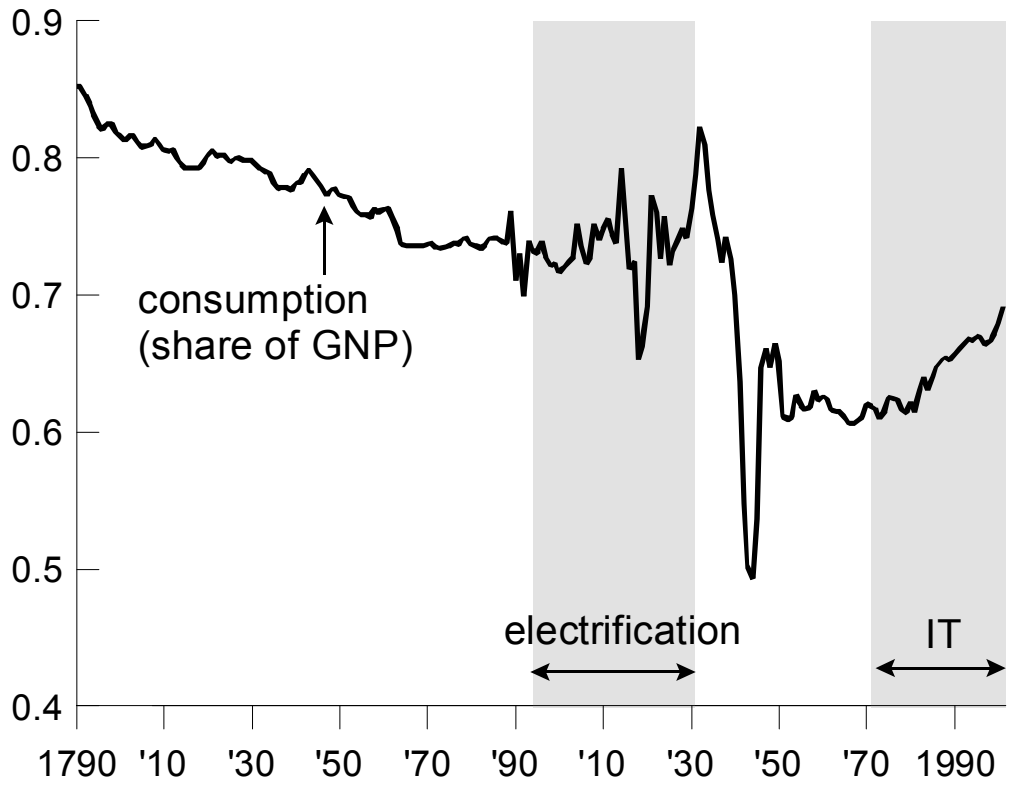

Figure 26: The ratio of consumption to income.

3.6 Interest rates and the trade deficit

First, if the productivity gains of the GDP are deferred, the consumption income ratio should rise. Second, the consumer becomes wealthier when the GPT arrives, interest rates should rise to choke off some of the increased consumption demand. Finally, some of the extra consumption comes from imports and so the trade deficit should rise. The evidence on these three point is mixed, but on balance favorable.

3.6.1 The predicted rise in the consumption-income ratio during GPT eras

Private consumption rises gradually during each GPT era, and this is set against a long-run secular trend for private consumption that is negative. Figure 26 shows the ratio of consumption to gross national product (GNP) since 1790.[20] As our GPT

[20]The series for consumption and GNP are from the Bureau of Economic Analysis (2002, table 1, pp. 123-24) for 1929-2001, Kendrick (1961, table A-IIb, cols. 4 and 11, pp. 296-97) for 1889-1929, and Berry (1988, table 9, pp. 25-26) for 1790-1889. The BEA figures are for personal consumption, but the Kendrick and Berry figures include the government sector as well. Since consumption in the

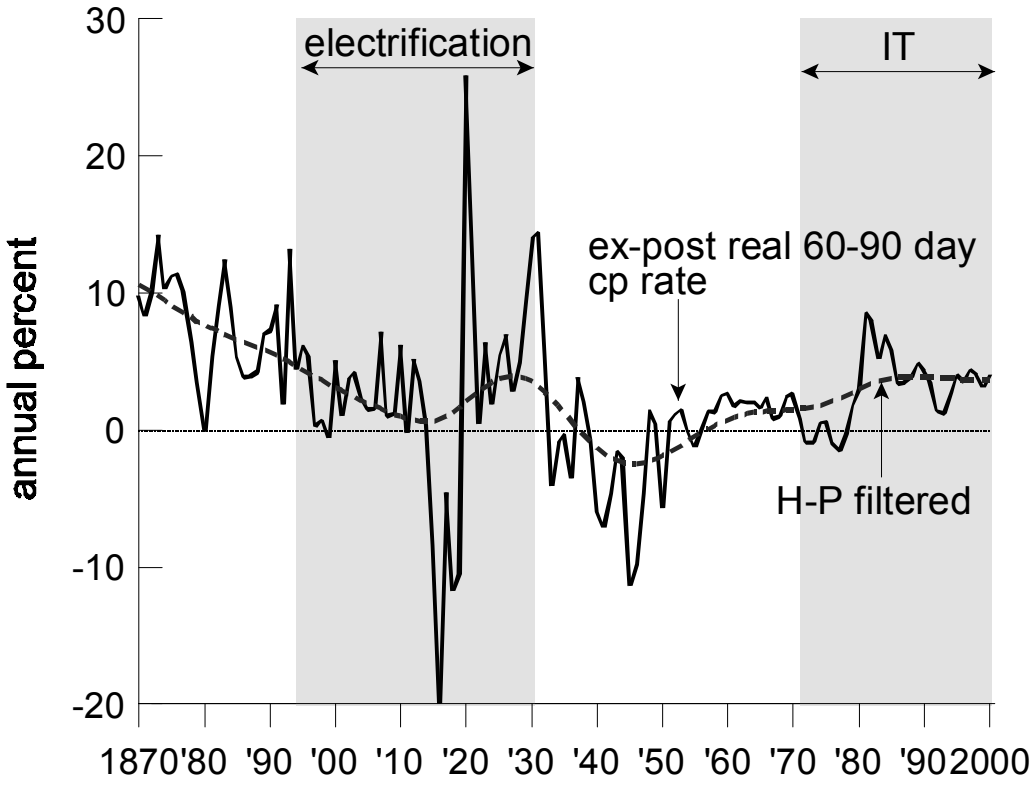

Figure 27: The ex-post real interest rate on commercial paper.

hypotheses would suggest, the arrival of Electricity in 1890 seems to mark the end of a long-term decline in the ratio that been underway for a century. And though the level of the series falls during the Great Depression and World War II, never to return to its pre-1930 levels, consumption takes another sharp upward turn near the start of the IT revolution, and has continued its rise to this day.

3.6.2 The predicted rise in interest rates

Figure 27 shows that ex-post real interest rates were about the same during the two GPT eras, and much lower in the middle 40 unshaded years of the 20th century.[21]

government sector was much smaller prior to the first World War, we suspect that the downward trend in the 19th century is a result of changing private consumption patterns rather than a reduction in the government sector's consumption.

[21] Commercial paper rates are annual averages from the FRED database for 1934-2001 and from Homer and Sylla (1991) for earlier years. We compute the ex-post return by subtracting inflation as computed by the growth of the implicit price deflator for GNP from the Bureau of Economic Analysis (2002) for 1929-2001 and Berry (1988) for earlier years.

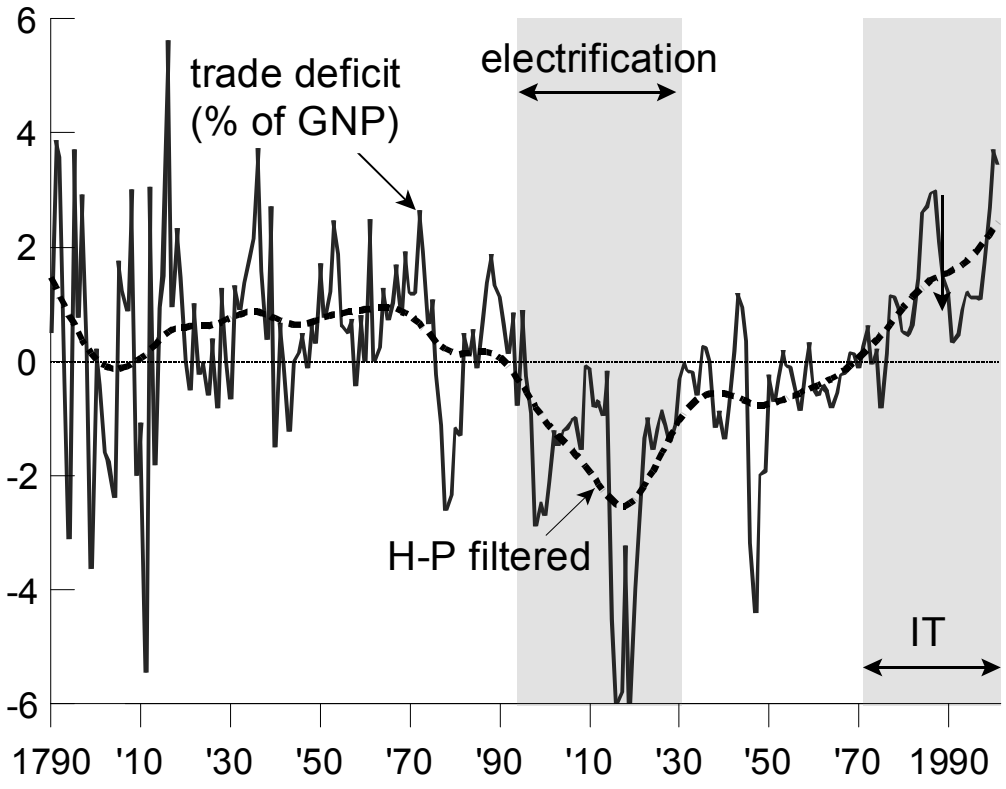

Figure 28: Trade deficit as a percent of GNP.

The dashed line is the H-P detrended series. The averages are

Era	Ex-post real interest rate
$1870 - 1893$	7.78
$1894 - 1930$	2.61
$1931 - 1970$	-0.16
$1971 - 2001$	2.94

We note, however, that the ex-post rate is so high in the first era, before 1894. If the arrival of Electricity and its impact was foreseen prior to 1994, interest rates would have risen earlier, but this probably does not explain why it is so high then. More likely, the pre-1995 era reflects the lack of financial development: The stock market was small then, and the financial market not as deep. This may have given rise to an overall negative trend in interest rates over the 130-year period as a whole.

3.6.3 The predicted rise in the trade deficit

Alternatively, a trade deficit should open up, and right away if the economy is open. Figure 28, which plots the trade deficit as a percentage of GNP since 1790 along with

an H-P trend, shows this to be the case at the start of the IT revolution, though not in the early years of Electrification.[22]

It is puzzling at first blush that the deficit did not appear during the IT era. If anything, it moves into surplus. Events in the rest of the world may explain a part of this. Europe needed to borrow heavily to finance its colonial wars and World War I, and the United States provided some of the loans. This may partly explain the surplus. The IT era is taking place while the world is largely at peace

4 Conclusion

Technological invention is uneven, and comes in bursts; that much has for a long time been clear to students of growth. Electricity and IT are, to most observers, the two most important GPTs to date, at least they seem so according to the three criteria that Bresnahan and Trajtenberg proposed. In this chapter we have analyzed how the U.S. economy reacted to the creation of these two GPTs. Having discussed in detail GPTs with reference to the Electricity and IT eras, we believe we have shown that the concept is a good way to organize how we think of technological change and its effects.

The Electricity and IT eras are similar, but they also different in important ways. Electrification was more broadly adopted, whereas IT seems to be technologically more revolutionary. The productivity slowdown is stronger in the IT era but the ongoing spread of IT and its continuing precipitous price decline are reasons for optimism about growth in the coming decades.

[22] GNP and total imports and exports of goods and services are from the Bureau of Economic Analysis (2002, table 1, pp. 123-24) for 1929-2001. For 1790-1920, imports and exports are from Bureau of Census (1975), series U-8 and U-1, p. 864, respectively), and the GNP series are from Kendrick (1961) and Berry (1988).

The Effects of Technical Change on Labor Market Inequalities*

Andreas Hornstein† Per Krusell‡ Giovanni L. Violante§

First Draft: September 24, 2003
This Draft: December 6, 2004

Abstract

In this chapter we inspect economic mechanisms through which technological progress shapes the degree of inequality among workers in the labor market. A key focus is on the rise of U.S. wage inequality over the past 30 years. However, we also pay attention to how Europe did not experience changes in wage inequality but instead saw a sharp increase in unemployment and an increased labor share of income, variables that remained stable in the U.S. We hypothesize that these changes in labor market inequalities can be be accounted for by the wave of capital-embodied technological change, which we also document. We propose a variety of mechanisms based on how technology increases the returns to education, ability, experience, and "luck" in the labor market. We also discuss how the wage distribution may have been indirectly influenced by technical change through changes in certain aspects of the organization of work, such as the hierarchical structure of firms, the extent of unionization, and the degree of centralization of bargaining. To account for the U.S.-Europe differences, we use a theory based on institutional differences between the United States and Europe, along with a common acceleration of technical change. Finally, we briefly comment on the implications of labor market inequalities for welfare and for economic policy.

Keywords: Inequality, Institutions, Labor Market, Skills, Technological Change.

1 Introduction

In this chapter we discuss the recent three decades of data on technology, productivity, and labor market outcomes. In particular, we explore the hypothesis that technological change has affected the labor market in various ways. We argue that (i) there is ample evidence indicating significant capital-embodied and/or skill-biased technological change and that (ii) this kind of technological change would plausibly lead to many of the transformations in the labor markets that we have observed. On the one hand, we are interested in possible implications of non-neutral technological change—of the kind we think we have experienced—on variables like wage inequality, unemployment, labor share, and unionization. On the other hand, we explore the possibility that the labor market can be used as an additional source of evidence of non-neutral technological change, a testing ground of sorts.

The past 30 years are particularly informative because they have contained rather important trend changes in several variables. We have seen a productivity slowdown common to all industrialized countries and common to almost all industries, together with continuing structural change away from manufacturing and toward services. An exception to this widespread productivity slowdown was the fast and accelerating productivity growth of in the industries producing investment goods, in particular those producing equipment. Only very recently has there been a more widespread acceleration of productivity growth. Of course, in this context we are arguably in the midst of an "Information Technology Revolution." We also discuss evidence of changes in the workplace—in how production within firms is organized—possibly reflecting underlying changes in technology.

In the labor market, we have seen a sharp increase in wage inequality in the United States contrasting a roughly flat development in Europe, whereas we have witnessed a strong increase in European unemployment and no trend in U.S. unemployment.[1] The organization of labor markets seems to have changed too: for example, unions have lost prevalence during this period, and to the extent there have been unions, centralized bargaining has been

[1] Although the word inequality literally would suggest a zero-one classification—either there is inequality or there is equality—we will use the term loosely to reflect some measure of dispersion. That is, we will attach quantifiers such as "more" or "less" to the word.

replaced by decentralized bargaining in many sectors. Are all these developments consistent with basic economic theory and a short list of underlying technological driving forces? We argue that they are. To make our argument more convincing, we also put the past three decades in a historical perspective, going back as far as the early 20th century with data on technological change and the skill premium.

One distinctive feature of this literature is that the many different ideas have been presented in a wide variety of theoretical frameworks ranging from the neoclassical Ramsey-Cass-Koopmans growth model to the Schumpeterian endogenous growth model; from the traditional McCall search model to the Lucas-Prescott island economy; from the Mortensen-Pissarides matching model to the competitive directed search framework; and from the Bewley-Aiyagari incomplete-markets model to Arrow-Debreu economies with limited enforcement. We think two main reasons exist for the lack of a unified framework of analysis. First, this field of research is still relatively young; second, departing from the competitive model in studying labor markets is fairly natural, and many alternative frameworks exist that incorporate frictions. The main drawback of the lack of a unifying framework—we will repeat it often in the chapter—is that making structurally based quantitative comparisons between different mechanisms is difficult.

To us, these heterogeneous approaches pose a formidable challenge in the exposition. Our solution has been to give priority to presenting a range of ideas, using a variety of theoretical setups, rather than to discuss in great detail a few more specific frameworks. This approach has necessitated a summarization of some rather rich models in a few key equations, which misses some of the elegance and richness of the original frameworks. We hope, however, that our spanning a wide spectrum of ideas and macroeconomic effects of technological change helps paint a picture that is broader and that, at least in an impressionistic way, suggests that the main underlying hypothesis we are proposing is quite reasonable.

The presentation of the ideas in this chapter is organized into four parts. In the first part, Section 2, we review the main trends in the data on technological change and labor market inequalities. We then cover two kinds of theories that could account for the data.

In the second part of the chapter we cover "neoclassical" theory (i.e., models where wages directly reflect marginal productivity). We view the firm as hiring labor of different skill levels in a competitive and frictionless labor market. Wages, thus, will be influenced by technology in a very direct way. Similarly, the returns to education, ability, and experience, which we discuss in detail in Sections 3 and 4, respectively, will be directly tied to changes in technology. Therefore, within these kinds of theories, the shape of the production function of the firm is crucial. We then move beyond the production function of the firm or, rather, we attempt to go inside it. In particular, Section 5 explores the possibility that the organization of the workforce also has changed within firms. These transformations, of which there is some documentation, are arguably also a result of the kind of technological change we look at in this chapter. We point, in particular, to a recent literature that explores how firms are organized and how the IT revolution, by inducing organizational changes in the firm, had a substantial impact on wage inequality.

The second class of theories we cover, in the third part of the chapter, relies more on frictions in the labor market and deals more directly with how this market is organized. Here, technological change can still directly influence wages but there are new channels. For one, wages may not only reflect marginal productivity. Moreover, now unemployment is more in focus and is a function of technology, and since unemployment—through workers' outside option—may also feed back into wages, the picture becomes yet more complex. In the context of how wages are set, we furthermore argue in Section 6 that the importance of unions and their modus operandi are influenced by technology and, more generally, that labor income as a share of total income may respond to technological change in the presence of unions. An important point that we make in Section 7 is that "luck" can be a key part of wage outcomes for individuals active in a labor market with frictions, such as the search/matching frameworks, and that the "return to luck" can be greatly affected by technology as well. Finally, government participation in labor markets—labor-market "institutions," in the form of unemployment benefits, firing costs, and so on—likely interacts with technology in determining outcomes, and Section 8 completes the third part of this chapter

by analyzing the interaction between technological shocks and labor market institutions in the context of the comparison between the United States and Europe.

The fourth and final part of the chapter asks the "So what?" question: given the significant transformations observed, is a government policy change called for? Our discussion here is very brief. It mainly points out that a basic element underlying any decisions on policy, namely, what the welfare outcomes of the changes in wages, unemployment, and so on, are for different groups in society, is studied only partially in the literature so far. Studies of changes in expected lifetime income of different groups exist, but it is reasonable to assume that risk matters too, especially with trend changes as large as those observed (at least to the extent they are hard to foresee and insure). In Section 9, we therefore cover some examples of more full-fledged attempts to look at the distribution of consumption and welfare outcomes of the changes in technology/labor market outcomes. Finally, Section 10 concludes the chapter.

2 A Look at the Facts

Before modelling the economic forces that connect changes in technology to labor market outcomes, it is useful to begin by summarizing how labor market inequalities and the aggregate technological environment evolved over the past three decades.

2.1 Labor Market Inequalities

In the late 1980s and early 1990s, an extensive body of empirical work has started to systematically document the changes in the U.S. wage structure over the past three decades. Levy and Murnane (1992) give the first overview of an already developed empirical literature. To date, Katz and Autor (1999) and, more recently, Eckstein and Nagypal (2004), offer the most exhaustive description of the facts. In between, numerous other papers have contributed significantly to our understanding of the data on wage inequality.[2]

[2]We refer the reader to the bibliographic lists in Levy and Murnane (1992), Katz and Autor (1999), and Eckstein and Nagypal (2004) for more details.

The typical data source used in the empirical work on the subject is the sequence of yearly cross-sections in the March *Current Population Survey (CPS)*. The other important data source is the longitudinal *Panel Study of Income Dynamics (PSID)*. In this section, we limit ourselves to stating the main facts and briefly commenting on them, omitting the details on the data sets, the sample selection, and the calculations that can be found in the original references. Unless otherwise stated, the data refer to a sample of male workers with strong attachment to the labor force, i.e., full-time, full-year workers.[3]

Observation 1 Wage inequality in the United States is today at its historical peak over the post World War II period. However, early in the century it was even larger. The returns to college and high school fell precipitously in the first half of the century and then rose again until now (Goldin and Katz, 1999).

In other words, the time series for inequality over the past 100 years is "U-shaped." Although the bulk of this chapter is devoted to interpreting the dynamics of the wage structure over the past three decades, it is useful to put the evidence in a historical perspective to appreciate that the high current level of inequality is not a unique episode in U.S. history. The rest of the facts characterize the evolution of inequality since the mid 1960s.[4]

Observation 2 Wage inequality increased steadily in the United States starting from the early 1970s. The 90-10 weekly wage ratio rose by 35 percent for both males and females in the period 1965-1995: from 1.20 to 1.55 for males, and from 1.05 to 1.40 for females. The increase in inequality took place everywhere in the wage distribution: both the 90-50 differential and the 50-10 differential rose by comparable amounts (Katz and Autor, 1999).

[3]Eckstein and Nagypal (2004) systematically document all the facts for males and females separately. Typically, measures of inequality in the literature refer to hourly or weekly wages, that is, they isolate the evolution of the "price" of certain labor market skills. The use of hourly or weekly wages then avoids the contamination of the data with endogenous labor supply decisions that, for example, is present in annual earnings.

[4]In Section 5, we return briefly to this historical pattern. In passing, we note that the data seems at odds with the so-called "Kuznets Hypothesis," i.e., the conjecture that income inequality first increases and then decreases as economies grow.

Qualitatively, the rise in inequality is present independently of the measure of dispersion and of the definition of labor income. For example, the standard deviation of log wages for males rose from 0.47 in 1965 to 0.62 in 1995, the Gini coefficient jumped from 0.25 to 0.34 (Katz and Autor, 1999), and the mean-median ratio rose from 1.00 to 1.18 over the same period (Eckstein and Nagypal, 2004). Inequality of annual earnings increased even more.[5]

Observation 3 The average and median wage have remained constant in real terms since the mid-1970s. Real wages in the bottom of the wage distribution have fallen substantially. For example, the 10th wage percentile for males declined by 30 percent in real terms from 1970 to 1990 (Acemoglu, 2002a).[6] On the contrary, salaries in the very top of the wage distribution have grown rapidly. In 1970, the workers in the top 1 percent of the wage distribution held 5 percent of the U.S. wage bill, whereas in 1998 they received over 10 percent (Piketty and Saez, 2003).

A large part of the absolute increase of top range salaries is associated with the surge in CEO compensation. Piketty and Saez (2003) document that in 1970 the pay of the top 100 CEOs in the United States was about 40 times higher than the average salary. By 2000 those CEOs earned almost 1,000 times the average salary.

We now list a set of facts on the evolution of *between-group* inequality, i.e. inequality between groups of workers classified by observable characteristics (e.g., gender, race, education, experience, occupation). For this purpose, it is useful to write wages w_{it} using the Mincerian representation

$$\ln w_{i,t} = X'_{i,t} p_t + \omega_{it}, \tag{1}$$

where X_{it} is a vector measuring the set of observable features of individual i at time t, p_t can be interpreted as a vector of prices for each characteristic in X, and ω_{it} is the residual unobserved component.

[5]The reason is, perhaps surprisingly, not a rise in the cross-sectional variance of hours worked, but rather a substantial increase in the wage-hours correlation over the past 30 years. See Heathcote et al. (2003) for an account of these facts.

[6]Note, however, that the wages of the 10th wage percentile have started to increase again since the late 1990s (Eckstein and Nagypal, 2004).

Observation 4 The returns to education increased slightly from 1950 to 1970, fell in the 1970s, increased sharply in the 1980s, and continued to increase, although at a slower pace, in the 1990s. For example, the college wage premium—defined as the ratio between the average weekly wage of college graduates (at least 16 years of schooling) and that of workers with at most a high school diploma (at most 12 years of schooling)—was 1.45 in 1965, 1.35 in 1975, 1.50 in 1985, and 1.70 in 1995 (Eckstein and Nagypal, 2004). If one estimates the coefficient on educational dummies in a standard Mincerian wage regression like (1), the finding is similar: the annual return to a college degree (relative to a high-school degree) was 33 percent in the 1980s and over 50 percent in the 1990s (Eckstein and Nagypal 2004).

We plot the college wage premium over the period 1963-2002 in Figure 1 (top panel).[7] Interestingly, if one slices up the college-educated group more finely into workers with post-college degrees and workers with college degree only, the rise in the skill premium is still very apparent. The return to post-college education relative to college education doubled from 1970 to 1990 (Eckstein and Nagypal 2004).

FIGURE 1

Observation 5 The returns to professional and white-collar occupations relative to blue-collar occupations display dynamics and magnitudes similar to the data stratified by education. For example, the professional-blue collar premium rose by 20 percent from 1970 to 1995 (Eckstein and Nagypal 2004).

Occupation is an interesting dimension of the wage structure that, until recently, received very little attention. For example, the "returns to occupation" appear large and significant, over and beyond returns to education. We discuss the theories of wage inequality that stress the changes in occupational structure in Section 7.

[7] Authors differ in their treatment of workers who have attended college for some years, but did not obtain a college degree. In Figure 1 (top panel), we have followed the bulk of the literature and assigned half of them to the numerator and half of them to the denominator (e.g., Autor et al. 1998).

Observation 6 The returns to experience increased in the 1970s and the 1980s and leveled off in the 1990s. For example, the ratio of weekly wages between workers with 25 years of experience and workers with 5 years of experience rose from 1.3 in 1970 to 1.5 in 1995 (Katz and Autor, 1999). An analysis by education group shows that the experience premium rose sharply for high-school graduates but remained roughly constant for college graduates (Weinberg, 2003b).

It is worth emphasizing, that although entry of the baby-boomers into the labor market in the early 1970s had a significant impact on the experience premium, the dynamics described above are robust to this and other demographic effects. See for example, Juhn et al. (1993).[8]

Observation 7 Inequality across race and gender declined since 1970. The black-white race differential, for workers of comparable experience, fell from 35 percent in 1965 to 20 percent in 1990 (Murphy and Welch, 1992). The female-male wage gap fell from 45 percent in 1970 to 30 percent in 1995 (Katz and Autor, 1999).

We plot of the gender wage gap over the period 1963-2002 in Figure 1 (bottom panel). A unifying theory of the changes in the wage structure based on technological change should have something to say about gender as well as race. Admittedly, these two dimensions of inequality have been largely neglected by the literature. We return briefly to the gender gap in Section 4.

Observation 8 The composition of the working population changed dramatically over the past 40 years: in the period 1970-2000, women's labor force participation rate rose from 49 percent to 73 percent; college graduates rose from 15 to 30 percent of the male labor force and from 11 to 30 percent of the female labor force; professionals soared from 24 to 33 percent of the male labor force and from 8 to 28 percent of the female labor force (Eckstein and Nagypal, 2004).

[8]More recently, however, Card and Lemieux (2001) have argued in support of some "vintage effects" in the return to education. In particular, they argue that the college-high school premium is somewhat larger among the most recent cohorts of young workers entering the labor market.

We plot the relative supply of skilled workers and female workers over the time period 1963-2002 in Figure 1 (top and bottom panel, respectively).[9]

In terms of equation (1) , one can define the between-group component of wage inequality as the cross-sectional variance of $X'_{it}p_t$, and the within-group component as the variance of the residual ω_{it}. The fraction accounted for by observable characteristics, in turn, can be decomposed into what is caused by a change in the dispersion in the quantities of observable characteristics (X_{it}), for given vector of prices, and what is due to a change in the prices associated to each observable characteristic (p_t), for a given distribution of quantities.

Observation 9 Overall, changes in quantities and prices of observable characteristics (gender, race, education, experience) explain about 40 percent of the increase in the variance of log wages from 1963 to 1995. The price component is by far larger than the quantity component. Increasing *within-group inequality*, i.e., wage dispersion within cells of "observationally equivalent" workers accounts for the residual 60 percent of the total increase. With respect to the timing, the rise in within-group inequality seems to anticipate that of the college premium by roughly a decade (Juhn et al. 1993).[10]

One can specify further the structure of the residual ω_{it} of equation (1), for example as

$$\omega_{it} = \phi_t \alpha_i + \varepsilon_{it},$$

where α_i is the permanent part of unobservable skills (e.g., "innate ability"), ϕ_t is its time-varying price, and ε_{it} is the stochastic component due to earnings shocks whose variance is also allowed to change over time. If one is prepared to assume that the distribution of innate ability in the population is invariant, then with the help of panel data one can separate the rise in the return to ability from the increase in the volatility of transitory earnings shocks.

Observation 10 Around one-half of the rise in residual earnings inequality is explained by the permanent components (e.g., a higher return to ability), with the rest accounted

[9]Skilled and unskilled labor are defined as in footnote 7.

[10]Notice that, typically, occupation is excluded from these regressions. Including occupation would reduce the fraction of unexplained wage variance.

for by transitory earnings shocks (Gottschalk and Moffitt 1994).[11]

Interestingly, the rise in the transitory component is not due to higher job instability or labor mobility (Neumark, 2000), but rather to more volatile wage dynamics, in particular faster wage growth on the job and more severe wage losses upon displacement (Violante 2002).

In Table 1 we report some key numbers on unemployment, wage inequality, and labor income shares for several OECD countries at five-year intervals from 1965 to 1995. We are particularly interested in the comparison between the United States and *continental* European countries (averaged in the row labeled Europe Average). For completeness, we include data for the United Kingdom and Canada, whose behavior falls somewhere between that of the United States and continental Europe.

TABLE 1

Observation 11 The time pattern of wage inequality over the past 30 years differs substantially across countries. The U.K. economy had a rise in wage inequality similar to that in the U.S. economy, except for the fact that the average real wage in the United Kingdom has kept growing (Machin 1996). Continental European countries had virtually no change in wage inequality, whereas over the same period they had large increases in their unemployment rates (roughly, all due to longer unemployment durations) and a sharp fall in the labor income share in GDP. On the contrary, in the United States both the unemployment rate and the labor share have remained relatively constant (Blanchard and Wolfers, 2000).

In 1965 the unemployment rate in virtually every European country was lower than in the United States. Thirty years later, the opposite was true: the U.S. unemployment rate rose only by 1.7 percent from 1965 to 1995, whereas the average unemployment rate increase of European countries was 8.4 percent.[12]

[11]Note that a rise in the return on ability does generate an increase in cross-sectional variation of wages because it multiplies individual ability in the log-wage Mincerian equation.

[12]Notice, however, that in the United States non-participation of the low-skilled males rose from 7 percent to 12 percent from the early 1970s to the late 1990s (Juhn, 1992 and Murphy and Topel, 1997).

The labor income share has declined only marginally in the United States—by 1.5 percentage points from 1965 to 1995—while on average it fell by almost 6 points in Europe. Wage inequality, measured by the percentage differential between the ninth and the first earnings deciles for male workers, rose only slightly in Europe by 4 percent in the period from 1980 to 1995, and it even declined in some countries (Belgium, Germany, and Norway). Recall that, over the same period, earnings inequality surged in the United States: the OECD data show a rise of almost 30 percent, close to the numbers we reported earlier in this section.

Interestingly, the European averages hide much less cross-country variation than one would expect, given the raw nature of the comparison. For example, in 11 out of the 14 continental European countries, the increase in the unemployment rate has been larger than 6 percentage points, and in 9 countries the decline in the labor share has been greater than 5 percentage points.

Recently, Rogerson (2004) has argued that if one focuses on *employment* rate differences between the United States and Europe rather than on unemployment rate differences, a new set of insights emerges from the data. Employment rates in the United States start to increase relative to European employment rates twenty years before the divergence in unemployment rates. Moreover, the increase in European unemployment rates is correlated with the decline of European manufacturing employment.

2.2 Technological Change

The standard measure of aggregate technological change, total factor productivity (TFP), does not distinguish between the different ways in which technology grows. First, technology growth may differ across final-output sectors and second, it may have different effects on the productivity of different input factors. The recent experience of developed countries, however, seems to suggest that in the past 30 years technological change has originated in particular sectors of the economy and has favored particular inputs of production.

Arguably, the advent of microelectronics (i.e., microchips and semiconductors) induced a sequence of innovations in information and communication technologies with two features.

First, *sector-specific* productivity (SSP) growth substantially increased the productivity of the sector that produces new capital equipment, making the use of capital in production relatively less expensive. Second, *factor-specific* productivity (FSP) growth favored skilled and educated labor disproportionately. In other words, the recent technological revolution has affected the production structure in a rather asymmetric way.

Our assessment of the importance of SSP and FSP changes relies heavily on observed movements in relative prices. For SSP change, we rely on the substantial decline of the price of equipment capital relative to the price of consumption goods, a process that does not show any sign of slowing down. On the contrary, it shows an acceleration in recent years. For FSP change, we rely on the substantial increase in the wage of highly educated workers relative to less educated workers, the skill premium.

We first review the Solow growth accounting methodology for TFP within the context of the one-sector neoclassical growth model and then introduce SSP accounting and how it applies to the idea of capital-embodied technical change.[13] Next, we discuss how an acceleration of capital-embodied technical change might relate to the much-discussed TFP growth slowdown in the '70s and '80s; here, we discuss the possible relevance of the concept of General Purpose Technologies (GPTs). Finally, we explain the mapping between relative wages and FSP changes.

2.2.1 Total Factor Productivity Accounting

Standard economic theory views production as a transformation of a collection of inputs into outputs. We are interested in how this production structure is changing over time. At an aggregate *National Income and Product Accounts* (NIPA) level we deal with some measure of aggregate output, y, and two measures of aggregate inputs: capital, k, and labor, l. The production structure is represented by the production function, F: $y = F(k, l, t)$. Since the production structure may change, the production function is indexed by time, t. Aggregate total factor productivity changes when the production function shifts over time, i.e., when

[13] Our presentation is instrumental to the discussion of the impact of technological change on labor markets, and hence it is kept to the bare minimum. Jorgenson's (2004) chapter of this Handbook provides an exhaustive treatment of traditional and modern growth accounting.

there is a change in output which we cannot attribute to changes in inputs. More formally, the marginal change in output is the sum of the marginal changes in inputs, weighted by their marginal contributions to output (marginal products), and the shift of the production function, $\dot{y} = F_k\dot{k} + F_l\dot{l} + F_t$.[14] This is usually expressed in terms of growth rates as

$$\hat{y} = \eta_k\hat{k} + \eta_l\hat{l} + \hat{A}, \text{ with } \hat{A} = F_t/F, \tag{2}$$

where hats denote percentage growth rates, and the weight on an input growth rate is the elasticity of output with respect to the input: $\eta_k = F_k k/F$ and $\eta_l = F_l l/F$. Alternatively, if we know the elasticities, we can derive productivity growth as output growth minus a weighted sum of input growth rates.

Solow's (1957) important insight was that, under two assumptions, we can replace an input's output elasticity—which we do not observe—with the input's share in total revenue, for which we have observations. First, we assume that production is constant returns to scale, i.e., that if we are to double all inputs, then output will double, implying that the output elasticities sum to one: $\eta_k + \eta_n = 1$. Second, we assume that producers act competitively in their output and input markets, i.e., that they take the prices of their products and inputs as given. Profit maximization then implies that inputs are employed until the marginal revenue product of an input is equalized with the price of that input. In turn, this means that the output elasticity of an input is equal to the input's revenue share. For example, for the employment of labor, profit maximization implies that $p_y F_l = p_l$, which can be rewritten as $\eta_l = F_l l/F = p_l l/p_y y = \alpha_l$ (p_i stands for the price of good i). With these two assumptions, we can calculate aggregate productivity growth, also known as total factor productivity (TFP) growth, as

$$\hat{A} = \hat{y} - (1 - \alpha_l)\,\hat{k} - \alpha_l\hat{l}. \tag{3}$$

The Solow growth accounting procedure has the advantage that its implementation does not require very stringent assumptions with respect to the production structure, except con-

[14] The marginal change of a variable is its instantaneous rate of change over time; that is, if we write the value of a variable at a point in time as $x(t)$, then the marginal change is the time derivative, $\dot{x}(t) = \partial x(t)/\partial t$. Nothing is lost in the following if the reader interprets $\dot{x}(t)$ as the change of a variable from year to year; that is, $x(t) - x(t-1)$.

stant returns to scale, and it does not require any information beyond measures of aggregate output and input quantities and the real wage. This relatively low information requirement comes at a cost: this aggregate TFP measure does not provide any information on the specific sources or nature of technological change.

Given available data on quantities and prices for industry outputs and inputs, it is straightforward to apply the Solow growth accounting procedure and obtain measures of sector-specific technical change (see, for example, Jorgenson et al., 1987). Recently Jorgenson and Stiroh (2000) have documented the substantial differences in output and TFP growth rates across U.S. industries over the period 1958-1996. In particular, they point out that TFP growth rates in high-tech industries producing equipment investment are about three to four times as high as a measure of aggregate TFP growth. Also based on industry data, Oliner and Sichel (2000) and Jorgenson (2001) attribute a substantial part of the increase of aggregate TFP growth over the second half of the 1990s to one industry: semi-conductors.

2.2.2 Sector-Specific Productivity Accounting

The convincing evidence for persistent differences of SSP growth raises the potential of serious aggregation problems for the analysis of aggregate outcomes. We now discuss SSP accounting in a simple two-sector growth model that focuses on the distinction between investment and consumption goods. This approach provides a straightforward measure of SSP growth, and it keeps the aggregation problems manageable. Based on this approach, we present evidence of substantial increases of the relative productivity in the equipment-investment goods producing industries and stagnant productivity in the consumption goods industries since the mid 1970s.

Greenwood et al. (1997) use a two-sector model of the economy—where one sector produces consumption goods and the other new capital—to measure the relative importance of total-factor productivity changes in each of these sectors. Goods —consumption, c and new capital, x—are produced using capital and labor as inputs to constant-returns-to-scale technologies,

$$c = A_c F(k_c, l_c) \text{ and } x = A_x F(k_x, l_x); \tag{4}$$

and total factor inputs can be freely allocated across sectors,

$$k_c + k_x = k \text{ and } l_c + l_x = l. \tag{5}$$

Note that we have assumed that factor substitution properties are the same in the two sectors; that is, the functions relating inputs to outputs are the same. One can show that with identical factor substitution properties, the two-sector economy is equivalent to a one-sector economy with exogenous changes in the relative price of investment goods, $1/q$

$$y = c + x/q = A_c F(k, l). \tag{6}$$

In particular, the relative price of investment goods is the inverse of the relative productivity advantage of producing new capital goods:[15]

$$q = A_x/A_c. \tag{7}$$

The relative productivity of the investment goods sector is also called "capital-embodied" technical change, because q can be interpreted as the productivity level (quality) embodied in new vintages of capital.[16]

Accounting for quality improvements in new products is a basic problem of growth accounting.[17] This is especially true for our framework since we measure investment in terms of constant-quality capital goods. In a monumental study, Gordon (1990) constructed quality-adjusted price indexes for different types of producers' durable equipment. Building on Gordon's work, Hulten (1992), Greenwood et al. (1997), and Cummins and Violante (2002) have derived aggregate time series for capital-embodied technical change in the U.S. economy.[18] They use the property just described: that the constant-quality price of investment

[15] Jorgenson (2004), in this handbook, labels this methodology, where *relative productivity* growth is measured off the decline in relative prices, the "price approach" to growth accounting.

[16] Define investments in consumption units as $i = x/q$. Then, the aggregate resource constraint reads

$$c + i = A_c F(k, l),$$

and the law of motion for capital in efficiency units is $k' = (1 - \delta) k + iq$.

[17] See this Handbook's chapter by Bils and Klenow (2004) on the measurement of quality for an overview of the different approaches.

[18] Hulten's series strictly uses Gordon's data and therefore spans until 1983. Greenwood et al. extend

relative to consumption (precisely, nondurable consumption and services) reveals the extent of productivity improvements. Their main finding is that:

Observation 12 Productivity growth in the sector producing equipment investment has accelerated relative to the rest of the economy since the early to mid-1970s.

The solid line in Figure 2 shows the relative productivity of the equipment investment goods sector, q, for the period 1947-2000, normalized to 1 in the first year. This index grows at an annual rate of about 1.6 percent until 1975 and at an annual rate of 3.6 percent thereafter. In the 1990s, productivity growth embodied in capital has been spectacularly high, reaching an average annual rate just below 5 percent.

FIGURE 2

The measurement of SSP growth through changes in relative prices requires that the price measures used are appropriately adjusted for quality improvements, presenting a problem for the time period studied since, arguably, the IT revolution has caused large improvements in the quality of durable goods and has led to the introduction of a vast range of new items. Therefore, alternative ways of measuring capital-embodied productivity advancements have been proposed. Hobijn (2000) calculates the rate of embodied technical change by calibrating a vintage capital model. His findings are very similar to the price-based approach, both in terms of the average growth rate, and in terms of the timing of the technological acceleration. Bahk and Gort (1993) and Sakellaris and Wilson (2004) use plant-level data to estimate production functions and assess the productivity effects of new investments. They estimate the growth rate of capital-embodied technical change to be between 12 and 18 percent per year, much higher than the rest of the literature.

Gordon's index to 1992 by applying a constant adjustment factor to the National Income and Product Accounts (NIPA) official price index. Cummins and Violante update the series to 2000. Starting with Gordon's quality-adjusted price indexes for a variety of equipment goods from 1947 to 1983, they estimate the quality bias implicit in the NIPA price indexes for that period. Using the official NIPA series, they then extrapolate the quality bias from 1984 to 2000 for each equipment type and aggregate into an index for equipment and structure.

We calculate the rate of SSP change in the consumption goods sector based on the standard Solow approach. It is well known that the U.S. labor income share in GDP has been remarkably stable for the time period considered. We therefore choose a Cobb-Douglas parametric representation of the production function,

$$y = A_c k^{\alpha} l^{1-\alpha}, \tag{8}$$

with labor income share, $1 - \alpha = 0.64$ (Cooley and Prescott 1995). Conditional on observations for real GDP (in terms of consumption goods), the real capital stock, and employment, we can use this expression to solve for the SSP of the consumption sector A_c.[19] The common finding from this computation, as evident from the dashed line in Figure 2, is

Observation 13 Productivity in the sector producing consumption goods (precisely, non-durable and services) shows essentially no growth over the two decades 1975-1995.

The approach of Greenwood et al. (1997) defines aggregate output in terms of consumption goods. This is rather non-standard. The usual approach, especially as applied to the study of SSP, defines aggregate output growth as a revenue-weighted sum of sectoral output growth rates: a Divisia index (see, e.g., Jorgenson 2001, or Oliner and Sichel 2000). For this more standard approach, one can write aggregate TFP growth as the revenue-weighted sum of sectoral TFP growth. While the Divisia-aggregator approach is a definition with some desirable properties, the Greenwood et al. (1997) approach is based on a particular theory and requires certain identifying restrictions concerning the production structure. Hall (1973) shows that in multi-sector models a unique output aggregator, that is, a function that relates some measure of aggregate output to some measure of aggregate input, exists if

[19] It is important to adjust the capital and labor input measure for quality change. As pointed out above, quality adjustment of investment is useful so as to capture investment-specific technical change. The capital stock is then calculated as the cumulative sum of past undepreciated constant-quality investment. From our discussion of wage inequality it follows that the labor input needs to be adjusted for two reasons. First, the skill premium has been increasing since the mid-1970s, and thus the productivity of skilled labor, A_s, is increasing faster than the productivity of unskilled labor, A_u. Second, at the same time, the relative supply of skilled labor has been increasing, inducing large changes in the composition of the stock of labor. To account for quality changes, we use the labor input index computed by Ho and Jorgenson (1999). The dotted line in Figure 2 plots this quality index for labor which grows at an average rate of 0.8% per year.

certain separability conditions for the aggregate production possibility frontier are satisfied. The conditions for such an output aggregator to exist are, essentially, the ones imposed by Greenwood et al. (1997).[20] Given the definition of aggregate output in equation (6), SSP for consumption, or A_c, is then sometimes interpreted as neutral, or disembodied, aggregate technological change.

2.2.3 Reconciling the Acceleration in Investment-Specific Productivity Growth with the Slowdown in TFP: General Purpose Technology and Learning

The stagnation of aggregate TFP since the mid-1970s—evident from Figure 2—accounts for the phenomenon often referred to as a "productivity slowdown" in the growth accounting literature.[21] How can we reconcile the acceleration of investment SSP with a slowdown of consumption SSP? One interpretation builds on learning-by-doing (LBD). New investment goods do not attain their full potential as soon as they are introduced but, rather, their productivity can stay temporarily below the productivity of older capital that was introduced same time ago. This feature is attributed to learning effects.[22]

These learning effects can be extremely important when the technological change is "drastic." Recent discussions suggest that the advent of microelectronics led to a radical shift in the technological paradigm, i.e., to a new "general purpose technology" (GPT). Bresnahan and Trajtenberg (1995) coined this term to describe certain major innovations that have the potential for pervasive use and application in a wide range of sectors of the economy. David (1990) and Lipsey et al. (1998) cite the microchip as the last example of such innovations that included, in ancient times, writing and printing and, in more recent times, the steam-engine and the electric dynamo.[23] Although it is hard to define the concept satisfactorily,

[20]For further details on this issue, see Hornstein and Krusell (2000).

[21]Since non-equipment investment represents more than three-fourths of GDP, the slowdown of consumption SSP change accounts for most of the slowdown of aggregate TFP change.

[22]The literature on learning effects is large. Lucas (1993) discusses the classic example of LBD related to the construction of the liberty ships of World War II. Bahk and Gort (1993) measure substantial LBD effects at the plant level. Irwin and Klenow (1994) present evidence of LBD in the production of semiconductors. Jovanovic and Nyarko (1995) document learning curves in several professions. Huggett and Ospina (2001) find evidence that the effect of a large equipment purchase is initially to reduce plant-level total factor productivity growth.

[23]Gordon (2000) offers a dissenting view on the issue of whether or not information technologies measure up to the great inventions of the past. In his view, the aggregate productivity impact of computers

given available data, we list as a "fact" the dominant view, which maintains that:

Observation 14 Technological change in the past 30 years displays a "general purpose" nature.

Though most of the evidence supporting this statement is anecdotal, there are some bits of hard evidence. Hornstein and Krusell (1996) document that the decline in TFP occurred roughly simultaneously across many developed countries. More recently, Cummins and Violante (2002) construct measures of productivity improvements for 26 different types of equipment goods. Using the sectoral input-output tables, they aggregate these indexes into 62 industry-level measures of equipment-embodied technical change, and document that their growth rate has accelerated by a similar amount in virtually every industry in the 1990s. Jovanovic and Rousseau (2004a) draw an articulated parallel between the diffusion of electricity in the early 20th century and the diffusion of information technologies (IT) eighty years later based on a variety of data. Their evidence supports the view that both episodes marked a drastic discontinuity in the historical process of technological change. Taken together, all these observations suggest that, similar to other past GPTs, IT has affected productivity in a general way over the past three decades.

There are two versions of the argument that IT are responsible for the observed productivity slowdown. According to one, the slowdown is real: when learning-by-doing is important in improving the efficiency of a production technique, abandoning the older, but extensively used technology to embrace a new method of production involves a "step in the dark" that can lead to a temporary slowdown in labor productivity (Hornstein and Krusell, 1996, Greenwood and Yorukoglu, 1997, and Aghion and Howitt, 1998, chapter 8).

An alternative, complementary version maintains that the slowdown is a statistical artifact due to mismeasurement: if the phase of IT adoption coincides with associated investments in organizational or intangible capital, as our Section 5 will suggest, then insofar as these investments are not included in the official statistics, measured TFP growth will first

and telecommunications equipment has been fairly small compared to, say, the telegraph, the railroad, or electricity.

underestimate and then overestimate "true" TFP growth (Hall, 2001, and Basu et al. 2003). The reason is that initially, when large investments in organizational capital are made, the "output side" of the mismeasurement is severe. Later, when the economy has built a significant stock of organizational capital, the "input side" of mismeasurement becomes dominant.

This explanation of the TFP slowdown is appealing, but extremely difficult to evaluate quantitatively because of the lack of direct evidence on how organizations learn. Using some theory, Hornstein (1999) argues that one key parameter is the fraction of knowledge that firms can transfer from the old to the new technology but also shows that the model's predictions vary significantly across plausible parameterizations. Atkeson and Kehoe (2002) build an equilibrium model to measure the dynamics of organizational capital during the "electrification of America". They criticize the Bahk and Gort (1993) view that organizational learning is reflected into an increase in the productivity of labor at the plant level: in an equilibrium model where labor is mobile, productivity is equalized across plants. Instead, they argue that when organizations learn they expand in size. Thus, cross-sectional microdata on the size distribution of plants allows to identify the structural parameters of the stochastic process behind organizational learning.

Finally, Manuelli (2000) argues that, even in absence of learning effects, the anticipation of a future technological shock embodied in capital can result in a transitional phase of slowdown of economic activity. In the period between the announcement and the actual availability of the new technology, the existing firms prefer exercising the option of waiting to invest and the new firms prefer delay entering. Consequently, output falls temporarily until the arrival of the new technology.[24]

2.2.4 Factor-Specific Productivity Accounting

In order to talk about changes in FSP, one possibility is to generalize the production function in equation (8) by disaggregating the contributions to production of the two labor inputs—skilled (e.g., more educated) and unskilled (e.g., less educated) labor. Suppose the aggregate

[24]We refer the reader to Hornstein and Krusell (1996) for a list of alternative explanations of the TFP slowdown that are not based on changes in technology.

labor input, l, is a CES function of skilled and unskilled labor, l_s and l_u, with FSPs A_s and A_u:

$$l = \left[(A_s l_s)^{\sigma} + (A_u l_u)^{\sigma} \right]^{1/\sigma}, \ \sigma \leq 1. \tag{9}$$

Relative wage data can then be employed to understand the nature and evolution of FSP in the economy. With competitive input markets, the relative wages are a function of the relative FSP and the relative labor supply:

$$\ln \left(\frac{w_s}{w_u} \right) = \sigma \ln \left(\frac{A_s}{A_u} \right) - (1 - \sigma) \ln \left(\frac{l_s}{l_u} \right). \tag{10}$$

The elasticity of substitution between skilled and unskilled labor here is $1/(1-\sigma)$. Katz and Murphy (1992) run a simple regression of relative wages on relative input quantities and a time trend to capture growth in the ratio $\frac{A_s}{A_u}$. They measure skilled labor input as total hours supplied to the market by workers with at least a college degree. Their estimate of the substitution elasticity—around 1.4 (or $\sigma = 0.29$)—indicates that a ten-percent increase in the relative supply of skilled labor implies a seven percent decline of the skill premium.[25] The estimated elasticity of substitution between factors, together with the growing skill premium, imply an increase in the relative FSP of skilled labor in excess of 11 percent per year. We conclude that the typical result of similar exercises on U.S. data is that:

Observation 15 Recent technological advancements have been favorable to the most skilled workers in the population. In other words, technical change has been *skill-biased*.

The "acceleration" in the rate of capital-embodied technical change, the "general purpose" nature of the new wave of technologies, and the "skill-biased" attribute of the recent productivity advancements are the three chief features of the new technological environment that seems to have emerged since the early to mid 1970s. The various economic theories that we are about to review in the rest of this chapter are built on various combinations of these features.

[25]The estimated input elasticity of about 1.4 is consistent with a large empirical literature on factor substitution that uses a wide array of data sets (time series as well as cross-section) and methods; see, e.g., Hamermesh (1993).

3 Skill-Biased Technical Change: Inside the Black Box

As we have just observed, the pattern of relative quantities of skills measured by education suggest that the behavior of the skill premium, that is, the increase in the wages of highly educated workers relative to those of less educated workers, should be attributed to a skill-biased labor demand shift, or to "skill-biased technical change." In the absence of a factor-bias in technological progress, the upward trend in the supply of skills documented in Figure 1 (top panel) would have reduced the skill premium.

Katz and Murphy (1992) were the first to use a production framework with limited substitution between skilled and unskilled labor to recover changes in relative FSP from changes in the skill premium. One should note a substantial drawback of the pure skill-biased technical change hypothesis: it is based on *unobservables* (relative FSP changes) that are measured residually from equation (10), so very much like TFP, it is a "black box". In this section we review the attempts to give some specific economic content to the notion of skill-biased technical change.

We start from the capital-skill complementarity conjecture advanced originally by Krusell et al. (2000). Next, we analyze models based on the Nelson-Phelps hypothesis: the adoption phase of a new technology requires skilled and educated workers. If one allows for an important role of FSP changes, then it is paramount to understand what economic forces induce these changes endogenously. In this context, we review the theory of "directed technical change" associated mainly to the work by Acemoglu (2002b, 2003b): exogenous spurts in the relative supply of skilled labor can induce the introduction of skill-biased technological advancements by affecting the incentives of the innovators.

3.1 Capital-Skill Complementarity

Krusell et al. (2000; KORV henceforth) argue that the dynamics of SSP that induced the substantial drop in the relative price of equipment capital is the force behind the rise in the skill premium. The decline in the price of equipment due to productivity improvements, especially that embodied in information and communication technologies, led to an increased

use of equipment capital in production. KORV observe that, at least since Griliches (1969), various empirical papers support the idea that skilled labor is relatively more complementary to equipment capital than is unskilled labor. As a result, the higher capital stock increased skilled wages relatively more than unskilled wages. Consequently, the skill premium increased.

Thus, the key elements in KORV's analysis are: 1) separating the effect of equipment capital from that of other capital, mainly structures, 2) allowing equipment to have different degrees of complementarity with skilled and unskilled labor, 3) measuring the efficiency units of capital, especially the new technologies, correctly.[26]

KORV capture the differential complementarity between capital and skilled and unskilled labor using the following nested CES production function of four inputs: structures, k_s; equipment, k_e; skilled labor, l_s; and unskilled labor, l_u:

$$y = k_s^{\alpha}\left[\lambda\left[\mu\left(A_{k_e}k_e\right)^{\rho} + (1-\mu)\left(A_s l_s\right)^{\rho}\right]^{\sigma/\rho} + (1-\lambda)\left(A_u l_u\right)^{\sigma}\right]^{\frac{1-\alpha}{\sigma}}, \tag{11}$$

with $\rho, \sigma \leq 1$. Profit-maximizing behavior of a price-taking firm implies that the skill premium can be approximately written as

$$\ln\left(\frac{w_s}{w_u}\right) \simeq \sigma \ln\left(\frac{A_s}{A_u}\right) - (1-\sigma)\ln\left(\frac{l_s}{l_u}\right) + \lambda\frac{\sigma-\rho}{\rho}\ln\left(\frac{k_e}{l_s}\right)^{\rho}. \tag{12}$$

KORV estimate $\sigma = 0.4$ and $\rho = -0.5$, and thus that the skill premium increases with the stock of equipment capital.[27] They find that the relative productivity of skilled labor grows

[26]The quality-adjusted equipment capital stock is again based on the work of Gordon (1990) and subsequent updates, especially for IT technology.

[27]With this nested CES in 3 factors (equipment, skilled and unskilled labor) it is unclear how to define capital-skill complementarity. One possible, but slightly unhortodox, definition is that the skill premium rises with the stock of equipment. A more traditional definition involves comparing the Allen elasticities of substitution. The elasticity of substitution between equipment and unskilled labor is $1/(1-\sigma)$, while the elasticity of substitution between equipment and skilled labor is

$$\frac{1}{1-\sigma} + \left(\omega_e + \omega_s\right)^{-1}\left[\frac{1}{1-\rho} - \frac{1}{1-\sigma}\right],$$

where ω_e and ω_s are, respectively, the income shares of equipment and skilled labor. Thus, according to both definitions, the parameter estimates in KORV imply that equipment capital is more complementary with skilled labor compared to unskilled labor. See Ruiz-Arranz (2002) for a discussion of the various definitions of elasticity of substitution in production function with more than 2 inputs. Interestingly, Ruiz Arranz divides equipment into finer categories and finds that IT capital (defined as computers, communication equipment and software) is the subgroup with the largest degree of capital-skill complementarity.

at a modest 3 percent per year, a much more plausible number than the one estimated by Katz and Murphy (1992). Overall, KORV show that with their estimated parameters, the relative wage movements in the data can be quite closely tracked. This includes the decline of the wage premium in the 1970s, attributable to an acceleration in the growth of college enrollment due to the Vietnam war draft and the entry of the baby-boom cohorts.[28]

From equation (12) it follows that the skill premium can increase, even if the relative productivity of skilled labor remains constant and the relative supply of skilled labor increases, provided the equipment-skilled labor ratio trends upward fast enough. From this perspective, the results of KORV complement Katz and Murphy's (1992) work: when capital and skills are complementary in production, capital accumulation can explain a large fraction of the residual trend in skill-biased productivity growth.[29]

3.1.1 Further Applications of the Capital-Skill Complementarity Hypothesis

In KORV, the production structure is "centralized" through an aggregate production function. Jovanovic (1998) models an economy with vintage capital where production is decentralized into machine-worker pairs. Newer machines are more productive than older machines, and workers differ in their innate skill level. The pair's output is a multiplicative function of these two inputs. Jovanovic assumes perfect information (no coordination frictions), and hence the labor market equilibrium assignment displays "positive sorting" between skills and machines' productivity (Becker, 1973), i.e., capital-skill complementarity emerges endogenously.[30] An acceleration in the growth rate of technology embodied in

[28]Lee and Wolpin (2004) find evidence of capital-skill complementarity both in the goods-producing industries and services in the U.S. economy, and argue that it is an important ingredient to explain the pattern of relative wages and relative labor inputs across the two sectors, over the past 50 years.

[29]Acemoglu (2002a) argues that if the capital-skill complementarity hypothesis is valid, then in equation (10) the relative price of equipment should proxy the shift in the demand for skills and perform better than a linear time trend. However, he finds the trend is always more significant. First, as equation (12) shows, the right variable to add to the Katz-Murphy equation is not the relative price of equipment, but the equipment-skill labor ratio. Second, even using this latter variable one would be bound to find that the linear time trend is more significant because in an OLS regression the estimated coefficient on the time trend converges to its true value at a faster rate than the coefficient on the equipment-skill ratio. More importantly, the key insight of KORV is to give an economic content to the "skill-biased technical change" view, by replacing an unobservable trend with an observable variable.

[30]Holmes and Mitchell (2004) start from a more primitive level where production combines tasks of various complexity and the production factors can perform tasks at a given setup-cost per task. They show that

machines, that is, an increase of the relative productivity differences across vintages, has two effects: 1) for a given age range of machines, it widens the underlying distribution of job productivity differences and, since in equilibrium high-skilled workers are assigned to high-productivity machines, it magnifies the skill premium; 2) the faster rate of obsolescence shortens the optimal life of capital, that is, the range of operative vintages narrows, which tends to weaken inequality since the least productive workers are now matched with better machines. As we will see, these two counteracting forces will survive in the frictional economies of section 7, in spite of the different nature of the equilibrium assignment of workers to machines.

The capital-skill complementarity hypothesis has proved to be helpful to interpret the dynamics of the skill premium in other countries. Perhaps the most interesting example is Sweden. Lindquist (2002) documents that the facts to be explained in Sweden are qualitatively similar to the U.S. facts: between 1983 and 1999 the college premium rose by over 20% and the supply of skilled workers increased substantially. Sweden represents an especially interesting test case for the KORV model because Swedish labor market institutions are commonly believed to play a crucial role in wage setting, arguably making market forces less critical in determining relative wage movements. The main result of Lindquist (2002) is that capital-skill complementarity explains close to half of the dynamics of the skill premium.[31]

How can one reconcile the traditional strength of labor market institutions, such as unions and collective bargaining, in the Swedish labor market with the finding that market forces account for a large part of relative wage dynamics? One possibility is that institutions set the aggregate share of income going to labor in any given period—possibly extracting rents from firms. The distribution of these rents among workers is then determined by their individual outside options, which differ across skill levels and are affected by technical change. In section 8 we develop further this conjecture in the context of the decline in union membership in the United States, but the economic linkages between the dynamics of

under reasonable primitive assumptions on setup costs for capital, skilled labor and unskilled labor, the former two inputs display a form of complementarity.

[31] Lindquist uses the KORV specification for aggregate technology in equation (11) and estimates $\rho = -0.92$ and $\sigma = 0.31$.

institutions and technological progress are far from being well understood.

More international evidence in favor of the capital-skill complementarity model is offered by Flug and Hercowitz (2000). They estimate a strong effect of equipment investment on relative wages and employment of skilled labor using a panel data set for a wide range of countries around the world.

Recently, the capital-skill complementarity idea has been imported into the study of inequality at the business-cycle frequency. The skill premium is found to be close to *acyclical* in the United States: its contemporaneous correlation with output is positive, but not statistically different from zero. Lindquist (2004) argues that, since unskilled labor is relatively more pro-cyclical than skilled labor, a Cobb-Douglas production function in three inputs (capital, skilled labor, and unskilled labor) would predict a strongly pro-cyclical skill premium. Inspection of equation (12) suggests that introducing capital-skill complementarity in production can help matching the data since, at impact, skilled hours respond more than the stock of equipment: the capital-skill complementarity effect is countercyclical and offsets the change in relative supply.[32]

In sum, the studies discussed in this section indicate that capital-skill complementarity is a quantitatively important ingredient in competitive theories of relative wage determination, within centralized as well as decentralized production structures and at high as well as low frequencies.

3.2 Innate Skills and the Nelson-Phelps Hypothesis

Nelson and Phelps (1966) argued that the wage premium for more skilled workers is not just the result of their having higher "static productivity". Workers endowed with more skills, they contended, tend to deal better with technological change in the sense that their productivity is less adversely affected by the turmoil created by technological transformations of the workplace, or in that it is less costly for them to acquire the additional skills needed to use a new technology. Greenwood and Yorukoglu (1997) cite sources reporting that the skill

[32]Within a similar framework, Cohen-Pirani and Castro (2004) argue that capital-skill complementarity is important for understanding why the volatility of skilled labor (relative to GDP) has tripled after 1985.

premium also rose during the course of the first industrial revolution. In the context of the recent "IT revolution", Bartel and Lichtenberg (1987) provide evidence that more educated individuals have a comparative advantage at implementing the new technologies and and Bartel and Sicherman (1998) argue that high-skilled workers sort themselves into industries with higher rates of technical change.

The theory has been formalized in various formats. Lloyd-Ellis (1999) embeds a race between the innovation rate and the "technological absorption rate" of workers (the maximum numbers of innovations that can be adopted per unit of time) in a general equilibrium model: at times when the innovation rate exceeds the absorption rate, wage inequality increases due to the fierce competition for scarce, adaptable labor. Galor and Moav (2000) formalize this hypothesis differently and assume that technological change depreciates the human capital of the unskilled workers faster than that of skilled workers (the "erosion effect"). Krueger and Kumar (2004) distinguish between workers with general education and workers with vocational skill-specific education and postulate that only the former type remains productive when new technologies are incorporated into production.

It is important to remark that this hypothesis, in all its versions, applies to educational skills as well as dimensions of skills that are not necessarily observable or correlated with education. Hence, it can potentially account for the rise in within-group (or residual) inequality. Ingram and Neumann (1999) offer some evidence on the increase in the return to certain categories of skills not fully captured by education. They match individual data on wages and occupations from the CPS with the skill content of several occupations, obtained from the *Dictionary of Occupational Titles* (DOT). DOT data contain information on how much each occupation requires of each of a wide range of skills such as verbal aptitude, reasoning development, numerical ability, motor coordination, and so on. Using factor analysis they group over 50 type of skills into four factors (intelligence, clerical skills, motor skills, and physical strength) and estimate that the return to "intelligence" has almost doubled from 1971 to 1998. Moreover, adding the quantity of this factor to a standard Mincerian wage regression weakens the implied increase in the returns to college education significantly.

The idea that the diffusion of IT may have raised the demand for adaptable skilled workers—thus, even within educational groups—has been formalized in various ways by Galor and Tsiddon (1997), Greenwood and Yorukoglu (1997), Caselli (1999), Galor and Moav (2000), and Aghion et al. (2002).

To illustrate the basic mechanism of such a theory, consider an economy where workers differ in their cost of learning the new technology.[33] Suppose that this economy starts in a steady-state equilibrium where production uses the "old" technology, $y_1 = A_1 k_1^{\alpha} l_1^{1-\alpha}$. The labor market is competitive; thus, in steady state, all workers are employed in the old sector and there is no wage inequality.

Suppose a new technology becomes available and the sector using this new technology can produce output with $y_0 = A_0 k_0^{\alpha} l_0^{1-\alpha}$ where $A_0 > A_1$. Because of the learning cost, labor is not perfectly mobile, and wages in the two sectors may differ. Capital, however, is free to move towards its more productive use, and factor-price equalization for capital yields

$$R_0 = R_1 \Rightarrow \frac{l_1}{k_1} = \left(\frac{A_0}{A_1}\right)^{\frac{1}{1-\alpha}} \frac{l_0}{k_0}. \tag{13}$$

It is straightforward to show that

$$w_0 = \left(\frac{A_0}{A_1}\right)^{\frac{1}{1-\alpha}} w_1 > w_1.$$

Therefore, in equilibrium, a premium emerges for those workers with low learning cost (i.e., high ability) who can adapt quickly and move to the new sector.

The skill premium increases due to two effects. With full mobility of labor, inequality would disappear. With no labor mobility and no capital mobility, the skill premium would reflect the productivity difference A_0/A_1. In this class of models, labor mobility is limited by the distribution of ability in the economy, but capital moves freely. Full mobility of capital induces a general equilibrium feedback that amplifies inequality: factor-price equalization requires capital to flow to the sector operating the new technology to equate marginal productivities of capital.[34] Thus, workers on the new technologies are endowed with more capital, which boosts their relative wages further.

[33] In the rest of this section, the exposition will be based mainly on the environment in Caselli (1999).

[34] One implication of this mechanism, evident from equation (13), is that a technological revolution should

In its typical version, the Nelson-Phelps hypothesis implies that the rise in the skill premium will be transitory: it is only in the early adoption phase of a new technology that those who adapt more quickly can reap some benefits. Over time there will be enough workers who learn how to work with the new technology to offset the wage differential. Note the difference with the KORV hypothesis, where the effect on the skill premium is permanent. Are new technologies and skills complement in the whole production process or just in the adoption phase? Chun (2003) uses industry-level data for the U.S. to disentangle the impact of "adoption" and "use" of IT. He finds that the increase in the relative demand of educated workers from 1970 to 1996 in the U.S. is related significantly to both factors, but quantitatively the impact of use is twice as large.

3.2.1 Further Applications of the Nelson-Phelps Hypothesis

Aghion (2002) and Borghans and ter Weel (2003) emphasize that the Nelson-Phelps approach can explain why, in the 1970s, the college premium declined at the same time that the wage dispersion within college graduates increased. The idea is that in the early phase of IT diffusion in the 1970s only educated workers with high ability adopt. Naturally, this higher return to ability increases within-group inequality. The contemporaneous acceleration in the growth of the supply of educated labor, due to exogenous factors, explains the relative fall in the average wage of college graduates.

Beaudry and Green (2003) compare the United States and Germany, highlighting an apparently puzzling feature of the data: the relative supply of skilled labor in the United States grew faster than in Germany, and yet the skill premium rose in the United States, but not in Germany. They outline a model that combines elements of Caselli (1999) and Krusell et al. (2000). Consider an economy where there are two technologies in operation and the "new" technology displays more capital-skill complementarity than the old one. An exogenous rise in the supply of skills increases the relative return to capital in the new sector. Capital then flows from the old to the new sector, and, ultimately, this higher capital

trigger a surge in the real rate of return on capital by a factor $(A_0/A_1)^{\frac{1}{1-\alpha}}$. Yearly U.S. long-term real interest rates were roughly 3 percent higher in the period 1980-1995 compared to the period 1965-1980. It is unclear whether this magnitude is quantitatively consistent with the observed increase in wage dispersion.

intensity can raise the relative wage of skilled labor if labor is not perfectly mobile because, as in Caselli's model, only skilled workers can quickly adapt. Thus, in the long-run, the country with the initial spur in the supply of skilled labor (the United States) finds itself with a larger skill premium.

In their original paper, Nelson and Phelps (1966) developed the concept of "technological gap", defined as the percentage difference between the technology operated by the typical machine in the economy and the one embodied in the leading-edge machine. They conjectured that a rise in the technological gap should be associated with a large skill premium because of the surge in the demand for educated workers needed to adopt the new, more productive technologies. Cummins and Violante (2002) use data on the quality-adjusted relative prices and quantities of equipment investment to construct a measure of the technological gap for the U.S. economy.[35] Figure 3 shows that the technological gap and the skill premium have moved largely in tune over the past half century, confirming—at least in the time-series dimension—even the most literal version of the Nelson-Phelps hypothesis.

FIGURE 3

Put differently, the size of the technological gap can be thought of a proxy for shifts in the relative demand of skilled workers.

3.3 Endogenous Skill-Biased Technical Change

In the literature we discussed so far, the sector bias and the factor bias of technical change were assumed to be exogenous. Over the past 20 years a substantial body of work in the field of growth theory has formalized the idea that the efforts of innovators are endogenous and

[35] Precisely, if q_t is the level of productivity embodied in the new investment at time t, then the average unit of productive capital in the economy at time t embodies a technology with productivity Q_t, defined as

$$Q_t = \sum_{j=0}^{\infty} (1-\delta)^j \, q_{t-j} \frac{i_{t-j}}{k_t},$$

where δ is the depreciation rate, i denotes investments and k the capital stock, both expressed in units of consumption. In other words, Q_t is the ratio between capital stock correctly measured in efficiency units (the numerator) and capital stock k not adjusted for quality. Then, the gap is defined as $\frac{q_t - Q_t}{Q_t}$.

respond to market incentives. The models belonging to the so-called "new growth theory" describe the endogenous determination of the *level* of innovative activity.

Recently, Acemoglu (1998, 2002b, 2003b) and Kiley (1999) have developed the idea that the composition, or *direction*, of innovations is also endogenous: if R&D activity can be purposefully directed towards productivity improvements of different inputs (capital, skilled labor, and unskilled labor), then it will be biased towards the factor that ensures the largest returns.

An important ingredient of this approach is that the returns to R&D targeted toward a given input are proportional to the total supply of that input, since "productivity" and "quantity" are complements in production. This creates a "market size" effect of R&D: productivity-improving resources are allocated to factor markets with large relative factor supplies.[36]

It is useful to see how this mechanism works within a simple model that represents a reduced form of the richer environments offered by Acemoglu and Kiley. Consider an economy with a given endowment of skilled and unskilled labor, l_s and l_u, and a production function (9) as in Section 2.2.4. Conditional on the FSPs, A_s and A_u, wages and employment are determined competitively, and the competitive equilibrium is Pareto-optimal. Now suppose that the Social Planner wants to maximize production subject to a given frontier of technological possibilities, that is, choices of A_s and A_u:

$$\max_{\{A_s, A_u\}} \left[(A_s l_s)^\sigma + (A_u l_u)^\sigma\right]^{1/\sigma}$$

$$s.t. \qquad \left[\lambda A_s^\phi + (1-\lambda) A_u^\phi\right]^{1/\phi} = 1.$$

Assume that the technological frontier is convex, that is, that $\phi > 1$. Rearranging the first-order conditions, one arrives at

$$\frac{A_s}{A_u} = \frac{\lambda}{1-\lambda}\left(\frac{l_s}{l_u}\right)^{\sigma/(\phi-\sigma)}, \tag{14}$$

which describes the optimal choice of skill-bias given the relative factor supply. The above equation shows that when skilled and unskilled labor are substitutes, $0 < \sigma \leq 1$, the skill

[36] It is useful here draw a parallel with certain traditional endogenous growth models, where the scale effect determines the level of the growth rate. See, Jones (2004) for a survey of the models with scale effects.

bias is increasing in the relative supply of skills. This latter parametric condition implies that the marginal product of each innovation is increasing in its corresponding factor.

A surge in the relative endowment of skilled labor, like the one witnessed by the U.S. economy in the postwar period, induces the adoption of more skill-biased technologies in production. This force tends to counteract the direct relative supply effect on wage inequality. Can the endogenous skill bias be so strong in the long run as to overturn the initial supply effect?

To answer this question, we substitute the expression for the skill bias, (14), into the expression for the skill premium, (10), and obtain

$$\ln\left(\frac{w_s}{w_u}\right) \propto \frac{\sigma - \phi\,(1-\sigma)}{\phi - \sigma} \ln\left(\frac{l_s}{l_u}\right).$$

We see that the skill premium is increasing in the relative supply of skilled labor as long as $\phi \in \left(\sigma, \frac{\sigma}{1-\sigma}\right)$. Thus, theoretically, it is possible to explain a positive long-run relationship between the relative supply of skilled labor and the skill premium as the one depicted in Figure 1 (top panel).

One limitation of existing models of directed technical change, and also of most of the literature surveyed in this section, is that arguments for the skill-premium focus on the response of a relative price to exogenous changes in relative factor supplies. Whereas one can reasonably assume that "ability" is largely pre-determined with respect to the point in the life-cycle when agents start making economic decisions, education is not. One would expect that changes in returns to education as large as the ones we observed in the past 30 years would significantly affect the incentives to acquire education. However, it is an open question to what extent the observed changes in returns were predicted by the cohorts affected by these returns when they made their education decisions.[37]

Models of directed technical change, augmented by an endogenous supply of skills, can give rise to multiple steady states. If the innovators expect the supply of educated workers to rise, they will invest in skill-biased R&D which, in turn, will augment the returns to college and induce households to acquire human capital, fulfilling the innovators' expectations.

[37] See Abraham (2003) for a related analysis.

3.3.1 Sources of the Skill-Bias in Recent Times

Equation (14) shows that the most natural candidate as engine of the recent skill-biased technical change was the rise in the relative supply of educated workers. The latter was, according to Acemoglu (2002a) largely exogenous, at least initially, and a result of the high college enrollment rates of the baby-boom cohort and of the Vietnam war draft. The crucial issue, still unresolved, is whether the necessary parametric restrictions discussed earlier are plausible, and whether the initial shock is large enough.[38] What other changes in the economic environment can be listed as potential sources of skill-biased innovations?

First, there are possible interactions between capital-skill complementarity and the direction of technical change. Hornstein and Krusell (2003) have taken a first step at incorporating the idea of factor-biased innovations into the KORV explanation of the skill premium. Intuitively, an acceleration in capital accumulation due, for example, to an exogenous fall in the price of capital increases the returns to skill-biased innovations if capital is more complementary with skilled labor. Hence, capital-embodied productivity improvements can be the source of factor-biased technical progress. For a calibrated version of their model, Hornstein and Krusell find that a persistent decline of the relative price of capital results in a temporary, but very persistent, increase of the skill premium. In their model the skill premium not only increases because of capital accumulation (as in KORV), but it also increases because of the endogenously induced spur of skill-biased technical change.

Second, the increased openness to trade can play a role. Using a Schumpeterian growth model, Dinopolous and Segerstrom (1999) argue that if trade liberalization boosts the profitability for monopolistic suppliers by increasing the size of their markets, then resources shift from manufacturing to R&D activities. If, in turn, R&D is a skill-intensive sector, the skill premium rises. This model determines endogenously the level of R&D, but does not display endogenous factor bias in the equilibrium innovation rate. In Acemoglu (2003c), the direction of technical change is related to international trade. A natural assumption about

[38] In the richer model developed by Acemoglu (2002b), this parametric restriction requires that the elasticity of substitution between skilled and unskilled labor be larger than 2. Most of the empirical literature on factor substitutability, however, points at values around 1.5 (Hamermesh 1993).

factor endowments is that in the United States the ratio of skilled to unskilled labor is higher than in the rest of the world. After the U.S. economy opens to trade, the world prices are determined by the aggregate relative factor endowment, and thus skill-intensive goods become relatively more expensive. In the class of models with an endogenous factor bias, factors which produce goods with the highest relative price—and the highest expected profits—will be the target of the largest amount of innovative activity (the "relative price" effect). Thus trade opening induces skill-biased technical change. This mechanism can, under some conditions, explain also the increase in the skill premium in less-developed countries documented, for example, by Robbins (1996).

Third, Cozzi and Impullitti (2004) argue that government policy may also have contributed to the bias in technical change. In the 1980s, U.S. technology policy rapidly shifted its priority from security and defense to economic competitiveness in order to counteract the emerging dominance of Japan in the sectors producing high-tech goods.[39] Within a Schumpeterian growth model, they show that when the government reallocates its expenditures towards the (high-tech) manufacturing goods with the highest potential quality improvement, it creates a market-size effect that can lead to a rise in the innovation rate in those sectors and a net increase in the demand for skilled R&D workers and their wages.[40]

Although we have learned from the above analyses about possible channels influencing the skill premium, there is little work that allows us to quantify each of the channels. A careful calibration and evaluation of a model which incorporates these various channels would be an important first step in this direction.

[39]Japan's share of the high-tech goods markets rose from 7 percent to 16 percent during the period 1970-1990, while at the same time the U.S. share declined from 30 percent to 21 percent. In 1963 government spending on defense represented 1.37 percent of GDP. In 1980, it was down to 0.57 percent.

[40]Like the Dinopolous and Segerstrom (1999) model, strictly speaking, this is not a model of directed-technical change, since skilled labor works only in the R&D sector, and each manufacturing sector employs unskilled labor. However, in a version of the model with endogenous factor-bias and a structure of manufacturing where high-tech goods are produced by skilled labor and low-tech goods by unskilled labor, the shift in technology policy would have the same qualitative effect.

3.4 A Historical Perspective on the Skill Premium

In Section 2 we have observed that, over the last 100 years, wage inequality first declined and then increased, with the turning point somewhere around 1950. Can the theoretical models developed to interpret the increasing wage inequality for the second half of the 20th century also account for the declining wage inequality of the first half of the 20th century?

3.4.1 Capital-Skill Complementarity

Figure 4 plots the relative price of equipment together with the returns to one year of education (both college and high school) since 1929.[41] The pattern is rather striking and is broadly consistent with an explanation based on the capital-skill complementarity hypothesis. During the first half of the century, the price of capital increased which slowed the demand for educated labor and the skill premium. Then around mid-century it started to decline, fostering a strong demand shift in favor of educated labor.

FIGURE 4

This extension of the KORV analysis to the whole 20th century is yet to be performed formally.[42] Thus, before one fully subscribes to this explanation, it is worth discussing the key assumption behind the model. Is it an accurate historical assessment that the introduction of new capital goods has systematically increased the productivity of skilled labor relative to the productivity of unskilled labor? In other words, when can one date the birth of work organizations displaying capital-skill complementarity?

According to Goldin and Katz (1998), until the early 20th century there was no trace of skill-biased technical change; rather, the opposite bias was at work. The origins of capital-

[41] The relative price is computed from series available on the BEA website. In particular, compared to the series discussed previously in the chapter, there are no quality adjustments. As a result, the acceleration which occurred since the mid 1970s is less evident here. The series on the return to education for 1939, 1949, 1959, 1969, 1979, 1989, and 1995 are taken from Table 7 in Goldin and Katz (1999) and interpolated linearly for the missing years in between. The first datapoint for 1929 is obtained by linear interpolation from 1914.

[42] Admittedly, the evidence in Figure 4 is rather indirect. Looking directly at the stock of equipment (unadjusted for quality improvements), its average annual growth rate in the periods 1930-1950, 1950-1980, 1980-2000 is, respectively, 2.2%, 5.0% and 4.2%. However, when quality-adjusted, the growth rate of equipment from 1980-2000 is close to 8% (Cummins and Violante, 2002). See also Hornstein (2004) for a discussion of historical trends of U.S. capital-output ratios.

skill complementarity are associated with the introduction of electric motors, and a shift away from assembly lines and toward continuous and batch processes. This development started in the second and third decades of the 20th century. In particular, the declining relative price of electricity, and the consequent electrification of factories, made it possible to run equipment at a higher speed. This, in turn, increased the demand for skilled workers for maintenance purposes. Since then, the introduction of new equipment, such as numerically controlled machines, robotized assembly lines, and finally computers further increased the relative productivity of skilled labor. Thus, we conclude that based on anecdotal evidence, the period portrayed in Figure 4 is one where capital-skill complementarity became more important.

Mitchell (2001), in a related interpretation on the last century of data, emphasizes the technological aspects of optimal plant size. Mitchell documents a striking similarity between the historical path of wage inequality and the pattern of average plant size in manufacturing which rose over the 1900-1950 period and shrunk between 1950 and 2000, thus almost producing the mirror image of inequality at low frequencies. The time-path of plant size can be interpreted as an indicator of the magnitude of the fixed costs of capital and fits well with the evidence of Figure 4.

In Mitchell's model, production requires performing a large set of tasks with capital and two types of labor, skilled and unskilled. Entrepreneurs face a fixed cost to operate capital, skilled labor, and unskilled labor. Unskilled labor has a higher fixed cost and a lower variable cost than does skilled labor; e.g., unskilled labor is specialized and needs a certain amount of training to perform all the tasks, whereas skilled labor is naturally able in multi-tasking.[43]

The move from craft shops to assembly lines (1900-1950) induced a rise in the fixed cost: the optimal size of the plant rose and with a larger size, plants optimally employed more unskilled workers with large fixed cost, but low variable cost (wages). The demand for

[43]This idea is further developed in Holmes and Mitchell (2004). This paper develops a theory of the intrinsic difference between three key factors of production: capital, unskilled labor, and skilled labor. Based on this theory, the authors develop implications for: 1) how capital and skill intensity vary as a function of size of plants, 2) the micro-foundations of capital-skill complementarity, 3) the effect of trade on the skill premium and the historical relationship between the plant size-skill correlation and the skill-premium.

unskilled workers rose, weakening the skill premium. As an illustration of the importance of fixed costs for this type of production method, recall that all Ford plants had to be closed and redesigned when the "Model T" was discontinued (Milgrom and Roberts, 1990).

The shift toward more flexible, numerically controlled machines and IT capital (1950-2000) led firms to adopt a smaller scale of production and employ more highly skilled workers whose low fixed cost makes them preferable to unskilled workers in small plants. The increased demand for skilled labor thus raised the skill premium. Based on a calibration exercise, the model can account for two thirds of the movements in the skill premium.[44]

3.4.2 Directed Technical Change

The theory of directed technical change maintains that a growth in the relative supply of a factor of production should induce technical change biased in favor of that factor. Historically, there are two important episodes of largely "exogenous" spurs in relative factor supply.

First, there was an increase in the supply of unskilled labor in urban areas of England during the 19th century. A careful look at the nature of technological progress over this period supports the theory. Goldin and Katz (1998) argue that in the 19th century the wave of technological innovations substituted physical capital and raw labor for skilled artisan workers (Braverman, 1974 and Cain and Paterson, 1986). For example, automobile production began in artisanal shops where the car was assembled from start to finish by a small group of "all-around mechanics." Only a few decades later, the Tayloristic model of manufacturing would bring together scores of unskilled workers in large-scale plants to assemble completely standardized parts in a fixed sequence of steps for mass production.

Second, there was a surge in skilled labor (i.e., workers with literacy and numerical skills) due to the "high-school movement" of 1910-1940. As pointed out by Aghion (2002), with respect to this episode, the theory finds weaker support. On the one hand, as we discussed earlier, it appears that the first part of the 20th century indeed marked the beginning of

[44]Note that this model implies that the origin of capital-skill complementarity is to be located only around 1950, later than what was argued in Goldin and Katz (1998).

a transformation in production methods biased towards skilled labor (from assembly lines to continuous and batch production processes). On the other hand, there was a decline in the returns to high school and the returns to college were stable (see Figure 4). Why is it that this wave of skill-biased technical change, which was as strong as the one 50 years later, did not have a similar impact on the wage structure? This question remains unanswered to date.[45]

3.5 Technology and the Gender Gap

Here we explore briefly the interaction between the gender gap and the advancements of technological change, both in the market and in the household.

3.5.1 Technological Change in the Market

As evident from Figure 1 (bottom panel), since the mid-1970s the gender wage gap has closed substantially. Several studies have concluded that this is due to a rise in relative labor demand for women, as supply cannot have played a large role (Bertola et al. 1997). Was the recent technological revolution "gender-biased"?

Consider a simple model where jobs differ in their requirement of physical effort and all jobs are necessary for production of the final good. At the same time, men and women have two traits: physical ability and cognitive ability. The theory of comparative advantage then implies that men will be most efficiently assigned to jobs with high physical requirements and that women should work on jobs with a large fraction of cognitive tasks.

The arrival of a new technology, like computers, that increases productivity relatively more on jobs with high cognitive content therefore tends to raise the average wage of women more than it raises the average wage of men. Weinberg (2003a) tests this theory on microeconomic data for the United States and finds that the increase in computer use for women can explain up to 50 percent of the increase in the relative demand for female employment.

It is worth noting that the gender premium fell in spite of the fact that the female-male

[45]Institutions might have played a role in the 1940s. Goldin and Margo (1992) argue that the National War Labor Board operated an explicit policy of wage compression during that period.

relative supply ratio grew almost by a factor of 2 between 1960 and 2000, i.e., by as much as the growth in the relative supply of college-educated labor. In the perspective of the directed technical change literature, one is left to ponder whether rising female participation was also a force that led innovators to spend resources on capital goods complementary with cognitive skills rather than with physical skills in order to exploit women's comparative advantage. This hypothesis remains to be analyzed in detail.

3.5.2 Technological Change in the Household

The postwar period witnessed another form of technological revolution: one that did not take place in factories and plants, but rather in the household. Greenwood et al. (2004) argue that the decline in prices of household appliances (refrigerators, vacuum cleaners, washers, dishwashers, etc.) worked as "engines of liberations" for women: new and more productive capital in the households could free up potential hours to be supplied in the labor market. In particular, as household durables were introduced into the economy, the effective wage-elasticity of female labor supply increases, which, in turn, helps explaining the sharp rise in female market participation, even in the presence of not-so-large changes in the gender wage gap.[46]

4 Technical Change and the Returns to Experience

According to Card and DiNardo (2002), one of the most important challenges to the hypothesis that the recent changes in the wage structure are linked to technological progress is to explain the combination of the rise in the returns to labor market experience for the low-educated workers in the population and the flat, or declining, pattern of the experience premium for college graduates.

It turns out that the existing theoretical literature does not provide a unified answer to the question of how technological change affects the experience premium. Examples of the literature we review in this section include job-specific or technology-specific experience that,

[46] We refer the reader to Greenwood and Seshadri (2004) in this Handbook for a detailed analysis of this channel.

in principle, may be adversely affected by technological change, but that may also benefit from technological change if that change is of a 'general purpose' variety, that is, if it makes experience more widely applicable.[47] We also look at general labor-market experience as a vehicle to lower the cost of adapting to technological change.

4.1 Experience with General Purpose Technologies

An important feature of the recent technological developments that has not received much attention in the literature on inequality is its *general purpose nature*. Aghion et al. (2002) formalize the idea of "generality" of a technology and build a theoretical framework to understand how it affects various dimensions of wage inequality, such as the experience premium. They model generality in relation to human capital: a more general technology allows a larger degree of *transferability* of sector-specific experience across the different sectors of the economy. For example, the ability to use computers for word-processing or programming is useful in numerous sectors and jobs in the economy.[48] Given that actual technological change is uneven across sectors, transferability of experience then increases the value of experience, that is, the experience premium.

Consider a simple overlapping-generations (OLG) model with two-period lived agents, and two production sectors indexed by $i = 0, 1$. Each cohort of agents has measure one and works in both periods. Technological progress results in capital-embodied innovations that increase productivity by a factor $1 + \gamma$ occurring in each of the two sectors in alternation. Let "0" denote the new sector in the current period. Suppose, for simplicity, that production takes place with a fixed amount of capital, normalized to one: the production function in sector i (in the stationary transformation of the model) is $y_i = A_i^{\alpha} h_i^{1-\alpha}$, where A_i measures

[47] We will return to the issue on how technological change interacts with the accumulation of job/technology-specific knowlege in the frictional models of Section 7.3.

[48] A survey conducted by the U.S. Bureau of Labor Statistics emphasizes that

> *"...the technology, network systems, and software is similar across firms and industries. This is in contrast to technological innovations in the past, which often affected specific occupations and industries (for example, machine tool automation only involved production jobs in manufacturing). Computer technology is versatile and affects many unrelated industries and almost every job category"* (McConnell, 1996, page 5).

the efficiency of capital in sector i ($A_0/A_1 = 1+\gamma$), and h_{it} measures the effective labor input in sector $i = 0, 1$.

Young agents are always productive on the new technology, whereas old workers can productively move to the new sector only with probability σ. This captures the idea that young workers are more "adaptable" than old workers, possibly because of vintage effects in their schooling, or because the ability to learn declines with age. Moreover, assume that this "adaptability constraint" is binding, in the sense that: (1) the equilibrium fraction σ^* of old workers who moves equals σ; and, (2) there is not enough labor mobility (σ is sufficiently low) to offset the impact on wages of the sectoral productivity differential $1+\gamma$.

Newborn agents start working in the new sector with initial knowledge normalized to 1.[49] Agents accumulate η additional units of experience through learning-by-doing in the first period of work. The generality of the technology determines the degree of skill transferability for the old workers, τ_o, i.e., the fraction of accumulated knowledge η a worker can carry over if she moves to the leading-edge sector at the beginning of her second period of life. The entire knowledge η can be used if the worker stays in the old sector.

Aggregate human capital in the old sector h_1 is determined by old, non-adaptable workers, a fraction $1-\sigma$, who have accumulated $1+\eta$ units of experience. Human capital in the new sector is determined by the new cohorts that have one unit of experience, and old adaptable workers with transferable experience, that is, $h_0 = 1+\sigma(1+\tau_o\eta)$. With competitive labor markets, the ratio between the prices of efficiency units of labor in the old and the new sector therefore is:

$$\frac{w_1}{w_0} = (1+\gamma)^{-\alpha}\left(\frac{h_0}{h_1}\right)^{\alpha} = (1+\gamma)^{-\alpha}\left[\frac{1+\sigma(1+\tau_o\eta)}{(1-\sigma)(1+\eta)}\right]^{\alpha}. \tag{15}$$

The steady-state experience premium, i.e. the average wage of old workers relative to the average wage of young workers, is therefore given by

$$x^* = \sigma(1+\tau_o\eta) + (1-\sigma)(1+\eta)\frac{w_1}{w_0}, \tag{16}$$

where one can see immediately that x^* is increasing in τ_o. That is, an increase in the generality of technological knowledge raises skill transferability and amplifies the experience

[49] Aghion et al. (2002) show that this is indeed the optimal choice of young cohorts, for general conditions.

premium of adaptable workers, who are able to transfer more of their cumulated skills. It also indirectly raises the experience premium of non-adaptable old workers by making effective adaptable labor input relatively more abundant in the economy, hence depressing the wage of young workers.

This result is particularly interesting in light of the fact that a version of this model that is based purely on the hypothesis that the rate of embodied technical change, γ, has accelerated would predict a decline in the experience premium. This is evident from the fact that the wage ratio w_1/w_0 is decreasing in γ: larger productivity differentials between the young and the old vintages represent a relative advantage to young workers who are more adaptable.

The more general model in Aghion et al. (2002) also features a flexible choice of capital. Another interpretation of generality of the technology offered in their paper is based on the *compatibility* of physical capital, i.e., the extent to which capital equipment embodying the old technology can be retooled—so as to embody the new leading-edge technology—and moved to the new sector. Under this interpretation, the arrival of a GPT, which increases the compatibility across vintages of capital, reduces the experience premium since it allows the transfer of more capital to the new sector where it benefits the young, inexperienced, but more adaptable workers.[50]

4.2 Vintage-Specificity of Experience

According to the GPT hypothesis, human capital becomes more transferable across sectors once the new technological platform has fully diffused throughout the economy. However, it is also reasonable to think that, at least in the transition phase, certain skills associated to the old way of producing quickly become obsolete. Or, put differently, human capital is vintage-specific. Thus, although in the final steady state skill transferability will be higher, it can undershoot during the transition.

[50]The model by Caselli (1999) outlined in section 3.2 has exactly this feature of capital mobility from the old technology to the new and more productive technology; thus, a version of that model where the young workers are those with the lowest learning cost would have the same counterfactual prediction for the experience premium.

To study the implications of vintage human capital for the experience premium, we can slightly modify the two-period OLG model in the previous section. To make this point starkly, consider the extreme case where old workers never find it profitable to move across sectors, so $\sigma^* = 0$, and suppose that when young workers join the new sector they lose a fraction $1-\tau_y$ of their initial knowledge (as before, normalized to 1). Modifying appropriately the equilibrium wage ratio (15) , equation (16) for the experience premium becomes

$$x^* = \frac{(\tau_y + \eta)\, w_1}{\tau_y w_0} = \frac{1}{(1+\gamma)^{\alpha}} \left[\frac{\tau_y + \eta}{\tau_y}\right]^{1-\alpha}, \tag{17}$$

which shows that x^* is decreasing in the skill transferability rate for young workers, τ_y. The arrival of a new technology that makes the knowledge of its (young) users obsolete can widen the returns to experience.

In analyzing earlier equation (16) we argued that a rise in γ would depress the experience premium, which is a problem for the pure "acceleration hypothesis". Vintage human capital can overturn this result. Suppose, as in Violante (2002), that the degree of skill transferability is decreasing in the speed of technological improvements, i.e. $\tau_y = (1+\gamma)^{-\tau}$. Then, it is easy to see from (17) that as long as $\tau > \alpha/(1-\alpha)$, the experience premium will rise after a technological acceleration, since the loss of vintage-specific human capital incurred by young workers is larger than the productivity improvement embodied in physical capital.[51] In Section 7.3 we return to the role of vintage human capital and discuss the plausibility of the assumption that the extent to which skills are transferable depends on γ.

4.3 Technology-Experience Complementarity in Adoption

According to the standard technology adoption models, the adopters of the new technology are likely to be the young workers because they face a lower learning cost or a longer time horizon to recoup the adoption costs. Weinberg (2003b) challenges this view and argues that there is one other force that gives more experienced workers an advantage: complementarity between new technologies and skills, together with the fact that more experienced workers are

[51] Note that this large skill loss for young workers does not necessarily imply that it is not optimal for them to begin working in the new sector. Indeed, by working with the new technology in the current period they improve *future* skill transferability.

more skilled, should lead to the prediction that older workers will adopt the new technology. What force dominates? And what are the implications for the experience premium?

Weinberg looks at the empirical pattern of computer usage (i.e., adoption of one of the new recent technologies) over the life-cycle and shows that it differs dramatically between high-school graduates and college graduates (see Figure 5).

FIGURE 5

Among uneducated individuals the profile is hump-shaped and peaks around 30 years of experience, while for educated individuals it is downward-sloping. As expected, the adoption rates for college graduates are higher at any given age.

These data suggest that the answer to the first question above depends on the level of schooling: for low-educated workers, experience is a substitute for general education, and the more experienced workers are also more productive in the new technology. Workers with high education levels are all equally adaptable to the new technology, so, for such workers, additional experience has a small marginal return in adoption. Since the learning cost increases with age, the youngest are more likely to adopt the new technology.

Adding to this mechanism the assumption that new technologies are more productive yields that the adopters gain a wage increase, which is consistent with the different pattern of the experience premium for low and high education groups that we described in Section 2.

4.4 On-the-Job Training with Skill-Biased Technological Change

The models reviewed in this section treat the degree of skill transferability or adaptability of workers as exogenous. If old workers recognize that "new knowledge" is necessary for dealing with the transformed technological environment, then one should expect that they would be willing to forego some resources to acquire such skills through training.

Mincer and Higuchi (1991) advanced this hypothesis and found some supporting evidence from U.S. sectoral data: industries with faster productivity growth were also the ones with steeper experience profiles and lower job-separation rates. They interpreted these facts as

reflecting the training channel in light of the findings of Lillard and Tan (1986) showing that the incidence of firm-specific on-the-job training is higher in sectors with high rates of productivity growth. Interestingly, Bartel and Sicherman (1998) document that the marginal impact of a rise in productivity growth on the likelihood of training (thus on the steepness of the wage profile) is stronger for low-educated workers, which is consistent with the pattern of the last 30 years mentioned in section 2.

The model developed by Heckman et al. (1998) explains the recent dynamics of the experience premium based precisely on this mechanism. To simplify the exposition, consider again a two-period OLG model where risk-neutral workers are endowed with a unit of human capital, work in both periods, and choose how much time to devote to on-the-job training and production in the first period. Training increases human capital in the second and final period. The problem of a worker at time t is:

$$\max_{\tau_t} \{w_t (1 - \tau_t) + \beta w_{t+1} h_{t+1}\}$$

$$s.t. \qquad h_{t+1} = \tfrac{A}{\theta} \tau_t^{\theta},$$

where τ_t is the fraction of the unitary time endowment spent in training, β is the discount factor, w_t is the wage rate at time t, and h_t is human capital at time t. We assume that production of human capital has decreasing returns in the time input. It is easy to see that optimal training and human capital are functions of expected wage growth:

$$\tau_t = \left(A\beta \frac{w_{t+1}}{w_t} \right)^{\frac{1}{1-\theta}} \text{ and } h_{t+1} = A^{\frac{1}{1-\theta}} \left(\beta \frac{w_{t+1}}{w_t} \right)^{\frac{\theta}{1-\theta}}.$$

The implied experience premium, that is, the wage of an experienced old worker relative to the wage of an inexperienced young worker at a given point in time, is then $x_t = h_t / (1 - \tau_t)$.

In a stationary state where $w_t = w^*$ for any t, the optimal fraction of time spent in training is $\tau^* = (A\beta)^{1/(1-\theta)}$, and the corresponding steady-state experience premium is

$$x^* = \frac{1}{\theta} \left(\frac{A^{\frac{1}{1-\theta}} \beta^{\frac{\theta}{1-\theta}}}{1 - (A\beta)^{\frac{1}{1-\theta}}} \right).$$

The steady-state experience premium is increasing in the productivity of training, A, and in the discount factor, β.

Suppose now that the economy undergoes a one-period transition toward a permanently higher level of skill-biased productivity. High-education (low-education) workers see their wage going up (down), i.e., $w_{t-1} = w_t = w^*$, $w_{t+n} = \bar{w}$ when $n > 1$, where for high-educated workers $\bar{w} > w^*$, and for low-educated workers $\bar{w} < w^*$. Since the two cases are perfectly symmetric, we solve for the transitional dynamics in the experience premium of the high-educated. Along the transition, in period t educated workers increase their investment in training since the anticipated rise in their wages increases the return to human capital accumulation, whereas in all future periods, i.e., $t+1$ and higher, educated workers do not change their human capital investment decision since their anticipated wage change is not affected:

$$\tau_t = \left(A\beta\frac{\bar{w}}{w^*}\right)^{\frac{1}{1-\theta}} > \tau^*, \tau_{t+n} = \tau^* \text{ for } n \geq 1.$$

The implied sequence of experience premia for educated workers is given by

$$x_t = \frac{h^*}{1-\tau_t} > x_{t+1} = \frac{h_{t+1}}{1-\tau^*} > x_{t+2} = x^*. \tag{18}$$

The experience premium first rises from x^* to x_t and then falls gradually towards the steady state. For low-educated workers, the opposite pattern will hold. If one thinks of time $t-1$ as 1965, i.e., the moment before the rise in inequality started, time t as 1975, and so on, this stylized model can qualitatively explain the rise in the experience premium for the less educated workers and the decline in the experience premium for the more educated in the 1980s.

The key force is the intertemporal substitution between working and training that the expected changes in wages bring along.[52] Also, as emphasized by Heckman et al. (1998), it is important to recognize that movements in earnings, $w(1-\tau)$, can differ from movements in skill prices w when labor supply is endogenous. The major limit of the theory is probably that the mechanism depends crucially on the ability of agents to perfectly foresee changes in wage rates decades in advance.

[52]Dooley and Gottschalk (1984) also explore a mechanism based on human capital investment in order to explain the rising inequality within cohorts of young workers in the United States. They attribute the changes in expected wages to aggregate fluctuations in labor force growth: the baby-boom and, subsequently, the baby-bust.

5 Inside the Firm: the Organization of Work

Hayek (1945) argued that a fundamental problem of societies is how to use optimally the knowledge that is available, but is dispersed across individuals. In frictionless markets, prices can solve this problem: they transmit knowledge about relative scarcity and relative productivity of resources. Since Coase (1937), it is well understood that frictions limit the efficiency of markets, and they divert certain transactions to occur within the boundaries of firms. Within the firm, the organization of work and production plays the role of the market as "information processor" to allow efficient use and transmission of knowledge.

It is therefore not surprising that the recent innovations that revolutionized the way in which information and communication takes place have affected the workplace organization within firms and the boundaries of firms. Their impact on the wage structure is perhaps less clear. The maintained hypothesis in the literature is that the recent episodes of reorganization of production, especially in manufacturing, have favored adaptable workers who have general skills and who are more versed at multi-tasking activities. An alternative view, which we will develop later in this section, is that organizational change is not induced by technological change, but that the increased relative supply of skilled labor created the incentives to change the organization of production.

5.1 The Milgrom-Roberts Hypothesis: IT-Driven Organizational Change

Milgrom and Roberts (1990) were the first to emphasize the interaction between the diffusion of information technologies in the workplace and the reorganization of production. Their hypothesis builds on the idea that information technologies reduce a set of costs within the firm which triggers the shift towards a new organizational design. First, electronic data transmission through networks of computers reduces the cost of collecting and communicating data, and computer-aided design and manufacturing reduces the costs of product design and development. Second, there are complementarities among a wide group of strongly integrated activities within the firm (product design, marketing, and production), and pronounced

non-convexities and indivisibilities in each activity.

As a result, as the marginal cost of IT declines, it is optimal to reorganize all activities to exploit this shock, and, due to non-convexities, organizational change can be sudden and drastic in nature. In particular, because of lower communication costs the layers in the hierarchical structure can be reduced, so that the organization of the firm becomes "flatter."[53] Workers no longer perform routinized, specialized tasks, but they are now responsible for a wide range of tasks within teams. These teams, in turn, communicate directly with managers. Because of the flexibility of IT capital, the scale of production decreases (recall the evidence in Mitchell (2001) on plant size), allowing greater production flexibility and product customization.

An elegant formalization of this hypothesis is contained in Bolton and Dewatripont (1994). They study the optimal hierarchical structure for an organization whose only objective is that of efficiently processing a continuous flow of information and show using their model that a reduction in communication costs leads to a flatter and smaller organization.

5.1.1 Implications for the Wage Structure

Although in their original papers neither Milgrom and Roberts nor Bolton and Dewatripont explore the implications of organizational change for the wage structure, a small but growing literature on IT-driven organizational change and inequality has developed since.

Lindbeck and Snower (1996) emphasize the "complementarity" aspect of the Milgrom-Roberts hypothesis. They consider a production function with two tasks and two types of workers. The Tayloristic model would assign one type of workers to each task, according to comparative advantages to exploit specialization. The alternative organization of production is the flexible model, where each type of worker performs both tasks. This more flexible organization is preferred when there are large informational complementarities across tasks. The introduction of IT capital amplifies these informational complementarities and makes the flexible organization more profitable. Moreover, firms increase the demand for skilled

[53]Rajan and Wulf (2003) use detailed data on job descriptions in over 300 large U.S. companies to document that the number of layers between the lowest manager and the CEO has gone down over time, i.e., organizations have become "flatter".

workers who are more adaptable and versed in multi-tasking, and the skill premium rises.

Möbius (2000) focuses on the "customization" aspect of organizational change. When products are standardized, demand is certain and production tasks perfectly predictable, inducing a high division of labor (the Tayloristic principle). New flexible capital allows firms to greatly expand the degree of product variety and customization in product markets. Larger variety implies a more uncertain demand mix because producers become subject to unpredictable "fad shocks" and producers therefore favor a flexible organization of production, with less division of labor. Once again, to the extent that the most skilled workers are also the most adaptable and versatile, the skill premium will increase.

The mechanism in Garicano and Rossi-Hansberg (2003) is based, instead, on the fall in the communication cost within the organization. Their paper has the particular merit of taking the literature on the internal organization of firms (e.g., Bolton and Dewatripont 1994) one step further by recognizing that organizational hierarchies and labor market outcomes are determined simultaneously in equilibrium. Consider an organization where managers perform the most difficult and productive tasks and workers specialize in a set of simpler tasks. Managers also spend a fraction of their time "helping" workers unable to perform their task, and by so doing, they divert resources away from their most productive activities. The fall in the cost of communication allows workers to perform a wider range of tasks, using a smaller amount of the manager's time. The implications for wage inequality are stark. First of all, since workers are heterogeneous in ability, and ability is complementary to the number of tasks performed, inequality among workers within the firm increases. Second, the pay of the manager relative to that of the workers rises because the manager can concentrate on the tasks with high return.

The previous papers have studied how IT-based advances have affected the organizational structure within firms. Saint-Paul (2001) addresses the spectacular rise in the pay of CEOs and a few other professions (e.g., sportsmen and performers) documented in Section 2 using a model where IT-based advances affect the organization of markets with frictions. Saint-Paul combines a model with "superstar" or "winner-take-all" effects (Rosen 1981) with the advent

of information technology. In his model, human capital has two dimensions: productivity, i.e., the ability to produce units of output, and creativity, i.e., the ability to generate ideas that can spread (and generate return) over a segment of an economy, called a "network." The diffusion of information technology expands networks increasing the payoff to the most creative workers and widening the income distribution at the top. However, as networks become large enough, the probability that within the same network there will be somebody with another idea at least as good rises: superstars end up competing against each other, mitigating the inegalitarian effects of information technology. Under certain parametric assumptions, inequality first rises and then falls over time.

5.1.2 Empirical Evidence on the Complementarity between Technology, Organizational Change and Human Capital

Bresnahan et al. (2002) investigate the hypothesis that IT adoption, workplace reorganization, and product variety expansion (customization) are complementary at the firm level. Their view is that simply installing computers or communications equipment is not sufficient for achieving efficiency gains. Instead, firms must go through a process of organizational redesign. The combination of IT investments and reorganization represents a skill-biased force increasing the relative demand for more educated labor.

Their empirical analysis is based on a sample of over 300 large firms in the United States, and their definition of organizational change is a shift towards more decentralized decision making and more frequent teamwork. They find a significant correlation between IT, reorganization, and various measures of human capital.[54]

In a related paper, Caroli and Van Reenen (2001) argue that the existence of complementarities between organizational change and the demand for skilled labor leads to three predictions: 1) organizational change should be followed by a declining demand for less skilled workers; 2) in the vein of the directed technical change hypothesis (see next section), cheaper skilled labor should increase the occurrence of organizational change; and 3) organizational change should have a larger impact in workplaces with higher skill levels.

[54]See Brynjolfsson and Hitt (2000) for a survey on the empirical work documenting the causal link from adoption of information technology and organizational transformation within the firm.

They test these predictions combining two data sets, one for the United Kingdom and one for France, with information on changes in work organization, working practices, and the skill level of the labor force. Interestingly, they also have information on the introduction of new IT capital, so they can distinguish the effect of organizational change from that of skill-biased technical progress. They find some supporting evidence for all three predictions.

Baker and Hubbard (2003) offer an example where technological change not only affects the organizational design of firms but also the boundary of firms. In particular, they study how IT may have reduced the moral hazard problem in the U.S. trucking industry. Drivers may simply operate the trucks as employees of the dispatching company, or they may actually own the trucks they operate. If the dispatcher owns the truck, there is only limited assurance that the driver will operate in a way that preserves the value of the asset, since the dispatcher cannot perfectly monitor the driving operations. When this moral hazard problem is severe, decentralized ownership will be the outcome, that is, the driver owns the truck. Using detailed truck-level data, Baker and Hubbard show that with the introduction of a new monitoring technology—on-board computers linked to the company servers—the share of driver-ownership decreased significantly.

5.2 Directed Organizational Change

An alternative hypothesis to that put forth by Milgrom and Roberts is contained in several papers discussing the parallel change in the organization and in the pay structure of work. This view maintains that the driving force of organizational shifts is not technology, but rather the secular rise in the supply of skilled workers that created incentives to modify the organization of production: directed organizational change of sorts.

Acemoglu (1999) models a frictional labor market where firms must choose the amount of capital, k, when they are vacant, before meeting the worker. Consider a simple static version of Acemoglu's model. There are two types of workers, skilled and unskilled, where ϕ is the fraction of skilled ones. Skilled workers have productivity, h_s, and unskilled workers, h_u, which we normalize to $1 < h_s$. Output on each job is given by $y_i = h_i^{\alpha} k^{1-\alpha}$, where $i = s, u$. Wages and profits and are, respectively, a fraction ξ and $1 - \xi$ of output net of the cost of

the capital installed k. The expected value of a firm choosing capacity k is

$$V(k) = (1-\xi)\left[\phi I^s\left(h_s^\alpha k^{1-\alpha} - k\right) + (1-\phi) I^u\left(k^{1-\alpha} - k\right)\right],$$

where I^i is an indicator variable that equals 1 if the firm accepts a match with a worker of type $i = s, u$ and 0 otherwise.[55] Suppose the firm chooses between two hiring strategies: a "pooling" strategy where it accepts all workers, $I^s = I^u = 1$, and a "separating" strategy where it only accepts skilled workers, $I^s = 1$, $I^u = 0$. Conditional on the hiring strategy, we can use the first-order condition to solve for the optimal choices of capacity, k^P and k^S. Substituting the capacity choice back into $V(k)$, the values of the two hiring strategies are:

$$\begin{aligned} V^P &= \kappa(1-\xi)\left[\phi h_s^\alpha + (1-\phi)\right]^{1/\alpha}, \\ V^S &= \kappa(1-\xi)\phi h_s, \end{aligned} \tag{19}$$

where κ is a constant depending only on α. Comparing these two values, we conclude that the payoff to the "separating" strategy, V^S, dominates the payoff of the "pooling" strategy, V^P, whenever

$$\left(\frac{1-\phi}{\phi^\alpha - \phi}\right)^{1/\alpha} < h_s. \tag{20}$$

Note that the left-hand side of this expression decreases in ϕ, the fraction of skilled workers. When the size of the skilled group is small, a "pooling" equilibrium arises where all firms invest the same amount of capital and search for both types of workers. As the relative size of the skilled group rises, the economy switches to a "separating" equilibrium where firms find it optimal to install more capital and accept exclusively skilled workers in their search process.[56] One can interpret the pooling and the separating equilibrium as different types of work organizations, displaying different degrees of segregation along the skill dimension within sectors. The switch from the low-segregation to the high-segregation organization stretches the wage structure and generates higher inequality.

In a related paper, Kremer and Maskin (1996) offer an alternative explanation for the rise in the degree of assortative matching in the workplace, using a frictionless assignment model.

[55] Here, for simplicity we assume that workers accept passively each job offer. We do not consider equilibria where firms randomize, i.e., where $I^i \in (0,1)$.

[56] In the more general version of the model, which is dynamic with free entry of firms, there are other firms who install a small amount of capital (unskilled jobs) and search exclusively for unskilled workers.

Their paper contains some suggestive evidence that the degree of sorting ("segregation") has risen within industries and plants. However, their model is based on an increase in the skill dispersion in the population, for which there is little evidence in the data.[57]

Thesmar and Thoenig (2000) embed a choice of organizational design into a Schumpeterian growth model. Firms can opt for a Tayloristic organization that has large product-specific set-up costs, with the benefit of a high level of productive efficiency. Alternatively, they can choose a new and more flexible organization that can be built with a lower initial fixed cost, but whose productivity level is lower.[58] As is common in this class of Schumpeterian models, there is an R&D sector, where product innovations are generated proportionately to the amount of skilled workers hired. The patent of each new product is then sold to a monopolistic producer who can choose optimally which organization of work to set up (Tayloristic or flexible) according to the volatility of the economic environment.

A rise in the supply of skilled workers will increase the innovation rate in the R&D sector: the higher the innovation rate, the shorter the product's life expectancy for a monopolistic producer, and the less profitable organizations with large fixed costs prove to be, compared to the more flexible production method. The model also produces a rise in segregation, since skilled workers tend to cluster into the R&D sector, as well as a rise in inequality as unskilled workers lose from the abandonment of the Tayloristic model since the production phase becomes less efficient.[59]

5.3 Discussion

The case examined by Baker and Hubbard (2003) is one where IT improves firms' monitoring ability of workers' effort. However, it is plausible that the trend towards a "flatter" organizational design where single-task routinized work is replaced by multi-tasking team-

[57]For example, Hoxby and Long (1998) report that the difference in the quality of education (measured by their wage) received by college students at more and less selective institutions has increased over time, but the increase is quantitatively small.

[58]This distinction between the Tayloristic firm and the new flexible firm is due to Piore and Sabel (1984).

[59]Duranton (2004) provides yet another framework for formalizing the concept of "skill segregation" in production and analyzes the implied wage structure in the economy. In his model, a rise in the relative supply of skilled workers can lead to higher segregation and more inequality.

work induces a *rise* in the cost of monitoring individual workers' effort. Firms would then, optimally, introduce incentive schemes (e.g., tournament contracts) with the result of increasing inequality in rewards. In other words, optimal contracts respond to technological and organizational changes that affect the extent of moral hazard within the firm. This line of research is largely unexplored at the moment.

All the models we surveyed in this section are qualitative in nature and, although they establish a logical link between organizational change and inequality, they do not provide any quantitative analysis. One of the main obstacles is that explicit models of organizations contain parameters and variables that are hard to observe, measure, and therefore calibrate (hierarchies, communication costs, number of tasks, etc.). Recently, several papers have started to measure, in various ways, "organizational capital" or "intangible capital" (see, e.g., Hall, 2001, McGrattan and Prescott, 2003, and Atkeson and Kehoe, 2002). A promising avenue for research would try to incorporate this measurement into models that link reorganization with changes in the stock of organizational capital and that relate the latter to the wage structure in order to perform a more rigorous quantitative analysis.

6 Technical Progress as a Source of Change in Labor Market Institutions

Throughout the chapter, up to this point, we have maintained a "competitive" view of the labor market and argued that skills are priced at their marginal product, potentially explaining large parts of the observed dynamics of inequality. However, the labor market displays very peculiar features compared to many other markets in the economy: a sizeable fraction of labor may be considered as under-employed in any given period (unemployment), individual workers often organize themselves into coalitions (unions), and wages frequently seem to be set through some explicit negotiation between firms and workers (individual and collective bargaining). These attributes of the labor market are, arguably, better captured by non-competitive models. We begin our departure from the purely competitive framework by introducing unions and collective bargaining.

Historically, unions and centralized bargaining have been key institutions in the determination of wages and other important labor market outcomes. Over the past 30 years, the economies of the United States and the United Kingdom experienced rapid deunionization. In the United States, in the late 1970s, 30 percent of male non-agricultural private-sector workers were unionized. By 2000, only 14 percent were unionized (Farber and Western, 2000). In the United Kingdom, union density among male workers was around 58 percent in the late 1970s and it has fallen uninterruptedly since to 30 percent today (Machin, 2000 and 2003). There is a variety of evidence that unions compress the structure of wages, even after controlling for workers' characteristics, and thus many economists suspect that their decline may have been an important factor in the increase in inequality in the Anglo-Saxon economies (see, e.g., Gosling and Machin, 1995, and DiNardo et al. 1996).

The existing literature has explored mainly two explanations for the decline in unions. The first generation of papers argued that an important force in the fall of unionization is the change in the composition of the economy away from industries, demographic groups, and occupations where union organization was comparatively cheaper and unions have been traditionally strong (Dickens and Leonard, 1985). However, Farber and Krueger (1992) estimate that compositional shifts can account for at most 25 percent of the decline in the United States and have played virtually no role since the 1980s. Machin (2003) reports that only around 20 percent of the U.K. union decline of the last two decades can be attributed to compositional change.

The second hypothesis is that the legal and political framework supporting union membership deteriorated in the 1970s and 1980s.[60] To date, this explanation seems to have gained rather broad acceptance, even though this view has limits as well. For example, the fall in union organizing activity precedes two key political events: the air-traffic controller strike of 1981 and Reagan's Labor Board appointments in 1983 (Farber and Western 2002). U.K. data also show that the fall in union membership pre-dates the first Thatcher government. Overall, we think that the forces behind rapid deunionization are not yet well understood.

[60]Some authors emphasized anti-union management practices (Freeman 1988). Others focused on changes in the composition of the National Labor Relation Board (Levy, 1985).

In most of continental Europe, unions are still strong, and there are no clear signs of decline in union coverage, but a marked change in union behavior has occurred over the past 30 years. Several indexes of coordination and centralization in unions' bargaining for Europe show a distinct trend towards more decentralized wage negotiations, especially in the Scandinavian countries, whose unionization rates are the highest (Iversen, 1998).

The standard explanation for the shift towards decentralized bargaining is based on the interaction between monetary policy and wage setting arrangements. With an independent national central bank, coordination in bargaining among unions is useful because it allows unions to internalize the implications of their wage claims on inflation. With the advent of the European monetary union and the institution of the European Central Bank within-country coordination proves less useful. However, the evidence in favor of this hypothesis is scant. First, monetary policy does not seem to Granger-cause centralization empirically (Bleaney, 1996). Second, we did not observe a substantial trend towards cross-border coordination in unions' bargaining.

Recently, a new hypothesis for deunionization and decentralization in unions' wage setting, based on skill-biased technological change, has been advanced by Acemoglu et al. (2001) and Ortigueira (2002). Their arguments rest on the view that unions are coalitions of heterogeneous workers which extract rents from employers and only exist insofar as members have an incentive to stay in the coalition and continue bargaining in a centralized fashion. The conjecture of these authors is that skill-biased technical change can dramatically alter such incentives.

6.1 Skill-Biased Technology and the Fall in Union Density

Here, we outline a reduced form model that conveys the basic trade-offs highlighted by Acemoglu et al. (2001). Suppose there are two kinds of workers l_s of which are skilled and $l_u = 1 - l_s$ of which are unskilled. If employed in the competitive sector, these workers will receive wages equal to their productivity, h_s and $h_u < h_s$, respectively. We will think of skill-biased technological change as a rise in h_s relative to h_u.

Workers can also be employed in unionized firms and receive wages, w_s and w_u. A main

characteristic of unions is that they compress wages. In our setup, this means that the wage gap between the unionized skilled and unskilled workers is smaller than the productivity gap, or

$$w_s - w_u = \kappa (h_s - h_u), \tag{21}$$

where $\kappa < 1$ is the degree of wage compression. This equation may arise for a variety of reasons. Collective decision-making within a union may reflect the preferences of its median voter, and if this median voter is an unskilled worker, he will try to increase unskilled wages at the expense of skilled wages. It is also possible that union members choose to compress wages because of ideological reasons or for social cohesion purposes. Or, in presence of idiosyncratic uncertainty, unions could offer insurance to their members by setting a flatter income profile. The empirical literature is broadly consistent with the notion that unions compress wages, though it does not distinguish among the various possible reasons for it (see Booth, 1995).

Union wages (w_s, w_u) must also satisfy some participation constraint for firms (who would otherwise either shut down or open a non-unionized plant). Suppose that this takes the form of non-negative profits:

$$h_s l_s + h_u (1 - l_s) + \Omega (h_s, h_u) - [w_s l_s + w_u (1 - l_s)] \geq 0, \tag{22}$$

where $\Omega (h_s, h_u) > 0$ is the additional contribution of unions to output, as a function of both types of labor.[61] This could be because unions, ceteris paribus, increase productivity (for example, Freeman and Medoff, 1984, and Freeman and Lazear, 1995, argue this). Or unions may encourage training (as in Acemoglu and Pischke, 1999).

Solving the wage compression and participation constraint equations (21) and (22) as equalities, we obtain the maximum wage that a skilled worker can be paid as a union member:

$$\overline{w}_s = h_s - (1 - l_s)(1 - \kappa)(h_s - h_u) + \Omega (h_s, h_u).$$

Intuitively, as w_s rises, w_u must increase too in order to satisfy the wage compression constraint (21) but since profits fall with labor costs there is an upper bound to the wage of a

[61] As long as unions are sustainable, all workers, skilled and unskilled, will prefer to join the union.

skilled union member. Skilled workers will remain union members as long as what they are paid as union members exceeds their competitive salary,

$$\overline{w}_s \geq h_s. \tag{23}$$

From the no-quit condition (23) and the wage compression constraint (21), it follows that $\overline{w}_u \geq h_u$, so unskilled workers will always remain unionized. Observe that the slope of the maximum union skilled wage $\overline{w}_s$ as a function of the productivity of skilled workers h_s is:

$$\overline{w}'_s(h_s) = 1 - (1 - l_s)(1 - \kappa) + \Omega_1(h_s, h_u),$$

Since $\kappa < 1$, as long as the benefits of unionization, $\Omega(h_s, h_u)$, do not increase too rapidly in h_s (i.e., the benefits of unionization do not increase much with skill-biased technical change), we have $\overline{w}'_s(h_s) < 1$. Hence, there exists a cutoff level, h_s^*, such that $\overline{w}_s(h_s) < h_s$ for any $h_s > h_s^*$. This implies that once technical change takes h_s above h_s^*, the wage compression imposed by unions becomes unsustainable, and skilled workers will break away from unions.

Notice that skill-biased technical change is the cause of the deunionization and directly increases inequality. However, deunionization itself contributes to inequality as well. Before deunionization, the wage gap between skilled and unskilled workers is $w_s - w_u \leq \kappa(h_s - h_u)$, and widens smoothly with skill-biased technical change. It is only after deunionization that it jumps up discretely to $w_s - w_u = h_s - h_u$. Therefore, although deunionization is not the primary cause of the surge in wage inequality, it amplifies the original effect of these economic forces by removing the wage compression constraint imposed by unions.

6.2 Skill-Biased Technology and the Fall in Centralized Bargaining

In many European countries—in particular among the Scandinavian countries—the so-called "Ghent system" creates a fiscal-policy link among unions. Under this system, unemployment benefits are administered by the individual unions, but they are funded by the government through aggregate labor income taxation. Hence, not only does the net income of unions' members depend on their negotiated wage, but, through the equilibrium tax rate, also on

the wage claims of other unions. Ortigueira (2002) outlines a model economy with this institutional feature, where there are two types of workers, skilled and unskilled, and two unions that can choose to coordinate their wage determination. Unemployment is generated through a frictional labor market with a standard matching function.

Under decentralized bargaining, unions take the tax as given. Ortigueira (2002) shows that there are two possible steady states: in one, unions expect a low tax, thus making moderate wage claims which, in turn, keep equilibrium unemployment and tax rate low, fulfilling the initial expectation; in the other steady state, unions expect a high tax rate, thus making strong wage claims that produce high unemployment and a high tax rate. This second equilibrium yields lower income and lower welfare for union members. Centralized bargaining avoids the coordination failure and the associated welfare losses that can arise in this "bad equilibrium," and hence it can be preferred by unions. Note, however, that the "good equilibrium" under decentralized bargaining is still the best outcome. It is the ex-ante uncertainty that the bad equilibrium could arise that makes coordination attractive.

However, consider what happens with the advent of a skill-biased technology that increases the demand for skilled workers sharply, reducing their unemployment incidence. When unemployment benefits are proportional to wages, the fact that skilled workers are much less likely to be unemployed decreases the social expenditures of the government. As a result, under decentralized bargaining, the equilibrium with high taxes and low welfare does not survive the advent of a skill-biased technology. This justifies the shift in unions' wage setting policies towards decentralization.[62]

6.3 Discussion

The testable implications that can be identified above are that (1) among the experienced workers, the most skilled leave the unions in response to technological improvements and that (2) among the new entrant cohorts, the most educated workers opt for non-unionized

[62]See also den Haan (2003) for a model with multiple steady states, one with low tax and unemployment rates and one with high tax and unemployment rates, applied to the U.S.-Europe comparison of labor market outcomes.

jobs. However, these implications are derived from theories of technology-induced deunionization that are rather exploratory; more sophisticated and rigorous models of unions (with endogenous membership and endogenous wage-compression mechanisms) are yet to be developed.

The recent empirical studies by Card (2001), for the United States, and Addison et al. (2004), for the United Kingdom, compare the unionization rate across several skill groups before and after the collapse in union density in these two countries (1973 and 1993 for the United States, and 1983 and 1995 for the United Kingdom). The common finding of these two papers, is that unionization declined most for the low- and middle-skill groups.[63] Taken at face value, this preliminary evidence is not favorable to the hypothesis discussed in this section. However, one has to be cautious in interpreting these results because this work does not control for unobserved heterogeneity.[64] Suppose that—as documented by Card (1996)—unobserved ability is higher among unionized workers with low observable skills. Given that unionized firms offer a compressed wage schedule, such a contract would attract the highest ability workers with low education and the lowest ability workers with high education. Moreover, assume that technological change induces a rise in the market return for innate ability, as discussed in section 3.2. Then, the theory suggests that one should observe exactly the cross-skill deunionization pattern documented from U.S. and U.K. data.

It should be mentioned that a technology-based theory of deunionization must also explain why union density did not fall (in fact, it expanded somewhat) in the public sector. Since the public sector is, by definition, sheltered from the international competition, it is reasonable to conjecture that the leap in competitive pressure faced by many manufacturing industries over the past 30 years eroded those rents that are, according to some researchers, at the heart of the existence of unions. A quantitative evaluation of the importance of this channel is yet to be performed.

[63]Note that wages in the union sector do not fully reflect skills. For this reason, these authors impute skill deciles to unionized workers based on what workers with similar observable characteristics (age, education, gender, race, etc.) would earn in the non-union sector.

[64]Card (2001) makes a rough adjustment for unobserved heterogeneity, based on Card (1996). A thorough analysis would require the use of longitudinal data, but both, Card (2001) and Addison et al. (2004), are restricted to repeated cross-sections.

Another avenue that so far has not been pursued is the analysis of deunionization in conjunction with the structural changes in workplace organization that occurred in the past 30 years. In Section 5, we argued that a distinct feature of the recent change in the production process, especially in manufacturing, is the switch from Tayloristic organizations, where workers repeatedly performed similar tasks around the conveyer belt, towards "flatter" organization built on teams where workers engage in multiple tasks and where the individual division of labor is much fuzzier. Union's wage setting arrangements, based on "equal pay for equal work", can be effective within a Tayloristic plant, but then become very inefficient in plants where production is organized through teams. There is no reason to assume that workers performing the same task will be equally productive, since they perform many other complementary operations simultaneously (see, e.g., Lindbeck and Snower, 1996).

7 Technological Change in Frictional Labor Markets

Most of the models presented so far feature an aggregate production technology, i.e., the production structure is centralized, and competitive labor markets. Constructing a frictional model of the labor market requires departing from both attributes and moving towards a decentralized production structure and a labor market with imperfect coordination between workers and firms in the matching process. This class of models gives rise to frictional equilibrium unemployment and "frictional equilibrium inequality". By frictional inequality, we mean wage dispersion that is purely an artifact of frictions and that, without frictions, would disappear. A useful way to think about this phenomenon is to introduce the concept of "return to labor market luck".

Throughout this chapter, we have discussed several models where technological progress produces a rise in the return to observable and unobservable *permanent* components of individual skills, such as educational attainment, age, and innate ability. These permanent factors greatly determine inequality of earnings among the population, but they are not by any means exhaustive. Earnings display a large *stochastic* component (e.g., events related to the luck of individuals, firms, or industries) that is responsible for their fluctuations around

the permanent component.[65]

Gottschalk and Moffitt (1994) were the first to ask how much of the observed increase in inequality is attributable to a rise in earnings volatility and instability around its permanent component. They used a simple statistical model where log wages, w_{it}, for an individual i at time t—net of their predictable age profile—are assumed to be the sum of two orthogonal components, a fixed individual effect, α_i, and a stochastic ($i.i.d$) component, ε_{it}. Using the covariance structure of wages within a panel of U.S. males (constructed from PSID data), they reached the conclusion that the fraction of the total increase in cross-sectional inequality attributable to a surge in earnings volatility is between one third and one half.[66] One can interpret this fact as a rise in frictional inequality, or in the "return to labor market luck." The argument set forth is that the rapid diffusion of a new technology leverages the importance of these stochastic factors, raising the premium to workers with no observable distinguishing characteristics other than their good fortune.

Most of the work we review uses the random matching model of the labor market (see, e.g., Mortensen and Pissarides, 1998, or Pissarides, 2000). In this framework the existence of frictions creates a bilateral monopoly as a result of a meeting between a vacant firm and a worker. Wages are determined by bargaining over total output, so more productive firms tend to pay more, creating wage dispersion among ex-ante equal workers. We start by studying how technological change affects unemployment in this class of models. Next, we move to wage inequality. Random matching is a somewhat extreme characterization of frictions. In the last part of the section we contrast random search models to directed search models.

[65] A large empirical literature documents wage dispersion among observationally equivalent workers that cannot be fully reconciled with unobserved heterogeneity in permanent components. Abowd et al. (1999) document that firm effects still play a role, after controlling exhaustively for individuals' effects. Krueger and Summers (1988) found that a worker moving from a high to a low wage industry is subject to a wage loss roughly equal to the inter-industry differential.

[66] The subsequent literature on the subject demonstrated the robustness of this result to richer statistical models for the stochastic component of wages. See Haider (2001), Heathcote et al. (2003), and Meghir and Pistaferri (2004) for the United States and Blundell and Preston (1998) and Dickens (2000) for the United Kingdom.

7.1 Technological Progress and Frictional Unemployment

There is a sizeable literature trying to characterize how equilibrium unemployment reacts qualitatively to variations of the rate of technological change within a matching model à la Diamond-Mortensen-Pissarides (DMP) with vintage capital à la Solow (1960). Two distinct approaches emerge from the literature.

The first, that can be attributed to Aghion and Howitt (1994), argues that when new and more productive equipment enters the economy exclusively through the creation of new matches—because existing matches cannot be "upgraded"—it has a Schumpeterian "creative-destruction" effect: new capital competes with old capital by making it more obsolete and tends to destroy existing matches, because workers are better off separating from their old matches to search for the new firms endowed with the most productive technology. Thus, unemployment tends to go up as growth accelerates, due to a higher job-separation rate.

The second approach, due to Mortensen and Pissarides (1998), proposes an alternative view whereby the new technologies enter into existing firms through a costly "upgrading" process of old capital. In the extreme case where upgrading is free, we have the Solowian model of disembodied technological change, even though the carrier of technology is equipment. The separation rate is unaffected by faster growth and all the effects work through job creation. For small values of the upgrading cost, unemployment falls with faster growth, thanks to the familiar "capitalization effect": investors are encouraged to create more vacancies, knowing that they will be able to incorporate (and hence benefit from) future technological advances at low cost.[67]

Hornstein et al. (2003b) try to resolve the issue quantitatively. When they parameterize the model to match some salient features of the U.S. economy, they find that, in the vintage-matching model, the link between capital-embodied growth and unemployment does not

[67] An interesting qualification to this result is provided by King and Welling (1995): if, unlike what is customarily assumed in this family of models, workers bear the full fixed search cost, then the capitalization effect leads to an increase in the number of searchers and to longer unemployment durations. See Pissarides (2000, chapter 3) for a detailed discussion on growth and unemployment in matching models of the labor market.

importantly depend on to what parties—new matches or old ones—the benefits of the technological advancement accrue. The intuition for this "equivalence result" is that upgrading can be much better than creative destruction only if it is very costly for vacant firms to meet workers, but the data on the low average unemployment and vacancy durations imply that, in the model, this meeting friction is minor. That paper also shows that the same data on average unemployment duration impose severe restrictions on how much frictional wage inequality the model can generate. In the standard search model, high dispersion of wage opportunities makes workers very demanding and increases unemployment spells. Thus, a high wage dispersion could only coexist, in equilibrium, with long unemployment durations.

We now turn to the analysis of how technological progress impinges on frictional inequality in random matching models. In these models, however, the limits on the extent of wage inequality due to luck emphasized in Hornstein et al. (2003b) apply as well.

7.2 Technological Heterogeneity and the Returns to Luck

In a frictional labor market populated by ex-ante equal workers, an increase in technological heterogeneity can increase the return to luck. We explain this mechanism within a simple framework based on Aghion et al. (2002).[68] Consider an economy populated by a measure one of infinitely lived, ex-ante equal, and risk-neutral workers as well as by the same measure of jobs. Jobs are machines embodying a given technology. The technological frontier advances every period at rate $\gamma > 0$. The machines have a productive life of two periods. An age $j \in \{0, 1\}$ machine that is matched with a worker produces output, $y_j = (1+\gamma)^{-j}h$ (normalized relative to the age 0 machine), where h represents the skill level of the workers.

The labor market is frictional, i.e., workers separated from their jobs are randomly rematched with a vacant machine. To simplify, we assume that they always make contact with a machine. We postulate that, upon contact, the bilateral monopoly problem is solved by a rent sharing mechanism setting wages to be a constant fraction, ξ, of current output, y_j, where ξ is a measure of the bargaining power of workers.

It is easy to see that in an equilibrium where all job offers are accepted, the lucky half

[68] See also Manuelli (2000) and Violante (2002).

of the workers will be employed on new machines and the unlucky half on old machines. The variance of log wages is simply given by $var(\log w) = \gamma^2/4$, which is increasing in the rate of embodied technological change. Intuitively, in this economy all the heterogeneity is generated by technological differentials across machines. A technological acceleration (rise in γ) amplifies the productivity gaps between jobs. Since in this non-competitive labor market individual wages are linked to individual output, this acceleration then also raises wage dispersion even among ex-ante equal workers, i.e., it raises the return to luck.[69] As in Jovanovic (1998), however, if the scrapping age of capital is endogenous, the model would display an offsetting force. This force is due to the fact that, when the growth rate is higher, machines becomes obsolete faster, and firms scrap machines earlier. Therefore the equilibrium age range of machines in operation shrinks, compressing technological heterogeneity.

7.3 Vintage Human Capital with Frictions

A technological acceleration not only affects transitory residual wage inequality through its impact on the underlying distribution of job productivity differences. The technological acceleration may also affect the distribution of worker productivity differences if it interacts with the accumulation of job/technology-specific knowledge.[70] Violante (2002) extends the above model to include vintage human capital. Employed workers accumulate, through learning-by-doing, knowledge about the technology they are matched with. We normalize the amount of specific skills cumulated after every employment period to 1, so that the learning curve of the workers is concave, i.e., learning is faster for workers with lower initial skills. To keep the model tractable, we also assume that skills fully depreciate after two periods.

A worker on a machine of age i who moves on to a machine of age j next period can

[69] This increase in wage inequality is mirrored by a rise in wage instability along the lifetime of each worker: given a certain amount of labor turnover, larger cross-sectional productivity differences translate into more volatile individual wage profiles.

[70] The accumulation of job/technology-specific knowledge is also at the heart of the discussion of the experience premium in section 4.

transfer h_{ij} units of the accumulated skills to the new job :

$$h_{ij} = \min\left\{(1+\gamma)^{\tau(j-i+1)}, 1\right\}, \tag{24}$$

with $\tau > 0$ and $i, j \in \{0, 1\}$. The fraction of skills that can be transferred from an old to a newer machine is proportional to the *technological distance* between the two machines through a factor $\tau \geq 0$. The presence of the term γ in the transferability technology is crucial: the rate of quality improvement of capital-embodied technologies determines the degree by which new technology is different, more complex, and richer than the previous generation of machines. A higher γ reduces skill transferability in the economy.[71] Equation (24) and the depreciation assumption implies that we have three skill levels in the economy:

$$h_{01} = 1, \quad h_{00} = h_{11} = (1+\gamma)^{-\tau}, \quad h_{10} = (1+\gamma)^{-2\tau}, \tag{25}$$

and the corresponding wage rates (normalized relative to the wage on an age 0 machine) are $w_{ij} = \xi h_{ij} (1+\gamma)^{-j}$, $i, j \in \{0, 1\}$. Note that, given this simple expression for wages, the variance of log wages can be written as

$$var(\widetilde{w}) = \gamma^2 var(j) + var(\widetilde{h}) - 2\gamma cov(\widetilde{h}, j), \tag{26}$$

which is the sum of technological heterogeneity (the force discussed earlier), ex-post skill heterogeneity among workers, and the degree of assortative matching between skills and technologies measured by their covariance.[72]

One can prove that, for large enough γ, workers separate from firms every period.[73]

[71] The book by Gordon (1990) provides several examples of quality improvement in equipment requiring the performance of new tasks in the associated jobs. In the aircraft industry in the 1970s, new avionics were introduced that provided a safer but more complex navigation system. In the telephone industry, around the mid-1970s, electromechanical telephone switchboards were replaced by more sophisticated and flexible electronic equipment with larger programming possibilities. In the software industry, since the early 1980s, every new version of a software is equipped with new features. Those users who remain attached to an old version are often unfamiliar with many features of the new version.

[72] A rise in the degree of assortative assignment between workers' skill and machines' productivity is equivalent to a *fall* in the covariance component (recall that j is machine's age, which is inversely related to productivity) and a rise in the variance of wages.

[73] This result is related to the intertemporal trade-off intrinsic in the separation decision: choosing to remain on the old vintage improves the current wage (no vintage-specific skill is lost), but worsens future wages because in the next period the worker will have older knowledge, with low degree of transferability. As γ goes up, the expected future wage loss from holding old skills increases faster than the current wage gain, inducing the worker to optimally anticipate its separation decision.

Under this optimal separation rule, the equilibrium level of wage dispersion is given by

$$var(\widetilde{w}) = \gamma^2 \left[\frac{1}{4} + \frac{1}{2}\tau \left(\tau - 1 \right) \right], \tag{27}$$

so it is increasing in γ whenever the variance is well defined (positive). In particular, the equilibrium displays $var(\widetilde{h}) = \frac{\gamma^2\tau^2}{2}$, and $cov(\widetilde{h}, j) = \frac{\gamma\tau}{4}$. The variance of skills is increasing in γ since a higher γ reduces the skill transferability of the bottom-end workers (h_{10}), while not affecting the skill level of the top end workers (h_{01}). The covariance between skills and age of technology is also increasing in γ, a force that restrains inequality because it worsens equilibrium sorting in the economy. The reason is that a larger γ reduces the skills of workers moving to the new technology relatively more than the skills of workers moving to old technologies.

A common criticism of this class of models is that the degree of churning in the labor market (i.e., labor mobility or job reallocation) has to rise in order to generate more volatile earnings, whereas the empirical literature documents no significant rise in labor mobility (Neumark, 2000).[74] This is a misconception. One way to unravel this issue exploits the equivalence between cross-sectional wage dispersion and individual wage instability in a model with ex-ante equal and infinitely lived agents. A technological acceleration has two effects. First, it curtails skill transferability, thereby increasing wage losses upon separation. Second, it reduces the average skill level of workers who find themselves, on average, on the steeper portion of a concave learning curve, which in turn implies higher wage growth on the job. Both these forces tend to raise individual earnings volatility, for any given level of labor mobility. Violante (2002) offers some evidence of wage losses upon separation and wage growth on the job being larger in the 1980s than in the 1970s and shows that a calibrated full-scale version of this model can account up to 90 percent of the rise in wage instability in the U.S. economy, while at the same time implying only a very modest rise in equilibrium labor turnover.

[74]The empirical literature on labor mobility contains partly opposing results: whereas Jovanovic and Rousseau (2004b) find a significant decline of labor mobility since the 1970s, Kambourov and Manovskii (2004) find that occupational mobility increased since the 1970s.

7.3.1 Occupation-Specific Human Capital

Occupation-specific experience may be one of the least transferable components of human capital, and a change in occupational mobility can have a big impact on the wage structure. Kambourov and Manovskii (2004) document an increase in occupational mobility in the United States from 16 percent in the early 1970s to 19 percent in the early 1990s.[75] Based on a calibration exercise Kambourov and Manovskii argue that 90 percent of the rise in residual inequality (i.e., in both the permanent and the stochastic component) is due to increased occupational mobility.

The authors build a model of occupation-specific human-capital accumulation based on the equilibrium search framework of Lucas and Prescott (1974). At any one time workers can work in one occupation only. Workers choose their occupation based on their occupation-specific experience. When working in an occupation, workers increase their specific experience, and they lose some of this experience when moving between occupations. A worker's wage in a given occupation depends on the specific experience and the occupation's productivity.

The productivity of occupations is subject to shocks, and increased variability of these shocks directly increases wage variability. However, the total impact of occupational productivity shocks on wage inequality depends on the occupational choice response of workers. Workers in an occupation whose productivity declines choose to move in search of better occupations, and, by so doing, they dampen the effect of the shock on inequality. When the increased variance of productivity shocks is accompanied by decreased persistence –as conjectured by the authors– workers in occupations hit by moderately negative shocks may choose not to switch occupation because occupations which look profitable today may turn quickly into unproductive ones. This latter effect amplifies the direct effect of the initial shocks.[76]

[75] Kambourov and Manovskii use occupational data from the PSID at the three-digit level, including almost 1000 occupational groups.

[76] The model of Bertola and Ichino (1995), discussed in section 8, generates increased wage inequality through a similar mechanism.

7.3.2 A Precautionary Demand for General Skills

Gottschalk and Moffitt (1994) found that the transitory component of inequality is larger (and increased more) for low-education workers. Gould et al. (2001) model this phenomenon using a vintage human capital model where risk-averse workers choose their level of education. They study an economy where workers are ex-ante heterogeneous with respect to permanent innate ability, and the return to college education is increasing in ability. High-ability workers obtain a college education that provides them with general skills which do not depreciate as technology advances. Low-ability workers do not acquire general skills in college; rather, they acquire technology-specific experience through on-the-job learning. Here, we refer to workers with a college education as skilled and to workers without a college education as unskilled.

Gould et al. (2001) consider a shock to the economy that simultaneously increases the rate of embodied technological change and the ex-ante variance of technological progress across jobs.[77] This shock increases the "precautionary" demand for college education, since holding technology-specific skills becomes more risky. The lowest ability threshold for college graduates falls, and thus permanent inequality increases within skilled workers and falls within the group of unskilled workers. At the same time, the rise in the variance of embodied technological change means that "skill erosion" has a bigger impact on the relative wages of unlucky and lucky unskilled workers, so the increase in their wage variance is mostly determined by transitory components.

This mechanism relies on the assumption that the variance of technical progress is heteroskedastic in the sense that it rises with its mean. We know very little about this property: Cummins and Violante (2002) analyze the whole cross-industry distribution of equipment-embodied technical change for 62 industries in the United States from 1947 to 2000 and find little evidence of changing variance, although the mean grows substantially over the period. However, they document a rise in the cross-sectoral variance of the "technological

[77] This view of the past 30 years as being a period of high "turbulence" is also present in several models of the differential labor market performance between the United States and Europe, see Section 8.

gap" between average capital and leading-edge machines.[78] According to the transferability technology (24), the technological gap closely measures the degree of skill erosion of an average worker displaced in a given industry.

7.3.3 Explaining the Fall in Real Wages

Interestingly, in a set of model economies with vintage human capital (Helpman and Rangel, 1999, Gould et al. 2001, Violante, 2002, or Kambourov and Manovskii, 2004), during the transition to the new steady state, and notwithstanding the technological acceleration, the fall in the average skill level of the workforce can generate a temporary slowdown in average wage growth and a fall in the real value of wages at the bottom of the distribution—two facts that have been documented extensively for the period of interest.

To illustrate this point, let us return to the model from Section 7.3. Note that in an equilibrium where workers separate every period—as assumed—each skill type represents one fourth of all workers. The four skills types are reported in expression (25) . It is immediate to see that the normalized average log level of skills is $-\tau\gamma$, and thus it falls unambiguously when γ increases. This opens the interesting possibility that, in the model, the average wage could decrease along the transition following a technological acceleration.

Suppose that at time t the economy is in steady state with $\gamma = \gamma_L$ (and with the productivity of the new machine normalized to 1). The average log wage is then $\widetilde{w}_t = -\tau\gamma_L - \gamma_L/2$. Suppose now that γ rises to γ_H. Then, some simple algebra shows that in the next period, the average log wage is

$$\widetilde{w}_{t+1} = \frac{\gamma_H}{2} - \frac{\tau}{2}(\gamma_L + \gamma_H) = \widetilde{w}_t - \frac{\tau}{2}(\gamma_H - \gamma_L) + \frac{1}{2}(\gamma_L + \gamma_H).$$

Thus, despite the technological acceleration, the average wage decreases along the transition if $\tau > (\gamma_L + \gamma_H)/(\gamma_H - \gamma_L)$, that is, if τ or the increase in γ are large.

An alternative explanation for the fall in real wages –which does not depend on vintage human capital– is advanced by Manuelli (2000) within a frictional labor market model where workers have bargaining power and can seize a fraction of the firm's future stream of profits,

[78] See section 3.2.1 for a formal definition of the technological gap.

through wage negotiations. Consider what happens when it is announced that: 1) a new technology will be available in the future; but 2) the incumbent firms will be able to adopt it only with some probability (as in Greenwood and Jovanovic, 1999). Existing firms will anticipate a future increase in wages, driven by the new, more productive entrants. Hence, there will be a transitional phase before the arrival of the new technology, where the market value of the incumbent firms will fall and, with them, the wages they currently pay.

7.4 Random Matching vs. Directed Search as Source of Luck

So far, we have analyzed economies where the friction is due to random matching. Wong (2003) argues that models with random matching can have counterfactual implications.[79] It is well known that in a matching model with two types of workers (skilled and unskilled) and two types of firms (high-tech and low-tech), there can be multiple equilibria (Sattinger, 1995). There are equilibria with perfect sorting where skilled (unskilled) workers are matched with high- (low-) tech firms and equilibria that display some degree of "mismatch." In the latter class of equilibria, luck plays a role as skilled workers, ex-ante equal, can end up in jobs with different productivities. Suppose output is the product between efficiency of capital, z_i, where $i = l, h$ and $z_h > z_l$, and efficiency of labor, h_j, where $j = s, u$ and $h_s > h_u$, i.e., $y_{ij} = z_i h_j$. A wave of skill-biased technical change (or a capital-embodied technological acceleration) that increases the relative productivity of high-tech jobs (i.e., the ratio z_h/z_l) makes high-tech firms more picky in their choice of workers, as now the same skill differences translate in larger output differences. The equilibrium with mismatch is less likely to survive. When the economy switches to the equilibrium with perfect sorting, luck-driven inequality among ex-ante equal workers falls to zero.[80]

One of the key reasons why the model has this counterfactual prediction is that, due to random matching, prices (wages) have no signaling value. Shi (2002) analyzes exactly the same framework (a two-worker, two-firm economy) but he replaces Nash bargaining and

[79] See also Albrecht and Vroman (2002) for a similar environment.

[80] The argument in Wong (2003) regarding models with random matching is quite general; e.g., it applies in the model by Acemoglu (1999). From equation (20) of Section 5, note that as h_s rises (skill-biased technical change), the pooling, or mismatch, equilibrium is less likely to survive, so within-group inequality falls.

random matching with wage posting and directed search, following the alternative approach of "competitive search" (Moen, 1997). His conclusion is that random matching is not essential for technical progress to leverage the effect of luck in the labor market: directed search works equally well.

In this environment, skilled workers only apply to high-tech jobs, while unskilled workers apply to both types of jobs. Ex ante, every unskilled worker is indifferent between jobs, but inequality is generated ex post. Since high-tech firms give always priority to skilled applicants, unskilled workers applying for high-tech jobs are less likely to become employed than are unskilled workers applying for low-tech jobs. Therefore unskilled workers applying for high-tech jobs have to be offered higher wages than in low-tech jobs.

With free entry, a rise in the relative productivity of high-tech jobs (skill-biased technical change) induces the creation of more high-tech vacancies. More unskilled workers become attracted to the high-tech sector and in equilibrium their job finding probability in the high-tech sector falls, so wages rise. In the meantime, fewer unskilled workers stay in the low-tech sector, so their wages fall. In sum, wage inequality among ex-ante equal workers rises with the degree of skill bias in technology.

Can one conclude that directed search models are more suitable than random search models for studying problems where heterogeneity is crucial, such as wage inequality? The answer depends on the dimension of inequality studied. Directed search seems a more reasonable assumption when the trait determining heterogeneity is observable (e.g., education, general experience), whereas random matching fits better in the analysis of wage inequality when the source of heterogeneity is not directly observable (e.g., ability or vintage-specific skills).

8 Technology-Policy Complementarity: United States vs. Europe

A large portion of this chapter has been dedicated to the analysis of a number of different economic models designed to decipher the dynamics of the U.S. wage distribution over the

past three decades, in light of changes in technology.

In this section we expand our viewpoint to include other dimensions of labor market inequality, which allows us to contrast the U.S. experience with the European experience. In Section 2 we documented that while wage inequality soared in the United States, both the labor share of income and the unemployment rate remained remarkably stable there. In sharp contrast, in most of the large continental European economies, the wage structure did not change much at all, while the labor share fell substantially and unemployment increased steadily. In particular, the increase in European unemployment largely reflects longer durations rather than higher unemployment incidence.

8.1 The Krugman Hypothesis

Why have we observed such different outcomes for two regions of the world standing at a similar level of development and, therefore, being subject to very similar aggregate shocks? Are we witnessing a sort of *devil's bargain*, i.e., a trade-off between inequalities: low unemployment can only be achieved by paying the price of soaring wage inequality? And, if so, what determines the position of each country along this trade-off?

In Table 2 we report, for the set of countries from Table 1, some indexes of the rigidity of various labor market institutions reproduced from Nickell and Layard (1999). The conclusion is unambiguous: compared to the United States, continental Europe has stricter employment protection legislation, more generous and longer unemployment benefits, less decentralized wage bargaining, and more binding minimum wage law.

TABLE 2

The large majority of papers in the literature have taken the data exhibited in Table 2 as uncontroversial evidence that the reason for the observed differences can be found in the differences in labor market institutions between United States and Continental Europe. Krugman (1994) was probably the first to provide a simple formalized model of this hypothesis. Simply put, the interaction between a severe technological shock and rigid European institutions have induced an adjustment through equilibrium *quantities* of labor (i.e., the

employment distribution), whereas in the flexible U.S. labor market, the adjustment occurred through *prices* (i.e., the wage distribution).

Several authors have tried to test the Krugman hypothesis econometrically. The typical analysis is based on a cross-country panel of institutions and shocks, i.e., it allows for changing institutions over time, beyond aggregate shocks. A statistical model linking shocks and institutions to the dynamics of unemployment and wage inequality is estimated to evaluate the role of shocks and institutions, first separately and then interacted. The shocks considered are usually of technological nature and are measured through changes in measured TFP and changes in the labor share of income, possibly capturing a form of capital-biased technical change. In all cases the shock is assumed to be common across countries.

Blanchard and Wolfers (2000) argue that changing institutions alone have little explanatory power. The performance of the statistical model in explaining cross-country patterns of unemployment rates improves once shocks and institutions are interacted: an equal-size technological shock has differential effects on unemployment when labor market institutions differ. Bertola et al. (2001) provide further evidence for this view. Bentolila and Saint-Paul (1999) also study the evolution of the labor share across OECD countries since 1970. Using panel data techniques, they find that in the presence of institutions that promote wage rigidity, shocks that reduce employment also significantly reduce the labor share of income. One common problem in this empirical literature is that the results are, in general, not robust to the chosen specification.[81]

Another problem of this methodology is that the economic mechanism behind the interaction between technology and policy is not explicit. Consistently with the approach we took in the chapter so far, we will devote more space to quantitative analyses based on "structural" equilibrium models. In the rest of this section, we present the various frameworks the literature has explored to understand the interactions between technological progress and labor market institutions in shaping the various dimensions of inequality. We have grouped

[81] The recent results in Nickell and Nunziata (2002) seem to support an explanation of cross-country unemployment differentials largely based on changing institutions, with a common technological shock playing only a minor role.

these frameworks into six categories, according to the type of technological shock modeled: 1) a rise in microeconomic turbulence, linked to some fundamental change in technology, 2) a slowdown in total factor productivity, 3) an acceleration in the rate of capital-embodied productivity improvements, 4) skill-biased technical change, 5) a technological innovation whose adoption is endogenous, and 6) the structural transformation from manufacturing to services.

8.2 Rise in Microeconomic Turbulence

In Section 2 we have documented that roughly one-half of the rise in cross-sectional wage differentials in the United States is not associated to a higher return to permanent skills. Rather, it is due to increased wage "instability" over the workers' life time. In other words, transitory idiosyncratic shocks to labor productivity and wages have become more important over time (Gottschalk and Moffitt 1994). These larger temporary wage movements constitute important evidence that there has been a rise in the degree of microeconomic turbulence in the U.S. economy.

More evidence comes from the firm side. Campbell et al. (2001) show that the cross-sectional variability of individual stock returns has trended upward from 1962 to 1997. Chaney et al. (2003) and Comin and Mulani (2003) use Compustat firm-level data to demonstrate that the firm-level volatility of real variables, such as investment and sales, has gone up from 1970-1975 to 1990-1995. Overall, these papers provide snapshots, from very different angles, of an economy where idiosyncratic turbulence and volatility have risen to a high level.

Bertola and Ichino (1995) and Ljungqvist and Sargent (1998, 2003) argue that a rise in microeconomic turbulence that interacted with more or less rigid institutions can explain the U.S.-Europe dichotomy. Interestingly, the former authors identify wage rigidity and strict employment protection laws as the culprits, while the latter emphasize the generosity of unemployment benefits. Note, though, that one key premise behind these theories is that the surge in turbulence is common to the United States and Europe. We are not aware of any empirical work documenting trends in microeconomic instability in continental Europe.

Currently, this represents a limit for this class of explanations.

8.2.1 The Role of Wage Rigidity

The framework proposed by Bertola and Ichino (1995) is inspired by the Lucas and Prescott (1974) island-model of equilibrium unemployment. The economy is populated with a measure, L, of risk-neutral workers and a measure one of firms, indexed by $i \in [0,1]$. Each firm is subject to idiosyncratic productivity shocks that follow a two-state Markov chain taking values $\left(A^G, A^B\right)$, with $A^G > A^B$, and with transition probability, p, that the state (good, G, and bad, B) changes. When labor mobility is perfect, employment adjusts across good and bad firms to equalize wage differentials, and a unique market-clearing wage rate arises in equilibrium, i.e., there is no wage inequality.

Consider now the case where wages are flexible, but where workers have to pay a fixed moving cost, $\kappa > 0$, to change firms (this is the U.S.-like economy). In any period, workers observe the productivity level in all firms, but moving takes one period. Hence, when they start working, productivity might change. It is easy to see that the value functions of a worker in good- and bad-state firms, respectively, are

$$W^G = w^G + \frac{1}{1+r}\left[pW^B + (1-p)\,W^G\right], \tag{28}$$

$$W^B = \begin{cases} w^B + \frac{1}{1+r}\left[pW^G + (1-p)\,W^B\right] & \text{if staying,} \\ w^B - \kappa + \frac{1}{1+r}\left[pW^B + (1-p)\,W^G\right] & \text{if moving.} \end{cases} \tag{29}$$

If workers leave bad firms in equilibrium, the marginal worker has to be indifferent between staying in a B firm or moving, yielding

$$W^G - W^B = \frac{1+r}{1-2p}\kappa.$$

Using (28) and (29) together with this condition, one arrives at the expression for equilibrium wage inequality:

$$w^G - w^B = \frac{r+2p}{1-2p}\kappa. \tag{30}$$

On the one hand, the closer p is to 0, the more permanent are productivity changes. This justifies a large amount of wage-equalizing mobility, and hence there is smaller ex-post wage

inequality across firms. On the other hand, the larger is the degree of volatility in the economy (the closer p is to $1/2$), the riskier it is to move for a worker, as the new firm can quickly turn into the B state, and the cost κ is wasted. In this case, mobility will be low and the ex-post wage differential will increase.

Now consider the same experiment in a Europe-like economy where wages are rigid, i.e., where $w^B = w^G = w$, and where firing costs are prohibitively high, so that employment at every firm is constant at $\bar{l}$. To analyze this situation, Bertola and Ichino assume that firm i has a linear marginal revenue product $\pi(l^i) = z^i - \alpha l^i$, so that the marginal values for a firm in the G and B state of a unit of labor, respectively, are

$$V^G = A^G - \alpha\bar{l} - w + \frac{1}{1+r}\left[pV^B + (1-p)V^G\right], \text{ and}$$

$$V^B = A^B - \alpha\bar{l} - w + \frac{1}{1+r}\left[pV^G + (1-p)V^B\right].$$

In an equilibrium with free-entry, the hiring firm in the G state will have $V^G = 0$. Hence, the system above can be easily solved for $\bar{l}$ to give

$$\bar{l} = \frac{A^G - w}{\alpha} - \left(\frac{p}{r+2p}\right)\left(\frac{A^G - A^B}{\alpha}\right), \tag{31}$$

which shows that a rise in p that increases the degree of turbulence in the rigid economy will reduce average employment, i.e., it will increase the unemployment rate, $L - \bar{l}$. The reason is straightforward: when firms are constrained in their ability to shed labor in the face of a negative shock, they will be very cautious in hiring new workers even in the high-productivity state. Note, in fact, that the larger is the productivity differential $A^G - A^B$ across states, the higher will average unemployment in the economy be.

In conclusion, a similar increase in economic uncertainty induces more caution in workers' mobility and larger wage differentials in an economy with flexible wages whereas it leads to more caution in firms' hiring and lower average employment in an economy with rigid wages and costly layoffs. This result remains qualitative, as the authors did not try an exploration of the quantitative importance of their mechanism. In particular, it would be of interest to study by how much labor turnover needs to decline in order to generate a rise in wage

inequality of the magnitude observed in the U.S. economy. Interestingly, as mentioned earlier, Jovanovic and Rousseau (2004b) document a substantial downward trend in labor mobility in the United States, from 50 percent in 1970 to 35 percent in 2000.

8.2.2 The Role of Welfare Benefits

Ljungqvist and Sargent (1998, 2003) propose an alternative mechanism based on the standard search model of unemployment (McCall 1970). Here, we present a stripped-down version of their argument. Consider an unemployed worker with skill level, h, who searches for a job, sampling wage offers every period from the stationary distribution, $F(w)$, with finite support $[\underline{w}, \bar{w}]$. Her skill level, when unemployed, decays at the geometric rate, δ, whereas, when employed, skills remain unchanged. Employment is an absorbing state (no exogenous breakup of jobs), and workers discount the future at rate r. Unemployment benefits are equal to b. The values of employment and unemployment for a worker of skills h are

$$W(w,h) = \frac{wh}{r}, \text{ and}$$

$$U(h) = b + \frac{1}{1+r}\int_{\underline{w}}^{\overline{w}} \max\left\{U(h'), W(w,h')\right\} dF(w)$$

$$s.t. \qquad h' = (1-\delta)h$$

respectively. The value of employment is simply the discounted present value of earnings, wh; the value of unemployment is given by the unemployment benefit plus the discounted future value of search with the lower skill levels $(1-\delta)h$. At the reservation wage, $w^*(h)$, the values of employment and unemployment are equalized, $U(h) = W(w^*(h), h)$. Standard algebra yields the following characterization of the reservation wage,

$$w^*\left(\frac{r+\delta}{1+r}\right) = r\frac{b}{h} + \frac{(1-\delta)}{1+r}\int_{w^*}^{\overline{w}} [1 - F(w)]\, dw. \tag{32}$$

Ljungqvist and Sargent model the increased turbulence in the economy as a rise in the "skill obsolescence" parameter δ. The introduction of a new technological paradigm, or an acceleration in the rate of technological change, can lead to a higher rate of obsolescence, insofar as skills are at least partly technology-specific (recall our discussion in Section 7).

It is straightforward to show, through simple comparative statics, that w^* falls with δ: a worker aware that her skills will become obsolete faster during unemployment chooses optimally to reduce her time spent searching and decreases her reservation wage. As a result, the unemployment duration falls.

However, an increase in δ has an equilibrium effect on the distribution of workers across skills: the average skill level in the population falls, and one can show that the reservation wage declines in the skill level, i.e., $dw^*/dh < 0$. The key behind this result is that the unemployment benefits, b, do not depend on the *current* skill level, h, of the unemployed workers, whereas wage offers are naturally linked to h. A fall in h worsens the value of the average wage offer relative to the value of remaining unemployed with benefits b. Thus, both the reservation wage and unemployment duration increase.[82] The net effect of these two forces is qualitatively ambiguous, and only a quantitative analysis can determine which force is paramount. Note that it is easy to show that the derivative, dw^*/dh, is increasing (in absolute value) in b. Thus, in Europe-like economies with more generous benefits, the second effect tends to be stronger.

Ljungqvist and Sargent embed this simple mechanism in a much richer and detailed model. They calibrate the increase in turbulence to reproduce average earnings losses upon separation of the size estimated in the labor economics literature and show that in economies with generous welfare state (high b), the rise in microeconomic uncertainty brings about a surge in unemployment comparable to the one observed in continental Europe, with all the increase explained by longer durations, as the data suggest. In a "laissez-faire" economy with low b, the faster rate of skill obsolescence barely has any effect.

A related explanation is set forth by Marimon and Zilibotti (1999). In their model, unemployment insurance has the standard result of reducing employment, but it also helps workers find a suitable job. They construct two artificial economies which only differ by the degree of unemployment insurance and assume that they are hit by a common technological shock which enhances the importance of "mismatch". This shock reduces the proportion of

[82] One can easily generalize the model to allow b to depend on past earnings (thus, on *past* skills when employed) and the mechanism described would still be in place. This is what Ljungqvist and Sargent do.

jobs which workers regard as acceptable in the economy with unemployment insurance, and unemployment doubles in the Europe-like economy.

In the Ljungqvist-Sargent and Marimon-Zilibotti frameworks, the shock-policy interaction operates entirely through the *labor supply* side. These authors essentially argue that unemployment in Europe went up because, for the jobless, it was more beneficial to collect unemployment insurance than to work at a low wage, given that technological change made their skills obsolete (or made it difficult to use them on the current jobs).

8.3 Slowdown in Total Factor Productivity

A decline of TFP growth rates, such as measured for the United States and Europe after the mid-1970s (see Section 2) can reduce employment in a matching framework through the standard "capitalization effect." Consider the decision of a firm to create a job: the firm will compare the set-up cost with the discounted present value of profits. In a growing economy, where technical change is disembodied and benefits all firms equally, a productivity slowdown increases the "effective rate" at which profits are discounted and discourages the creation of new jobs (Pissarides 2000).

den Haan et al. (2001) evaluate this explanation quantitatively within the context of a standard matching model, à la Mortensen-Pissarides (1998). They find that for this channel to have a significant effect on unemployment, one needs to put restrictions on the shape of the cross-sectional distribution of firms' productivities. Since useful data to test these restrictions are scant, the mechanism remains largely unexplored.

Interestingly, in the same paper the authors argue that once the Ljungqvist and Sargent mechanism is embedded into a model with endogenous job destruction, the comparative statics for increased turbulence are reversed, i.e., unemployment falls. The reason is that as the speed of skill obsolescence rises, workers become more reluctant to separate, and job destruction falls.[83] This force dominates the effect described in the previous section.

[83]Recall that the original Ljungqvist and Sargent model is a standard search model where separations occur exogenously. Hence, workers are unable to respond to a negative shock hitting their job. In a matching model with wage bargaining, the workers can allow the firm to keep a larger fraction of output in order to avoid a separation in the face of a shock.

Ljungqvist and Sargent (2003) counter-argue that such an economic mechanism would be relevant only if every worker who separates (including those who quit voluntarily) were hit by faster skill obsolescence. In their view, a more reasonable assumption is that only the workers who suffer an exogenous layoff see their skills decreasing, in which case the original result in Ljungqvist and Sargent (1998) remains intact.

8.4 Acceleration in Capital-Embodied Technical Change

Several measures of embodied technical change suggest that the rate of technical change accelerated around the mid-1970s in the U.S. economy (see Section 2, especially Figure 2). A recent OECD study (Colecchia and Schreyer 2002) measures the decline in relative price for several high-tech equipment items across various countries in Europe from 1980 to 2000 and concludes that European countries experienced an acceleration quantitatively comparable to the United States. Jorgenson (2004, Table 3.5) measures the growth in the quality of the aggregate stock of capital across some OECD countries and finds that, even though the United States had the fastest average annual growth (1.5 percent from 1980 to 2001), Germany and Italy were quite close, with 1.3 percent and 1.1 percent annual growth rates, respectively.

Hornstein et al. (2003a) study precisely whether the interaction between an acceleration in capital-embodied growth, common between the United States and Europe, and certain labor market institutions whose strength differs between the United States and Europe, can explain the simultaneous evolution of the three dimensions of labor market inequalities quantitatively: the unemployment rate, the labor share, and wage inequality.

Their environment builds on the matching model with vintage capital developed by Aghion and Howitt (1994).[84] Consider a continuous-time economy populated by a stationary measure one of ex-ante equal, infinitely lived workers who supply one unit of labor inelastically. Workers are risk-neutral and discount the future at rate r. Production requires

[84]For expositional purposes, we simplify the framework in Hornstein et al. (2003a) substantially here. In particular, in the equilibrium of the original model, there are vacant firms with old vintages of machines, while here we make the standard assumption of matching models that all vacant firms embody the leading-edge technology.

one machine and one worker. Machines are characterized by their age, a, translating into match productivity, $e^{-\gamma a}$, where γ is the rate of technological progress embodied in capital.[85]

At any time firms can freely enter the market and post a vacancy at a cost, κ. Then they proceed to search for a worker in a frictional labor market governed by a standard constant-returns-to-scale matching function. Once matched, they produce and share output with the worker in a Nash fashion, with ξ denoting the bargaining power of the worker. At age $\bar{a}$ (determined endogenously), capital is scrapped and the job is destroyed.[86] Two key labor market policies are modeled explicitly: unemployment benefits b, and an employment protection system that combines a hiring subsidy T and an equal-size firing tax upon separation.

As is standard in this framework, it is possible to reduce the equilibrium of the model to two key equations—the job creation condition and the job destruction condition—in two unknowns, θ and $\bar{a}$. These equations, respectively, read

$$\begin{aligned} \kappa &= q(\theta)(1-\xi)S(0;\bar{a}) \\ e^{-\gamma\bar{a}} &= b + p(\theta)\xi S(0;\bar{a}) - (r-\gamma)T. \end{aligned} \tag{33}$$

Here, $q(\theta)$ and $p(\theta)$ are the meeting probabilities for firms and workers, respectively, expressed as a function of the vacancy-unemployment ratio, θ. We denote by $S(0,\bar{a})$ the "surplus" of a match of age 0, conditional on destruction taking place at age $\bar{a}$: the surplus is the value of the relationship for the parties (the discounted present value of the output stream), net of their outside options. Clearly the surplus is increasing in $\bar{a}$, as a longer match yields a bigger surplus.

The job-creation curve states that vacancies are created (and $q(\theta)$ falls) until the expected return of the marginal vacancy equals its cost, κ. The job-destruction curve states that, at age $\bar{a}$, the pair is indifferent between continuing operating the machine, which gives output

[85] As usual, we normalize all variables concerning a vintage a machine relative to the corresponding variable of the newest machine.

[86] Productivity improvements enter the economy only through new capital. This is the typical Schumpeterian "creative-destruction" mechanism, which is at the heart of unemployment in this class of models. As mentioned in section 7.1, Hornstein et al. (2003b) show that if one takes the view that technical progress can also benefit old machines, i.e., if old machines can be "upgraded" into new ones at a cost, then the model yields quantitatively similar results.

$e^{-\gamma\bar{a}}$, and separating, which yields the respective outside options for worker and firm (zero in equilibrium for the firm, because of free entry), net of the firing tax.

FIGURE 6

Figure 6 depicts the comparative statics of a rise in γ in a rigid economy (high b, high T) and in a flexible economy ($b = T = 0$) in the $(\theta, \bar{a})$ space.[87] Note that a low value for $\bar{a}$ corresponds to high separation rate and unemployment incidence, whereas a low value for θ corresponds to long unemployment durations. Thus, the two axes depict the two dimensions of equilibrium unemployment. To illustrate the result more sharply, we have chosen values for b and T in the rigid economy such that the initial equilibrium in the two economies is the same. This is possible since generous benefits and strict employment protection have offsetting effects on job destruction, while they are neutral on job creation, as evident from equations (33). The model is therefore consistent with an initial situation where, originally, the labor markets of the United States and Europe looked alike, as the data for the 1960s show. Figure 6 illustrates that a rise in γ has a dramatically different impact across the two economies, especially regarding the amplitude of the shift in the job destruction curve.

To understand intuitively the economic forces at work, it is useful to think of the acceleration in equipment-embodied technology as an "obsolescence shock." As the rate of productivity growth of new capital accelerates, existing capital-worker matches—which have old vintages of capital—become obsolete faster. In the United States, this loss of economic value is to a higher extent borne by workers, whose wages fall in order to keep firms from scrapping capital and breaking up earlier to invest in better machines.

In Europe, however, labor payments are kept artificially high by generous unemployment benefits and by rents on firing costs, which make wages downwardly rigid. As a result, firms must bear the initial adjustment by destroying matches earlier and creating fewer jobs. The corresponding sharp increase in unemployment greatly improves the relative bargaining position of firms, which can now push workers closer to their outside option, thus reducing

[87] Once we recognize that $p'(\theta) > 0$, $q'(\theta) < 0$, and $S'(\cdot, \bar{a}) > 0$, understanding the slope of the two curves in (33) is immediate.

the labor share of output. Since the outside option is constant across all workers, this force also limits the rise in wage inequality that comes about with faster technical change because of larger productivity differentials across machines.[88] Thus, in response to a technological acceleration, an economy with rigid, European-like institutions would experience a higher unemployment rate, a more pronounced decline in the labor share, and a slower rise in wage inequality than would be observed in a more flexible economy.

Quantitatively, a permanent rise in the rate of capital-embodied productivity growth of the magnitude observed in the data can replicate a large fraction of the differential increase in the unemployment rate and of the capital share between the flexible U.S. economy and the rigid Europe-like economy (with the increase in unemployment taking place along the duration margin, as in the data). Wage inequality increases in the U.S.-like economy and declines in the rigid economy, but the changes generated by the model are rather small (recall our discussion of section 7.1).

8.5 Skill-Biased Technical Change

A number of explanations for the rise in wage inequality in the United States—many of which we have reviewed in Section 3—build on the idea of skill-biased technical change. Could this type of technological advancement, interacted with more rigid institutions, also be at the origin of the rise in European unemployment?

Mortensen and Pissarides (1999) explore this question in a model where the economy is populated by a finite number of types of workers, ex-ante different in their skill (productivity level). Skill is observable (e.g., education), and all workers endowed with the same skill level are segmented in their own labor market, which is modeled as frictional with a standard matching function governing the meeting process.

In this model, unemployed workers receive welfare benefits which are partly proportional to their wage (and skill level), and partly lump-sum. The equilibrium unemployment is decreasing and convex in the skill level: low-skill markets have higher unemployment, as

[88] This mechanism, which is based on technological heterogeneity and the existence of quasi-rents for workers, is the same as that analyzed in Section 7.2.

benefits represent a form of wage rigidity that is more binding at low levels of skills. As benefits become more generous, the convexity becomes more pronounced.

The skill-biased shock is introduced as a mean-preserving spread in the skill distribution, calibrated to match the rise in wage inequality in the economy with low benefits, like the United States. The model predicts a sharp surge in unemployment in the economy with generous benefits, due to the convex equilibrium relationship between unemployment and the skill level. A crucial ingredient of the Mortensen-Pissarides mechanism, which is present also in the Hornstein et al. (2003a) setup, is that welfare benefits are not fully proportional to wages and productivity; rather, they have a "flat", lump-sum component. If they were fully proportional, every skill market would just be a rescaled version of the highest-skill market, with the same unemployment rate. Hansen (1998) studies the institutional details of the welfare state in several European countries and argues that flat "social assistance" benefits are an important component of these welfare systems.[89]

Finally, the Mortensen and Pissarides model has the counterfactual implication that the rise in unemployment is concentrated among the low-skilled workers, whereas Nickell and Bell (1996) and Gottschalk and Smeeding (1997), among others, conclude that data from many European countries support the conclusion that unemployment rose proportionately across the entire skill spectrum.

8.6 Endogenous Technology Adoption

A careful look at Table 1 shows a non-monotonic evolution of the labor share in many European countries: the labor share rose between 1965 and 1980, only to decline sharply afterwards. In some countries this pattern is striking. In Portugal, for example, the labor share skyrocketed from 56 percent to 75 percent in the period 1965-1980, and then plunged to 68 percent by 1995. Blanchard (1997) and Caballero and Hammour (1998) proposed an

[89] Another key assumption is that markets are segregated across skills. This setup allows the model to avoid the criticism by Wong (2003) that skill-biased technical change can reduce the amount of mismatch and decrease within-group inequality. Mortensen and Pissarides describe their workers as differing in educational attainment. Given the observability of education, modeling firms as able to direct their search (and segregate the economy) seems appropriate.

explanation for these dynamics based on the idea that technological advancement responds to the relative cost of factor inputs.

The late 1960s and early 1970s witnessed a rapid evolution of capital-labor relationships in favor of labor in many European countries: "pro-labor" measures were introduced with the objective of consolidating unions' power, increasing the generosity and coverage of unemployment benefits, making economically motivated dismissals harder to justify.[90] The result was, in the language of Caballero and Hammour, an "appropriability shock" that shifted bargaining power away from capital.

In a model where the technological menu for capital-labor substitutability is fixed in the short run, but endogenous in the long run, one will observe an initial rise in the labor share as a result of such a shock. However, as time goes by, more and more firms respond to this institutional "pro-labor" push by introducing new technologies that substitute capital for labor. Therefore, in the long run the capital-labor ratio rises, and both the labor share and employment decline, as observed in the last two decades in Europe.

Why do the U.S. data not display the same pattern? According to Blanchard (1997), since the initial appropriability shock was much smaller, so was the response of capital. A natural question arises, if one follows this logic through: is it only a coincidence that the technological change away from unskilled labor was biased towards capital in Europe and toward skilled labor in the United States?

According to Acemoglu (2003a) the direction of the bias in technological innovations is endogenous (see also our discussion in Section 3) and institutional differences can be key in explaining different biases between the United States and Europe. Consider a flexible economy, like the United States, where firms can either produce with one unit of skilled labor with productivity h_s or one unit of unskilled labor with productivity h_u, where $h_u < h_s$. Output is $y_i = h_i$, with $i = u, s$, and the wage paid to the worker is simply a fraction, ξ, of output. Firms can also choose to pay a fixed cost, κ, and adopt a new technology that

[90]The "French May" in 1968 and the "Hot Italian Autumn" of 1969 are stark manifestations of the power of the labor movements in that period of European history.

increases output by a factor $1 + A < h_s/h_u$. Consider first an equilibrium where

$$\kappa > (1 - \xi) Ah_s > (1 - \xi) Ah_u,$$

so that it is not profitable for firms to implement the new innovation, and wage inequality is simply given by $w_s/w_u = h_s/h_u$. Suppose now that, due to technological progress, the cost of capital decreases to a new value, $\kappa' < \kappa$, such that it is always profitable to adopt it for skilled workers, but not for unskilled workers, i.e.,

$$(1 - \xi) Ah_s > \kappa' > (1 - \xi) Ah_u.$$

As a result of this adoption decision, wage inequality jumps to the higher level $(1 + A) h_s/h_u$ in the U.S. economy.

Consider now an alternative economy, like Europe, where, because of some institutional constraint, wages cannot fall below a fixed level, $\bar{w}$, where $\xi h_s > \bar{w} > \xi (1 + A) h_u$, so that the constraint is binding for the unskilled workers, even in the case of adoption, but never for the skilled workers.

Whenever the new cost level, κ', satisfies

$$Ah_u > \kappa' > (1 - \xi) Ah_u$$

in Europe, the new technology will be adopted also with unskilled workers; this is an effect of the minimum wage constraint. The intuition for this result is that, since firms in Europe pay a fixed wage $\bar{w}$ to the unskilled workers, whether or not they adopt the new technology, the institutional constraint makes the firm the residual claimant on output, once $\bar{w}$ is paid. The new technology increases output without changing the wage payment, and thus it may be optimal to adopt in an economy with wage rigidity and not to adopt in an economy with wage flexibility, with the obvious implication that inequality will not increase in Europe.[91]

Formalized models, where the direction of technical change is endogenous, are still in their infancy: in the case of this application to the U.S.-Europe comparison, one important

[91] This hypothesis is also consistent with the fact that, at least until the impressive productivity surge of 1995-2000, labor productivity grew faster in Europe (e.g., in France, Germany, Italy, and the United Kingdom) compared to the United States (Jorgenson 2004, Table 3.16).

extension would be verifying if this result survives when the "institutional wage rigidity" is endogenized so that it can respond to changes in the technological environment.

8.7 Sectoral Transformation

The standard approach to the U.S.-Europe differentials is built on comparing the diverging dynamics in the *unemployment* rate. Rogerson (2004) argues that the analysis of relative unemployment rates is misleading, and if one focuses instead on *employment-population ratios*, new insights surface.

In particular, Rogerson shows two new features of the data: 1) the relative deterioration of European employment starts as early as in the 1950s, whereas unemployment rates start diverging in the mid-1970s; 2) the deterioration of European unemployment is largely explained by the differential in manufacturing employment growth.[92]

These facts lead Rogerson to focus on the importance of the structural transformation occurring in the economy, i.e., the secular pattern of reallocation of resources across broad sectors of the economy: first from agriculture to manufacturing, and then from manufacturing to services. Expressed in terms of the shocks-institutions paradigm that we have highlighted in this section, the relevant shock is the transformation of modern economies into service-driven economies, and the relevant institutions are those which hampered the full development of a service sector in Europe.

Although this new approach is still in its infancy, and as such it lacks a quantitative assessment within a rigorous equilibrium model, it appears to be quite promising.

8.8 Discussion

Nickell and Layard (1999), in a widely cited piece in the most recent edition of the *Handbook of Labor Economics,* carefully review the empirical literature and conclude that time spent worrying about the effects of several labor market institutions on cross-country unemployment differentials is largely wasted, given these effects seem small and are often even

[92]The concept of "relative deterioration" refers to the difference between the U.S. variable (employment rate or unemployment rate) and its European counterpart.

ambiguous in sign. From the perspective of the research surveyed in this section, however, it seems that when institutional differences are studied in conjunction with technological change, the results are more encouraging.

Of course, much is still far from being well understood. First, once we recognize that the interaction of shocks and institutions is important, what are the key common shocks and the crucial institutional differences that can account for the facts? One would, for example, like to see a unified structural equilibrium framework where several shocks and institutions are jointly analyzed in order to investigate which shock-policy interaction is quantitatively important and which is not.

Second, in answering this question, more "discipline" is needed in the quantitative analysis. Often, the approach in the literature is to calibrate the shock by matching either the rise in wage inequality or the fall in the labor share. We maintain the view that changes in employment/unemployment, wage inequality, and income shares are intimately related and must be explained jointly: they are dimensions along which the model should be evaluated rather than calibrated. Thus, the shock should be calibrated, as much as possible, using independent observations. The use of data on technological change such as that for the relative price of equipment goods is such an example.

Third, it is important to note that we are not aware of any quantitative model of a rigid Europe-like economy that can generate a rise in equilibrium unemployment which is similar across all skill levels, which is what the data suggest.

Fourth, the literature is split between labor-supply models (Ljungqvist and Sargent; Marimon and Zilibotti) and labor-demand models (Bertola and Ichino; Caballero and Hammour; Hornstein et al.). Obviously, interpreting the European and U.S. labor market outcomes in terms of "labor demand" or "labor supply" is not mutually exclusive. In a theoretical framework with elements of vintage human capital and vintage physical capital, an embodied technological acceleration will also worsen the rate of skill obsolescence—exactly as in Ljungqvist and Sargent's paper. The next generation of investigations of the European (un-)employment puzzle should bring together supply and demand forces and allow a joint

evaluation of their respective strength.

9 Welfare and Policy Implications

In traditional growth theory, technological progress is largely associated with productivity advancements, reflected in improvements in average wages, from which it would follow that there are welfare gains. While the first generation of growth models is based on the representative-agent assumption, the model economies we studied in these chapter are built on a heterogenous-agents model. By raising the wage differential between more and less skilled workers (between-group inequality) and by amplifying the amount of labor market uncertainty faced by ex-ante equal households in the economy (residual inequality), in these economies technological change can lead to welfare costs, at least for certain groups of workers, and it has first-order implications for policy. In what follows we give an account of some early work on the subject.

9.1 Lifetime Earnings Inequality

The majority of the empirical investigations on rising inequality in the United States focus on the cross-sectional distribution of wages and earnings. Friedman (1982) argues that data on cross-sectional inequality at a point in time are difficult to interpret, as they provide no information on the degree of economic mobility: the same distribution can be generated either by a "dynamic society" or by a "status society".

A better measure of inequality, which incorporates some of Friedman's concerns, is provided by the distribution of lifetime earnings. A stark example of the pitfalls implicit in making welfare and policy statements simply based on distributions at a point in time is provided by Flinn (2002). Flinn compares Italy and the United States and documents that, although the dispersion in cross-sectional yearly earnings inequality in the United States is several times larger than in Italy, the distribution of lifetime earnings in the United States is more compressed due to larger individual variability of labor income and shorter duration of non-employment experiences. In other words, in Friedman's language, Italy somewhat

surprisingly looks more like a "status society" than does the United States.[93]

Two papers, so far, have studied the change in the distribution of lifetime earnings in the United States in the past three decades through the lenses of a structural model.[94] Heckman et al. (1998) solve a deterministic competitive OLG model with endogenous human capital accumulation to study the implications of the widening educational premium for lifetime-earnings inequality across cohorts.[95] Their model implies that the low-educated cohorts entering in the mid-1980s are those suffering the largest drop in lifetime earnings from skill-biased technical change: roughly 11 percent. At the same time, they calculate a rise in lifetime earnings of 6 percent for the college graduates in the same cohort.

Similarly, Bowlus and Robin (2003) use a search model with risk-neutrality, estimated on matched CPS data from 1977 to 1997, to study how changes in wage and employment dynamics over the past thirty years have affected the evolution of lifetime labor income inequality in the U.S. labor market. They find that the median worker suffered only a small decline in present value lifetime earnings, but that there is large heterogeneity across educational groups with lifetime earnings declining by over 25 percent for high-school graduates and increasing by almost 20 percent for college graduates.

These numbers are over twice as large as those in Heckman et al. (1998). One reason is that Heckman et al. model the acquisition of education and the costs associated with schooling explicitly. A large fraction of the changes in lifetime earnings is attributable to the surge in the returns to education: since education in reality is the outcome of a costly investment choice, the difference in earnings alone likely overstates the true welfare differential between the two groups in the analysis of Bowlus and Robin.

[93] Cohen (1999) performs a similar exercise between the United States and France and finds that, using annual wages, inequality in the United States is 60 percent greater than in France, but based on lifetime earnings, the difference reduces to 15 percent.

[94] See Aaronson (2003) for a measurement of changes in lifetime earnings inequality not based on a structural model.

[95] We have discussed a simple version of this model in Section 4.

9.2 Consumption Inequality

There is a definite gain in moving from studying hourly wages to lifetime labor income, if one wants to make inference on welfare. However, one important limit of the studies above is that they effectively assume complete insurance against those transitory income fluctuations that cancel out in the long run and thus do not affect lifetime income. With imperfect insurance against labor market risk, consumption is not determined only by purely permanent shocks that translate one-for-one into permanent income, but the degree of earnings variability and its persistence become important, too. In this sense, consumption is an even better measure of welfare than lifetime earnings.

The evidence based on *Consumption and Expenditure Survey (CEX)* data suggests that consumption inequality rose slightly during the first half of the 1980s (Cutler and Katz, 1992, and Johnson and Shipp, 1997) and has remained roughly stable thereafter (Krueger and Perri, 2002). Interestingly, Blundell and Preston (1998) document that in Britain, where the increase in wage inequality followed a pattern similar to the United States, the rise in consumption inequality was also strong until the early 1980s, but weaker afterwards. This path of consumption inequality is, at first sight, puzzling, especially since wage inequality keeps increasing in the 1990s, albeit at a slower pace. Three explanations for this puzzle have been provided so far.

Krueger and Perri (2002) developed the first formal model to solve this apparent puzzle. They consider an Arrow-Debreu economy with limited enforcement of contracts (Kocherlakota, 1996). In this economy, the degree of insurance market completeness is endogenous and responds to changes in income risk: as income shocks become larger and more persistent, the value of autarky declines, so agents are willing to enter more often into risk-sharing agreements. The central message of Krueger and Perri is that the rise of labor market inequality led to a development in financial markets—in particular the sharp expansion of consumer credit in the 1990s—and to a larger extent of risk sharing, limiting the rise in consumption inequality in this period.

Heathcote et al. (2003) offer an alternative interpretation for this pattern of rising and

then flattening consumption inequality. Through a statistical decomposition of the rise in wage dispersion into permanent and transitory components, they conclude that the relative importance of the two components changes substantially over the sample period. From the late 1970s to around 1990 the permanent component increases sharply, but in the 1990s it ceases to grow, whereas there is a substantial increase in the variance of transitory shocks. A standard overlapping-generations model with "exogenously" incomplete-markets (Huggett 1996) predicts a trajectory for consumption inequality similar to the data: as the shocks become more transitory, they are easier to insure and tend to have a smaller impact on consumption. The finding that the first phase of the rise in inequality (1980s) had a more permanent nature than the second (1990s) is common to a number of empirical studies (Moffitt and Gottschalk, 1994, for the United States, and Dickens, 2000 and Blundell and Preston, 1998 for the United Kingdom). To our knowledge, there is no attempt to link this pattern of persistence with the nature of technical progress.

The third explanation is provided by Attanasio et al. (2003) who argue that once measurement error in the CEX data is properly taken into account, consumption inequality keeps rising also in the 1990s, and, hence, that there is no puzzle.

9.3 Welfare Implications

Studying consumption inequality is a further improvement toward the understanding of the welfare costs of rising inequality, but a complete welfare analysis cannot abstract from leisure.

One approach that has been taken in the literature makes minimal assumptions regarding the structure of the underlying economic model. Krueger and Perri (2003), in an exercise similar in spirit to that in Attanasio and Davis (1996), estimate a stochastic process directly on consumption and leisure data from the CEX and use standard intertemporal preferences to compute the welfare costs of rising inequality. The computation of welfare losses "under the veil of ignorance," i.e., before the worker finds out whether she will be high- or low-skilled, yields numbers between 1 percent and 2 percent, with a difference in the welfare losses between the 90th percentile (net winners) and the 10th percentile (net losers) of just over 10 percent. To put this number in perspective, the estimate of Bowlus and Robin (2003)

is 50 percent.

This approach is based entirely on revealed preferences, and has the advantage that no restrictive assumptions have to be made on the degree and the nature of market completeness. However, without a structural model (like those of Bowlus and Robin, 2003; and Heckman et al. 1998), strong faith must be placed in the reliability of the consumption and hours data from the CEX. In particular, if there are large transitory measurement errors, then one would overestimate the extent of economic mobility and underestimate the welfare losses coming from the change in the wage structure. Moreover, all that can be assessed through this methodology is the welfare cost of changes in consumption and leisure inequality, without knowing exactly what fraction of these changes are attributable to rising wage inequality rather than, for example, tax reforms or changes in financial and insurance markets that occurred over the same period.

A second approach, developed by Heathcote et al. (2003), builds on three steps: 1) an estimation of the dynamics of permanent and transitory components of individual wages over the period of interest, 2) a calibration of an OLG model with endogenous leisure and consumption choices and incomplete markets, 3) simulation of the model to compute the welfare costs of the changes in wage dynamics. This approach, thus, is fully structural, and, as such, it does not rely heavily on survey data on consumption and hours worked. Rather, welfare calculations are based on the changes in the model-generated consumption and leisure paths due exclusively to observed and well-measured changes in the wage process over the period. At the same time, it incorporates a realistic range of insurance avenues (a saving technology, labor supply, and social security) without going as far as assuming complete markets.

According to the calculations of Heathcote et al., (2003), welfare losses "under the veil of ignorance," although varied by cohort, average 2.5 percent across all cohorts, with a peak of 5 percent for the cohorts entered in the mid-1980s. The low-skill workers suffer a loss of 16 percent, and the high-skill workers enjoy a welfare gain of 13 percent. These numbers fall in between the estimates of Bowlus and Robin (2003) and those of Heckman et al. (1998).

Two main conclusions emerge. First, the welfare consequences of the observed rise in labor market risk are quite different across groups of workers: whereas the high-skill, high-educated workers are the winners, the low-skill, low-educated workers are the losers. Second, the ex-ante welfare loss from the rise in labor market risk in the United States is of the order of 2 percent of lifetime consumption, which is a rather large number.

9.3.1 Insurance and Opportunities in the Welfare Analysis of Wage Inequality

The quantitative studies on the welfare consequences of the recent rise in inequality point to a sizeable welfare loss. But does the absence of full insurance always imply a welfare decrease when risk increases? The answer is no. We have already mentioned the case studied by Krueger and Perri (2002) where, with endogenous market incompleteness, a rise in uncertainty can lead to more risk sharing in society and increase welfare. The same result can arise for different reasons in models where the extent of risk-sharing is limited exogenously (Bewley-Aiyagari economies). Consider, as do Heathcote et al. (2004), an economy populated by a measure one of infinitely-lived agents with preferences

$$U = E_0 \sum_{t=0}^{\infty} \beta^t \left[\frac{c_t^{1-\gamma} - 1}{1-\gamma} - \varphi \frac{h_t^{1+\sigma}}{1+\sigma} \right], \tag{34}$$

where $1/\gamma$ is the elasticity of intertemporal substitution and $1/\sigma$ is the Frisch elasticity of labor supply. Each agent i starts with zero wealth and faces log-normal productivity shocks to the efficiency units of labor ω_{it}. Shocks can be decomposed into two orthogonal components:

$$\ln \omega_{it} = \alpha_i + \varepsilon_{it}, \quad \text{with } \alpha_i \sim N\left(-\frac{v_\alpha}{2}, v_\alpha\right), \text{ and } \varepsilon_{it} \sim N\left(-\frac{v_\varepsilon}{2}, v_\varepsilon\right)$$

where α_i is the permanent-uninsurable component and ε_{it} is the transitory-insurable component. Note that the means have been normalized so that a rise in the variance of either component does not affect the average level of efficiency units.

After computing the allocations and substituting them into preferences (34), one can calculate the welfare gain of an increase in the two components of wage uncertainty—expressed

as the equivalent consumption variation. The main finding is that one can obtain an (approximate) closed-form expression for the welfare gain $\mathcal{W}$

$$\mathcal{W} \;=\; \frac{1}{\sigma}\Delta v_{\varepsilon} - \frac{(\gamma-1)+\gamma\,(1+\sigma)}{\gamma+\sigma}\Delta v_{\alpha}. \tag{35}$$

This expression only depends on two elasticity parameters (γ, σ) and on the change in the two variances $(\Delta v_{\alpha}, \Delta v_{\varepsilon})$. The key feature to note, in the above equation, is that the welfare gain is not always negative. For example, as $\gamma \to 0$ (risk-neutrality), the welfare gain is positive and proportional to the rise in overall inequality $(\Delta v_{\varepsilon} + \Delta v_{\alpha})$ through the Frisch elasticity.[96]

To understand this result, one has to keep in mind that there are two distinct effects of a rise in labor market uncertainty. On the one hand, "decreased insurance" induces a welfare loss. For example, as risk-aversion rises with γ or as the permanent-uninsurable component v_{α} expands, the second term becomes larger and the overall welfare gain tends to become negative. On the other hand, "improved production opportunities" induce a welfare gain. In presence of elastic labor supply (σ low), households supply more hours when they face a good productivity shock and enjoy leisure at times of low-productivity. When the variance of productivity shocks rises, this intertemporal behavior can improve households' welfare. The net effect depends on the parameterization of preferences and on the empirical assessment of what fraction of the rise in inequality is insurable.

9.3.2 Discussion

Economists have just started to tackle these issues, and many questions still lie ahead. One key area to explore is the role of the family in determining the welfare implications of the rise in wage inequality. Two offsetting forces are at work. First, there is positive assortative matching between spouses along the skill/education dimension. Second, shocks are imperfectly correlated between spouses (Hyslop 2001). While the first feature amplifies the surge in inequality and worsens welfare inequalities across families, the second establishes

[96] This qualitative result can be reproduced also starting from Cobb-Douglas preferences, albeit the expression in (35) is different.

a role for intra-family insurance in dampening the rise in labor market risk. Only a careful quantitative analysis can determine which force is dominant.

Finally, the current welfare studies abstract from some first-order "social" consequences of the rise in inequality and the fall in the wages of the unskilled, such as the decline in labor market participation for low-educated males (Murphy and Topel 1997), the rise in the crime rate (Kelly 2000), and the decline in the marriage rate (Gould and Paserman 2003).[97]

9.4 Brief Directions for Policy

Welfare losses originating from the rise in U.S. inequality in the past three decades are almost one hundred times larger than the standard estimates of the costs of business cycles (Lucas 2003). In this sense, policies that act by reallocating risk across agents (like social insurance policies) are a macroeconomic priority compared to policies that reduce the impact of aggregate risk (like monetary or fiscal stabilization policies). But among the myriads of possible government interventions, what are the right redistributive policies?

In Sections 3.2 and 7 we discussed two complementary views of the link between technology and inequality. The first of these views is that technological progress in the past three decades has been complementary to certain permanent individual characteristics, such as ability or education (technology-skill complementarity). The second view is that labor market history is scattered with shocks and stochastic events related to the luck of individuals, firms or industries that determine the degree of fanning out of the skill and earnings distributions among ex-ante equal workers. The rapid diffusion of a new technology amplifies the importance of these stochastic factors, increasing overall earnings instability (technology-luck complementarity).

The emphasis we placed on these two approaches is not just for classification purposes, since they have profoundly different policy implications. Insofar as we are interested in designing policies that reduce inequalities among households, models of technology-ability complementarity suggest that the intervention should be targeted early in the life of an

[97] Gould and Paserman argue that the higher male inequality in the United States increased the option value for single women to search longer for a husband.

individual, possibly during childhood when the key components of learning ability are being formed. Models of technology-luck complementarity seem to call for interventions that allow the disadvantaged (or unlucky) workers to rebuild their skill level after a shock, such as displacement due to skill obsolescence, has hit.

Examples of both types of policies are abundant in the U.S. economy.[98] In general, the most recent evaluations of programs entailing expenditures and treatment at early childhood report remarkable success. In contrast, the available evidence indicates that welfare-to-work and training programs directed toward adult workers are rather inefficient, as they generate only modest increases in permanent earnings levels (LaLonde et al. 1999).

According to Heckman (2000), the reason for the divergence in outcomes across these two classes of policies is twofold. First, investments in human capital at old ages are less efficient, since the elderly worker has less time to recoup the investment; second, "learning begets learning," so human capital, skills, and abilities acquired at a young ages facilitate future learning.

In this sense, policymakers should have a life-cycle perspective: lifting the unskilled, displaced adults into skilled status is much easier and more efficient if the same workers have been developing their learning ability throughout childhood and youth, possibly with the help of government intervention. For the more mature low-skilled workers with limited learning ability who are subject to unavoidable wage losses due to biased technological change, targeted wage subsidies can be more effective than retraining programs.

10 Concluding Remarks

This chapter argues that labor market inequalities are shaped by technological change through a variety of economic mechanisms. Within the technology-labor market nexus, however, which of the specific mechanisms we evaluate are most likely to survive the test of

[98] Programs like the Perry Pre-School program and the Syracuse Pre-School program provide intense family development support to disadvantaged children at very young ages (from birth to 5 years). The Harlem program ensures frequent individual teacher-child sessions for children of age 3-5. Several programs for adult retraining of displaced workers were initiated throughout the United States under the Job Training Partnership Act of 1982 and the Economic Dislocation and Worker Adjustment Assistance Act of 1988.

time?

Before answering this question, it is useful to put things in perspective and recall that most of the statements we have made in this chapter are not all meant to represent general insights; rather, they allude to a particular historical episode. Specifically, technology has not always been skill-biased in the past: the transformation from artisanal workplaces to the factory in the 19th century had much the opposite effect (Goldin and Katz, 1998). Moreover, not all the drastic productivity advancements in the past were embodied in equipment: electricity was to a large extent embodied in new structures, as the electrification of production required a whole new blueprint for the plant (Atkeson and Kehoe, 2002). Even in reference to this particular historical episode, there are serious dissenting views on the overall impact of IT on the macroeconomy (e.g., Gordon 2000) and on the role of technology in explaining the observed changes in the U.S. wage structure (e.g., Card and DiNardo, 2002).

In returning to the original question, we identify three rather general categories that we find particularly interesting and plausible.

The first idea is *factor-specificity* of the recent technological advancements. In particular, the embodiment of productivity improvements in equipment capital goods, and the skill-bias of such productivity improvements. Whether in the Nelson-Phelps version of skills as a vehicle of adoption and innovation, or in the version of skills and capital as complementary in production, the skill-bias of the IT revolution is one of the most robust and pervasive in the literature. Skill-biased technical change and capital-skill complementarity are crucial to explain the climb of the skill premium, notwithstanding the continuous growth in the relative supply of skilled labor. A growing and promising avenue of research is on the endogenous determinants of the factor-bias in technological advancements (Acemoglu 2002b, 2003b).

The second idea is *vintage human capital*. The technological specificity of knowledge appears to be an important idea to explain some of the most puzzling aspects of the data such as the rise in within-group or "residual" inequality, the fall of the real wages at the bottom of the skill distribution, the growth in the returns to experience, and the slowdown of output growth in the aftermath of a technological revolution.

The third idea is the *interaction between technology and the organization of labor markets.* Radical technological developments, like those we have witnessed in the past three decades, are bound to interact deeply with the various aspects of the structure of labor markets, like the organization of production within the firm, labor unions, and labor market policies. Through this interaction, the literature has successfully interpreted the move from the Tayloristic to the flatter multi-tasking organizational design of firms, the decline of unionization, and the upward trend in unemployment rate in Europe. In particular, the comparison of the U.S. and European experiences seems a fruitful way of studying this channel.

These ideas are the building blocks of the most successful and influential papers in the first generation of models that we have surveyed in this chapter. Where will the literature go next? We argued in various parts of the chapter that one major weakness of this literature is the scarcity of rigorous quantitative evaluations of the theories proposed. Most of the papers reviewed are qualitative in nature. This is not too surprising, given the young vintage of the literature (which developed only starting from the mid 1990s), and given that, in any field, it naturally takes a long time before a handful of theoretical frameworks emerge as successful and begin to be used for a systematic quantitative accounting of the facts (e.g., the search and matching model in the theory of unemployment, and the neoclassical and the endogenous growth model in the theory of cross-country income differences). In this chapter we have highlighted some features that seem important for a successful theory of the link between technological change and labor market outcomes. Quantitative theory should be a priority within this field of research over the years to come.

Note: Data on unemployment rates are from Blanchard and Wolfers (2000). Data on labor shares are from Blanchard and Wolfers (2000) except the 1995 entry for Austria, Denmark, Ireland and Portugal which was computed directly from OECD data. Inequality is measured as the 90-10 log-wage differential for male workers. The data are taken from the OECD Employment Outlook (1996, Table 3.1). Austria: the measure is the 80-10 differential and data in the 1985 column are for 1987. Belgium: the measure is the 80-10 differential and data in the 1995 column are for 1993. Denmark: 1985 and 1990 columns are for 1983 and 1991 respectively. Finland: data in the 1985 column are for 1986. Germany: data in the 1985 and 1995 columns are for 1983 and 1993 respectively. Italy: data in the 1985, 1990 and 1995 columns are for 1984, 1991 and 1993 respectively. Netherlands: the measure of inequality is for males and females. Norway: data in the 1985 and 1990 columns are for 1983 and 1991 respectively. Moreover, the measure of inequality is for males and females. Portugal: data in the 1990 and 1995 columns are for 1989 and 1993 respectively. Canada: data in the 1980 and 1985 columns are for 1981 and 1986 respectively. For all countries, except US and UK, data in the 1995 column are for 1994. Europe average: unweighted mean of European countries, except UK.

Table 1: Data on the evolution of the labor share, the unemployment rate, and wage inequality across OECD countries from 1965-1995.

Cross-country institutions data (1984-1995)

	Labor Standards	Employment Protection	Union Density	Bargaining Centralization	Ratio of min. to avg. wage	Benefit Repl. Rate	Benefit Duration

Preliminary

A Unified Theory of the Evolution of International Income Levels

Stephen L. Parente
and
Edward C. Prescott*

ABSTRACT: This paper develops a theory of the evolution of international income levels. In particular, it augments the Hansen-Prescott theory of economic development with the Parente-Prescott theory of relative efficiencies and shows that the unified theory accounts for the evolution of international income levels over the last millennium. The essence of this unified theory is that a country starts to experience sustained increases in its living standard when production efficiency reaches a critical point. Countries reach this critical level of efficiency at different dates not because they have access to different stocks of knowledge, but rather because they differ in the amount of society-imposed constraints on the technology choices of their citizenry.

1. Introduction

Over the last decade, a fairly complete picture of the evolution of international income levels has emerged. Figure 1 plots the path of gross domestic product (GDP) per capita for four major regions of the world relative to the leader going back to 1700 using data from Maddison (1995). In 1700, the living standard of the richest country was less than three times the living standard of the poorest country.[1] This is the nature of the disparity prior to 1700 as well, as no single country experienced sustained increases in its living standard over the pre-1700 period. After 1700, huge differences in international incomes emerged, as some countries experienced sustained and large increases in their living standards well before others.

England was the first country to develop, that is, to realize sustained increases in per capita income. The exact date at which England began to develop is subject to debate. Some historians such as Bairoch (1993) place this date at around 1700. Western European countries and countries that were ethnic offshoots of England began to develop shortly thereafter. At first, the increases in income experienced by these early developers were irregular and modest in size. For example, Bairoch (1993) reports that it took England nearly 100 years to double its income from its 1750 level. However, after the start of the twentieth century, these increases have been larger and relatively regular with income doubling every 35 years in these countries—a phenomenon Kuznets (1966) labels *modern economic growth*.

Countries located in other regions of the world started the development process later in time. For these countries, the gap in income with the leader continued to widen

[1] Bairoch (1993) estimates this difference in 1700 to be smaller than a factor of two.

prior to the time they started modern economic growth. For Latin America, the beginning of the twentieth century is the approximate start of modern economic growth. For Asia, the middle of the twentieth century is the approximate start of modern economic growth. For Africa, modern economic growth has yet to start: although per capita income has increased in nearly every African country since 1960, the increases have been modest and irregular in the period that has followed. Because of these later starting dates, the disparity in international income levels increased to their current-day levels.

Some countries and regions have dramatically reduced their income gap with the leader subsequent to starting modern economic growth. For example, in the postwar period, Western Europe has managed to eliminate much of its income gap with the United States, the leader since 1890. Asia is another region that has been catching up with the leader in the postwar period. The catch-up in Asia, in fact, has been dramatic because of the growth miracle countries of Japan, South Korea, and Taiwan that doubled their income in a decade or less. Latin America, in contrast, is an example of a region that has not eliminated its gap with the leader since starting modern economic growth. Latin American per capita income has remained at roughly 25 percent of the leader for the last 100 years.

A theory of the evolution of international income levels must account for these facts. The theory must generate an initial period with living standards at the pre-1700 level followed by a long transition period to modern economic growth. The theory must generate different starting dates for the transition to modern economic growth across countries. Namely, it must identify some factor or set of factors that differs across countries and that delays the start of the transition by as much as two centuries. The

theory must also account for the sizable and persistent differences in living standards that characterize the experience of countries that have been experiencing modern economic growth for as long as 100 years. Finally, the theory must be consistent with *growth miracles*, namely, the large increases in relative income experienced by some initially poor countries in a relatively short period of time after 1950.

There are well-tested theories of some of these phenomena, but not a comprehensive theory that accounts for all of them. This paper unifies these well-tested theories and examines whether the unified theory can account for all of these phenomena.[2] A well-tested theory of the first phenomenon, the pattern of an initial period of stagnant living standards followed by a transition to modern economic growth, is provided by Hansen and Prescott (2002). The Hansen and Prescott theory is a combination of two long-standing and successful theories: the classical theory of the pre-1700 period and the neoclassical theory of the post-1900 period.

The classical economists, in particular, Malthus (1797) and Ricardo (1817), developed a theory that accounts well for the constant living standard that characterized the pre-1700 era. The main feature of this theory is an aggregate production function characterized by fixed factors, the most important of which is land. According to this theory, increases in knowledge lead to increases in output that are completely offset by increases in population. As a result, living standards do not increase. Economists have also had for a long time a good theory of modern economic growth that has characterized the United States and much of Western Europe since 1900. Solow (1970) developed his

[2] Ngai (2000) provides a unification of these theories along the lines of this paper.

growth model specifically to account for this post-1900 pattern of growth. The main feature of this theory is also an aggregate production function, but one with no fixed factor of production. According to this theory, improvements in technology that lead to more output being produced with the same resources are not offset by increases in population. As a result, living standards rise.

Hansen and Prescott (2002) unify the classical and modern growth theories by allowing people to use both the traditional production function and the modern production function. They show that when total factor productivity (TFP) associated with the modern production function reaches a critical level, the economy moves resources out of the traditional sector and into the modern sector. This is the date at which the transition begins. The transition is found to last a long period, roughly a century. The model thus gives rise to a pattern of economic development characterized by a long initial period of economic stagnation, followed by a long transition, followed by modern economic growth, as observed in Western Europe and its offshoots.

The Hansen and Prescott theory is not a theory of the evolution of international income levels because it does not address the issues of different starting dates of the transition to modern economic growth, sizeable income differences for countries experiencing modern economic growth, and growth miracles. Some factor that differs across countries must be added to the Hansen and Prescott theory to make it a theory of the evolution of international income levels.

Parente and Prescott (2000) develop a theory that accounts for the sizable differences in living standards for countries experiencing modern economic growth and that accounts for growth miracles. More specifically, they develop a theory of a country-

specific TFP and then introduce this factor into a model in which only the modern production function is available. Their theory of country-specific TFP, which they refer to as a *theory of relative efficiency*, is based on policy differences. More specifically, the theory shows how various policies that constrain choices of technology and work practices at the level of the production unit determine the aggregate efficiency at which a country uses its resources in production. The development of a theory of relative efficiencies is essential. Despite the fact that there is ample empirical evidence that countries differ in relative efficiencies, a theory of international income levels that takes countries' TFPs as exogenous is sterile, because it offers no policy guidance.

In this paper, we augment the Hansen and Prescott theory of economic development with the Parente and Prescott (2000) theory of relative efficiencies and show that the resulting unified theory is a theory of the evolution of international income levels. In this unified theory, a country begins its transition to modern economic growth when the efficiency with which it uses resources in the production of goods and services in the modern sector reaches a critical point. Countries reach this critical level of efficiency at different dates not because they have access to different stocks of knowledge, but rather because they differ in the amount of society-imposed constraints on the technology choices of their citizenry. We show that plausible differences in efficiencies delay the start of the transition to modern economic growth by more than two centuries, as observed in the data. Additionally, we show that the augmented model accounts well for the growth miracles that a number of countries experienced subsequent to 1950. Changes in a country's institutions that result in large increases in the efficiency

with which resources can be used in production give rise to growth miracles. Thus, the unified theory accounts for the way international income levels have evolved.

The paper is organized as follows. Section 2 starts with a review of the classical theory of the pre-1700 income level followed by a review of the neoclassical growth theory of modern economic growth. It then concludes with a review of how Hansen and Prescott (2002) combine these two theories into a single theory of economic development. Section 3 deals with the second component of the theory, namely, differences in efficiencies. It reviews the Parente and Prescott (2000) theory of relative efficiencies. Section 4 develops the unified theory of international income levels. In Section 4, a model based on the unified theory is developed and calibrated to the U.K. and U.S. development experiences over the last three centuries. The calibrated model is used to examine the effect of differences in efficiencies across countries on the start of the transition to modern economic growth and the effect of an increase in a country's efficiency on the subsequent path of its per capita GDP. Section 5 examines the development experiences of individual countries and groups of countries over the last three centuries within the context of the theory. Section 6 concludes the paper.

2. A Theory of Economic Development

In this section, we present the theory of economic development put forth by Hansen and Prescott (2002). We do this in three stages. First, we describe the classical component of that theory and derive its equilibrium properties. Next, we describe the modern growth component of that theory, and also derive its equilibrium properties. The last stage merges these two components and, in doing so, presents the Hansen and Prescott model of economic development.

Figure 2 describes the general pattern of economic development. More specifically, Figure 2 reports per capita income of the leader country dating back to 2000 B.C. Up until 1700, the living standard in the leader country, or any other country for that matter, displayed no secular increase. These living standards were significantly above the subsistence level. In 1688, for example, the poorest quarter of the population in England—the paupers and the cottagers—survived on a consumption level that was roughly one-fourth the national average.[3] A few societies, such as the Roman Empire in the first century, the Arab Caliphates in the tenth century, China in the eleventh century, and India in the seventeenth century realized some increase in their per capita income. However, these increases were not sustained. After 1700, per capita income in England started to increase. Over the next 150 years, these increases in the leader country were modest in size and irregular. However, since 1900, these increases have been larger and fairly regular, with per capita income doubling roughly every 35 years.

Technology was not stagnant over any part of this time period. Economic historians have documented a steady flow of technological innovations in this 2000 B.C. to A.D. 1700 period.[4] Yet these innovations prior to 1700 did not translate into increased living standards. Instead they translated into increased population: as total output increased, the population adjusted so as to maintain a constant level of per capita output. After 1700, these innovations did translate into increases in living standards.

[3] See Maddison (1991, p. 10) and Bairoch (1993, pp. 101–108).

[4] See Mokyr (1990) for a review of this literature.

2A. Classical Theory: The Pre-1700 Era

Classical economists, most notably Malthus and Ricardo, devised a theory that accounts well for the constant level of per capita income that characterized the pre-1700 era. The theory predicts a trade-off between living standards and population size. This trade-off exists because population growth is an increasing function of per capita consumption and because there is an important fixed factor of production, namely, land. A key implication of this theory is that there is a constant standard of living to which the economy adjusts. The theory predicts that increases in the stock of usable knowledge, which could translate into increases in living standards, instead translate into an increase in population.

Malthus' theory of population is a biological one rather than an economic one. According to his theory, fertility rises and mortality falls as consumption increases. Being classical, the model has no utility theory and so agents have no decision over the number of children they have. Recently a number of authors, including Tamura (1988), Becker, Murphy, and Tamura (1990), Doepke (2000), Galor and Weil (2000), and Lucas (2002), have generated Malthus-like population dynamics in a neoclassical model with household utility defined over consumption of goods and number of children. These models follow Becker (1960) by having a trade-off between quality and quantity of children.

We take an alternative approach, one that has society determining the size of its population through its institutions and policies. We likewise add household preferences to the classical theory of production. However, we define household preferences only over household consumption and not the quantity of children. Consequently, in this societal

theory of population growth, the quantity of children is treated as exogenous from the standpoint of the household.

The reason we take this societal approach to population growth is twofold. First, there is no tested theory of population dynamics, and once modern economic growth begins, demographics play a secondary role in development. Second, and more important, the approach reflects the view that groups of individuals, namely, societies, have had a much larger say in deciding how many children a family has than the family itself. Societies have instituted and continue to institute policies that give them their desired population size. Often the policies of society are not what individual families want. In modern China, for example, a law effectively limits many households to one child. By contrast, Iran in the 1980s wanted a higher population and so implemented subsidies to encourage people to have more children. After achieving its objective, the government stopped these subsidies in the 1990s and began to subsidize contraceptives. India today, wanting a lower population growth rate, has set up family planning programs in many regions. In all these cases, the effects of policy upon demographics are dramatic. Even in poor and rural Indian villages, which did not experience any increase in human capital or income, policy has led to a dramatic decline in population growth rates.

Why did society choose population size prior to 1700 so as to maintain the same constant living standard? The answer relates to the fact that land was an essential input to the production process in the pre-1700 era. In particular, as a valuable resource, land was subject to expropriation by outsiders. Prior to modern times, a small group of people with large amounts of quality-adjusted land and therefore a high income standard could not defend this land from outside expropriators. For this reason, there was a maximal

sustainable living standard. Society set up social institutions that controlled population so as to maintain the highest possible living standard consistent with the ability to defend itself from outside expropriators. Once an economy switches to the modern production technology, land is no longer an important input, so its defense is not an issue. At the stage when the modern production technology dominates, society sets up its social institutions that it sees as maximizing living standards subject to a constraint that a society perpetuates itself.

For the purpose at hand it is not essential that we model society's choices of institutions that affect fertility choices. Instead, it is sufficient to treat the growth rate of population in a simple mechanical way, namely, as a function of average consumption. In order to reflect society's choices, it must display two properties. First, the function must have a large slope, in the neighborhood of the pre-1700 consumption level. Second, for high levels of average consumption, the slope of the function must be near zero. The first property is only relevant for the theory of the pre-1700 era. The second property is only relevant for the theory of the post-1900 period. This is the approach that we take in this chapter.

With this in mind, we now proceed with a neoclassical formulation of the classical theory of constant living standards. There is a single good in the model that can be used for either consumption or investment purposes. The good is produced with a constant returns to scale technology that uses capital, labor, and land. An infinitely lived household owns the economy's land and capital and rents them to firms in the economy. Land is fixed and does not depreciate. The household is made up of many members, each of whom is endowed with one unit of time. The household uses its capital, labor, and land

income for consumption and investment purposes. The growth rate of population is a function of average consumption of household members. A household member's utility in the period is defined over the member's consumption in the period. The household's objective is to maximize the sum of each member's utility. The details of the economy are described as follows.

Technology

The classical theory of production is given by a Cobb-Douglas technology,

$$Y_{Mt} = A_{Mt}\, K_{Mt}^{\phi} N_{Mt}^{\mu} L_{Mt}^{1-\phi-\mu}. \tag{2.1}$$

In equation (2.1), Y_{Mt} is output, K_{Mt} is capital, N_{Mt} is labor, and L_{Mt} is land in period t. A_{Mt} is a total factor productivity (TFP) parameter, ϕ is the capital share parameter, and μ is the labor share parameter. The Cobb-Douglas assumption implies unit elasticity of substitution.[5] We allow for exogenous growth in TFP. More specifically, we assume that technology grows at the exogenous rate of γ_M; that is, $A_{Mt} = (1+\gamma_M)^t$. This assumption reflects the fact that technological change was evident from 2000 B.C.[6]

Output can be used for either consumption or investment purposes. The resource constraint for the economy is given by

$$C_t + X_t = Y_{Mt}, \tag{2.2}$$

where C_t denotes total consumption and X_t denotes total investment.

[5] The precise value of the elasticity of substitution between land and the other factors is not important provided that it is not greater than one. The evidence is that throughout most of history the substitution of these other factors for land was limited and, if anything, this elasticity of substitution was less than one. The unit elasticity assumption is made because it simplifies the analysis.

[6] We follow Hansen and Prescott's convention of using the letter *M* to index variables associated with the classical production function.

Preferences

Household preferences are added to the classical theory of production as follows. Period utility of each household member is defined over the member's consumption of the final good. We assume a log utility function, because it is in the class of utility functions that is consistent with a constant-growth equilibrium and because empirically it is consistent with a wide variety of micro and macro observations. Household utility in each period is the sum of each individual member's utility in the period. Strict concavity of individual household members' preferences implies that the household's utility is maximized by giving equal consumption to each member. For this reason, the discounted stream of utility of the household is just

$$\sum_{t=0}^{\infty} \beta^t N_t \log(c_t), \tag{2.3}$$

where β is the time discount factor, c_t is consumption of a household member, and N_t is household size.

As is evident from equation (2.3), we are using a dynastic construct. This is in contrast to Hansen and Prescott (2002), who use a two-period overlapping generations construct. We adopt an infinitely lived household framework rather than the two-period overlapping generations framework for two reasons. First and foremost, the empirical counterpart of a period is a year, while in the two-period overlapping generations construct, the empirical counterpart of a period is 35 years. Thirty-five years is simply too long a period for examining the model's ability to account for the large increases in output realized in a short period of time after 1950 by countries such as Japan and South Korea and for the long transition to modern economic growth.

Second, the size of the effect associated with differences in savings rates on an economy's steady-state per capita output level depends importantly on the construct that is used. The level effects are in fact larger with the dynastic construct. This is important for judging whether differences in savings rates can account for the large differences in transition dates as well as the large differences in incomes that continue to exist between economies that have started modern economic growth. Thus, if plausible differences in savings rates cannot give rise to 200-year delays in development in the dynastic construct, then it follows that some factor other than savings rates accounts for the pattern of development.[7] This is the conclusion of the quantitative exercises undertaken by Parente and Prescott (2000). The choice of construct is not important, however, in assessing the plausibility of other factors such as efficiency, as reflected in TFP, differences: the size of the level effects is the same regardless of whether the dynastic or overlapping generations construct is employed.

Endowments

Each member of the household is endowed with one unit of time, which the member can supply to firms in the economy to earn wage income. The household is also endowed with the economy's stock of land and capital, which the household rents to firms in the economy. Land in the economy is fixed in supply: it cannot be produced, and it does not depreciate. Without loss of generality, the total quantity of land in the economy is normalized to one. Since land has no alternative use aside from production, the input to production in each period is one. Capital is assumed to depreciate and evolves according to the following law of motion:

[7] See Hendricks (forthcoming) for a more detailed explanation of this phenomenon.

(2.4) $$K_{t+1} = (1-\delta)K_t + X_t,$$

where δ is the depreciation rate.

Population Dynamics

As mentioned earlier, because we take a societal approach to population size, we model population growth as a function of the average consumption level of household members. More specifically, we assume that the number of agents born into a household in period $t + 1$ depends on the average consumption level of household members from period t. Let N_t denote the number of household members in period t, and let c_t denote their average consumption level. Then,

(2.5) $$N_{t+1} = g(c_t)N_t.$$

The function g is the growth factor of population from one period to the next. The classical prediction of a stable living standard at the pre-1700 level, c_M, requires that the function g have a sufficiently large and positive slope at c_M and that $g(c_M) = (1+\gamma_M)^{1/(1-\phi-\mu)}$. This c_M is the maximal living standard consistent with a society being able to defend its land.

Equilibrium Properties

For such a population growth function, there is a steady-state equilibrium with a constant living standard c_M and a population growth rate equal to $(1+\gamma_M)^{1/(1-\phi-\mu)} - 1$. This constant living standard satisfies $g(c_M) = (1+\gamma_M)^{1/(1-\phi-\mu)}$. Were the living standard to rise above c_M, say, because of plague or drought, population increase would exceed technical advances and the living standard would then fall until it returned to c_M. If for some reason c were below c_M, the population growth factor would be less than the one needed to

maintain the living standard, and the living standard would increase until it was again c_M. Along the steady-state equilibrium path, aggregate output, capital, consumption, and the rental rate of land all grow at the rate of the population. Per capita variables as well as the rental price of labor and capital are all constant. Increases in technology in this model simply translate into a higher population rather than higher living standards. This is precisely the pattern of development observed prior to 1700.

2B. Modern Growth Theory: The Post-1900 Era

The classical theory accounts well for the pattern of economic development up to 1700. However, it does not account for the increase in living standards that occurred after 1900. Since about 1900, the growth rate has been roughly constant, with a doubling of per capita output every 35 years. Modern growth theory, in contrast, does. We now turn to that theory.

Besides the roughly constant rate of growth achieved by developed countries over the last century and a half, a number of other features of post-1900 growth in the United Kingdom and some other countries are noted by Kaldor (1957). These additional modern economic growth facts are roughly that the consumption and investment shares of output are constant, the share of income paid to capital is constant, the capital-to-output ratio is constant, and the real return to capital is constant.

Modern growth theory accounts well for these modern growth facts. Quantitatively, the steady-state equilibrium of the economy mimics the long-run observations of the United Kingdom and the United States. This is no surprise: Solow (1970) developed the theory with these facts in mind. A key feature of that theory is a Cobb-Douglas production function that includes no fixed factor of production and that is

subject to constant exogenous technological change. More specifically, the production technology for the composite good that can be used for either consumption or investment purposes is given by

$$Y_{St} = A_{St}\ K_{St}^{\theta}\ N_{St}^{1-\theta}\ . \tag{2.6}$$

In equation (2.6), Y_{St} is output, K_{St} is capital, and N_{St} is labor in period t. The parameter θ is capital's share, and the parameter A_{St} is TFP. TFP grows exogenously at the constant, geometric rate γ_S. As can be seen, the critical difference between the classical and modern growth production functions is that the modern growth function does not include the fixed factor input land.[8]

Because the final objective of this section is to merge the classical theory and the modern growth theory into a single model, we maintain the same assumptions regarding preferences, endowments, and population dynamics as in the preceding subsection. The household in the model rents capital to firms and supplies labor. It uses its capital and labor income to buy consumption for household members and to augment the household's stock of capital.

In contrast to the classical theory, population growth in the modern theory does not have any consequences for the growth rate of per capita variables in the long run. The choice of the population growth function is therefore unimportant in this respect. The standard procedure is to assume a population growth function $g(c)$ that is constant over the range of sufficiently high living standards associated with the modern growth era. Population thus grows at a constant exponential rate.

[8] Again, we follow Hansen and Prescott's convention of using S to index variables associated with the modern growth production function.

Clearly, population cannot grow at an exponential rate forever. At some population level, natural resources would become a constraining factor. If population were ever to reach this level, it would be unreasonable to abstract from land as a factor of production. But societies control their population so that it never reaches this level. Indeed, reproduction rates have fallen dramatically in the last 50 years, so much in the rich countries, in fact, that these countries must increase their fertility rates to maintain their population size in the long run. This suggests a population growth function that asymptotically approaches one. This is an additional property we impose on the population growth function in the analysis that follows.

In the case where the population growth function is a constant, per capita output, consumption, and capital all increase at the rate $(1+\gamma_S)^{1/(1-\theta)}$ along the equilibrium constant growth path. The rental price of labor also grows at this rate. The rental price of capital, in contrast, is constant. Capital's share of income is also constant and equal to θ, as is consumption's share and investment's share of output. As can be seen, the growth rate of the economy's living standard is independent of the economy's population growth rate: the only thing that matters is the exogenous growth rate of technological change. The population growth rate does have a level effect, but it is small. Thus, unlike in the model of the pre-1700 era, the population growth function in the model of the post-1900 era has only a minor role.

2C. The Combined Theory

The classical theory accounts well for the constant living standard that characterizes the pre-1700 era, and the modern growth theory accounts well for the doubling of living standards every 35 years that characterizes the post-1900 experience of

most of the currently rich, large, industrialized countries. In the period in between, living standards increased in these countries, but at a slower and far more irregular rate compared to the post-1900 period.

We seek a theory of this development process, namely, a theory that generates a long period of stagnant living standards up to 1700, followed by a long transition, followed by modern economic growth. Given the success of the classical theory and the modern growth theory in accounting for the pre-1700 and post-1900 eras, the logical step, and the one taken by Hansen and Prescott (2002), is to merge the two theories by permitting both technologies to be used in both periods. We now present the combined theory of Hansen and Prescott, and we use that theory to organize and interpret the development path of the leading industrialized country over the 1700–2000 period.

In the combined theory of Hansen and Prescott (2002), output in any period can be produced using the traditional and/or the modern growth production functions. Both technologies, therefore, are available for firms to use in all periods.[9] Capital and labor are not specific to either production function. In light of these assumptions, the aggregate resource constraint for the combined model economy is

$$N_t c_t + X_t \leq Y_{Mt} + Y_{St} = Y_t, \tag{2.7}$$

the capital rental market clearing constraint is

$$K_t = K_{Mt} + K_{St}, \tag{2.8}$$

and the labor market clearing condition is

[9] The maximum output that can be produced if both technologies are available is characterized by a standard aggregate production function $Y_t = A_t F(K_t, L_t, N_t)$. By *standard* we mean that it is weakly increasing and concave, homogenous of degree one, and continuous. Even though both the Malthus and the Solow production functions are Cobb-Douglas technologies, the function *F* is not Cobb-Douglas.

(2.9) $$N_t = N_{Mt} + N_{St}.$$

Household preferences continue to be given by equation (2.3). Additionally, the population growth function continues to be given by equation (2.5), and it displays the properties that the function has a large slope in the neighborhood of the pre-1700 consumption level and a slope near zero for large levels of consumption.

In their combined theory, Hansen and Prescott assume that the rate of TFP for the classical production function and the rate of TFP for the modern economic growth production function are each constant over time. We deviate from Hansen and Prescott on this dimension. Although we maintain their assumption that the rate of TFP growth associated with the traditional technology is constant, we assume that the rate of TFP growth associated with the modern growth technology increases over time, converging asymptotically to the modern growth rate. We make this alternative assumption in light of the historical evidence on technological change and the empirical counterparts of the two production functions.

The empirical counterpart of the classical production function is a traditional technology for producing goods and services that is most commonly associated with the family farm. A key feature of this production technology is that it is based on the use of land in the production of hand tools and organic energy sources. For this technology, the historical record shows gradual improvements in these methods over the last 2,000 years at a roughly constant rate change.[10] The empirical counterpart of the modern growth production function is a modern technology that is most commonly associated with the

[10] The exception to this constant rate of growth might be the Green Revolution in the middle of the twentieth century, where the introduction of new seed varieties resulted in large increases in farm yields associated with traditional farming methods.

factory.[11] A key feature of this technology is that it uses machines driven by inanimate sources of energy. For this technology, the historical record suggests modest growth in the eighteenth century, followed by much higher growth in the nineteenth and twentieth centuries. Consequently, a more plausible assumption is that the growth of TFP associated with the modern production function increased slowly after 1700 and converged to the rate associated with the modern growth era shortly after 1900.

We emphasize that traditional production occurs in household production units with most of the resources being allocated to producing household consumption and only a limited amount to trade. There was little scope for people working in these sectors to develop more efficient production methods. Rapid increases in productivity occurred only when goods developed in the industrial sector were introduced in farming. The reaper and the tractor dramatically increased productivity on farms. Insecticides and fertilizers also contributed to productivity, as did the development of hybrid corn and new seeds. This is all well-documented by Johnson (2000).

An economy that starts out using only the traditional production function will eventually use the modern one. To see this, suppose that it were never profitable for firms to use the modern production function. Then the economy's equilibrium path would converge to the steady state of the pre-1700-only model. The steady state of that model is characterized by constant rental prices for capital and labor, r_M and w_M. Capital and labor are not specific to any one technology. Thus, a firm that first considers using the modern production function can hire any amount of capital and labor at the factor rental prices r_{Mt}

[11] The distinction between technologies is, thus, not along the lines of agriculture and manufactures. In this classification, modern agriculture with its use of synthetic fertilizers and tractors is associated with the modern growth production function.

and w_{Mt}. Profit maximization implies that a firm will not choose to operate the modern growth technology if

$$A_{St} < \left(\frac{r_{Mt}}{\theta}\right)^{\theta}\left(\frac{w_{Mt}}{1-\theta}\right)^{1-\theta}. \tag{2.10}$$

This inequality must be violated at some date. Asymptotically, the rental prices would approach constant values if only the classical production function were operated, and so the right-hand side of (2.10) is bounded. The left-hand side is unbounded because TFP in the modern function grows forever at a rate bounded uniformly away from zero. The inequality given by (2.10), therefore, must be eventually violated. At the date when TFP in the modern production function surpasses the critical level given by the right-hand side of (2.10), the economy will start using the modern growth production function. This marks the beginning of the Industrial Revolution. This result is independent of the size differences in the growth rates of TFP associated with the traditional and modern production functions.

Over the transition, more and more capital and labor will be moved to the modern production sector. The rental price of labor will show a secular rise. The traditional production function will, however, continue to be operated, though its share of output will decline to zero over time, because of the assumptions that land is used only in traditional production and that its supply is inelastic.

We now use the combined theory to organize and interpret the development path of the industrial leader over the 1700–2000 period. The empirical counterpart of a period is a year. The initial period of the model is identified with the year 1675. We attribute the stagnation of the leader prior to 1700 to a low level of TFP associated with the modern production function to warrant use of the modern production function. We attribute the

start of economic growth of the leader in 1700 to growth in TFP associated with the modern production function so that its level exceeds the critical value given by equation (2.10). Lastly, we attribute the rising rate of growth of per capita output of the leader from 1700 to 1900 to greater use of the modern production function and the rising rate of growth of TFP.

We proceed to parameterize the model. The model is calibrated so that the economy starts to use the modern production function around the year 1700. Following Hansen and Prescott, the model is calibrated so that the steady state of the classical-only model (subsection 2A) matches pre-1700 observations and the steady state of the modern growth-only model (subsection 2B) matches the post-1900 growth experience of the United States.

In the calibration, we deviate from Hansen and Prescott along two dimensions. First, we calibrate the population growth function so that it matches Maddison's (1995) estimates for U.K. population growth rates over subperiods of the 1675–1990 period. Given our theory of population growth, it is more appropriate to use the time series data from a particular country to restrict the population growth function for that country rather than cross-section data as Hansen and Prescott do. Second, we calibrate the annual growth rate of TFP for the modern production function so that it remains at the traditional rate up until 1700, increases linearly to one-half of its modern growth rate in 1825, and then increases linearly to its modern growth rate in 1925.

Following Hansen and Prescott, we pick the initial capital stock and the initial population so that if only the traditional production function were available, the equilibrium would correspond to the steady state of the pre-1700 model and there would

be no incentive to operate the modern production function if it were available. This ensures that in period 0 only the traditional production function is operated and that there is a period of constant living standards.

Table 1 lists the values for each of the model parameters and provides comments where appropriate. The population growth rate function implied by the U.K. population growth data used in the computation is depicted in Figure 3.

For the parameterized model economy, it takes 150 years before 95 percent of the economy's output is produced in the modern sector. Figures 4–6 depict the model economy's development path along a number of other dimensions. Figure 4 compares period *t* per capita output relative to 1700 per capita output for the model economy and the industrial leader as reported by Maddison (1995, Tables 1.1 and C.12). According to the model, an economy that begins the transition in 1700 will be approximately 28 times richer in 1990 as it was in 1700. Figure 5 depicts the growth rate of per capita output for the model economy over the 1700–2000 period. The growth rate of per capita output is slow at the onset of the transition, less than 1 percent per year on average. One hundred years later, the growth rate is near the modern growth rate of 2 percent per year. This pattern is primarily a consequence of the assumption that TFP growth for the modern technology increases slowly over the 1700–1990 period. Figure 6 depicts the path of the rental prices of capital and labor over the 1700–2000 period. As can be seen, the real wage rate increases steadily once the transition begins. The real interest rate, in contrast, shows very little secular change over three centuries. These latter predictions conform well to the pattern of development associated with England, the United States, and other early developers.

Table 1. Restricted Parameter Values

Parameter	Value	Comment
γ_M–growth rate of TFP for traditional production	.0009	Consistent with pre-1700 world population average annual growth rate of .003
ϕ–capital share in traditional production	.10	
μ–labor share in traditional production	.60	Chosen so that labor's share does not vary with the level of development as reported by Gollin (2002)
A_{M0}–initial TFP for traditional production	1.0	Normalization
δ–depreciation rate	.06	Consistent with U.S. capital stock and investment rate since 1900
γ_S–asymptotic TFP growth rate for modern production	.012	2 percent rate of growth of per capita GDP in modern growth era
θ–capital's share in modern production	.40	U.S. physical capital's share of output
A_{S0}–initial TFP for modern production	.53	1700 starting date given initial period for model is 1675
β–subjective time discount factor	.97	Consistent with real rate of interest between 4 and 5 percent in modern growth era

The predictions of the model are not sensitive to the value of the capital share parameter in the modern growth production function. This is an important result, because the magnitude of the capital share with a broad definition of capital that includes intangible as well as tangible capital could well be greater than the 0.40 share value used in the above exercise. The paths of per capita GDP, its growth rate, and rental prices are nearly identical to those shown in Figures 4–6 for alternative values of the capital share in the modern production function. The transition still takes a long time. For a capital share as high as 0.70, 140 years elapse before 95 percent of the economy's capital is produced using the modern production function.

3. A Theory of Relative Efficiencies

The Hansen and Prescott theory of economic development reviewed in Section 2 is not a theory of the evolution of international income levels. It does not address the issue of why modern economic growth started at different dates in different countries. India, for example, began modern economic growth nearly 200 years later than did the United Kingdom. As a result, India's income level relative to the leader fell from 50 percent in 1770 to only 5 percent in 1970. Neither does the theory address the issue of why some countries that have been experiencing modern economic growth for a century have failed to narrow the income gap with the industrial leader. Latin America, for example has remained at roughly 25 percent the U.S. income level since the second half of the nineteenth century when modern economic growth began there. The theory does not address the issue of why some countries in the 1950–2000 period have been able to substantially narrow the income gap with the industrial leader. These countries include Italy, Japan, Korea, Spain, and Taiwan, and all of which experienced a growth miracle. Some factor that differs across countries must be added to the Hansen and Prescott theory to make it a theory of the evolution of international income levels.

One might be led to introduce differences in TFP associated with the modern production to the model, because the Hansen and Prescott theory of development predicts that per capita income in a country starts to increase once TFP in the modern sector reaches a critical level. Moreover, there is ample evidence that countries (at least those experiencing modern economic growth) differ along this dimension.[12] Although it would be easy to introduce such differences into the Hansen and Prescott theory, it would not be

[12] See, for example, Klenow and Rodriguez-Clare (1997), Hall and Jones (1999), and Hendricks (2002).

useful, as long as country-specific TFP differences are treated exogenously. Absent a theory of the country-specific TFP component, the theory of the evolution of international income levels is sterile because it offers no policy guidance. What is needed is a policy-based theory of why TFP differs across countries at a point in time.

Parente and Prescott (2000) develop a theory of TFP that attributes differences in TFP to country-specific policies that both directly and indirectly constrain the choice of production units. Their theory of TFP is more appropriately called a *theory of relative efficiencies*. This is because Parente and Prescott (2000) decompose a country's TFP into the product of two components. The first component is a pure knowledge or technology component, denoted by *A*. The second is an efficiency component, denoted by *E*. In the context of the Hansen and Prescott model, the modern growth production function is

$$Y_{St} = E_S A_{St} \; K_{St}^{\theta} \; N_{St}^{1-\theta} . \tag{3.1}$$

The technology component of TFP, A_{St}, is common across countries. It is the same across countries because the stock of productive knowledge that is available for a country to use does not differ across countries.[13] The efficiency component differs across countries as the result of differences in economic policies and institutions. Here we consider the case in which a country's economic policies and institutions do not change, so E_s is not subscripted by *t*. The efficiency component is a number in the (0,1] interval. An efficiency level less than one implies that a country operates inside the production possibilities frontier, whereas an efficiency level equal to one implies that a country

[13] Much of the stock of productive knowledge is public information, and even proprietary information can be accessed by a country through licensing agreements or foreign direct investment.

operates on the production possibility frontier. Differences in efficiency, therefore, imply differences in TFP.

Relative efficiencies at a point in time, and not absolute efficiencies, can be determined using the production function and the data on quantities of the inputs and the output. Thus, it is not possible to determine if any country has an efficiency level equal to one, although we tend to doubt that this is the case. Changes in relative efficiencies of a given country can also be determined conditional on an assumption on the behavior of the technology component of TFP such as that it grows at some constant rate.

We now present the Parente and Prescott (2000) theory of relative efficiencies. To keep the analysis manageable, we present the theory of relative efficiencies in the context of an economy in which only the modern production function is available. The theory constitutes a theory of the aggregate production function when there are constraints at the production unit level. In light of this, we first review the theory underlying the aggregate production function. We then show how policy constraints give rise to an aggregate production function with a different efficiency level. We follow this by providing estimates of cross-country relative efficiencies associated with the modern production function using the mapping from policy to aggregate efficiency derived in this section with estimates of the costs imposed by a country-specific policy. Finally, we conclude this section with a discussion of why constraints on the behavior of the production units exist.

The Aggregate Production Function

Before developing the mapping from policy to aggregate efficiency, we briefly review the theory of the aggregate production function associated with modern growth.

The theory underlying the aggregate production function is as follows. In each period, there is a set of plant technologies *B*. A plant technology $b \in B$ is a triplet that gives the plant's output y_b and its capital and labor inputs, k_b and n_b. A plan $\{\lambda_b\}$ specifies the measure of every type of plant operated. The aggregate production function, that is, the maximum *Y* that can be produced given aggregate inputs *K* and *N*, is

$$Y = F(K, N) = \max_{\lambda \geq 0} \sum_b \lambda_b y_b \tag{3.2}$$

subject to the two resource constraints

$$\sum_b \lambda_b k_b \leq K \tag{3.3}$$

$$\sum_b \lambda_b n_b \leq N\,. \tag{3.4}$$

Assuming that this program has a solution, which it will under reasonable economic conditions, the aggregate production function will be weakly increasing, weakly concave, homogeneous of degree one, and continuous.

Empirically, the Cobb-Douglas aggregate production function is the one consistent with the post-1850 modern economic growth era. The question then is, What set of technologies *B* gives rise to the Cobb-Douglas aggregate production function? One such set is the set of plant technologies defined by

$$y \leq d(n) k^{\theta}\,. \tag{3.5}$$

The function $d(n)$ is an increasing and continuous function of the labor input. Assuming that $n^* = \arg\max d(n)\, n^{\theta-1}$ exists, the aggregate production function is

$$Y = A\, K^{\theta} N^{1-\theta}, \tag{3.6}$$

where $A = \max d(n)\, n^{\theta-1}$. With the assumption that the function d increases over time, the expression A will increase over time.

Consequences of Constraints for Aggregate Efficiency

Next, consider the plant production technology with constraints imposed on it. We consider two types of policy. The first type constrains how a particular plant technology can be operated. The second type constrains the choice of the production units that can be operated. For sure, a number of other types of policy have a similar effect, but they are not considered by Parente and Prescott (2000).[14]

The first type constrains how a given technology is operated. A policy that gives rise to this type of constraint is a work rule, which dictates the minimum number of workers or machines needed to operate a plant technology. In particular, suppose constraints are such that the input to a $b = (k,n,y)$ type plant must be $\phi_K k_b$ and $\phi_N n_b$ for all plant types where ϕ_K and ϕ_N exceed one. This implies that a particular technology, if operated, must be operated with excessive capital and labor. With these constraints, the aggregate production function is

$$Y = \phi_N^{\theta-1}\phi_K^{-\theta} A\ K^{\theta} N^{1-\theta} = E_S\ A\ K^{\theta} N^{1-\theta}, \tag{3.7}$$

where $E_S \equiv \phi_K^{-\theta}\phi_N^{\theta-1}$. This is the aggregate production function used in Section 2. If the nature of the constraints were to double the capital and labor requirements, then the efficiency measure would be one-half. If the nature of constraints is to quadruple both the capital and labor requirements, then the efficiency measure would be one-fourth.

[14] For example, Schmitz (2001) suggests a mapping of government subsidies to state-owned enterprises and aggregate efficiency.

The second type of policy constrains the choice of the production units that can be operated. This type of constraint can map into the efficiency parameter of an aggregate production with a composite capital stock made up of both physical and intangible components. Any policy that serves to increase the amount of resources the production unit must spend in order to adopt a better technology is a constraint of this nature. Such policies and practices take the form of regulation, bribes, and even severance packages to factor suppliers whose services are eliminated or reduced when a switch to a more productive technology is made. In some instances, the policy is in the form of a law that specifically prohibits the use of a particular technology. The empirical evidence suggests that this second type of constraint is more prevalent than the first.[15]

Following Parente and Prescott (2000), let the output of a quality *b* plant be given by the following equation:

$$y_t = b\, k_{Pt}^{\theta_P} [\min(n_t, \bar{n})]^{\theta_n} \qquad \bar{n} > 0, \quad \theta_P < 1. \tag{3.8}$$

With this technology, a minimum number of workers, $\bar{n}$, is required to operate a plant. The variable k_P denotes the physical capital input. The subscript *P* is introduced in order to differentiate physical capital from intangible capital. There are no increasing returns to scale in the economy, because if the inputs of the economy are doubled, the number of plants doubles.[16]

A plant's quality is a choice variable. To improve its quality, resources are needed. This resource cost is the product of two components. The first component is technological in nature and reflects the cost in the absence of constraints. The second

[15] See Parente and Prescott (2000) for a survey of this evidence.

[16] See Hornstein and Prescott (1993) for a detailed coverage of this technology.

component, denoted by ϕ_I, reflects the constraint itself. The function that gives the required resources a plant must expend to advance its quality from b to b' is

$$x_{bb'} = \phi_I \int_b^{b'} \left(\frac{s}{W_t} \right)^{\alpha} ds. \tag{3.9}$$

W_t is the stock of pure knowledge in the world in period t. Its growth rate is exogenous and equal to γ_W. Thus,

$$W_{t+1} = W_0 (1 + \gamma_W)^t. \tag{3.10}$$

Integrating (3.9) yields

$$x_{It} = \phi_I \frac{b_{t+1}^{\alpha+1} - b_t^{\alpha+1}}{W_0^{\alpha} (1+\gamma)^{\alpha t} (1+\alpha)}.$$

Let

$$k_{It} = \frac{\phi_I b_t^{\alpha+1}}{W_0^{\alpha} (1+\gamma)^{\alpha(t-1)} (1+\alpha)}.$$

The plant technology is specified by

$$y_t = \mu \phi^{-\theta_I} (1+\gamma)^t k_{It}^{\theta_I} k_{Pt}^{\theta_P} [\min(\bar{n}, n_t)]^{1-\theta_n}, \tag{3.11}$$

with

$$k_{It+1} = (1 - \delta_I) k_{It} + x_{It}, \tag{3.12}$$

where δ_I and μ are functions of α, γ, ϕ_I, and W_0 and $\theta_I = 1 - \theta_P - \theta_n$. The variable k_{It} has the interpretation of the plant's intangible capital stock, as it is the value of the plant's past investments in quality improvements. The sum of θ_I and θ_P is strictly less than one, so there is an optimal plant size.

Aggregating over plants implies the following equilibrium aggregate production relation:

(3.13) $$Y_t = E_S A_0 (1+\gamma_S)^t K_{It}^{\theta_I} K_{Pt}^{\theta_P} N_t^{1-\theta_P-\theta_I},$$

with $E_S \equiv \phi^{-\theta_Z}$. The laws of motion for the aggregate capital stocks are

(3.14) $$K_{I,t+1} = (1-\delta_I)K_{It} + X_{It}$$

(3.15) $$K_{P,t+1} = (1-\delta_P)K_{Pt} + X_{Pt}.$$

Now if the intangible capital stock has the same depreciation rate as physical capital, then the aggregate production relation with two capital stocks given by (3.13) maps into an aggregate production function with one capital stock and a large value for the capital share.[17] More specifically, the capital share in the one-capital-stock model, θ, is the sum of θ_I and θ_P. The relations between the two capital stocks, K_I and K_P, and the composite capital stock, K, are

(3.16) $$K_{It} = \frac{\theta_I}{\theta} K_t$$

(3.17) $$K_{Pt} = \frac{\theta_P}{\theta} K_t.$$

In the experiments that follow, this effectively is the underlying aggregate production function for the modern sector in the combined development theory of Hansen and Prescott when we consider capital share values greater than 0.40.[18]

[17] This requires an assumption that there is an additional resource cost associated with maintaining the plant's current quality. Such a cost could reflect, among other things, training for young workers who replace old workers retiring in the previous period.

[18] We say *effectively* because there are two technical issues in the combined theory when capital is broadly defined. First, if intangible capital is not an input into the traditional production function, then the economy will need to make some investments specifically in intangible capital prior to switching to the modern production function. Second, after the transition, as new plants open, they will have a lower technology level compared to older plants.

Estimates of Aggregate Relative Efficiency

The mappings developed in the preceding subsection allow us to impute the aggregate relative efficiency associated with the modern production function for various constraints. In general, the size of the effect of the constraint on a country's aggregate efficiency depends on the factor input affected by the constraint and on that input's share in the production function. In the special case where the constraints affect all inputs equally, that is, $\phi = \phi_n = \phi_I = \phi_P$, the individual factor shares are unimportant and the efficiency level of a country is just $E_s = \phi$. Hence, the implied difference in relative efficiencies is equal to the implied cost differences of policy. Thus, if the cost difference in policies between two countries is a factor of five, the implied factor difference in aggregate relative efficiency is also five.

Are factor differences in relative efficiency greater than five reasonable? Obviously, it is not possible to answer this question definitively without a comprehensive international study of the total costs of the constraints imposed by society. Some estimates of the cost differences associated with some country-specific policies do exist. Studies that estimate the costs of certain policies of individual countries that affect the technology and work practice choices of the production units located there do find that these costs vary systematically with income levels, with large differences existing between rich and poor countries. These studies suggest that factor differences in relative efficiencies could be easily as great as five.

For example, Djankov et al. (2002) calculate the costs associated with the legal requirements in 75 countries that an entrepreneur must meet in order to start a business. They find that the number of procedures required to start up a firm varies from a low of 2

in Canada to a high of 20 in Bolivia and that the minimum official time required to complete these procedures ranges from a low of 2 days in Canada to a high of 174 days in Mozambique. These costs do not reflect any unofficial costs involved with starting a firm, such as bribes, or bureaucratic delays. Because these official cost measures are positively correlated with indexes that incorporate measures of bribes, the true difference in start-up costs between low-cost and high-cost countries is surely even larger than those reported in the study.

Reasons for Constraints

The evidence strongly suggests that production units in poor countries are severely constrained in their choices, and the costs associated with these constraints are large. This prompts the question, Why does a society impose these constraints? A large number of studies, some of which are surveyed in Parente and Prescott (2000), suggest that constraints typically are imposed on firms in order to protect the interests of factor suppliers to the current production process. These groups stand to lose in the form of reduced earnings if new technology is introduced. These losses occur because either the input they supply is specialized with respect to the current production process or the monopoly power granted to them over the supply of a particular input is eroded.[19]

4. A Unified Theory of the Evolution of International Incomes

In this section we unify the Parente and Prescott (2000) theory of relative efficiencies and the Hansen and Prescott (2002) theory of development. The unified

[19] Parente and Prescott (1999) show in a model with no capital how a monopoly right granted to factor suppliers can significantly lower a country's efficiency. Herrendorf and Teixeira (2003) extend this model to include physical capital and show that these monopoly rights have even larger effects on a country's efficiency.

theory is then used to organize and interpret the evolution of international income levels. We unify the Parente and Prescott (2000) theory and the Hansen and Prescott theory as follows. We assume that technological increases in both sectors result from growth in world knowledge. Consequently, the technology component of TFP in each production function is the same across countries at any point in time. The paths for the technology components of TFP are determined as in subsection 2C by requiring that the leader country with an efficiency parameter in the modern sector set to one start its transition to modern economic growth in 1700. We then introduce differences in this efficiency parameter across countries. Given a country's relative efficiency parameter and the common path of the technology components of the TFPs, we compute the equilibrium path of the economy.

As mentioned in Section 3, we doubt than any country has or had an efficiency parameter equal to one. The assumption that efficiency in the leader is one in the unified theory is not important to any of the results as it is just a normalization. Again, only relative efficiencies matter and can be determined. This is the case for countries at a given time and across time in a given country.

We do not introduce cross-country differences in the efficiency parameter associated with traditional production. As mentioned in the introduction, incomes did differ slightly prior to 1700, with the richest countries being no more than two or three times richer than the poorest. One possible explanation for these pre-1700 differences in income levels is that countries differed in policies that increased the inputs required for producing goods with the traditional production function. Because this technology corresponds to traditional farming and even manufactures produced within a home

setting, we think the effect of policy differences for relative efficiencies associated with traditional production is small. For this reason, we favor the alternative explanation that some countries were better able to defend themselves from outside expropriations because of geography and thus were able to maintain a higher constant living standard during the pre-1700 era. Countries that enjoyed such an advantage were England and Japan.

We interpret delays in the start of the transition to modern economic growth to late starters having a lower relative efficiency in the modern sector, at least up until the date their transitions began. We attribute the persistent percentage between a country that started modern economic growth later than did the industrial leader to the continuation of its low relative efficiency. Finally, we attribute catch-up, including growth miracles, to large increases in relative efficiency in countries.

We begin by computing the relative efficiency of a late starter required to delay the start of its transition by a given length of time. The size of the required efficiency difference between the leader and the laggard that gives rise to any given delay is a function of the capital share parameter in the modern production function. *Main finding:* The differences in relative efficiency required to generate delays in starting dates of the lengths observed in the historical data are reasonable for all capital shares above 0.40.

We then compute the entire equilibrium path of these late starters assuming that their efficiency levels relative to the leader never change. The main finding is that the gap in incomes between late and early starters never narrows. Large differences in incomes exist even after the late starters are in the modern economic growth phase. In fact, the gap between the leader and late starters increases for some time after the laggards have started

the transition to modern economic growth. This is the case even though the transition period of late starters is shorter compared to early starters. The difference in relative efficiencies between late and early starters needed to generate a given factor difference in per capita outputs when both sets of countries are experiencing modern economic growth again depends upon the capital share parameter.

The final set of experiments allows for a one-time increase in a country's relative efficiency parameter. We assume that the change is unexpected from the standpoint of the late starter and viewed as permanent in nature. We then compute the equilibrium path relative to the leader's level and determine the country's output relative to the leader subsequent to the change. *We find that the late starter's path of output relative to the leader subsequent to the change in its efficiency parameter is consistent with the experience of growth miracle countries such as Japan, but only if the capital share is between one-half and two-thirds.*

The finding that capital's share must be large for the unified theory to be a successful theory of the evolution of international income levels has important implications for the size of investment in intangible capital. Namely, it implies that the size of this investment is a large fraction of GDP. Investment in intangible capital goes unmeasured in the national income and product accounts. Thus, it is not possible to determine whether a large capital share is plausible by examining national account data. One must examine micro evidence to determine the plausibility of a large capital share. Thus, we conclude this section by examining the micro evidence on the size of unmeasured investment in the economy. We conclude from this evidence that the size of

unmeasured investment in the economy is as large as the size predicted by the unified theory.

Delays in Starting Dates

We first examine whether the unified theory predicts large delays in the start of the transition to modern economic growth that some countries have experienced. In particular, we determine the size of the difference in efficiency required to delay the start of the transition to modern economic growth by a certain number of years.

For the purpose at hand, it is important to provide a more thorough picture of the different starting dates for the transition corresponding to the experiences of individual countries. An issue is how to date the start of modern economic growth. Our definition of the *start* of modern economic growth is the earliest point in a country's history with the property that the trend growth rate is 1 percent or more for all subsequent time.[20] Figure 7 shows the path of output in a number of countries relative to the industrial leader going back to 1800. As can be seen, starting dates vary substantially across countries. Mexico started the transition to modern economic growth sometime between 1800 and 1850; Japan started sometime between 1850 and 1900. Brazil started in the early twentieth century, and India started its transition sometime between 1950 and 1980. As a result of these different starting dates, the disparity in income has increased.

The key expression for determining the delay in the starting date associated with differences is equation (2.12), which rewritten in relative efficiencies is

$$E_S^i A_{St} < \left(\frac{r_{Mt}}{\theta}\right)^{\theta} \left(\frac{w_{Mt}}{1-\theta}\right)^{1-\theta}. \tag{4.1}$$

[20] The concept of trend employed here is a highly smoothed path of per capita income.

A country will not use the modern production function as long as the relation given by (4.1) is satisfied. Once a country's efficiency, $E_S A_{St}$, exceeds the critical level given by the right-hand side of (4.1), which it must, the country begins its transition to modern economic growth. Assuming as we do that relative efficiencies associated with the traditional production function do not differ across countries, the rental prices of land and labor will not differ much across countries over the periods when each country specializes in the traditional production function.[21] Consequently, this critical level of efficiency will not differ much across countries. It follows that the difference in starting dates between two countries *i* and *j*, with different relative efficiencies, is approximately given by the dates t_i and t_j for which

$$E_S^i A_{St_i} = \left(\frac{r_M}{\theta}\right)^{\theta} \left(\frac{w_M}{1-\theta}\right)^{1-\theta} = E_S^j A_{St_j} . \tag{4.2}$$

It is not obvious looking at equation (4.2), but the required relative efficiency E_S^i / E_S^j that gives rise to a particular delay in the start of the transition depends on the size of the capital share in the modern production function. The reason for this is that the required factor difference in relative efficiencies equals the factor difference in the stock of pure knowledge, A_s, between starting dates. It follows that the required relative efficiency difference is smaller for larger increases in the stock of pure knowledge between starting dates. The size of the increase in the stock of pure knowledge depends importantly on its asymptotic growth rate, γ_S. The value of this parameter is calibrated so that the growth rate of per capita output associated with the steady-state rate of the

[21] They are roughly equal because the rental prices will not be constant in all periods that the economy specializes in the traditional production function. This is because agents will start to accumulate more capital per household member in anticipation of the modern production function being used.

modern-growth-only model, given by $(1 + \gamma_S)^{1/(1-\theta)}$, equals 2 percent per year. Thus, the calibrated value of γ_S and hence the size of the increase in pure knowledge between starting dates t_j and t_i, depends on capital's share in the modern growth production function.

We now compute the efficiency of the early starter relative to a late starter required to generate a given delay in the transition to modern economic growth. We do this for a range of the capital share parameters, since the value of capital's share is not well restricted. For each capital share value, we recalibrate the asymptotic growth rate of pure knowledge, γ_S, and the value of A_{s0} so that the country with $E_s = 1$ always starts its transition in 1700. These are the only parameters whose values are changed in the experiments.

We assume that late starters are endowed with an initial capital stock equal to the steady-state level associated with the classical model of subsection 2A. For the purpose of determining the date at which an economy starts to use the modern growth function, it is not necessary that we fully specify the population growth function of the late starters. In particular, it is not necessary to specify the population growth function for consumption levels sufficiently greater than the constant consumption level, c_m, associated with the pre-1700 period. For consumption levels below this, we use a population growth function with a sufficiently large and positive slope at c_M and for which $g(c_M) = (1+\gamma_M)^{1/(1-\phi-\mu)}$. These assumptions ensure that the living standard in a late starter is roughly constant prior to the period it begins its transition.

Table 2 reports the efficiency of the early starter relative to the late starter required to generate a 100-year, a 200-year, and a 250-year delay in the transition to

modern economic growth. These delays roughly represent the difference in the start of the transition to modern economic growth between England and Mexico, England and Japan, and England and India. As Table 2 shows, the factor difference in efficiency needed for a given delay decreases as the modern production capital share increases. The size of the required difference needed to delay the start of development for 250 years is plausible for all values of θ in Table 2, with $\theta = 0.40$ probably at the lower bound of plausible values.

Table 2. Required Factor Difference in Relative Efficiencies for Delays

θ	1800 Start	1900 Start	1950 Start
.40	1.60	3.2	5.7
.50	1.25	2.5	4.0
.60	1.20	2.2	3.3
.70	1.18	1.9	2.5

No Catch-Up After the Transition

A number of countries, many of which are located in Latin America, started their transitions to modern economic growth in the nineteenth century. Despite this, these countries have failed to eliminate the gap with the leader over the last century. We now examine whether the model can account for this feature of the data. In particular, we seek to determine if the model predicts a narrowing of income levels once a country begins modern economic growth absent any changes in relative efficiency.

We address this question by examining whether the model absent any assumed subsequent changes in relative efficiencies predicts a narrowing or widening of income levels between early and late starters. In particular, we now compute the equilibrium paths of per capita output for the model economies associated with the required

differences in relative efficiencies reported in Table 2. We also report their relative incomes.

Before undertaking these experiments, it is necessary to address two issues. First, it is necessary to specify the population growth rate function for the late starters in these experiments because increases in population affect the size of the increases in per capita output over the transition. For this specification, we simply use the post-1800 population growth rates of Mexico for the model economy that starts its transition in 1800, the post-1900 population growth rates of Japan for the model economy that starts its transition in 1900, and the post-1950 population growth rates of India for the model economy that starts its transition in 1950. These population growth data are taken from Lucas (2002, Table 5.1). Second, for capital share values that reflect a broad concept of capital, it is necessary to adjust output by the amount of investment in intangible capital. This adjustment must be made in order to compare the predictions of the model with the national income and product account data, because the latter fails to measure investments in intangible capital.

A country's unmeasured investment as a fraction of its measured output can be determined given the decomposition of the capital share between its physical capital and intangible capital components. For a given total capital share, the physical capital component can be calibrated to the ratio of investment to physical capital to measured GDP in the leader countries of roughly 20 percent. In particular, the share parameters can be calibrated to the steady state of the modern growth-only-economy using this observation from the leader countries. With value of the individual share parameters in

the modern growth production function, it is possible to compute the amount of unmeasured investment at any date of the equilibrium path.

Table 3 reports the size of the intangible capital share parameter and the asymptotic ratio of intangible capital investment to GDP for each of the total capital share values considered in Table 2. As the total capital share increases, both the intangible capital share and the intangible capital investment share of GDP increase. The sizes of the unmeasured investment shares range from 0.0 for $\theta = 0.40$ to 0.50 for $\theta = 0.70$.

Table 3. Implied Intangible Capital Share and Investments

θ	θ_I	$X_I/(Y-X_I)$
.40	.00	.00
.50	.28	.26
.60	.41	.41
.70	.53	.62

Figure 8 plots the path of per capita GDP for late starters relative to the leader over the 1700 to 2050 period. The paths correspond to the case where $\theta = 0.40$. The paths are essentially the same for the other capital share values. For this reason, we do not report their paths in the paper. Asymptotically, the model is just the steady state of the modern growth model of subsection 2B, and so income differences are just $(E_s^i / E_s^j)^{1/(1-\theta)}$. For the 1800 starter, the asymptotic relative income level is 50 percent of the leader, for the 1900 starter it is 16 percent, and for the 1950 starter it is 6 percent.

Most of the difference in relative incomes in 2000 is the consequence of the poor country starting the development process later. However, even after starting to develop, a late starter's disparity with the leader increases, although at a much slower rate than before. There are two reasons for this. First, the disparity continues to increase because

the traditional production function is still widely used at the start of the transition and the growth rate of TFP associated with the traditional production function is lower than the growth rate of TFP associated with the modern production function. Second, the population growth in these countries tends to be higher compared to the leader over the comparable period. The disparity with the leader stops increasing only after the modern production function starts being used on a large scale. For the 1800 starter, the disparity stops increasing around 1900. For the 1900 starter, the disparity stops increasing around 2000. And for the 1950 starter, the disparity stops increasing around 2050.[22] The increase in disparity over the 1950–2000 period for the 1950 starter is consistent with the fact that many sub-Sahara African countries have fallen further behind the leader in the 1950–2000 period despite experiencing absolute increases in living standards over this period.

Laggards do experience larger increases in their income over their transition periods compared to earlier starters. For example, the country that starts its transition in 1700 realizes a factor increase of 1.2 in its per capita income by 1750. In comparison, the country that starts its transition in 1900 realizes a factor increase of 2 in its per capita income over the next 50 years.[23] The reason for this difference is that the growth rate of knowledge associated with the modern production function is initially low, but rises over time. Thus, TFP growth in the modern production function over a late starter's transition period is higher compared to an earlier starter's transition period. This gives late starters an inherent advantage.

[22] This is a key difference between our formulation and that of Ngai (2000). Ngai examines the effect of policy on the starting date within Hansen and Prescott's overlapping generations model. In contrast, she finds that some part of the income gap will be eliminated once poor countries start their transitions.

[23] This assumes the same population growth functions for both economies.

The data needed to verify whether this pattern exists are not readily available. In particular, per capita output numbers going back to the eighteenth century exist for only a limited number of countries. Although it is not possible to say whether transition periods have become shorter over time, there is strong evidence that late starters have been able to double their incomes in far shorter time periods compared to earlier starters.

Figure 9 documents this general pattern. It plots the number of years a country took to go from 10 percent to 20 percent of the 1985 U.S. per capita income level versus the first year that country achieved the 10 percent level. The 1985 U.S. level was 20,000 in 1990 dollars. The set of countries considered had at least 1 million people in 1970 and had achieved and sustained per capita income of at least 10 percent of the 1985 U.S. level by 1965. There are 56 countries that fit these criteria and for which data are available. Of these 56 countries, all but four managed to double their per capita income by 1992. The four exceptions all had protracted armed insurgencies that disrupted their development.

The difference in the length of the doubling period between the sets of late and early starters is dramatic. For early starters, which are those achieving 10 percent of the 1985 U.S. level before 1950, the median length of the doubling period is 45 years. For late starters, defined as those achieving 10 percent of the 1985 U.S. level after 1950, the median length of the doubling period is 15 years. The choice of starting level is not important. A similar pattern emerges when the starting level is fixed at 5 percent and at 20 percent of the 1985 U.S. level.

Although the model absent changes in relative efficiency infers an advantage to late starters, quantitatively it is inconsistent with the number of years in which many late starters have been able to double their income. Many late starters that doubled their

income in less than a 35-year period after 1950 did in fact narrow the gap with the leader over that period. The unified theory absent changes in relative efficiencies does not predict any catch-up for late starters. For the theory to account for this catch-up, it must consider changes in relative efficiency in a given country over time.

Catch-Up and Growth Miracles

We now examine whether the theory can account for the record of catch-up. A key feature of the evolution of international income levels is that many countries have been able to narrow the gap with the leaders, with some realizing large increases in output relative to the leader in a relatively short period of time. Countries such as Botswana, China, Japan, South Korea, and Taiwan were all able to double their living standards in less than a decade at some point in time over the post-1950 period. These growth miracles are a relatively recent phenomenon and are limited to countries that were relatively poor prior to undergoing their miracle. No country at the top of the income distribution has increased its per capita income by a factor of 4 in 25 years, and the leader has always taken at least 80 years to quadruple its income.

To account for the catch-up, including growth miracles, the theory, therefore, requires an increase in the efficiency of a country relative to the leader.[24] In light of the Parente and Prescott (2000) theory, these changes in relative efficiency are easy to understand. Namely, they reflect policy changes. Following an improvement in policy that leads to a significant and persistent increase in efficiency, the theory predicts that the income of a late starter will go from its currently low level relative to the leader to a

[24] Additionally, an increase in efficiency can hasten the start of the transition to modern growth for countries that have not already begun this phase of development.

much higher level. As it does, its growth rate will exceed the rate of modern growth experienced by the leader countries, and the gap in incomes will be narrowed.

We now consider an increase in a late starter's relative efficiency. In particular, we examine whether the unified theory can account for the growth miracle of Japan.[25] Figure 10 depicts the path of per capita output for the Japanese and U.S. economies over the 1900 to 1995 period. There is really nothing special about Japan versus other economies that similarly experienced growth miracles. The precise time period of the Japanese growth miracle we consider in the analysis is the 1957–69 period. We choose this period because by 1957 Japan had fully recovered from the wartime disruptions. Moreover, this period is one of the most dramatic in terms of Japan's catch-up. In this 12-year period, per capita GDP doubled from 25 percent of the leader to 50 percent of the leader (Summers and Heston, 1991). This catching up was not the result of the leaders' growth rate slowing down. Indeed, U.S. per capita GDP grew by 40 percent in this period. The Japanese economy in this period is a dramatic example of catching up.

In the experiment, we assume that there is an unexpected increase in 1957 in the relative efficiency of the model economy, which started its transition in 1900, to the leader's level. This assumption is made because the data suggest that Japan in the 1957–69 period was converging to the U.S. balanced growth path. In calculating the equilibrium path of the model economy following this increase, we take the initial population to be the population corresponding to the equilibrium path of the model economy that starts the transition in 1900. The initial capital stock is assumed to be such

[25] Ngai (2000) studies this same issue within the Hansen and Prescott model.

that per capita GDP relative to the leader equals 25 percent.[26] The population growth rate function for the model economy is the same as before and is based on Japanese population dynamics.

The important finding is that the total capital share must be large for an economy to take 12 years to move from 25 percent to 50 percent of the leader. Figure 11 plots the path of per capita GDP predicted by the model economy over this period for various values of θ. For a value of θ equal to 0.40, the predicted path shows too large an increase over the period. At the other end of the range, namely, $\theta = 0.70$, the predicted path shows too small an increase over this time period. This leads us to conclude that capital share values in the range of 0.55 and 0.65 are consistent with the growth miracles. [27]

It is possible to introduce this increase in efficiency in the poor country at a much earlier date, say in 1800. The theory does not, however, predict that the poor country will experience a growth miracle. The theory, therefore, is consistent with the fact that growth miracles are a relatively recent phenomenon. Growth miracles are a relatively recent phenomenon because, as Figure 8 shows, differences in relative incomes between the low-efficiency and high-efficiency countries widen over time before leveling off. This widening is due to growth in the stock of pure knowledge associated with the modern production function, which the high-efficiency country uses from a very early date. Thus, as one goes back in time, the gap that a low-efficiency country could close by becoming a high-efficiency country becomes smaller and smaller. Obviously, if the gap is less than

[26] In the case where capital is broadly defined, we assume the initial mix of physical and intangible capital is optimal in the sense that returns would be equal.

[27] There are a number of reasons to believe that capital's share may be somewhat less than 0.60. For one, we abstracted from leisure. For another, we abstracted from household durables. For an in-depth discussion of this issue, see Parente and Prescott (2000).

50 percent, the low-efficiency country can never double its income in less than a decade. For the same reason, the unified theory is consistent with the fact that late starters have been able to double their incomes in far shorter times compared to early starters.

The theory is also consistent with the fact that growth miracles are limited to countries that were initially poor at the time their miracles began. Growth miracles are limited to this set of countries because a growth miracle in the theory requires a large increase in a country's relative efficiency. A large increase in efficiency can only occur in a poor country with a currently low efficiency parameter. This rules out a rich country, which by definition uses its resources efficiently.

Unmeasured Investment

For capital shares that are consistent with the evolution of international income levels, the implied size of unmeasured investment is between 35 and 55 percent of GDP. Are these intangible capital investment share numbers plausible? This is not an easy question to answer. The difficulty in coming up with measures of the size of intangible capital investment is that the national income and product accounts (NIPA) treat investments in intangible capital as ordinary business expenses. Parente and Prescott (2000) attempt to estimate the size of intangible capital investment in the U.S. economy. They conclude that the size of this investment may be as large as 50 percent of GDP. In constructing their estimates, Parente and Prescott (2000) use the principle implied by theory that *investment* is any allocation of resources that is designed to increase future production possibilities. Using this principle, they identify such activities as starting up a new business, learning-on-the-job, training, education, research and development, and

some forms of advertising as investments in intangible capital.[28] Such estimates are consistent with capital share values between one-half and two-thirds.

5. Catching Up

The implication of the theory is that countries will be rich if they do not constrain production units as to which technologies can be operated and the manner in which a given technology can be operated. Currently poor countries will catch up to the industrial leaders in terms of production efficiency if existing barriers to efficient production are eliminated and an arrangement is set up to ensure that barriers will not be re-erected in the future. The removal of such constraints is a necessary condition for catching up. As discussed in Section 3, there is strong evidence that suggests that these constraints exist to protect the interests of industry groups vested in the current production process. As such, their removal is likely to be contentious. For this reason, it is instructive to examine the record on catch-up in greater depth for the purpose of determining the reasons for circumstances under which barriers to efficient use of technology were reduced and catching up with the efficiency leader occurred.

Catching up is not uniform across regions in this period, as can be seen in Figure 12. Latin America began modern economic growth in the late nineteenth century and has not subsequently closed the living standards gap with the industrial leader. Its per capita income remained at roughly 25 percent of the industrial leader throughout the twentieth century. In comparison, Asian countries with the exception of Japan began modern

[28] Additionally, McGrattan and Prescott (2002) estimate the size of unmeasured investment in the corporate sector only and conclude that it is roughly 10 percent of GDP.

economic growth later. This set of countries experienced significant catching up in the 1970–2000 period.

The large Western European countries, namely, Germany, Italy, and France, caught up to the industrial leader in the post–World War II period after trailing the leader for 100 years. Modern economic growth in these countries began about 1840. At that time, their living standard was about 60 percent of the industrial leader, which at that time was the United Kingdom. For nearly 100 years, these countries maintained an income level that was about 60 percent that of the industrial leader. In the post–World War II period, output per hour worked in these countries, which is a good measure of living standards because it recognizes the value of nonmarket time, increased from 38 percent of the U.S. level in 1950 to 73 percent in 1973 and to 94 percent in 1992. Today, most of the difference in per capita output between the Western European countries and the United States is accounted for in differences in the fraction of time that people work in the market, and not in the efficiency with which resources are used.

Another important example of catching up is the U.S. development experience in the 1865–1929 period. In 1870, U.K. per capita GDP was nearly a third higher than that of the United States. By 1929, the United Kingdom's per capita GDP was a third lower than that of the United States. The dramatic growth performance of the United States in this period is an important fact that needs to be explained.

Reasons for Catching Up

We begin with the Asian catching-up observation. Countries such as South Korea, Taiwan, and Japan were forced to adopt policies that did not block efficient production as a condition for support from the United States. Further, the need to finance national

defense made protecting those with vested interests in inefficient production too expensive to South Korea and Taiwan. These development miracles along with the Hong Kong and Singapore growth miracles made it clear to the people of the democratic states in the region that the policy that their elected representatives followed mattered for their living standard. Their elected representatives had no choice but to cut back on protecting industry insiders with vested interests in inefficient production or be voted out of office.

The rapid development of China began in 1978 when the Chinese government became more decentralized, with much of the centralized planning system dismantled. Although the central government gave more power to regional governments, it did not give the regional governments the right to restrict the flow of goods across regions. In fact, when individual regions attempted to erect trade barriers in the late 1980s and early 1990s, the central government immediately took steps to restore the free flow of goods and services.[29] The resulting competition between businesses in different provinces led to rapid growth in living standards.

The comparison of Russia's performance under capitalism with China's is interesting and informative. Russia's experiment with capitalism to date can only be considered a failure, as its output has actually contracted since 1992. In contrast to China, there is no free trade club in Russia. Migration of individuals between regions is restricted, and local and regional governments have the power to discriminate against producers from other member states operating within their borders. Parente and Riós-Rull (2001) argue that establishing a decentralized system with competition between regions in Russia was undoubtedly a much more difficult endeavor compared to China for a

[29] See Young (forthcoming).

number of reasons. First, by being more industrialized at the time of its transition, Russia had more vested interest groups. Second, Soviet central planners concentrated industry in particular regions, without an economic justification for such locations.

Turning now to the questions of why the United States caught up with and surged past the United Kingdom in the 1865–1929 period and why Western Europe caught up with the United states in terms of labor productivity in the 1957–93 period, our answers are as follows. The answer to the first question is that the United Sates was and continues to be a free trade club, while the United Kingdom was not a member of a free trade club in this earlier period. Our definition of a *free trade club* is as follows. A set of states constitutes a free trade club if it meets two conditions. Member states cannot impose tariffs and other restrictions on the import of goods and services from other member states. In addition, member states must have a considerable degree of economic sovereignty from the collective entity. Just as no single state is able to block the movement of goods between states, the collective entity cannot block the adoption of a superior technology in one of its member states. Thus, a free trade club in our definition is far more than a set of countries with a free trade agreement.

In democratic states with legislatures representing districts, vested interests in other districts have a limited ability to block the adoption of technology in a given district if the citizens of the given district want that technology adopted. In the United States, for example, Toyota was able to locate an automobile plant with its just-in-time production in Tennessee in 1985. Those with vested interests in the less efficient technology in Michigan and other states with a large automotive industry were not able to prevent this from happening. The people in Tennessee wanted the large construction project in their

state and the high paying jobs in the automobile factory. Thus, the United States is a free trade club. With the formation of NAFTA and the recent approval of the free trade agreements with Chile and Singapore, the set of states constituting the free trade club to which the U.S. states belong may be getting larger.

The European Union has become an equally important free trade club. Its states enjoy even greater sovereignty than do U.S. member states. However, the German state cannot block the Toyota introduction of just-in-time production in Wales even though German politicians would if they could in response to domestic political pressure. If Toyota starts gaining market share, it will not be long before the auto industry throughout Europe adopts the superior technology, and productivity in the production of automobiles increases. This is just competition at work.

The historical statistics lend strong empirical support to the theory that a trading club arrangement results in greater efficiency of production. Table 4 reports labor productivity for the original members of what became the European Union and the labor productivity of members that joined in the 1970s and 1980s. Productivities are reported for an extended period before the EU was formed as well as for the period subsequent to its creation.

The Treaty of Rome was signed in 1957 by Belgium, France, Italy, Netherlands, Luxembourg, and West Germany to form the union. In 1973 Denmark, Ireland, and the United Kingdom joined. In 1981 Greece joined, followed by Portugal and Spain in 1986. The most recent additions are Austria, Finland, and Sweden in 1995.

One striking fact is that prior to forming the European Union, the original members had labor productivity that was only half that of the United States. This state of

affairs persisted for over 60 years with no catching up. However, in the 36 years after forming what became the EU, the Treaty of Rome signers caught up with the United States in terms of labor productivity. The factor leading to this catch-up is an increase in the efficiency with which resources are used in production. Changes in capital/output ratios are of little significance in accounting for the change in labor productivity.

Also reported in Table 5 is the productivity of the EU countries that joined the union in 1973. These countries experienced significant productivity catch-up subsequent to joining the union. It will be interesting to see if Greece and Portugal, the two EU countries that have far lower productivity than the other EU members, continue to improve their relative productivity performance.

Another interesting comparison is between the productivity performance of Switzerland and the Western European countries that did not join the EU until 1995. Norway was not included in this set of countries because of the large size of its oil industry. We label this set of four countries *other*. Table 5 reports labor productivities of these other countries relative to the original EU countries.

The important finding is that the original EU countries and the other countries are equally productive in the prewar period. In the 36 years from 1957 to 1993, the other countries fell from 1.06 times as productive as the original EU countries to only 0.81 as productive in 1993. This constitutes strong empirical evidence that membership in the EU fosters higher productivity.

Table 4. Labor Productivities of European Union Members as a Percentage of U.S. Productivity[a]

Year	Original Members	Members Joining in 1973
1870	62	
1913	53	
1929	52	
1938	57	
1957	53	57
1973	78	66
1983	94	76
1993	102	83
2002	101	85

[a] The prewar numbers are population weighted labor productivity numbers from Maddison (1995). The postwar numbers are also population weighted and were obtained from Maddison's Web page, http://www.eco.rug.nl/GGDC/index-series.html#top.

Table 5. Labor Productivity of Other Western European Countries as a Percentage of Original EU Members[a]

Year	Others / Original
1900	103
1913	99
1938	103
1957	106
1973	96
1983	85
1993	81

[a] The prewar figures are from Maddison (1995). For this period, GDP per capita is used as a proxy for productivity. The postwar numbers are also population weighted and were obtain from Maddison's Web page, http://www.eco.rug.nl/GGDC/index-series.html#top.

A free trade club, which prohibits individual states from discriminating against the goods produced in other member states and against producers from other member states operating within their borders, has the advantage that industry insiders in the various member states face elastic demand for what they supply. As a consequence, they are not hurt by the adoption of more efficient production methods as the increase in output leads to an increase in employment in that industry. If demand were inelastic, an increase in efficiency would lead to a fall in employment, something which industry insiders strongly oppose.

Industry studies document the effect of free trade of goods and services on the adoption of better technology and work practices. Galdon and Schmitz (1998), for example, document the effect of increased competition in iron ore mining in the 1980s.

Increased competition from Brazilian iron ore mines had major consequences for productivity in U.S. mines. Output per unit of input increased by a factor of 2 as competition made it in the interest of specialized factor suppliers to permit the doubling of productivity. Ferreira and Rossi (forthcoming) document large increases in output per worker in 16 industries in Brazil at the two-digit level following the trade liberalization in the early 1990s. After declining at an annual rate of 1.6 percent per year from 1985 to 1990, it increased at a rate of 6 percent per year thereafter. The increases in productivity were associated with a decline in employment and hours.

We turn now to Latin America and why Latin America failed to catch up. There was no free movement of goods and people between the set of relatively sovereign states. A consequence of this is that often industry insiders in the sovereign states faced inelastic demand for their products or services, and this led them to block the adoption of more efficient production practices. If Brazil were to decentralize and restrict the authority of its central government to be like the United States in the 1865–1930 period, Brazil would quickly become as rich as Western Europe and the United States, or maybe richer.

6. Concluding Remarks

Will the whole world be rich by the end of the twenty-first century? The implication of the theory reviewed in this chapter is that a country will catch up to the leading industrial countries only if it eliminates the constraints relating to the use of technology. Although it is clear what a country must do to become rich, it is not clear whether a country will have either the political will or political power to make the necessary reforms. Removal of the constraints to the efficient use of resources is bound to be contentious, because such constraints typically exist to protect specialized groups of

factor suppliers and corporate interests. As recent events in Argentina show, these groups can overthrow a government.

The increase in the number of free trade clubs in the last decade, the central Andean Community and North America, for example, is evidence that some countries have achieved the political will to reduce these constraints. However, the lack of the emergence of free trade clubs in many other regions of the world, particularly Africa, the Indian subcontinent, and South America, is evidence of a lack of political will. A thorough understanding of why one country has this political will and another does not is something we are currently lacking. If we had this understanding it might be possible to determine what should be done to minimize the resistance to reform by groups with interests vested to current production processes.

A first step in addressing this issue is to understand how constraints to the efficient use of resources come to exist in the first place. Surely, many constraints exist to protect the vested interests of individuals in the status quo. What we really seek to understand is the mechanism by which these groups and their interests succeed in getting these constraints put in place. Policy, namely, the imposition of constraints on the efficient use of resources, is undoubtedly the outcome of a game between policymakers and the economy's actors. Consequently, fruitful research in this area will most likely require a game-theoretical approach. Some progress is being made in this area. Grossman and Helpman (1994), Krusell and Ríos-Rull (1996; 2002), Holmes and Schmitz (1995; 2001), McDermott (1999), Kocherlakota (2000), Ngai (2000), Bridgman, Livshits, and MacGee (2001), Parente and Ríos-Rull (2001), Samaniego (2001), Teixeira (2001), and

Parente and Zhao (2002) all deal with this issue. In our view, this area of research will dominate the study of development and growth in the years to come.

March 2005

Abstract: This paper integrates in a unified and tractable framework some of the key insights of the field of international trade and economic growth. It examines a sequence of theoretical models that share a common description of technology and preferences but differ on their assumptions about trade frictions. By comparing the predictions of these models against each other, it is possible to identify a variety of channels through which trade affects the evolution of world income and its geographical distribution. By comparing the predictions of these models against the data, it is also possible to construct coherent explanations of income differences and long-run trends in economic growth.

JEL codes: F10, F15, F40, F43, O11, O40 and O41.

Keywords: Economic growth, international trade, globalization.

I dedicate this research to the memory of Rudi Dornbusch, the best mentor, colleague and friend a young economist could have hoped for, and always capable of making others see things differently. This is a draft of a chapter in the forthcoming *Handbook of Economic Growth* edited by Philippe Aghion and Steven Durlauf. I am thankful to Fernando Broner, Gino Gancia and Francesc Ortega for their useful comments and to Matilde Bombardini, Philip Sauré and Rubén Segura-Cayuela for providing excellent research assistance. I am also grateful to the Fundación Ramón Areces for its generous financial support.

Table of Contents

"All theory depends on assumptions that are not quite true. That is what makes it theory. The art of successful theorizing is to make the inevitable assumptions in such a way that the final results are not very sensitive. A "crucial" assumption is one on which the conclusions do depend sensitively, and it is important that crucial assumptions be reasonably realistic. When the results of a theory seem to flow specifically from a special crucial assumption, then if the assumption is dubious, the results are suspect."

Robert M. Solow [1956, p. 65]

0. Introduction

The world economy has experienced positive growth for an extended period of time. Figure 1 plots average world per capita income from 1500 to today, using data from Maddison's classic study of long run trends in the world economy. The most salient feature of the growth process is its nonlinear nature. For most of the past five hundred years, the world economy settled in a path of stagnation with little growth. But sometime around the early nineteenth century the world economy entered a path of sustained and even accelerating growth. While per capita income grew only by eighteen percent from 1500 to 1820, it has then grown by more than seven hundred and fifty percent from 1820 to today. And this growth has been far from steady. It averaged 0.53 percent from 1820 to 1870, and more than doubled to 1.30 from 1870 to 1913. Growth declined to 0.91 percent during the turbulent period that goes from 1913 to 1950, and then exploded to an unprecedented 2.93 percent from 1950 to 1973. Since then growth has markedly declined to 1.33 percent, even though this period still constitutes the second best growth performance in known human history.

This economic growth has not been distributed equally across the different regions of the world economy. Figure 2 shows per capita income growth for the different regions of the world economy in various time periods. Differences in

regional growth experiences are quite remarkable.[1] Growth took off in Western Europe and its offshoots in the early nineteenth century and never stopped again. But other regions took longer to participate in the growth of the world economy. Perhaps the most dramatic case is that of Asia, which basically did not grow until 1950 just to become then the fastest growing region in the world. Another extreme case is that of Africa, which still today is unable to enjoy growth rates that would be considered modest in other regions. Another salient feature of the growth process is therefore its uneven geographical distribution: in each period there are some regions that have been able to grow and prosper, while others have been left behind.

World economic growth has been accompanied by more than proportional growth in world trade. Figure 3 shows the evolution of world trade as a share of world production since 1870. The picture is quite clear: from 1870 to 1998 growth in world trade has quadrupled growth in world income. There also appears to be a strong positive correlation between growth in per capita income and growth in trade. Figure 4 plots the growth rates of these two variables against each other using pooled data from various regions and periods. The simple correlation between these variables is 0.64, and the regression results indicate that regions and periods with X percent higher than average trade growth tend to have per capita income growth which is 0.3·X higher than average. It almost goes without saying that this statistical association between income and trade does not imply causation in any direction. But it strongly suggests that these variables are somehow related, and that there might be substantial payoffs to working with theories that jointly determine them.[2]

[1] To get a sense of the magnitudes involved, remember that an annual growth rate of G leads per capita income to multiply itself by a factor $F \approx \exp\{G \cdot T\}$ in T years. For instance, in the last quarter of the twentieth century Asia has been able to increase its per capita income by a factor of 2.5, while Latin America has only managed to increase its per capita income by a factor of 1.2 and Africa has stagnated. Even a cursory look at the data shows that this disparity in growth performances constitutes the norm rather than the exception.

[2] For empirical work on the (causal) effect of trade on income levels and income growth see Sachs and Warner [1995], Frankel and Romer [1999], Ades and Glaeser [1999], Alesina, Spolaore, and Wacziarg [2000 and their chapter in this handbook], Rodriguez and Rodrik [2000], Alcalá and Ciccone [2003 and 2004], and Dollar and Kraay [2003].

Despite this apparent relationship between income and trade, a substantial part of growth theory is built on the assumption that countries live in autarky and that there is no trade among them.[3] This is obviously a dubious assumption. But is it also a "crucial" one? And if so, what alternative assumptions would be reasonably realistic? At an abstract level, these are the questions that I attempt to answer here. A recurring theme throughout this chapter is that the growth experiences of the different world regions are intimately linked and cannot be analyzed in isolation. We therefore need a global view of economic growth that looks at the different regions of the world as parts of a single whole. Formally, this means that we should develop and systematically study world equilibrium models. These models and their predictions constitute the specific focus of this chapter. [4]

Rather than providing an all-encompassing survey of the field, my goal in writing this chapter has been to develop a unified and yet tractable framework to discuss key insights of the fields of international trade and economic growth. In particular, I examine a sequence of world equilibrium models that share a common description of technology and preferences but differ on their assumptions about trade frictions. By comparing the predictions of these models against each other, it is possible to identify a variety of channels through which trade affects the evolution of world income and its geographical distribution. By comparing their predictions against the data, it is also possible to construct coherent explanations of income differences and long run trends in economic growth. When viewed as a group, these models show that much is known about the relationship between income and trade. Despite this, I still feel we are only exploring the tip of the iceberg. The research program sketched here is ambitious, fun and it could eventually lead to a much deeper understanding of the forces that drive modern capitalist economies.

[3] A brief examination of the different chapters of this handbook should quickly convince anyone doubting this statement.

[4] Without doubt, the seminal book by Grossman and Helpman [1991] is the single most influential contribution to the development and study of world equilibrium models of the growth process. It heavily influenced a whole generation of PhD students, like myself, that were searching for dissertation topics when the book first appeared. But there are, of course, many other important contributions. The bibliography at the end of this chapter is an (admittedly imperfect) attempt to list all published papers that use world equilibrium models to study the growth process. I apologize to the authors of any relevant paper that has been overlooked.

The rest of this chapter contains four sections. The first one describes growth in the integrated economy. This is an imaginary world where trade costs are negligible and geography does not matter. Section two introduces two trade frictions: the immobility of production factors and the absence of international financial markets. Section three adds a third trade friction: costs of transporting goods. The fourth and final section briefly concludes by taking stock what we have learned and pointing out potential avenues for further research.

1. The integrated economy

Imagine a world without borders, a world in which all goods and factors can be transported across different regions at negligible cost. Some industries spread their production process across many regions searching for the ideal environment for each specific phase of production. Other industries choose instead to concentrate production in a single region to exploit increasing returns to scale. Regardless of an industry's particular circumstances, its location choice maximizes productivity and is not affected by the local availability of production factors and/or final customers. If a region does not have the necessary production factors, these can be imported from abroad. If a region does not have enough customers, the goods produced can be exported abroad. In this world, global market forces arbitrage away regional differences in goods and factor prices and all the gains from trade are reaped. This imaginary world is the integrated economy, and is the subject of this section.

The integrated economy provides a natural benchmark for the study of economic growth in an interdependent world. Moreover, its simplicity and elegance encapsulates the essence of what growth theory is all about: deriving strong results using minimalist models. In the spirit of the so-called "new growth theory", I shall use a model that jointly determines the stock of capital and the level of technology.

Admittedly, the model is somewhat lopsided. On the one hand, it contains a fairly sophisticated formulation of technology that includes various popular models as special cases. On the other hand, it uses a brutal simplification of the standard overlapping-generations model as a description of preferences. Despite this, I do not apologize for the imbalance. A robust theme in growth theory is that the interesting part of the story is nearly always on the technology side, and rarely on the side of preferences.

This section develops the basic framework that I use throughout the chapter. Sub-section 1.1 describes the integrated economy, while sub-section 1.2 derives its main predictions for world growth. Sub-section 1.3 goes back to a period in which all the regions of the world lived in autarky, and compares the growth process of this world with the integrated economy. This is just the first of various attacks to the question of globalization and its effects on the world economy.

1.1 A workhorse model

Consider a world economy inhabited by two overlapping generations: young and old. The young work and, if productive, they earn a wage. The old retire and live off their savings. All generations have size one. There are many final goods used for consumption and investment, indexed by $i \in I$. When this does not lead to confusion, I shall use I to refer both to the set of final goods and also to the number of final goods. As we shall see later, the production of these final goods requires a continuum of intermediate inputs. There are two factors of production: labor and capital. For simplicity, I assume capital depreciates fully within one generation.[5] The world economy contains many regions. But geography has no economic consequences since goods and factors can be transported from one region to another at any time at negligible cost.

[5] The main role of this assumption is to ensure that investment is always strictly positive. This simplifies the presentation without substantially affecting the main results.

The citizens of this world differ in their preferences and access to education. S_t members of the generation born in date t are patient and maximize the expected utility of old age consumption, while the rest are impatient and maximize the expected utility of consumption when young. The utility function has consumption as its single argument, and it is homothetic, strictly concave and identical for all individuals. H_t members of the generation born in date t can access education and become productive, while the rest have no access to education and remain unproductive.[6] I refer to S_t and H_t as "savings" and "human capital", and I allow them to vary stochastically over time within the unit interval. Assuming that savings and human capital are uncorrelated within each generation, we obtain:

$$(1) \qquad K_{t+1} = S_t \cdot w_t \cdot H_t$$

$$(2) \qquad C_t = (1 - S_t) \cdot w_t \cdot H_t + r_t \cdot K_t$$

where K_t and C_t are the average or aggregate capital stock and consumption; and w_t and r_t are the wage and rental rate of capital. Equation (1) states that the capital stock equals the savings of the young, which consist of the wage of those that are patient and productive. The assumption that capital depreciates fully in one generation implies that the capital stock is equal to investment. Equation (2) says that consumption equals the wage of the impatient and productive young plus the return to the savings of the old.[7]

Consumption and investment can be thought of as composites or aggregates of the different final goods. A very convenient assumption is that both composites

[6] The assumption that labor productivity is either one or zero is extreme, but inessential. We could also think of H_t as the average labor productivity of the world economy. The assumption that human capital is not industry specific is widespread, but not entirely innocent. See Basu and Weil [1998] and Brezis, Krugman and Tsiddon [1993] for interesting implications of relaxing this assumption.

[7] This representation of savings and consumption is nothing but a stripped-down version of Modigliani's life-cycle theory of savings. It abstracts from other motives for savings such as leaving bequests. These could be easily re-introduced in the theory through suitable and well-known modifications of the preferences of individuals. I shall not do this to keep the analysis as simple as possible. I conjecture that the bulk of the basic intuitions and results presented here would not be meaningfully affected by these extensions.

take the same Cobb-Douglas form with spending shares that vary across industries, i.e. σ_i with $\sum_{i \in I} \sigma_i = 1$. Since there is a common ideal price index for consumption and investment, it makes sense to use it as the numeraire and this implies that aggregate spending is given by $E_t \equiv C_t + K_{t+1}$. To sum up, we have that:

(3) $E_{it} = \sigma_i \cdot E_t$ for all $i \in I$

(4) $1 = \prod_{i \in I} \left(\frac{P_{it}}{\sigma_i} \right)^{\sigma_i}$

where E_{it} and P_{it} are the total spending on and the price of the final good of industry i. Equation (3) states that spending shares are constant, while Equation (4) sets the common price of consumption and investment equal to one.

Production of final goods uses labor, capital and a continuum of different varieties of intermediate inputs, indexed by $m \in [0, M_{it}]$ for all $i \in I$. As usual, I interpret the measure of input varieties, M_{it} for all $i \in I$, as the degree of specialization or the technology of the industry. This measure will be determined endogenously as part of the equilibrium. The technology of industry i can be summarized by these total cost functions:

(5) $B_{it} = \left[\frac{1}{Z_{it}} \cdot \left(\frac{w_t}{1-\alpha_i} \right)^{1-\alpha_i} \cdot \left(\frac{r_t}{\alpha_i} \right)^{\alpha_i} \right]^{1-\beta_i} \cdot \left[\int_0^{M_{it}} p_{it}(m)^{1-\varepsilon_i} \cdot dm \right]^{\frac{\beta_i}{1-\varepsilon_i}} \cdot Q_{it}$ for all $i \in I$

(6) $b_{it}(m) = \frac{1 + q_{it}(m)}{Z_{it}} \cdot \left(\frac{w_t}{1-\alpha_i} \right)^{1-\alpha_i} \cdot \left(\frac{r_t}{\alpha_i} \right)^{\alpha_i}$ for all $m \in [0, M_{it}]$ and $i \in I$

where $0 \leq \beta_i \leq 1$, $\varepsilon_i > 1$ and $0 \leq \alpha_i \leq 1$; Q_{it} is total production of final good i; $q_{it}(m)$ and $p_{it}(m)$ are the quantity and price of the m^{th} input variety of industry i; and the variables Z_{it}

are meant to capture the influence on industry productivity of geography, institutions and other factors that are exogenous to the analysis.[8] I loosely refer to the Z_{it}s as "industry productivities" and assume they vary stochastically over time within a support that is strictly positive and bounded above. Equation (5) states that the technology to produce the final good of industry i is a Cobb-Douglas function on human and physical capital, and intermediate inputs. The latter are aggregated with a standard CES function. Equation (6) states that the production of intermediates is also a Cobb-Douglas function on human and physical capital, and that there are fixed and variable costs.[9] I interpret the fixed costs as including both the costs of building a specialized production plant and the costs of inventing or developing a new variety of intermediate. An important simplifying assumption is that input varieties become obsolete in one generation and, as a result, all generations must incur these fixed costs.[10]

Since there are constant returns in the production of final goods, it is natural to assume that final good producers operate under perfect competition. Therefore, prices and intermediate input demands are given as follows:

$$(7) \qquad P_{it} = \frac{\partial B_{it}}{\partial Q_{it}} \qquad \text{for all } i \in I$$

$$(8) \qquad q_{it}(m) = \frac{\partial B_{it}}{\partial p_{it}(m)} \qquad \text{for all } m \in [0, M_{it}] \text{ and } i \in I$$

Equation (7) states that price equals marginal cost, while Equation (8) uses Shephard's lemma to describe the demand for intermediate inputs. Equations (5) and (8) imply that an increase in the price of a given input variety lowers its market share. But Equation (3) shows that the lost market share goes entirely to other input

[8] Although popular, this is a quite simplistic view of the effects of geography and institutions. See Levchenko [2004] for an interesting discussion of alternative ways of modeling the effects of institutions.
[9] As usual, the fixed cost is paid if and only if there is strictly positive production.
[10] This assumption is crucial for tractability, since it eliminates a potentially large set of state variables, i.e. M_{it} for all $i \in I$.

varieties of the same industry and does not affect the industry's overall market share.

Since the production of intermediate inputs exhibits increasing returns that are internal to the firm, input producers cannot operate under perfect competition. I assume instead they operate under monopolistic competition with free entry. This has the following implications:

(9) $$p_{it}(m) = \frac{e_{it}(m)}{e_{it}(m) - 1} \cdot \frac{\partial b_{it}(m)}{\partial q_{it}(m)} \qquad \text{for all } m \in [0, M_{it}] \text{ and } i \in I$$

(10) $$p_{it}(m) \cdot q_{it}(m) = b_{it}(m) \qquad \text{for all } m \in [0, M_{it}] \text{ and } i \in I$$

where $e_{it}(m)$ is the price-elasticity of input demand: $e_{it}(m) = -\frac{p_{it}(m)}{q_{it}(m)} \cdot \frac{\partial q_{it}(m)}{\partial p_{it}(m)}$ with the derivative in this definition being applied to Equation (8). Equation (9) states that monopolistic firms charge a markup over marginal cost that is decreasing on the demand elasticity faced by the firm. As usual, the CES formulation implies that this demand elasticity is equal to the elasticity of substitution among inputs, i.e. $e_{it}(m)=\varepsilon_i$. Equation (10) states that profits must be zero and this is, of course, a direct implication of assuming free entry.

Finally, we must impose appropriate resource constraints or market-clearing conditions:

(11) $$P_{it} \cdot Q_{it} = E_{it} \qquad \text{for all } i \in I$$

(12) $$H_t = \sum_{i \in I} H_{it} \qquad \text{with} \quad H_{it} = \frac{\partial B_{it}}{\partial w_t} + \int_0^{M_{it}} \frac{\partial b_{it}(m)}{\partial w_t} \cdot dm$$

(13) $$K_t = \sum_{i \in I} K_{it} \qquad \text{with} \quad K_{it} = \frac{\partial B_{it}}{\partial r_t} + \int_0^{M_{it}} \frac{\partial b_{it}(m)}{\partial r_t} \cdot dm$$

where H_{it} and K_{it} are the labor and capital demanded by industry i. Since the integrated economy is a closed economy, Equation (11) forces the aggregate supply of each good to match its demand, while Equations (12)-(13) state that the aggregate supply of labor and capital must equal their demands. The latter are the sum of their industry demands, and these are calculated using Shephard's lemma.

This completes the description of the model. For any admissible initial capital stock and sequences for S_t, H_t, and Z_{it}, an equilibrium of the integrated economy consists of sequences of prices and quantities such that Equations (1)-(13) hold in all dates and states of nature. The assumptions made ensure that this equilibrium always exists and is unique. I shall show this by construction in the next section.

The reader might be wondering why I have not formally introduced financial markets. I have allowed individuals to construct their own capital and use it as a vehicle to carry on their savings into retirement (a world of family-owned firms?). But I have not allowed them to trade securities in organized financial markets. The reason is simply to save notation. The assumptions made ensure that asset trade does not matter in this world economy. [11] To see this, assume there exist sophisticated financial markets where all individuals can trade a wide array of state-contingent securities. Naturally, the old would not be able to trade these securities since they will not be back to settle claims one period later. But the young would not trade with each other either. Impatient young would not be willing to trade securities since they do not have income in their old age and are happy to consume all their income during their youth. Patient young are the only ones willing and able to trade these securities. But they all have identical preferences and face the same distribution of returns to capital, and therefore they find no motive to trade with each other. Thus, we can safely assume the integrated economy contains sophisticated

[11] This statement is not entirely correct. It applies to assets whose price reflects only fundamentals, but without additional assumptions it does not apply to securities whose price contains a bubble. I shall disregard the possibility of asset bubbles in this chapter, although this is far from an innocuous assumption. See Ventura [2002] for an example where asset bubbles have an important effect on the growth of the world economy and its geographical distribution.

financial markets that allow individuals to enter contracts that specify exchanges of various quantities of the different goods to be delivered at various dates and/or states of nature. It just happens that these financial markets do not make any difference for consumption and welfare.

1.2 Diminishing returns, market size and economic growth

To study the forces that determine economic growth in the integrated economy, it is useful to start with a familiar expression:

$$(14) \qquad \frac{K_{t+1}}{K_t} = s_t \cdot \frac{Q_t}{K_t}$$

where Q_t is the integrated economy's output or production, i.e. $Q_t \equiv \sum_{i \in I} P_{it} \cdot Q_{it}$; and s_t is the economy's (gross) savings rate, i.e. $s_t \equiv \frac{K_{t+1}}{Q_t}$. Equation (14) states that the (gross) growth rate of the capital stock is equal to the savings rate times the output-capital ratio or average product of capital. If this product stays above one asymptotically, the world economy exhibits sustained or long run growth. Otherwise, economic growth eventually ceases and the world economy stagnates. We shall study then the determinants of savings and the average product of capital.

To compute the savings rate, remember that industry i receives a share σ_i of aggregate spending of which a fraction $1-\alpha_i$ goes to labor. Adding across industries, it follows that aggregate labor income is $w_t \cdot H_t = (1-\alpha) \cdot Q_t$, where α is the aggregate or average share of capital, i.e. $\alpha \equiv \sum_{i \in I} \sigma_i \cdot \alpha_i$. Since only the patient young save, the savings rate consists of the fraction of labor income in the hands of patient consumers:

(15) $s_t = (1-\alpha)\cdot S_t$

Since the savings rate is bounded above, sustained economic growth requires that the average product of capital remain above one as the economy grows. But what determines the aggregate output-capital ratio? I shall answer this question in a few steps, so as to develop intuition.

The first step consists of finding the output-capital ratio of a given industry as a function of its technology and factor proportions:[12]

(16) $$\frac{Q_{it}}{K_{it}} = \left(\frac{\varepsilon_i}{\varepsilon_i - 1}\right)^{-\beta_i} \cdot M_{it}^{\frac{\beta_i}{\varepsilon_i - 1}} \cdot Z_{it} \cdot \left(\frac{K_{it}}{H_{it}}\right)^{\alpha_i - 1} \qquad \text{for all } i \in I$$

Equation (16) shows the effects of changes in factor proportions on the industry's output-capital ratio, *holding constant technology*. Since there are diminishing returns to physical and human capital in production, we find the standard result that increases in the physical to human capital ratio reduce the output-capital ratio. But technology is endogenously determined in this model, and it depends on the size of the industry:[13]

(17) $$M_{it} = \frac{\beta_i}{\varepsilon_i} \cdot Z_{it} \cdot H_{it}^{1-\alpha_i} \cdot K_{it}^{\alpha_i} \qquad \text{for all } i \in I$$

Equation (17) shows that increases in factor usage or industry size raise the incentives to specialize and therefore improve technology. The larger is the size of the market, the easier it is to recoup the fixed costs of producing a new input variety

[12] From Equations (7) and (11) find that $P_{it}\cdot Q_{it}=B_{it}$, and use this to eliminate B_{it} from Equation (5). Then, solve Equation (9) with Equation (6), substitute into Equation (5) and eliminate factor prices by noting that the industry factor shares, i.e. $w_t\cdot H_{it}/P_{it}\cdot Q_{it}$ and $r_t\cdot K_{it}/P_{it}\cdot Q_{it}$ are given by $1-\alpha_i$ and α_i, respectively.

[13] Symmetry of intermediates and perfect competition in the final goods industry implies that $M_{it}\cdot p_{it}\cdot q_{it}=\beta_i\cdot P_{it}\cdot Q_{it}$; where p_{it} and q_{it} are the common price and quantity of all varieties of intermediates of industry i. Then, use Equations (6), (9) and (10) to eliminate p_{it} and q_{it} from this expression. Finally, eliminate factor prices once again by noting that the industry factor shares are $1-\alpha_i$ and α_i.

and therefore the higher is the number of input varieties that can be sustained in equilibrium. We can now put these two pieces together and write the output-capital ratio as follows:

$$(18) \qquad \frac{Q_{it}}{K_{it}} = A_{it} \cdot H_{it}^{\mu_i \cdot (1-\alpha_i)} \cdot K_{it}^{\mu_i \cdot \alpha_i - 1} \qquad \text{for all } i \in I$$

where μ_i is a measure of the importance of market size effects, i.e. $\mu_i = 1 + \frac{\beta_i}{\varepsilon_i - 1}$;

and A_{it} is a measure of industry productivity, i.e. $A_{it} = \left(\frac{\varepsilon_i}{\varepsilon_i - 1}\right)^{-\beta_i} \cdot \left(\frac{\beta_i}{\varepsilon_i}\right)^{\frac{\beta_i}{\varepsilon_i - 1}} \cdot Z_{it}^{\mu_i}$. I shall refer to both Z_{it} and A_{it} as "industry productivities" when this is not a cause for confusion. Equation (18) summarizes the aggregate industry technology and shows direct and indirect effects of factor usage on the industry's output-capital ratio. Increases in human capital raise the output-capital ratio, as the direct positive effect of making physical capital scarce is reinforced by the indirect effect of increasing input variety. Increases in physical capital have an ambiguous effect on the output-capital ratio, as the direct negative effect of making physical capital abundant and the positive indirect effect of increasing input variety work in opposite directions. If diminishing returns are strong and market size effects are weak ($\mu_i \cdot \alpha_i < 1$) increases in physical capital reduce the industry's output-capital ratio. If instead diminishing returns are weak and market size effects are strong ($\mu_i \cdot \alpha_i \geq 1$) increases in physical capital raise the industry's output-capital ratio.

The next step is to aggregate these effects across industries. To do this, note first that factor allocations and aggregate output are determined as follows:[14]

[14] Equations (19) and (20) are direct implications of the constant factor and spending shares. One way to think about Equation (21) is as the definition of the Cobb-Douglas aggregate that defines consumption and investment and therefore underlies Equations (3) and (4). Another way of thinking about Equation (21) is as an implication of Equations (3), (4) and (11).

(19) $H_{it} = \sigma_i \cdot \frac{1-\alpha_i}{1-\alpha} \cdot H_t$ for all $i \in I$

(20) $K_{it} = \sigma_i \cdot \frac{\alpha_i}{\alpha} \cdot K_t$ for all $i \in I$

(21) $Q_t = \prod_{i \in I} Q_{it}^{\sigma_i}$

Equations (19) and (20) show that the equilibrium allocations of human and physical capital to industry i depend on the corresponding factor share and the size of the industry. Equation (21) says that output is a Cobb-Douglas aggregate of industry outputs. This is, of course, the production function associated with the cost function in Equation (4). It is now immediate to substitute Equations (18), (19) and (20) into Equation (21) to find the aggregate output-capital ratio of the world economy:

(22) $\frac{Q_t}{K_t} = A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_t^{\mu\cdot\alpha+\upsilon-1}$

where μ is the average value of μ_i, i.e. $\mu \equiv \sum_{i \in I} \sigma_i \cdot \mu_i$; υ is the covariance between μ_i and α_i, i.e. $\upsilon \equiv \sum_{i \in I} \sigma_i \cdot (\mu_i - \mu) \cdot (\alpha_i - \alpha)$; and A_t is an aggregate measure of productivity, i.e. $A_t \equiv \prod_{i \in I} \left[\sigma_i^{\mu_i} \cdot \left(\frac{1-\alpha_i}{1-\alpha} \right)^{\mu_i \cdot (1-\alpha_i)} \cdot \left(\frac{\alpha_i}{\alpha} \right)^{\mu_i \cdot \alpha_i} \cdot A_{it} \right]^{\sigma_i}$. Equation (22) is the aggregate production function and will play an important role in what follows. It shows that the industry intuitions on the effects of changes in factor usage carry on to the aggregate effects of changes in factor supplies. While increases in human capital unambiguously raise the output-capital ratio, increases in physical capital have ambiguous effects.[15] If the "representative" industry has strong diminishing returns and weak market-size effects ($\mu\cdot\alpha+\upsilon<1$) physical capital accumulation

[15] Note that $\mu\cdot(1-\alpha)-\upsilon \geq 0$.

reduces the aggregate output-capital ratio. If instead the "representative" industry has weak diminishing returns and strong market-size effects ($\mu\cdot\alpha+\upsilon\geq 1$) physical capital accumulation raises the output-capital ratio.

We are ready now to characterize the process of economic growth in the integrated economy. Substituting Equation (22) into Equation (14), we obtain the following law of motion for the capital stock:

$$(23) \qquad K_{t+1} = s_t \cdot A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_t^{\mu\cdot\alpha+\upsilon}$$

Equation (23) shows that the integrated economy behaves as if it were a Solow model with a Cobb-Douglas production function that exhibits increasing returns to scale, i.e. the sum of the share coefficients is $\mu\geq 1$. Figures 5 and 6 illustrate the dynamics of the stock of physical capital with the help of two simple examples. The first example is the "deterministic" world where savings, human capital and productivity are constant over time, i.e. $\{s_t,H_t,A_t\}=\{s,H,A\}$ for all t. The second example is the "stochastic" world where savings, human capital and productivity fluctuate between a "bad" state with $\{s_t,H_t,A_t\}=\{s_B,H_B,A_B\}$ and a "good" state with $\{s_t,H_t,A_t\}=\{s_G,H_G,A_G\}$; with $s_G \cdot A_G \cdot H_G^{\mu\cdot(1-\alpha)-\upsilon} > s_B \cdot A_B \cdot H_B^{\mu\cdot(1-\alpha)-\upsilon}$. The central point of these examples is to show that economic growth solves a tension between diminishing returns and market size effects.

Figure 5 shows the case in which diminishing returns are strong and market-size effects are weak, i.e. $\mu\cdot\alpha+\upsilon<1$. The top panel depicts the evolution of the "deterministic" world. There is a unique steady state and the stock of physical capital converges monotonically towards it from any initial position. The steady state is stable because increases (decreases) in the stock of physical capital lower (raise) the output-capital ratio and lead to a lower (higher) growth rate. The bottom panel shows that the "stochastic" world exhibits similar dynamics, with the stock of physical capital monotonically converging to a steady state interval, rather than a steady state

value. Once the stock of physical capital is trapped within this interval, its growth rate fluctuates between positive and negative values and averages zero in the long run. These examples illustrate why sustained growth is not possible if diminishing returns are strong and market size effects are weak.

Figure 6 shows the case in which diminishing returns are weak and market-size effects are strong, i.e. $\mu \cdot \alpha + \upsilon \geq 1$. The top panel shows the "deterministic" world again. There is unique steady state that is unstable. If the stock of physical capital starts above the steady state, it grows without bound at an accelerating rate. If it starts below, the stock of physical capital contracts over time also at an accelerating rate. The steady state is now unstable because increases (decreases) in the stock of physical capital raise (lower) the output-capital ratio and lead to a higher (lower) growth rate. The bottom panel shows that the "stochastic" world also exhibits similar dynamics. One difference however is that there is no steady state. Instead, there is a threshold interval. If the stock of physical capital is above (below) this interval, it grows (contracts) at an accelerating rate. If the stock of physical capital starts within the threshold interval, it fluctuates within it until it eventually exits. This happens with probability one, and only luck determines when this exit occurs and whether the world economy exits above and enters an expansionary path or, alternatively, it exits below and enters a contractionary path. Therefore, sustained growth is possible (but not necessary) if diminishing returns are weak and market size effects are strong.

This model suggests a simple account of the history of the world economy since the 1500s. It is based on the "stochastic" world of Figure 6 and it goes as follows: for centuries, the size of the world economy was too small to generate sustained growth. Located within the threshold interval, the world economy was subject to periodic expansions and contractions with virtually zero average growth. This is consistent with Maddison's calculation that the world economy grew only about eighteen percent from 1500 to 1820. But this was an unstable situation in the very long run. The Industrial Revolution marks the moment in which, after a series of favorable shocks, the world economy reached enough size to exit the threshold

interval and started traveling on the path of accelerating growth reported in Figure 1. As a result of this successful exit, the world economy grew more than seven hundred and fifty percent from 1820 to 1998.

Although suggestive, this account is far too sketchy and incomplete to be taken seriously. Moreover, I find highly improbable that the last five hundred years of the world economy can be understood in terms of a model that postulates negligible costs of transporting goods and factors and constant world population. Surely the demographic revolution and the process of globalization have both played central roles in shaping the growth process during this period. This chapter is not the place for a discussion of the growth effects of the demographic revolution.[16] But it is definitely the place to study the growth effects of globalization, and we turn to this topic next.

1.3 The effects of economic integration

Assume the world economy initially consisted of many regions or locations separated by geographical obstacles that made the costs of transporting goods and factors among them prohibitive. As a result, these regions were forced to live in autarky. I index these regions by $c \in C$, and let them differ on their savings, human capital, industry productivities and initial capital stock, i.e. on $S_{c,t}$, $H_{c,t}$, $Z_{c,it}$ and $K_{c,0.}$ When this does not lead to confusion, I shall use C to refer to both the set of regions and also to the number of regions. Throughout, I denote world aggregates by omitting the region sub-index. Typically, world aggregates refer to the sum of all corresponding regional variables. For instance, world aggregate savings, human and

[16] In this model, a sustained increase in population would generate sustained growth even if $\alpha \cdot \mu + \upsilon < 1$. The reason is that, holding constant both factor endowments and productivity, population growth increases the size of the market and this raises income. I have ruled out this possibility by simply assuming that the world population is constant. Given the purpose of this chapter, I think this is not a "crucial" assumption. But it might be so in other contexts. See Jones' chapter in this volume for a thorough and clear discussion of scale effects in growth models.

physical capital are $S_t = \sum_{c \in C} S_{c,t}$, $H_t = \sum_{c \in C} H_{c,t}$ and $K_t = \sum_{c \in C} K_{c,t}$. But there will be some exceptions. For instance, the relationship between $Z_{c,it}$ and the corresponding world aggregate Z_{it} is a bit more intricate and will be explained shortly.

Although it is not really necessary to take a stand on the geographical distribution of population, I assume throughout that it is equally distributed across regions. This simplifies somewhat the presentation since absolute and per capita regional comparisons coincide. For instance, if $S_{c,t}>S_{c',t}$ then c also has higher savings per person than c'. Note also that, as the number of regions becomes arbitrarily large, the size of each of them becomes arbitrarily small and the effects of shocks to their characteristics on world aggregates become arbitrarily small. This limiting case is usually referred to as the small economy assumption.

The model of globalization considered here is embarrassingly simple: at date t=0, all the geographical obstacles to trade suddenly disappear forever and the costs of transporting goods and factors fall from prohibitive to negligible. What are the effects of such a dramatic reduction in transport costs on world economic growth and its geographical distribution? To answer this question, we must characterize the growth process in the autarkic world economy and in the integrated world economy and compare them. Although this way of modeling globalization and its effects is almost a caricature, it turns out to be quite useful to develop intuitions that survive as we move to more sophisticated and realistic models.

In the world of autarky, each region constituted a smaller version of the integrated economy. Therefore, the world economy at t<0 can be described by:[17]

(24) $Y_{c,t} = A_{c,t} \cdot H_{c,t}^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_{c,t}^{\mu\cdot\alpha+\upsilon}$ for all $c \in C$

(25) $K_{c,t+1} = s_{c,t} \cdot A_{c,t} \cdot H_{c,t}^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_{c,t}^{\mu\cdot\alpha+\upsilon}$ for all $c \in C$

[17] Equation (25) is an analogue to Equation (23), while Equation (24) follows from the region counterparts to Equation (22) and the fact that $Y_{c,t}=Q_{c,t}=C_{c,t}+K_{c,t}$ in autarky.

where $Y_{c,t}$ is the income of the region and, in autarky, it coincides with its production and spending, i.e. $Y_{c,t}=Q_{c,t}=E_{c,t}$; and $A_{c,t}$ is the corresponding measure of regional productivity, i.e. $A_{c,t} \equiv \prod_{i \in I}\left[\sigma_i^{\mu_i} \cdot \left(\frac{1-\alpha_i}{1-\alpha}\right)^{\mu_i \cdot (1-\alpha_i)} \cdot \left(\frac{\alpha_i}{\alpha}\right)^{\mu_i \cdot \alpha_i} \cdot A_{c,it}\right]^{\sigma_i}$ with $A_{c,it} = \left(\frac{\varepsilon_i}{\varepsilon_i - 1}\right)^{-\beta_i} \cdot \left(\frac{\beta_i}{\varepsilon_i}\right)^{\frac{\beta_i}{\varepsilon_i - 1}} \cdot Z_{c,it}^{\mu_i}$. Equations (24) and (25) have been discussed at length already and need no further comment.

In the integrated economy it is not possible in general to determine the production or spending located in a given region. Since goods and factors can move at negligible cost, any geographical distribution of production and factors that ensures all production takes place in the regions with the highest industry productivity is a possible equilibrium. Despite this indeterminacy, prices and aggregate quantities are uniquely determined as shown in section 1.2. This means that it is possible to track the stock of physical capital owned by the original inhabitants of region c and their descendants as well as their income:[18]

(26) $$Y_{c,t} = \left[(1-\alpha) \cdot \frac{H_{c,t}}{H_t} + \alpha \cdot \frac{K_{c,t}}{K_t}\right] \cdot A_t \cdot H_t^{\mu \cdot (1-\alpha) - \upsilon} \cdot K_t^{\alpha \cdot \mu + \upsilon} \qquad \text{for all } c \in C$$

(27) $$K_{c,t+1} = \frac{S_{c,t} \cdot H_{c,t}}{S_t \cdot H_t} \cdot s_t \cdot A_t \cdot H_t^{\mu \cdot (1-\alpha) - \upsilon} \cdot K_t^{\alpha \cdot \mu + \upsilon} \qquad \text{for all } c \in C$$

for all $c \in C$ and $t \geq 0$; and A_t is a measure of world productivity. Remember that we have now specified a set of industry productivities for each region, $Z_{c,it}$. But we only specified one set of industry productivities for the integrated economy in section 1.1.

[18] Equation (26) follows from adding the income from human and physical capital of the inhabitants of the region, and noting that aggregate or world shares of human and physical capital are constant and equal to 1-α and α, respectively. Equation (27) follows from Equations (1) and (23), and the observation that wages are the same for all productive workers of the world. Without loss of generality, I keep assuming that there is no trade in securities.

The reason was that industries never locate in a region that offers less than the highest possible productivity. As a result, in the integrated world economy the only industry productivities that matter are the highest ones, i.e. $Z_{it} = \max_{c \in C}\{Z_{c,it}\}$. This implies that $A_t \geq A_{c,t}$ for all $c \in C$, and we can interpret aggregate productivity not as average productivity, but instead as the highest possible productivity or the world productivity frontier. With this in mind, Equation (27) traces the holdings of capital of the original inhabitants of region c and their descendants, while Equation (26) describes their income.

We are ready now to examine the growth effects of economic integration. Consider first the static or impact effects on the incomes of regions. A bit of straightforward algebra shows that:[19]

$$(28) \quad \ln\left(\frac{Y^{I}_{c,0}}{Y^{A}_{c,0}}\right) = \underbrace{\ln\left(\frac{A_0}{A_{c,0}}\right)}_{\substack{higher \\ productivity}} + \underbrace{\ln\left(\frac{(1-\alpha)\cdot\frac{H_{c,0}}{H_0} + \alpha\cdot\frac{K_{c,0}}{K_0}}{\left(\frac{H_{c,0}}{H_0}\right)^{1-\alpha}\cdot\left(\frac{K_{c,0}}{K_0}\right)^{\alpha}}\right)}_{\substack{improved\ \ factor \\ allocation}} + \underbrace{\ln\left(\frac{H_0^{1-\alpha}\cdot K_0^{\alpha}}{H_{c,0}^{1-\alpha}\cdot K_{c,0}^{\alpha}}\right)^{\mu-1}}_{\substack{increased \\ market\ \ size}} \geq 0$$

where $Y^{I}_{c,0}$ is the actual income of the inhabitants of region c at date t=0, and $Y^{A}_{c,0}$ is the income they would have had at date t=0 if globalization had not taken place. Since each of the terms in Equation (28) is non-negative, the first result we obtain is that the overall impact or static gains from economic integration are non-negative as well.

These gains can be decomposed into three sources corresponding to each of the terms of Equation (28). The first one shows the growth of income that results

[19] To derive this expression I have assumed a zero cross-industry correlation between α_i and μ_i, i.e. υ=0. This parameter restriction is useful because it allows us to unambiguously disentangle the "increased-market-size" and "improved-factor-allocation" effects.

from moving industries from low to high productivity locations. This term would vanish if region c had the highest productivity in all industries. The second term shows the growth of income that results from relocating factors away from those regions and/or industries in which they were abundant in autarky into those in which they were scarce. This term would vanish if region c had world average factor proportions. The third term shows the growth in income that is due to an increase in market size that allows industries to support a higher degree of specialization. This term would vanish if the size of region c were arbitrarily large with respect to the rest of the world. An implication of Equation (28) is that the static gains from economic integration are greater for regions with low productivity, extreme factor proportions and modest amounts of physical and human capital.

If coupled with an appropriate transfer scheme, globalization leads to a Pareto improvement in the world economy. Equation (28) shows that, with the same production factors, the integrated economy generates more output than the world of autarky. It is therefore possible to implement a transfer scheme that keeps constant the income of all current and future young and gives more income to all current and future old. Under this transfer scheme, investment and the stock of physical capital would be unaffected by economic integration. But the production and consumption of all generations born at date t=0 or later would increase. Of course, there exist many alternative transfer schemes that ensure that globalization benefits all. Moreover, since each region gains from trade there exist Pareto-improving transfer schemes that can be implemented without the need for inter-regional transfers. That is, ensuring that globalization generates a Pareto improvement does not require compensation from one region to another.

How “large” the transfer scheme must be to ensure that economic integration leads to a Pareto improvement? The answer is “not much” if most of the gains from economic integration come from higher productivity and increased market size. The reason is that in this case all factors share in the gains from integration. The required transfer scheme could be “substantial” if the gains from integration come mostly from

improved factor allocation. This is because within each region the owners of the abundant factor obtain more than proportional gains from integration while the owners of the region's scarce factor might have losses. In this case, implementing a Pareto improvement requires a transfer from the former to the latter.

Without a transfer scheme, it is relatively straightforward to trace the dynamic effects of economic integration. Assume for simplicity that the world contains many symmetric regions so that before integration all of them had the same law of motion. The top panel of Figure 7 shows the effects of economic integration in the "deterministic" world when diminishing returns are strong and market size effects are weak. Economic integration raises the steady state stock of physical capital and sets up a period of high growth that eventually ends. It is straightforward to see that the effects would be similar in the "stochastic" world, with economic integration permanently raising the steady state interval. Using the jargon of growth theory, if $\mu\cdot\alpha+\upsilon<1$ economic integration has level effects on income. The bottom panel of Figure 7 shows the opposite case in which diminishing returns are weak and market size effects are strong. In this case, economic integration shifts down the steady state value, increasing the growth rate permanently. Once again, it is straightforward to see that the effects would be similar in the "stochastic" world, with trade shifting the threshold interval to the left. Using again the jargon of growth theory, if $\mu\cdot\alpha+\upsilon\geq1$ integration has growth effects on income.

It is tempting now to revisit our earlier account of the history of the world economy since the 1500s, and propose an alternative version which is also based on the "stochastic" world with $\mu\cdot\alpha+\upsilon>1$. It goes as follows: for centuries, the world economy consisted of a collection of autarkic regions that were too small to sustain economic growth. Located within the threshold interval, these regions were subject to periodic expansions and contractions with virtually zero average growth. Once again, this is consistent with Maddison's calculation that the world economy grew only about eighteen percent from 1500 to 1820. The Industrial Revolution occurs when a series of reductions in trade costs between some British regions raised their

combined size above the threshold interval and set them on the path of accelerating growth. As time went on, more and more regions joined the initial core and the Industrial Revolution spread throughout Britain and moved into France, Germany and beyond. It is therefore a reduction of trade costs and the progressive extension of markets that made possible sustained growth and allowed the world economy to grow more than seven hundred and fifty percent from 1820 to 1998. This might also explain why this growth in world income was accompanied by an even higher growth in world trade.[20]

This view of the development process is also broadly consistent with the general observations about inequality between center and periphery discussed in the introduction. Regions that join the integrated economy (the "center") become rich and take off into steady growth. Regions that do not join the integrated economy (the "periphery") are left behind, technologically backward and capital poor. As more and more regions enter the integrated economy, those that are left behind become relatively poorer and world inequality increases. Eventually all regions will enter the integrated economy and world inequality will decline. Therefore, this model generates an inverted U-shape or Kuznets curve, with world inequality rising in the first stages of world development and declining later. Pritchett [1997], Bourguignon and Morrison [2002] and others have shown that world inequality has increased from 1820 to now. It remains to be seen if this inequality will decline in the future.

This stylized model also illustrates some of the conflicts that globalization might create. It follows from Equation (28) that the gains from trade are large for regions whose factor proportions are far from the world average. Ceteris paribus, this means that regions in the center would like that new entrants into the integrated economy to move the world average factor proportions away from them. In fact, unless productivity and market size effects are substantial, the entry of a large region creates losses to other regions with similar factor proportions. This implies, for instance, that the Chinese process of economic integration should be seen with

[20] The word "might" reflects the earlier observation that regional production and therefore trade is indeterminate in the integrated economy.

some concern in countries with similar factor proportions such as Mexico and Indonesia, but with hope in the European Union or the United States.

This view of globalization and growth leads to a powerful prescription for economic development: open up and integrate into the world economy. I believe this is a fundamentally sound policy prescription, and history is largely consistent with it. But there are a number of important qualifications that this stylized model cannot capture. Integrating into the world economy is not an “all-or-nothing” type of affair in which regions move overnight from autarky to complete integration. The process of economic integration is slow and full of treacherous steps. Obtaining general prescriptions for development in a world of imperfect integration has proved to be a much more challenging task. I shall come back to this important point later, but we must first introduce trade frictions into the story.

2. Specialization, trade and diminishing returns

Let us revise our model of globalization. As in section 1.3, assume that at date t=0 the costs of transporting goods across regions suddenly fall from prohibitive to negligible. Unlike section 1.3, assume now that the costs of transporting factors across regions remain prohibitive after date t=0. An implication of this setup is that globalization equalizes goods prices across regions, but it does not necessarily equalize factor prices. This particular view of globalization has a longstanding tradition in trade theory and the goal of this section is to analyze it.

Assuming that human capital is immobile internationally is somewhat dubious, as there are some well-known examples of large contingents of people working overseas. But most of the results discussed here would go through with only minor changes under the weaker and reasonably realistic assumption that international

flows of people are quantity constrained, although not necessarily at zero.[21] Assuming that physical capital is immobile is appropriate for buildings and structures and, probably, not too unreasonable for the most important types of machinery and equipment. Moreover, assuming that existing physical capital cannot be transported does not preclude physical capital to effectively "move" across regions over time, as it declines in some regions through depreciation and increases in others through investment.[22]

If physical capital is immobile, pieces of capital located in different regions might offer different return distributions. This opens up a role for financial markets. Although the old and the impatient young still have no incentive to trade securities, the patient young now have a motive. Those that are located in regions where physical capital offers an attractive distribution of returns want to sell securities and use the proceeds to finance additional purchases of domestic physical capital. Those patient young that are located in regions where physical capital offers an unattractive distribution of returns want to buy securities and reduce their holdings of domestic physical capital. And, regardless of their location, the patient young want to buy and sell securities in order to share regional risks. Thus, the immobility of physical capital creates a potentially important role for international financial markets: the geographical reallocation of investments and production risks.

Despite this, I will not let international financial markets play this role. This failure of financial markets could be due to technological motives or informational problems of various sorts. But I prefer instead to think of it as being caused by lack of incentives to enforce international contracts. In the integrated economy,

[21] Of course, this becomes a weak or empty excuse if quantity constraints respond to economic incentives in a systematic way. See Lundborg and Segerstrom [2002] and Ortega [2004] for models in which this happens.

[22] Remember that we have assumed that physical capital depreciates in one generation. Therefore, assuming physical capital is immobile only means that it is not possible at date t to move around the stock of physical capital created and deployed at date t-1, and that is being used for production at date t. But it is certainly possible to choose where to deploy the new stock of physical capital created at date t that will be used for production at date t+1. The effects of physical capital immobility would be more severe quantitatively with a slower rate of depreciation. Note also that immobility matters only because physical capital is irreversible or putty-clay. In fact, it would be logically inconsistent to assume that physical capital is immobile if it could be converted back into mobile goods.

individuals could enter into contracts that specify exchanges of various quantities of the different goods to be delivered at various dates and/or states of nature. It is standard convention to refer to the signing of contracts that involve only contemporaneous deliveries as “goods” trade, while the signing of contracts that involve future (and perhaps state contingent) deliveries is usually referred to as “asset” trade. Both types of trade require sufficiently low costs of transporting goods. But asset trade also requires that the signing parties credibly commit to fulfill their future contractual obligations. The domestic court system punishes those that violate contracts, thus creating the credibility or trust that serves as the foundation for domestic financial markets. But there is no international court system that endows sovereigns with the same sort of credibility, and this hampers international financial markets. I assume next this problem is so severe that it precludes all asset trade.

Unlike the integrated economy, in the world analyzed in this section each region’s total production, spending and capital stock are always determined. Since trade balances and current accounts are zero, the income of each region equals the value of both its production and spending, i.e. $Y_{c,t}=Q_{c,t}=E_{c,t}$. Since the only vehicle for savings available to the young is physical capital, analogues to Equations (1)-(2) apply to each region. We can therefore write regional incomes and the laws of motion of regional capital stocks as follows:

(29) $Y_{c,t} = w_{c,t} \cdot H_{c,t} + r_{c,t} \cdot K_{c,t}$ for all $c \in C$

(30) $K_{c,t+1} = S_{c,t} \cdot w_{c,t} \cdot H_{c,t}$ for all $c \in C$

These Equations apply to all the models of this section, including the world of autarky before globalization. Therefore, a complete analysis of the world income distribution and its evolution requires us to determine the cross-section of factor prices, i.e. $w_{c,t}$ and $r_{c,t}$ as a function of the state of the world economy. The latter consists of the savings, factor endowments and industry productivities of all regions

of the world, i.e. $S_{c,t}$, $H_{c,t}$, $K_{c,t}$ and $Z_{c,it}$ for all $i \in I$ and all $c \in C$; plus the date, since trade in goods is only possible if $t \geq 0$.

The rest of this section is organized as follows. Sub-section 2.1 studies further the world of autarky, while the rest of the section studies the world after globalization. In sub-section 2.2, we explore a world in which frictions to factor mobility and asset trade are not binding after globalization. Sub-section 2.3 provides a formal description of the model. Sub-sections 2.4 and 2.5 examine worlds where frictions to factor mobility and asset trade remain binding after globalization.

2.1 Economic growth in autarky

The analysis of the effects of globalization starts in the world of autarky. As explained in section 1.3, before globalization each region is a smaller and less efficient version of the integrated economy and factor prices can be written as:[23]

(31) $$w_{c,t} = (1-\alpha) \cdot A_{c,t} \cdot H_{c,t}^{\mu \cdot (1-\alpha) - \upsilon - 1} \cdot K_{c,t}^{\mu \cdot \alpha + \upsilon} \qquad \text{for all } c \in C$$

(32) $$r_{c,t} = \alpha \cdot A_{c,t} \cdot H_{c,t}^{\mu \cdot (1-\alpha) - \upsilon} \cdot K_{c,t}^{\mu \cdot \alpha + \upsilon - 1} \qquad \text{for all } c \in C$$

Equations (31)-(32) describe the cross-section of factor prices. Holding constant factor endowments, regions with higher than average industry productivities have higher than average factor prices. Holding constant industry productivities, the relationship between factor prices and factor endowments depends on two familiar forces: diminishing returns and market size. For a given set of industry technologies, an increase in one factor makes this factor relatively more abundant, lowering its price and raising the price of the other factor. But an increase in one factor also raises income and demand in all industries, improving industry technologies and

[23] These Equations follow from Equation (24) and the observation that the shares of human capital and physical capital are 1-α and α.

raising the prices of both factors. Equations (31)-(32) put these two effects together. Hence, regions with higher-than-average human capital have higher-than-average rental rates for all parameter values, and also higher-than-average wages if $\mu\cdot(1-\alpha)-\upsilon>1$. Similarly, regions with higher-than-average physical capital have higher-than-average wages for all parameter values, and also higher-than-average rental rates if $\mu\cdot\alpha+\upsilon>1$.

It follows from Equations (29)-(32) that, before globalization, we can write regional incomes and capital stocks as follows:[24]

(33) $Y_{c,t} = A_{c,t} \cdot H_{c,t}^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_{c,t}^{\mu\cdot\alpha+\upsilon}$ for all $c \in C$

(34) $K_{c,t+1} = s_{c,t} \cdot A_{c,t} \cdot H_{c,t}^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_{c,t}^{\mu\cdot\alpha+\upsilon}$ for all $c \in C$

Equation (33) shows the income of regions, and it can be used to determine the relative contribution of factor endowments and productivity to income differences. For instance, assume income is λ times higher than average in a given region. It could be that in this region human capital is $\lambda^{1/(\mu\cdot(1-\alpha)-\upsilon)}$ higher than average or that physical capital is $\lambda^{1/(\mu\cdot\alpha+\upsilon)}$ higher than average. It could also be that the region's productivity in industry i is $\lambda^{1/\sigma_i\cdot\mu_i}$ times higher than average.[25] Naturally, it could also be any combination of these factors.

Equation (34) is the law of motion of the capital stocks and can be used to analyze the dynamic response to a region-specific shock to savings, human capital and/or industry productivity. Positive (and permanent) shocks to any of these variables raise the region's capital stock and income. As Equation (34) shows, these shocks have growth effects if $\alpha\cdot\mu+\upsilon\geq1$, but only have level effects if $\alpha\cdot\mu+\upsilon<1$. Regardless of the case, the effects of these shocks never spill over to other regions.

[24] These Equations are identical to Equations (24)-(25) and have been reproduced here only for convenience.
[25] Here industry productivity means $Z_{c,it}$, and not $A_{c,it}$.

Assume the joint distribution of savings, human capital and industry productivities is stationary. Then, Equations (33)-(34) imply a strong connection between the cross-sectional and time-series properties of the growth process.. If diminishing returns are strong and market size effects are weak, i.e. if $\mu\cdot\alpha+\upsilon<1$, world average income ($Y_t$) and its regional distribution ($Y_{c,t}/Y_t$) are both stationary. If instead diminishing returns are weak and market size effects are strong, i.e. $\mu\cdot\alpha+\upsilon>1$, world average income and its regional distribution are both non-stationary. This result provides a tight link between the long run properties of the growth process and the stability of the world income distribution. A weaker version of this result assumes that the world productivity frontier (A_t) is non-stationary but regional productivity gaps ($A_{c,t}/A_t$) are stationary. Under this assumption, world average income is non-stationary even if diminishing returns are strong and market size effects are weak.

It is commonplace among growth theorists to interpret cross-country data from the vantage point of the autarky model.[26] One influential example is the work of Mankiw, Romer and Weil [1992]. They combined Equations (33)-(34) to obtain an Equation relating income to savings, human capital, country productivity, and lagged income; and estimated it using data for a large cross-section of countries. They interpreted the residuals of this regression as measuring differences in country productivities and measurement error, and concluded that differences in savings and human capital explain (in a statistical sense) about 80 percent of the cross-country variation in income. Their procedure imposed the restriction $\mu=1$ (and therefore $\upsilon=0$) and yielded an estimate of α of about two thirds. Hall and Jones [1999] and Klenow and Rodríguez-Clare [1997] interpreted this high estimate of α as a signal that the regression was miss-specified. Their argument was that savings, human capital and productivity were positively correlated and the omission of productivity from the

[26] Unfortunately, the absence of direct and reliable measures of productivity precludes carrying out formal tests of the theory. The most popular empirical response to this problem has been to simply assume the theory is correct and use available data to make inferences about the determinants of the world income distribution and its evolution.

regression biased upwards the estimate of α. These authors used Equations (33)-(34) to calibrate country productivities keeping the assumption that μ=1, but instead imposing a value of α of about one third.[27] With these productivities at hand, they found that about two thirds of the variation in incomes reflects variation in productivity, and only one third can be attributed to cross-country variation in savings and human capital.

Another influential example of the use of the autarky model to interpret available data is Barro [1991] who found that, after controlling for human capital and saving rates, poor countries tend to grow faster than rich ones. This finding has been labeled "conditional convergence" since it implies that, if two countries have the same country characteristics, they converge to the same level of income.[28] If Equations (33)-(34) provide a good description of the real world, observing conditional convergence is akin to finding that $\mu \cdot \alpha + \upsilon < 1$.[29] Many have therefore interpreted the conditional convergence finding as evidence that diminishing returns are strong relative to market size effects.

These inferences about the nature of the growth process heavily rely on Equations (33)-(34), and these Equations have been derived from a theoretical model that assumes that all regions of the world live in autarky. This assumption is obviously unrealistic. Is it also crucial? And if so, what alternative assumption would be reasonably realistic? I next turn to these questions. But the script should not be surprising. Globalization (as described at the beginning of this section) has profound effects on the world income distribution and its evolution. The newfound ability of regions to specialize and trade alters, sometimes quite dramatically, the effects of

[27] This value corresponds to the share of capital in income in national accounts. This sort of calibration exercise is known as development accounting. Caselli's chapter in this volume is the definitive source on this topic.

[28] As Barro himself emphasized, this does not mean that per capita incomes tend to converge unconditionally since countries with high initial incomes also tend to have good country characteristics. There is a large number of papers that try to determine whether there is conditional convergence and measure how fast it takes place. See, for instance, Knight, Loayza and Villanueva [1993] and Caselli, Esquivel and Lefort [1996].

[29] An additional maintained assumption of this line of research is that savings, human capital and productivity are jointly stationary.

factor endowments and industry productivities on factor prices. This is most clearly illustrated in subsection 2.2, which depicts a world in which goods trade allows the world economy to replicate the prices and allocations of the integrated economy. Of course, this is not a general feature of goods trade. Subsection 2.3 prepares the ground for the analysis of worlds where economic integration is imperfect and factor prices vary across regions. This analysis is then performed in subsections 2.4 and 2.5.

2.2 Factor price equalization

A good starting point for the analysis of the world economy after globalization is to ask whether restricting factor mobility matters at all. Somewhat surprisingly, the answer is "perhaps not". As Paul Samuelson [1948, 1949] showed more than half a century ago, goods trade might be all that is needed to ensure global efficiency. When this happens, we say that the equalization of goods prices leads to the equalization of factor prices. I shall describe Samuelson's result and its implications step by step, so as to develop intuition.[30]

Consider the set of all possible partitions of the world factor endowments at date t, H_t and K_t, among the different regions of the world or, for short, the set of all possible factor distributions. This set is formally defined as follows:

$$(35) \qquad D_t \equiv \left\{ (H_{c,t}, K_{c,t}) \text{ for all } c \in C \;\middle|\; H_{c,t} \geq 0,\ K_{c,t} \geq 0 \ \text{ s.t. } \sum_{c \in C} H_{c,t} = H_t \text{ and } \sum_{c \in C} K_{c,t} = K_t \right\}$$

Define FPE_t as the subset of D_t for which the world economy replicates the prices and allocations of the integrated economy. To construct FPE_t, fix $d_t \in D_t$ and consider the integrated economy prices and quantities. At these prices, consumers

[30] The analysis here follows a long tradition in international trade. See Norman and Dixit [1989], Helpman and Krugman [1985] and Davis [1995].

are willing to purchase the integrated economy quantities of the different goods and also have enough income to do so. At these prices, producers located in regions with the highest industry productivities are willing to produce the integrated economy quantities of the different goods using the integrated economy quantities of factors. If these producers can find these quantities of factors in their regions, the integrated economy prices and quantities are in fact the equilibrium ones and we say that $d_t \in FPE_t$. Otherwise, the integrated economy prices and quantities cannot be the equilibrium ones and we say that $d_t \notin FPE_t$. Therefore, the set FPE_t can be formally defined as follows:

$$
\begin{aligned}
FPE_t \equiv \Bigg\{ d_t \in D_t \;\Big|\; & \exists x_{c,it}(m) \geq 0,\ x^F_{c,it} \geq 0 \text{ with } \sum_{c \in C} x_{c,it}(m) = 1,\ \sum_{c \in C} x^F_{c,it} = 1 \text{ and} \\
& x_{c,it} = (1-\beta_i) \cdot x^F_{c,it} + \frac{\beta_i}{M_{it}} \cdot \int_0^{M_{it}} x_{c,it}(m) \cdot dm; \text{ such that :} \\
& \text{(R1) } x_{c,it} = 0 \text{ if } Z_{c,it} < \max_{c \in C} \{Z_{it}\}; \\
& \text{(R2) } H_{c,t} = \sum_{i \in I} x_{c,it} \cdot H_{it} \text{ and } K_{c,t} = \sum_{i \in I} x_{c,it} \cdot K_{it}; \text{ and} \\
& \text{(R3) } x_{c,it}(m) \in \{0,1\} \text{ for all } m \in [0, M_{it}] \text{ and } i \in I \Bigg\}
\end{aligned}
\tag{36}
$$

where M_{it}, H_{it} and K_{it} are defined in Equations (17), (19) and (20). To understand this definition, interpret $x_{c,it}$ as the share of the world production of industry i located in region c at date t; and note that this share includes the production of intermediate inputs, $x_{c,it}(m)$, and final goods, $x^F_{c,it}$. Definition (36) then says that $d_t \in FPE_t$ if it is possible to achieve full employment of human and physical capital in all regions producing only in those regions with the highest productivity (requirement R1), using the same factor proportions as in the integrated economy (requirement R2), and without incurring the fixed cost of production more than once (requirement R3). The set FPE_t is never empty since the factor distribution that applies in the integrated economy always belongs to it. In fact, the set FPE_t consists of all the factor

distributions that are equilibria of the integrated economy. The larger is the size of the indeterminacy in the geographical distribution of production and factors of the integrated economy, the larger is the size of FPE_t.

The patterns of production and trade that support factor price equalization after globalization are easy to state and quite intuitive:

1. *In regions where human (physical) capital is relatively abundant, production shifts towards industries that, on average, use human (physical) capital intensively. Excess production in these industries is converted into exports that finance imports of industries that use physical (human) capital intensively.*

Example 2.1.1: Consider a world economy with H- and K-industries, such that $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume $\alpha_i=\alpha_H$ if $i \in I^H$, and $\alpha_i=\alpha_K$ if $i \in I^K$; and $\alpha_H<\alpha_K$; and $\beta_i=0$ for all $i \in I$. All regions have the same industry productivities, but A-regions have a higher ratio of human to physical capital than B-regions. Factor price equalization is possible if the differences in factor proportions between A- and B-regions are not too large relative to the differences in factor proportions between H- and K-industries. Figure 8 shows the geometry of this example. Since all regions have the same factor costs, industries use the same factor proportions in all regions. A-regions contain a more than proportional fraction of the integrated economy's H-industry, and a less than proportional fraction of the K-industry. The opposite happens in B-regions. This is how specialization and trade ensure that in this world economy factor endowments are used efficiently.

2. *In industries where a region's productivity is less than the world's highest, production falls to zero and domestic spending shifts towards imports. To finance*

the latter, production expands in industries in which the region has the highest possible productivity and the excess production is exported abroad.

Example 2.1.2: Consider a world economy with H- and K-industries, such that $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume $\alpha_i=\alpha_H$ if $i \in I^H$, and $\alpha_i=\alpha_K$ if $i \in I^K$; and $\alpha_H<\alpha_K$; and $\beta_i=0$ for all $i \in I$. Within each type there are "advanced" and "backward" industries. A-regions have the highest possible productivity in all industries, regardless of whether they are "advanced" or "backward". B-regions have the highest possible productivity only in "backward" industries. Factor price equalization is possible if the combined factor endowments of A-regions are large enough and the subset of "advanced" industries is not too large. Figure 9 shows the geometry of this example. Since all regions have the same factor costs, only producers located in regions with the highest productivity can survive international competition. A-regions produce the integrated economy quantities of "advanced" goods and a fraction of the integrated economy quantities of "backward" goods. B-regions produce the remaining quantities of "backward" goods. This is how specialization and trade ensure that in this world economy production takes place only where industry productivities are higher.

3. *Within each industry, only one region produces each input variety and exports it to all other regions. If an industry is split among various regions, there is likely to be two-way trade within the same industry*.[31]

Example 2.1.3: Consider any of the world economies of the previous examples, but assume now that $\beta_i=1$ for all $i \in I$. Assume $d_t \in FPE_t$. Since the fixed costs of

[31] I say "likely to be" because a region might produce the final good for domestic use, and import the necessary input varieties. It is usual in trade models to set $\beta_i=1$ and then drop the "likely to be" from the statement.

producing inputs contain the cost of building a specialized production plant, all input producers choose to concentrate their production in one region in order not to duplicate these costs. Therefore, each region produces a disjoint set of input varieties. This is how specialization and trade allow the world economy to exploit increasing returns to scale and therefore benefit from a larger market size.

By adopting these patterns of specialization and trade, the world economy is able to reap all the benefits of economic integration without any factor movements. Using the jargon of trade theory, goods trade is a "perfect substitute" for factor movements if $d_t \in FPE_t$. When this is the case, factor prices are given by:

(37) $w_{c,t} = (1-\alpha) \cdot A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon-1} \cdot K_t^{\mu\cdot\alpha+\upsilon}$ for all $c \in C$

(38) $r_{c,t} = \alpha \cdot A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_t^{\mu\cdot\alpha+\upsilon-1}$ for all $c \in C$

The world economy is able to operate at the same level of efficiency as the integrated economy despite the immobility of factors. Equations (31)-(32) showed that, before globalization, cross-regional differences in factor proportions and industry productivities lead to differences in the way industries operate (i.e. their factor proportions and productivity) and also in the size of their markets. Regions with a high ratio of human to physical capital have high wage-rental ratios. Regions with high industry productivities and abundant human and physical capital have high factor prices. But Equations (37)-(38) show that, after globalization (and if $d_t \in FPE_t$), cross-regional differences in factor proportions and industry productivities neither change the way industries operate, nor do they affect the size of their markets. Goods trade allows regions to absorb their differences in factor endowments and industry productivities by specializing in those industries that use their abundant factors and have the highest possible productivity, without the need for having different factor prices. Goods trade also eliminates the effects of regional size on factor prices by creating global markets.

These observations have important implications for the world income distribution and, consequently, for any attempt to determine the relative contribution of factor endowments and productivity to income differences. Substituting Equations (37)-(38) into Equation (29), we find that:

$$(39) \qquad Y_t = A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_t^{\mu\cdot\alpha+\upsilon}$$

$$(40) \qquad \frac{Y_{c,t}}{Y_t} = (1-\alpha)\cdot\frac{H_{c,t}}{H_t} + \alpha\cdot\frac{K_{c,t}}{K_t} \qquad \text{for all } c\in C$$

A comparison between these Equations and Equation (33) shows that the relative contribution of factor endowments and productivity to income differences is fundamentally affected by globalization. Equation (33) differs from Equations (39)-(40) in three important respects: the elasticity of substitution between domestic human and physical capital is one in Equation (33) but infinite in Equations (39)-(40); domestic productivity appears in Equation (34) but not in Equations (39)-(40); and income is homogeneous of degree μ on domestic factor endowments in Equation (34) but only of degree one in Equation (39)-(40). Each of these differences echoes a different aspect of globalization, and I shall discuss them in turn.

Globalization raises the elasticity of substitution between human and physical capital from one to infinity because structural transformation (a shift towards industries that use the abundant factor) replaces factor deepening (forcing industries to use more of the locally abundant factor) as a mechanism to absorb differences in factor proportions. Assume a region has a ratio of human to physical capital λ times higher than average. Before globalization, each of its industries is forced to operate with a ratio of human to physical capital that is λ times average, and this requires a wage-rental ratio that is λ^{-1} times average. After globalization, the region simply shifts its production towards industries that are human-capital intensive, keeping the ratio of human to physical capital of its industries constant. This does not require changes in the wage-rental ratio.

Globalization eliminates differences in industry productivities as a source of income differences because structural transformation (a shift towards industries that have high productivity) also replaces productivity deepening (forcing low-productivity industries to produce) as a mechanism to absorb differences in industry productivities. Assume now that a region has average factor endowments but higher than average industry productivities. For instance, the region's productivity is λ times higher than the rest of the world in a subset of industries of combined size σ, and equal to the rest of the world in the remaining ones. Before globalization, this productivity advantage allows the region to produce $\lambda^{\sigma \cdot \mu}$ output than average with the same factors, holding constant technology. After globalization, the region takes over all world production of those industries in which its productivity is higher and scales back the rest of its industries. This allows the rest of the world to take full advantage of the region's high productivity and catch up with it in terms of income (even though not in productivity).

Globalization reduces the effects of factor endowments on relative incomes because it converts regional markets into global ones. Assume now that a region has average industry productivities, but its human and physical capitals are both λ times above average. Before globalization, the region's higher factor endowments allow it to produce more output than the average region. This effect is further reinforced because the region's larger market size allows it to have a better technology than average. Therefore, in autarky the region's income is λ^{μ} times higher than the world's average. After globalization, this additional market size effect disappears since the relevant market is the world market and this is the same for all regions. Therefore, after globalization the region's income is only λ times higher than the world average income.

Globalization also influences the dynamics of the world economy. Assume $d_t \in FPE_t$ for all t, then it follows from Equation (30) and (37)-(38) that:

(41) $$K_{t+1} = s_t \cdot A_t \cdot H_t^{\mu\cdot(1-\alpha)-\upsilon} \cdot K_t^{\mu\cdot\alpha+\upsilon}$$

(42) $$\frac{K_{c,t+1}}{K_{t+1}} = \frac{S_{c,t} \cdot H_{c,t}}{S_t \cdot H_t} \qquad \text{for all } c \in C$$

A comparison between these Equations and Equation (34) shows how globalization affects the dynamic responses to region-specific shocks. After globalization, positive (and permanent) shocks to savings and human capital still raise a region's capital stock and income. But now the effects of these shocks spill over to other regions. Shocks to productivity can only affect a region's income if they push outward the world productivity frontier. And, in this case, all countries equally benefit.[32]

Another important implication of Equations (39)-(42) is that globalization breaks down the connection between the long run properties of the growth process and the stability of the world income distribution.[33] Assume again that the joint distribution of savings, human capital and productivities is stationary. Then, Equation (41) shows that it still is the relative strength of diminishing returns and market size effects that determines whether world average income is stationary or not. But Equation (42) shows that now the world distribution of capital stocks is stationary regardless of parameter values. The same applies to the world income distribution (see Equation (40)). Therefore, all regions share a common growth rate in the long run. The reason is simple: physical capital accumulation in high-savings and high-human capital regions is absorbed by increased production in industries that use physical capital intensively, and this lowers the prices of these industries and increases the prices of industries that use human capital intensively. This increases wages and savings in low-savings and low-human capital regions. In a nutshell,

[32] See Ventura [1997] and Atkeson and Kehoe [2000] for analyses of shocks to small open economies in the factor-price-equalization world.
[33] Ventura [1997] provides a dramatic example of this by constructing a world in which time-series convergence to a steady state is associated with cross-sectional divergence and vice versa.

movements in goods prices positively transmit growth across regions and ensure the stability of the world income distribution. [34]

The main feature of the factor-price-equalization world is that diminishing returns and market size effects are global and not local. This observation has important implications for growth theory. Explanations for why the world grows faster today than in the past should feature diminishing returns and market size effects in the lead role, and relegate savings and human capital to a secondary one. But explanations of why some countries grow faster than others should do exactly the opposite, giving the lead role to savings and human capital and relegating diminishing returns and market size effects to a secondary role. A distinctive feature of the integrated economy is therefore a sharp disconnect between the determinants of average or long run growth and the determinants the dispersion or the cross-section of growth rates.[35]

The factor-price-equalization world neatly illustrates the potential effects of trade on the world income distribution and its dynamics, and it shows why and how goods trade can be a perfect substitute for factor movements. But the real world has not achieved yet the degree of economic integration that this model implies. One does not need sophisticated econometrics to conclude that wages vary substantially around the world. It is less obvious but probably true as well that rental rates also vary substantially around the world. These differences in factor prices indicate that regional differences in factor endowments and/or industry productivities are so large that goods trade cannot make up for factor immobility.

---

[34] As a general proposition, it is not necessary that trade leads to the stability of the world income distribution. In fact, the study of the stability of world income distribution has received considerable attention recently. While Acemoglu and Ventura [2002] rely on specialization to generate a stable world income distribution, Deardorff [2001] presents a model in which mere differences in initial endowments create persistent difference in world income and "club convergence". Krugman [1987] and Howitt [2000] rely on endogenous technology change to generate such effects. See Brezis, Krugman, and Tsiddon [1993] for a model of human capital accumulation that explains leapfrogging in the international income distribution.

[35] One implication of this is that Barro's conditional convergence finding cannot be used to determine whether diminishing returns are weak or strong relative to market size effects. See Ventura [1997].

What trade always does is to create a global market in which only the most competitive producers of the world can survive. Trade forces high-cost industries to close down and offers low-cost industries the opportunity to grow. If $d_t \in FPE_t$, all regions contain enough of these low-cost industries to employ all of their factors at common or equalized factor prices. But this need not be always the case. If $d_t \notin FPE_t$, regions with low industry productivities and sizeable factor endowments are forced to offer cheap factors to compete, while regions with high industry productivities and small factor endowments are able to enjoy expensive factors. These price differences indicate that factors are not deployed where they should and the world economy does not operate efficiently. To study the origins and effects of these world inefficiencies, it is necessary first to review some formal aspects of the model after globalization.

2.3 Formal aspects of the model

As mentioned already, in the absence of asset trade analogues of Equations (1) and (2) apply now to each region of the world economy. A regional analogue to Equation (3) also applies since it is a direct implication of our Cobb-Douglas assumption for the consumption and investment composites. Since all regions share spending patterns and face the same goods prices, the price of consumption and investment is the same for all. We keep this common price as the numeraire and, as a result, Equation (4) also applies. Equations (5)-(6) describing technology apply to all regions, with the corresponding factor prices and industry productivities.

After globalization, Equations (7)-(10) describing pricing policies, input demands and the free-entry condition apply only to those regions that host the lowest-cost producers of the world. The rest cannot compete in global markets. To formalize this notion, define the following sets of industries:

$$(43) \qquad I_{c,t} \equiv \left\{ i \in I \;\middle|\; c \in \arg\min_{c' \in C} \left\{ \frac{1}{Z_{c',it}} \cdot \left(\frac{w_{c',t}}{1-\alpha_i} \right)^{1-\alpha_i} \cdot \left(\frac{r_{c',t}}{\alpha_i} \right)^{\alpha_i} \right\} \right\} \qquad \text{for all } c \in C$$

An industry belongs to $I_{c,t}$ if and only if producers located in region c are capable of competing internationally in this industry at date t.[36] Note that a region can be competitive in a given industry because it offers high productivity or a cheap combination of factor prices. The main implication of goods trade is that industries do not locate in regions where they are not competitive:

$$(44) \qquad Q_{c,it} = 0 \qquad \text{if } i \notin I_{c,t} \qquad \text{for all } i \in I \text{ and } c \in C$$

Since goods markets are integrated, Equation (11) describing market clearing in global goods markets still applies. But now Equations (12)-(13) describing market clearing in global factor markets must be replaced by analogue conditions imposing market clearing in each regional factor market:

$$(45) \qquad H_{c,t} = \sum_{i \in I} H_{c,it} \qquad \text{with} \quad H_{c,it} = \frac{\partial B_{c,it}}{\partial w_{c,t}} + \int_0^{M_{it}} \frac{\partial b_{c,it}(m)}{\partial w_{c,t}} \cdot dm \qquad \text{for all } c \in C$$

$$(46) \qquad K_{c,t} = \sum_{i \in I} K_{c,it} \qquad \text{with} \quad K_{c,it} = \frac{\partial B_{c,it}}{\partial r_{c,t}} + \int_0^{M_{it}} \frac{\partial b_{c,it}(m)}{\partial r_{c,t}} \cdot dm \qquad \text{for all } c \in C$$

Equations (45)-(46) state that the regional supplies of labor and capital must equal their regional demands. The latter are the sum of their industry demands, and these are calculated by applying Shephard's lemma to Equations (5) and (6).

[36] This follows directly from the cost functions in Equations (5)-(6) and the observation that all producers in the world face the same world demand.

This completes the formal description of the model. For any admissible set of capital stocks, i.e. $K_{c,0}$ for all $c \in C$, and sequences for the vectors of savings, human capital and industry productivities, i.e. $S_{c,t}$, $H_{c,t}$, and $A_{c,it}$ for all $c \in C$ and for all $i \in I$, an equilibrium of the world economy after globalization consists of sequences of prices and quantities such that the equations listed above hold at all dates and states of nature. Although there might be multiple geographical patterns of production and trade that are consistent with world equilibrium, the assumptions made ensure that prices and world aggregates are uniquely determined.[37]

We are ready now to re-examine the effects of globalization on factor prices and the world income distribution. We have already found that, if $d_t \in FPE_t$, globalization eliminates all regional differences in factor prices and permits the world economy to operate at the same level of efficiency as the integrated economy. In this case, global market forces are strong enough to ensure that diminishing returns and market size effects have a global rather than a regional scope. This is no longer the case if $d_t \notin FPE_t$ since globalization cannot eliminate all regional differences in factor prices. These factor price differences reflect inefficiencies of various sorts in the world economy.

Efficiency requires that factor usage within an industry be the same across regions. This is a direct implication of assuming diminishing returns to each factor in production. The problem, of course, is that regional factor proportions vary. Structural transformation allows regions to accommodate all or part of their differences in factor proportions without factor deepening. If there are enough industries that use different factor proportions, factor prices are equalized across regions. If there are not enough industries that use different factor proportions, regions must lower the price of their abundant factor and raise the price of their

[37] Despite the indeterminacy in trade patterns, the trade theorist will immediately recognize that, if $\beta_i=1$ for all $i \in I$, the volume of trade is determined and the popular gravity equation applies to this world economy.

scarce one to attract enough firms to employ their factor endowments. In this case, industries in different regions use different factor proportions and the world economy is inefficient. Subsection 2.4 studies the properties of the growth process in this situation.

Efficiency also requires that industries locate in those regions that offer them the highest possible productivity. Structural transformation allows regions to accommodate all or part of their differences in industry productivities without productivity deepening. If all regions have enough industries with the highest productivity, factor prices are equalized across regions. If some regions do not have enough industries with the highest productivity, they are forced to produce in low productivity industries and must lower their factor prices to be able to compete internationally. Subsection 2.5 shows how this affects the properties of the growth process.

In the presence of these two types of inefficiency, diminishing returns retain a regional scope even after globalization. Regional differences in factor prices still reflect regional differences in factor abundance and industry productivities, although the mapping between these variables is much more subtle than in the world of autarky. However, even in the presence of these inefficiencies regional differences in factor prices cannot reflect regional differences in market size. For market size effects to retain a regional scope after globalization we need to introduce impediments to goods trade. And this task is left for section 3.

2.4 Limits to structural transformation (I): factor proportions

It follows from Definition (36) that factor prices are equalized if and only if it is possible to achieve full employment of human and physical capital in all regions producing only with the highest productivity (requirement R1), with the factor proportions used in the integrated economy (requirement R2), and without incurring

a fixed cost more than once (requirement R3). Moving away from the factor-price-equalization world means that we must consider the violation of one or more of these requirements. Since the market for each input is "small", I assume that regions are large enough to ensure that requirement R3 is always satisfied.[38] Therefore, in the remainder of this section I will focus on violations of requirements R1 and R2. In this subsection, we study the effects on the growth process of violations to requirement R2, keeping the assumption that requirement R1 is not binding. This assumption will be removed in sub-section 2.5.

To formalize the notion that requirement R1 is not binding, define $I^*_{c,t}$ as the set of industries in which region c has the highest possible productivity: $I^*_{c,t} \equiv \left\{ \mathrm{i} \in I \;\middle|\; \mathrm{c} \in \underset{\mathrm{c'} \in C}{\arg\max} \left\{ Z_{\mathrm{c'},\mathrm{it}} \right\} \right\}$ for all $c \in C$. To ensure that requirement R1 is not binding in the models of this section, for each of them I first construct the set of "unrestricted" world equilibria by assuming that $I^*_{c,t} = I$ for all $c \in C$. As mentioned, all these equilibria share the same prices and world aggregates, but might exhibit different geographical patterns of production. In these "unrestricted" world equilibria, some industries might not operate in all regions. Naturally, prices and world aggregates would not be affected if regions did not have the best possible technologies in some or all of the industries in which they do not produce. Therefore, we can trivially relax the assumption that $I^*_{c,t}$ contains all industries, and instead assume only that there exists an "unrestricted" equilibrium such that, for all $c \in C$, the industries not included in $I^*_{c,t}$ do not operate in the region. This defines the extent to which regional differences in industry productivities are allowed in this section. It follows that requirement R1 is never binding and comparative advantage is determined solely by regional differences in factor proportions.

[38] I shall explore the effects of violations to requirement R3 in sections 3.2 and 3.3.

In the worlds we consider in this sub-section it is not possible in general to employ all factors in all regions using the techniques of the integrated economy. Even if they concentrate all of their production in industries that use human capital intensively, regions with abundant human capital might lack enough physical capital to produce with the factor proportions that these industries would use in the integrated economy. These regions are therefore forced to use a higher proportion of human capital in their industries and this requires them to have a lower wage-rental ratio than in the integrated economy. Naturally, the exact opposite occurs in regions with abundant physical capital. This situation can be aptly described as a geographical mismatch between different factor endowments.

To study the causes and effects of this mismatch, I present two examples that help build intuitions that apply more generally. The first example is the two-industry case that is so popular in trade theory:

Example 2.4.1: Consider a world economy with H- and K-industries, $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume $\alpha_i=\alpha_H$, $\sigma_i=\sigma_H$ and $\max_{c\in C}\{Z_{c,it}\} = Z_{Ht}$ if $i\in I^H$, $\alpha_i=\alpha_K$, $\sigma_i=\sigma_K$ and $\max_{c\in C}\{Z_{c,it}\} = Z_{Kt}$ if $i\in I^K$, with $\alpha_H \leq \alpha_K$. (Note that $I^H\cdot\sigma_H + I^K\cdot\sigma_K=1$) For simplicity, assume also that $\varepsilon_i=\varepsilon$ and $\beta_i=\beta$ for all $i\in I$. The first step is to relate prices and world income to production:[39]

$$(47) \quad P_{it} = \sigma_i \cdot \frac{\prod_{i'\in I}\left(\sum_{c\in C} Q_{c,i't}\right)^{\sigma_i}}{\sum_{c\in C} Q_{c,it}} \qquad \text{for all } i\in I$$

$$(48) \quad Y_t = \prod_{i\in I}\left(\sum_{c\in C} Q_{c,it}\right)^{\sigma_i}$$

[39] These Equations follow from Equations (3) and (4).

Equation (47) can be thought of as the "demand" side of the model, since it shows how prices depend negatively on quantities, while Equation (48) simply describes world income. The "supply" side of the model is given by the following set of Equations:[40]

$$(49)\quad \frac{(1-\alpha_k)\cdot P_{Kt}}{w_{c,t}}\cdot\sum_{i\in I^K} Q_{c,it}+\frac{(1-\alpha_H)\cdot P_{Ht}}{w_{c,t}}\cdot\sum_{i\in I^H} Q_{c,it}=H_{c,t} \qquad \text{for all } c\in C$$

$$(50)\quad \frac{\alpha_k\cdot P_{Kt}}{r_{c,t}}\cdot\sum_{i\in I^K} Q_{c,it}+\frac{\alpha_H\cdot P_{Ht}}{r_{c,t}}\cdot\sum_{i\in I^H} Q_{c,it}=K_{c,t} \qquad \text{for all } c\in C$$

$$(51)\quad \left(\frac{w_{c,t}}{1-\alpha_H}\right)^{1-\alpha_H}\cdot\left(\frac{r_{c,t}}{\alpha_H}\right)^{\alpha_H}\geq\frac{\varepsilon-1}{\varepsilon}\cdot Z_{Ht}\cdot p_{Ht}=\left(A_{Ht}\cdot P_{Ht}\right)^{\frac{1}{\mu}}\cdot\left(\sigma_H\cdot Y_t\right)^{\frac{\mu-1}{\mu}}=\phi_H\cdot f_{Ht} \quad \text{for all } c\in C$$

$$(52)\quad \left(\frac{w_{c,t}}{1-\alpha_K}\right)^{1-\alpha_K}\cdot\left(\frac{r_{c,t}}{\alpha_K}\right)^{\alpha_K}\geq\frac{\varepsilon-1}{\varepsilon}\cdot Z_{Kt}\cdot p_{Kt}=\left(A_{Kt}\cdot P_{Kt}\right)^{\frac{1}{\mu}}\cdot\left(\sigma_K\cdot Y_t\right)^{\frac{\mu-1}{\mu}}=\phi_K\cdot f_{Kt} \qquad \text{for all } c\in C$$

where $\phi_i=(1-\alpha_i)^{\alpha_i-1}\cdot\alpha_i^{-\alpha_i}$ for all $i\in I$; and f_{Ht} and f_{Kt} are measures of the lowest factor costs in the world for the H- and K-industries since in equilibrium $f_{it}=\min_{c\in C}\left\{w_{c,t}^{1-\alpha_i}\cdot r_{c,t}^{\alpha_i}\right\}$ for all $i\in I$. Equations (49)-(50) are factor market clearing conditions, while Equations (51)-(52) are just a transformation of the pricing equations of each industry (for both final goods and intermediate inputs). Naturally, these pricing equations hold with strict equality if there is positive production in the corresponding industry. Equations (49)-(52) determine the production of each type of industry and the factor prices of region c, as a function of world prices and income.[41]

[40] Equations (49)-(50) follow from Equations (45) and (46), while Equations (51)-(52) follow from Equations (7) and (9) after using Equation (17) to eliminate the number of input varieties.

[41] If one is willing to take goods prices and factor endowments parametrically and further assume that the pricing equations hold with strict equality, it is possible to derive two popular results of trade theory from Equations (49)-(52). The Stolper-Samuelson effect says that an increase in the relative price of an industry leads to a more than proportional increase in the price of the factor that is used intensively in this industry and a decline in the price of the other factor. The Rybcynski effect says that an increase in a factor endowment leads to a more than proportional increase in the production of the industry that uses this factor intensively and a decline in the production of the other industry.

Equations (47)-(52) determine prices and quantities as a function of the distribution of factor endowments. Together with the regional analogues to Equation (1), the initial condition and the dynamics of the exogenous state variables, these Equations provide a complete characterization of the world equilibrium. Next, I describe some its most salient features.

Regions with extreme factor proportions have specialized production structures, while regions with intermediate factor proportions have diversified production structures. Let C_{Kt} (C_{Ht}) be the set of regions where there is production only in K-industries (H-industries), and let C_{Mt} be the set of regions where there is production in both types of industries. In fact, it follows from Equations (49)-(52) that these sets of regions are defined as follows:

$$(53) \quad C_{Kt} = \left\{ c \in C \;\middle|\; \frac{H_{c,t}}{K_{c,t}} \leq \frac{1-\alpha_K}{\alpha_K} \cdot \left(\frac{f_{Kt}}{f_{Ht}} \right)^{\frac{1}{\alpha_K - \alpha_H}} \right\}$$

$$(54) \quad C_{Ht} = \left\{ c \in C \;\middle|\; \frac{H_{c,t}}{K_{c,t}} \geq \frac{1-\alpha_H}{\alpha_H} \cdot \left(\frac{f_{Kt}}{f_{Ht}} \right)^{\frac{1}{\alpha_K - \alpha_H}} \right\}$$

$$(55) \quad C_{Mt} = \left\{ c \in C \;\middle|\; \frac{1-\alpha_K}{\alpha_K} \cdot \left(\frac{f_{Kt}}{f_{Ht}} \right)^{\frac{1}{\alpha_K - \alpha_H}} < \frac{H_{c,t}}{K_{c,t}} < \frac{1-\alpha_H}{\alpha_H} \cdot \left(\frac{f_{Kt}}{f_{Ht}} \right)^{\frac{1}{\alpha_K - \alpha_H}} \right\}$$

It follows from Equations (51)-(52) that factor prices are the same for all $c \in C_M$. If the dispersion in regional factor proportions is not too large, and the dispersion in factor intensities is not too low, C_{Kt}=C_{Ht}=$\varnothing$ and there is factor price equalization. Otherwise, this world economy exhibits a limited version of the factor price equalization result since factor prices are still equalized for all $c \in C_{Mt}$. It is common in

trade theory to refer to a group of regions that share the same factor prices as a "cone of diversification". In fact, we can write the wage and the rental as a function of f_{Ht} and f_{Kt} as follows:

$$(56) \quad w_{c,t} = \begin{cases} (1-\alpha_K)\cdot\phi_K \cdot f_{Kt} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{-\alpha_K} & \text{if } c \in C_{Kt} \\ f_{Kt}^{\frac{-\alpha_H}{\alpha_K-\alpha_H}} \cdot f_{Ht}^{\frac{\alpha_K}{\alpha_K-\alpha_H}} & \text{if } c \in C_{Mt} \\ (1-\alpha_H)\cdot\phi_H \cdot f_{Ht} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{-\alpha_H} & \text{if } c \in C_{Ht} \end{cases}$$

$$(57) \quad r_{c,t} = \begin{cases} \alpha_K \cdot \phi_K \cdot f_{Kt} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{1-\alpha_K} & \text{if } c \in C_{Kt} \\ f_{Kt}^{\frac{1-\alpha_H}{\alpha_K-\alpha_H}} \cdot f_{Ht}^{\frac{\alpha_K-1}{\alpha_K-\alpha_H}} & \text{if } c \in C_{Mt} \\ \alpha_H \cdot \phi_H \cdot f_{Ht} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{1-\alpha_H} & \text{if } c \in C_{Ht} \end{cases}$$

The wage is continuous and weakly declining on the human to physical capital ratio, while the rental is also continuous but increasing on this same ratio. The most noteworthy feature of these relationships is that they exhibit a "flat" for the set of human to physical capital ratios that define the cone of diversification. The top panel of Figure 10 shows how the wage-rental varies with a region's ratio of human to physical capital. Regional differences in this ratio reflect factor abundance in the usual way. In regions with a high (low) ratio of human to physical capital the price of human capital is low (high) relative to physical capital. Factor prices do not reflect however regional differences in industry productivities and/or market size.

It is now straightforward to compute the world income distribution as a function of f_{Ht} and f_{Kt}:

$$(58)\quad Y_{c,t}=\begin{cases}\phi_K\cdot f_{Kt}\cdot H_{c,t}^{1-\alpha_K}\cdot K_{c,t}^{\alpha_K} & \text{if } c\in C_{Kt}\\ f_{Kt}^{\frac{-\alpha_H}{\alpha_K-\alpha_H}}\cdot f_{Ht}^{\frac{\alpha_K}{\alpha_K-\alpha_H}}\cdot H_{c,t}+f_{Kt}^{\frac{1-\alpha_H}{\alpha_K-\alpha_H}}\cdot f_{Ht}^{\frac{\alpha_K-1}{\alpha_K-\alpha_H}}\cdot K_{c,t} & \text{if } c\in C_{Mt}\\ \phi_H\cdot f_{Ht}\cdot H_{c,t}^{1-\alpha_H}\cdot K_{c,t}^{\alpha_H} & \text{if } c\in C_{Ht}\end{cases}$$

We can use Equation (58) to re-evaluate earlier results about the relative contribution of factor endowments and industry productivities to income differences across regions. The first result is that the elasticity of substitution between human and physical capital is one outside the cone of diversification, but infinity within the cone. This elasticity reflects the relative importance of structural transformation and factor deepening as means to absorb regional differences in factor proportions. The second result is that regional differences in industry productivities continue not playing a role in determining regional income differences. This, of course, is not surprising given the assumption we have made about requirement R1 not being binding. The third and final result is that relative incomes are homogenous of degree one on factor endowments. This not surprising either since it simply confirms the absence of market size effects at the regional level.

We can also write the dynamics of the capital stock as a function of f_{Ht} and f_{Kt}:

$$(59)\quad K_{c,t+1}=\begin{cases}S_{c,t}\cdot(1-\alpha_K)\cdot\phi_K\cdot f_{Kt}\cdot H_{c,t}^{1-\alpha_K}\cdot K_{c,t}^{\alpha_K} & \text{if } c\in C_{Kt}\\ S_{c,t}\cdot f_{Kt}^{\frac{-\alpha_H}{\alpha_K-\alpha_H}}\cdot f_{Ht}^{\frac{\alpha_K}{\alpha_K-\alpha_H}}\cdot H_{c,t} & \text{if } c\in C_{Mt}\\ S_{c,t}\cdot(1-\alpha_H)\cdot\phi_H\cdot f_{Ht}\cdot H_{c,t}^{1-\alpha_H}\cdot K_{c,t}^{\alpha_H} & \text{if } c\in C_{Ht}\end{cases}$$

The specific dynamics of this example are hard to determine, since f_{Ht} and f_{Kt} change from generation to generation. It is easy to construct examples in which the world economy moves towards factor-price equalization; examples in which the world economy moves away from factor-price equalization; or examples in which the world economy alternates between periods in which factor prices are equalized and periods in which they are not. These dynamics depend on all the parameters the

model (including initial condition) and the evolution of the exogenous state variables, i.e. savings, human capital and industry productivities. Regardless of the specific dynamics, the world income distribution is stable if the joint distribution of these variables is stationary. Economic growth is positively transmitted across regions through changes in goods prices. This stabilizing role of trade is further reinforced by the fact that regions outside the cones cannot absorb capital accumulation through structural transformation and, consequently, experience diminishing returns in production.

Identifying cones of diversification is important because regional differences in factor proportions lead to structural transformation inside them, but to factor deepening outside them. In example 2.4.1, there is one of such cones and contains regions with intermediate factor proportions. Regions with extreme factor proportions do not belong to any cone. This need not be always the case, as the next example shows.

Example 2.4.2: Consider a world economy with H-, M- and K-industries, $I^H \cup I^M \cup I^K = I$, $I^H \cap I^M = \varnothing$, $I^H \cap I^K = \varnothing$ and $I^M \cap I^K = \varnothing$. Assume α_i=0 and $\max_{c \in C}\{Z_{c,it}\} = Z_{Ht}$ if $i \in I^H$; α_i=α_M and $\max_{c \in C}\{Z_{c,it}\} = Z_{Mt}$ if $i \in I^M$; and α_i=1 and $\max_{c \in C}\{Z_{c,it}\} = Z_{Kt}$ if $i \in I^K$. For simplicity, assume also that ε_i=ε and β_i=β for all $i \in I$. The "demand" side of this model is still described by Equations (47)-(48), but the "supply side is now given by:

(60) $$\frac{(1-\alpha_M)\cdot P_{Mt}}{w_{c,t}} \cdot \sum_{i \in I^M} Q_{c,it} + \frac{P_{Ht}}{w_{c,t}} \cdot \sum_{i \in I^H} Q_{c,it} = H_{c,t} \qquad \text{for all } c \in C$$

(61) $$\frac{P_{Kt}}{r_{c,t}} \cdot \sum_{i \in I^K} Q_{c,it} + \frac{\alpha_M \cdot P_{Mt}}{r_{c,t}} \cdot \sum_{i \in I^M} Q_{c,it} = K_{c,t} \qquad \text{for all } c \in C$$

(62) $$w_{c,t} \geq \frac{\varepsilon - 1}{\varepsilon} \cdot Z_{Ht} \cdot p_{Ht} = \left(A_{Ht} \cdot P_{Ht}\right)^{\frac{1}{\mu}} \cdot \left(\sigma_H \cdot Y_t\right)^{\frac{\mu-1}{\mu}} = f_{Ht} \quad \text{for all } c \in C$$

(63) $$\left(\frac{w_{c,t}}{1-\alpha_M}\right)^{1-\alpha_M} \cdot \left(\frac{r_{c,t}}{\alpha_M}\right)^{\alpha_M} \geq \frac{\varepsilon - 1}{\varepsilon} \cdot Z_{Mt} \cdot p_{Mt} = \left(A_{Mt} \cdot P_{Mt}\right)^{\frac{1}{\mu}} \cdot \left(\sigma_M \cdot Y_t\right)^{\frac{\mu-1}{\mu}} = \phi_M \cdot f_{Mt} \quad \text{for all } c \in C$$

(64) $$r_{c,t} \geq \frac{\varepsilon - 1}{\varepsilon} \cdot Z_{Kt} \cdot p_{Kt} = \left(A_{Kt} \cdot P_{Kt}\right)^{\frac{1}{\mu}} \cdot \left(\sigma_K \cdot Y_t\right)^{\frac{\mu-1}{\mu}} = f_{Kt} \quad \text{for all } c \in C$$

Unlike the previous example, we find now that regions with extreme factor proportions have diversified production structures, while regions with intermediate factor proportions have specialized production structures. These sets of regions are now given by:[42]

(65) $$C_{Kt} = \left\{ c \in C \,\middle|\, \frac{H_{c,t}}{K_{c,t}} \leq \frac{1-\alpha_M}{\alpha_M} \cdot \left(\frac{f_{Kt}}{f_{Mt}}\right)^{\frac{1}{1-\alpha_M}} \right\}$$

(66) $$C_{Ht} = \left\{ c \in C \,\middle|\, \frac{H_{c,t}}{K_{c,t}} \geq \frac{1-\alpha_M}{\alpha_M} \cdot \left(\frac{f_{Mt}}{f_{Ht}}\right)^{\frac{1}{\alpha_M}} \right\}$$

(67) $$C_{Mt} = \left\{ c \in C \,\middle|\, \frac{1-\alpha_M}{\alpha_M} \cdot \left(\frac{f_{Kt}}{f_{Mt}}\right)^{\frac{1}{1-\alpha_M}} < \frac{H_{c,t}}{K_{c,t}} < \frac{1-\alpha_M}{\alpha_M} \cdot \left(\frac{f_{Mt}}{f_{Ht}}\right)^{\frac{1}{\alpha_M}} \right\}$$

Regions in C_{Kt} (C_{Ht}) produce in the M-industries and the K-industries (H-industries), while regions in C_{Mt} produce only in M-industries. Factor prices are determined as follows:

[42] Note that the sets C_{Kt} and C_{Ht} never intersect in world equilibrium. Assume the opposite, then it follows that equilibrium input prices must satisfy $f_{Mt} < (f_{Ht})^{1-\alpha_M} \cdot (f_{Kt})^{\alpha_M}$. But if this inequality held nobody would produce in M-industries and markets for the products of these industries would not clear.

$$(68)\qquad w_{c,t} = \begin{cases} f_{Mt}^{\frac{1}{1-\alpha_M}} \cdot f_{Ht}^{\frac{-\alpha_M}{1-\alpha_M}} & \text{if } c \in C_{Kt} \\ (1-\alpha_M)\cdot\phi_M \cdot f_{Mt} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{-\alpha_M} & \text{if } c \in C_{Mt} \\ f_{Ht} & \text{if } c \in C_{Ht} \end{cases}$$

$$(69)\qquad r_{c,t} = \begin{cases} f_{Kt} & \text{if } c \in C_{Kt} \\ \alpha_M \cdot \phi_M \cdot f_{Mt} \cdot \left(\frac{H_{c,t}}{K_{c,t}}\right)^{1-\alpha_M} & \text{if } c \in C_{Mt} \\ f_{Mt}^{\frac{1}{\alpha_M}} \cdot f_{Ht}^{\frac{\alpha_M - 1}{\alpha_M}} & \text{if } c \in C_{Ht} \end{cases}$$

Once again, the wage is continuous and weakly declining on the human to physical capital ratio, while the rental is also continuous but increasing on this same ratio. But now these relationships exhibit at most two "flats", one for each set of human to physical capital ratios that defines a cone of diversification. Regional differences in factor prices reflect again factor abundance in the usual way. This world economy contains at most two cones of diversification.[43] Regions with extreme factor proportions belong to one of them, while regions with intermediate factor proportions do not. The middle panel of Figure 10 shows how the wage-rental varies with a region's ratio of human to physical capital.

It is straightforward to compute the analogues of Equation (58)-(59) for this example and check that the mapping from factor endowments to incomes and capital accumulation is also linear within the cones and takes the Cobb-Douglas form outside of them. The picture of the growth process that comes out of this example is therefore very similar to the on in Example 2.4.1.

[43] I say "at most" because it is also possible that $\underline{R}_{Mt} = \overline{R}_{Mt}$, in which the case there would be a single cone. Cuñat and Mafezzoli [2004a] analyze a similar model under the assumption that none of the regions of the world have specialized production structures, i.e. C_{Mt}=∅.

Examples 2.4.1 and 2.4.2 can be generalized by introducing further industries with different factor intensities. As we do so, the potential number of cones increases. But the overall picture remains the same. The world economy sorts itself out in a series of cones of diversification. The bottom panel of Figure 10 depicts a case with multiple cones of diversification.[44] Small regional differences in factor proportions lead to structural transformation within cones, but to factor deepening outside them. Large regional differences in factor proportions might span one or more cones and therefore lead to a mix of structural transformation and factor deepening. Therefore, the world of diversification cones can be seen as being somewhere in between the world of factor-price-equalization and the world of autarky.[45]

In the light of these results, we must slightly revise our earlier discussion of the effects of globalization on the source of income differences. As in the world of factor-price equalization, differences in domestic productivities cannot be a source of income differences and relative incomes are homogeneous of degree one with respect to factor endowments. But unlike the world of factor-price-equalization, the elasticity of substitution between domestic factors is no longer infinity but instead lies somewhere between one (outside cones) and infinity (within cones). As mentioned, this elasticity measures the relative importance of structural transformation and factor deepening as a means to accommodate regional differences in factor proportions. And this relative importance in turn depends on various factors, most notably how dispersed are factor intensities across industries. Two extreme examples make this point forcefully. If the dispersion in industry factor intensities is extreme, i.e. $\alpha_i \in \{0,1\}$ for all $i \in I$, then regional differences in factor proportions always lead to structural transformation and the world income distribution is given by

[44] Dornbusch, Fischer and Samuelson [1980] develop a similar model with a continuum of goods that vary in their factor intensity, although they do not specifically study the formation of cones.
[45] In pure Heckscher-Ohlin models, Deardorff [2001] and Cuñat and Maffezzoli [2004a] generate "club convergence". Stiglitz [1970] and Devereux and Shi [1991] are examples where cones of diversification establish due to inherently different time-preferences and incomes diverge. Oniki and Uzawa [1965] analyze conditions for diversification cones in two-sector model.

Equations (39)-(40).[46] If the dispersion in industry factor intensities is instead negligible, i.e. $\alpha_i=\alpha$ for all $i \in I$, then regional differences in factor proportions always lead to factor deepening and the world income distribution is given by:[47]

(70) $$Y_{c,t} = A_t \cdot H_{c,t}^{1-\alpha} \cdot K_{c,t}^{\alpha}$$

As in the world of autarky, the elasticity of substitution across factors is one (see Equation (33)). But unlike the world of autarky, regional differences in industry productivities and market size play no role in explaining regional income differences.

We do not need to revise however our earlier discussion of how globalization affects the dynamic responses to region-specific shocks. In this respect, the world with diversification cones offers the same insights as the world of factor-price-equalization. Region-specific shocks to savings and human capital have positive effects that spill over to other regions, while shocks to industry productivities only have effects if they push outwards the world productivity frontier. Economic growth is positively transmitted across regions through changes in goods prices and this keeps the world income distribution stable. In fact, this force towards stability is further reinforced in regions that are outside a cone by the existence of diminishing returns in production.

We conclude therefore that violations to requirement R2 do not alter much the picture came out of the factor-price-equalization world. Surely the geographical mismatch between different factor endowments implied by these violations might generate large inefficiencies that, in turn, might lead to sizeable regional differences in factor prices. Therefore, there might be important quantitative differences between a world with many diversification cones and the world of factor-price-equalization. But the qualitative properties of the growth process of these two worlds remain relatively close to each other, and far away from those of the world of autarky.

[46] This is the model used by Ventura [1997].
[47] One of many ways to find this result is as the appropriate limiting case of Examples 2.4.1 or 2.4.2.

2.5 Limits to structural transformation (II): industry productivities

Consider next worlds where requirement R1 is either binding or fails. Regions with few high-productivity industries might find that even if they concentrate all of their production in those industries, they cannot employ all of their factors and produce the same quantities as the integrated economy. These regions are therefore forced to exceed the production of the integrated economy in those industries and/or move into low-productivity industries. Whatever the case, this requires these regions to offer low factor prices to employ all of their factors. This situation can be aptly described as a geographical mismatch between industry productivities and factor endowments.

To make further progress, it is necessary to be more explicit about why and how industry productivities differ across regions. The first example considers the case in which regional differences in productivities take the popular factor-augmenting form:

Example 2.5.1: Consider a world where $Z_{c,it} = \pi_{c,Ht}^{1-\alpha_i} \cdot \pi_{c,Kt}^{\alpha_i}$ for all $i \in I$ and all $c \in C$; with $\sum_{c \in C} \pi_{c,Ht} \cdot \frac{H_{c,t}}{H_t} = 1$ and $\sum_{c \in C} \pi_{c,Kt} \cdot \frac{K_{c,t}}{K_t} = 1$. As usual, $\pi_{c,Ht}$ and $\pi_{c,Kt}$ are interpreted as labor- and capital-augmenting productivity differences, The world productivity frontier is given by $Z_{it} = \max_c \{\pi_{c,Ht}^{1-\alpha_i} \cdot \pi_{c,Kt}^{\alpha_i}\}$. In the integrated economy, industries would be located exclusively in the regions that are in this frontier. The set FPE_t is "small" and, except for a few very special or knife-edge cases, factor-price equalization is not possible and requirement R1 fails. [48]

[48] Take, for instance, the case of two regions and two industries. If one region has the highest productivity in both industries the only factor distribution that leads to factor-price equalization is the one

To understand the logic of this world, it is useful to follow the usual procedure of re-normalizing the model in terms of "efficiency" or "productivity-equivalent" factor units. That is, we can pretend that regional factor endowments are given by $\hat{H}_{c,t} = \pi_{c,Ht} \cdot H_{c,t}$ and $\hat{K}_{c,t} = \pi_{c,Kt} \cdot K_{c,t}$ for all $c \in C$; and that industry productivities are identical across regions, i.e. $\hat{Z}_{c,it} = 1$ for all $i \in I$ and all $c \in C$. Then, productivity-adjusted factor prices are given by $\hat{w}_{c,t} = \frac{w_{c,t}}{\pi_{c,Ht}}$ and $\hat{r}_{c,t} = \frac{r_{c,t}}{\pi_{c,Kt}}$. The key observation is that the re-normalized model is formally equivalent to the model of the previous section.[49] Therefore, all the results we obtained in the previous sections regarding the cross-section of factor prices also apply here to productivity-adjusted factor prices, i.e. $\hat{w}_{c,t}$ and $\hat{r}_{c,t}$; but not to factor prices as usually measured, i.e. $w_{c,t}$ and $r_{c,t}$.[50]

As the worlds of the previous section, this world economy sorts itself out in a series of cones of diversification. All regions within a cone have the same productivity-adjusted factor prices, although possibly different factor prices as usually measured. Regional differences in productivity-adjusted factor proportions lead to structural transformation within cones, and to factor deepening across them. When all regions are located within a single cone, we have the conditional factor-price-equalization result emphasized by Trefler [1993]. That is, regional differences in factor prices reflect only differences in factor-augmenting productivities and are not related to differences in productivity-adjusted factor proportions.

---

in which all factors are located in this region. If instead each region has the highest productivity in a different industry, the only factor distribution that leads to factor-price equalization is the one in which each region receives the exact quantity of factors that its high-productivity industry uses in the integrated economy.

[49] The re-normalized model is a bit less general than the model of the previous section since it does not display regional differences in industry productivities. We could (trivially) generalize this example to allow for regional differences in industry productivities, but keeping the assumption that requirement R1 is not binding in the re-normalized model.

[50] For instance, Equations (56)-(57) describe the productivity-adjusted factor if we further assume that the world economy contains two types of industries as in Example 2.4.1. Similarly, Equations (68)-(69) describe productivity-adjusted factor prices if we instead assume that the world economy contains three types of industries as in Example 2.4.2.

Although the presence of factor-augmenting productivity differences does not alter much the formal or mathematical structure of the model, it has important implications for the question of why some regions are richer than others. Unlike the worlds of section 2.4, we now have that productivity differences become a source of income differences across countries. For instance, if all regions belong to a single cone of diversification we have the following counterpart to Equation (40):

$$(71) \qquad \frac{Y_{c,t}}{Y_t} = (1-\alpha)\cdot\frac{\pi_{c,Ht}\cdot H_{c,t}}{H_t} + \alpha\cdot\frac{\pi_{c,Kt}\cdot K_{c,t}}{K_t} \qquad \text{for all } c\in C$$

Alternatively, if all the industries in the world have the same factor intensity we have the following counterpart of Equation (70):

$$(72) \qquad Y_{c,t} = A_{c,t}\cdot H_{c,t}^{1-\alpha}\cdot K_{c,t}^{\alpha}$$

where $A_{c,t} = \hat{A}_t\cdot\pi_{c,Ht}^{1-\alpha}\cdot\pi_{c,Kt}^{\alpha}$.[51] The inability of the world economy to match best technologies with appropriate factors moves us a step closer to the world of autarky, since regional productivities now affect regional incomes. Moreover, since now the world operates below its productivity frontier shocks to regional factor productivities have effects even if they do not push this frontier. Note however that, as in the worlds of section 2.4, the elasticity of substitution between domestic factors still lies somewhere between one (outside cones) and infinity (within cones); and relative incomes are homogeneous of degree one with factor endowments.

The rest of the picture of the growth process that comes out of this world remains close to the world of factor-price-equalization. Region-specific shocks to savings and human capital have positive effects that spill over to other regions. Economic growth is positively transmitted across regions through goods prices and

[51] This model therefore provides an alternative theoretical foundation for the work of Mankiw, Romer and Weil [1992], Hall and Jones [1999] and Klenow and Rodríguez-Clare [1997].

this keeps the world income distribution stable. If the conditional version of the factor-price-equalization theorem does not hold, regions outside the cones experience diminishing returns and this reinforces the effects of changes in product prices on the stability of the world income distribution.

Assuming that regional productivity differences take the factor-augmenting form discussed in example 2.5.1 is popular because it yields tractable models. But the factor-augmenting view of productivity differences hides some interesting effects of trade on the world income distribution and its stability. One reason is that, in the world of factor-augmenting productivity differences, comparative advantage is still determined solely by regional differences in factor proportions, albeit productivity-adjusted ones. The next example provides a dramatic illustration of how regional differences in industry productivities could determine comparative advantage, and how this brings about a new effect of trade on the world income distribution:

Example 2.5.2: Consider a world with many industries and regions. Assume that $Z_{c,it} = 1$ if $i \in I^*_{c,t}$, and $Z_{c,it} = 0$ if $i \notin I^*_{c,t}$; where $I^*_{c,t}$ for all $c \in C$ constitutes a partition of I: $\bigcup_{c \in C} I^*_{c,t} = I$ and $I^*_{c,t} \cap I^*_{c',t} = \varnothing$ for all $c \in C$ and $c' \in C$. Assume also that $I^*_{c,t} \neq \varnothing$ for all $c \in C$. That is, each region knows how to produce a disjoint subset of goods. Since only one region knows how to produce each good, the corresponding industry is located in that region. That is, $I_{c,t} = I^*_{c,t}$ for all $c \in C$, regardless of the factor distribution. In this world, comparative advantage is driven solely by regional differences in industry productivities, and differences in factor proportions play no role. In this example, requirement R1 does not fail but it is binding, except for a few very special and knife-edge cases.

A bit of straightforward algebra shows that production and factor allocations are given as follows:

(73) $$Y_{c,t} = \sum_{i \in I^*_{c,t}} \phi_i \cdot f_{it} \cdot H_{c,it}^{1-\alpha_i} \cdot K_{c,it}^{\alpha_i} \quad \text{for all } c \in C$$

(74) $$H_{c,it} = \frac{\sigma_i}{\sum_{i' \in I^*_{c,t}} \sigma_{i'}} \cdot \frac{1-\alpha_i}{\sum_{i' \in I^*_{c,t}} \sigma_{i'} \cdot (1-\alpha_{i'})} \cdot H_{c,t} \text{ if } i \in I^*_{c,t}; \text{ and } H_{c,it} = 0 \text{ if } i \notin I^*_{c,t}$$

(75) $$K_{c,it} = \frac{\sigma_i}{\sum_{i' \in I^*_{c,t}} \sigma_{i'}} \cdot \frac{\alpha_i}{\sum_{i' \in I^*_{c,t}} \sigma_{i'} \cdot \alpha_{i'}} \cdot K_{c,t} \text{ if } i \in I^*_{c,t}; \text{ and } K_{c,it} = 0 \text{ if } i \notin I^*_{c,t}$$

where, as usual by now, $\phi_i = (1-\alpha_i)^{\alpha_i - 1} \cdot \alpha_i^{-\alpha_i}$ and $f_{it} = \min_{c \in C} \left\{ w_{c,t}^{1-\alpha_i} \cdot r_{c,t}^{\alpha_i} \right\}$ for all $i \in I$.

Equation (73) describes the world income distribution as a function of factor allocations and goods prices, while Equations (74)-(75) provide the equilibrium factor allocations as a function of aggregate factor endowments. By substituting Equations (74)-(75) into Equation (73), we obtain the world income distribution as a function of factor endowments and input prices.[52] It is immediate to show that the elasticity of substitution between human and physical capital is between one and infinity; that regional differences in industry productivities affect regional differences in income; and that the world income distribution is homogeneous of degree one with respect to factor endowments.

These results are obtained from a relationship between incomes, factor endowments and industry productivities that holds constant input prices. Once we substitute input prices into this relationship, we find that the world income distribution is given by:

(76) $$\frac{Y_{c,t}}{Y_t} = \sum_{i \in I^*_{c,t}} \sigma_i \qquad \text{for all } c \in C$$

[52] This relationship is formally analogous, for instance, to Equation (58) in Example 2.4.1.

Equation (76) states that the share of world income of each region equals that share of world spending on the industries located in the region, and it does not depend on domestic factor endowments. What is going on? Assume a region has a ratio of human to physical capital λ times higher than average. Since the region is producing a fixed set of goods, it is forced to operate with a ratio that is λ times higher than average, and this requires a wage-rental ratio that is λ^{-1} higher than average. Therefore the elasticity of substitution between human and physical capital in production is one. What is different here is that relative incomes are now homogeneous of degree zero with respect to factor endowments. Assume a region's human and physical capitals are both λ times average. Since production is homogenous of degree one with factor endowments, its production of all industries is λ times average. But since the country faces a demand for its products with price-elasticity equal to one, the prices of its products are λ^{-1} times average. As a result, the income of the region is just average, despite its factor endowments being λ times average.

So what should we conclude about the degree of homogeneity of relative incomes with respect to factor endowments? As Equations (73)-(75) and (76) show, in empirical applications it will depend on whether we are holding goods prices constant or not. If we are holding these prices constant, then relative incomes are homogeneous of degree one in factor endowments. If we are not holding goods prices constant, then the degree of homogeneity of relative incomes with respect of factor endowments lies between zero and one. In this example, this degree of homogeneity is zero because regional differences in factor endowments are absorbed by regional variation in the quantities produced of each input. In Examples 2.4.1, 2.4.2 and 2.5.1, this degree of homogeneity was one because regional differences in factor endowments were absorbed by regional variation in the number of input varieties produced. The next example, inspired by Dornbusch, Fischer and Samuelson [1977], neatly clarifies this point by showing an intermediate world where both margins are at work.

Example 2.5.3: Consider a world with two regions, C={N,S}; and a continuum of industries, I=[0,1]. Assume all industries have the same factor intensity, $\alpha_i=\alpha$ for all $i \in I$. For simplicity, let also $\varepsilon_i=\varepsilon$ and $\beta_i=\beta$ for all $i \in I$. It follows immediately that: [53]

$$(77) \quad Y_{c,t} = \phi \cdot f_{c,t} \cdot H_{c,t}^{1-\alpha} \cdot K_{c,t}^{\alpha} \qquad \text{for all } c \in C$$

where $\phi = (1-\alpha)^{\alpha-1} \cdot \alpha^{-\alpha}$; and $f_{c,t}$ is a measure of factor costs of region c, i.e. $f_{c,t} = w_{c,t}^{1-\alpha} \cdot r_{c,t}^{\alpha}$ for all $c \in C$. To characterize the world income distribution in this world, we need to determine factor costs. Equation (77) is akin to Equation (58) or Equations (73)-(75) in the sense that it shows the world income distribution as a function of factor endowments and input prices. Not surprisingly, these relative incomes are homogeneous of degree one with respect to factor endowments. The next step is to determine input prices and substitute them into Equation (77).

Define $T_i \equiv \frac{Z_{N,it}}{Z_{S,it}}$ for all $i \in I$ as the industry productivity of North relative to South. Then, assign indices or order goods so that T_i is non-increasing in i. Note that T_i might be neither continuous nor invertible.[54] It follows from this ordering that $I_{N,t} \equiv \left\{ i \in I \;\middle|\; \frac{f_{N,t}}{f_{S,t}} \le T_i \right\}$ and $I_{S,t} \equiv \left\{ i \in I \;\middle|\; \frac{f_{N,t}}{f_{S,t}} \ge T_i \right\}$. That is, North (or N) specializes on low-index industries while South (or S) specializes in high-index industries. The cutoff industry, i*, is determined as follows:[55]

[53] This follows directly from the observation that the share of human and physical capital in income are 1-α and α, respectively.
[54] This ranking can vary over time, but this does not play any role here. Without loss of generality, the reader can focus on the case in which the ranking is time-invariant.
[55] If T_i is not invertible in the region of interest, this condition determines a set of candidate values for i*.

(78) $$\frac{f_{N,t}}{f_{S,t}} = T_{i^*}$$

Let X_i be world share of spending on all industries with indices equal or lower than i, that is, $X_i \equiv \int_0^i \sigma_j \cdot dj$. Note that X_i is non-decreasing in i, and takes values zero and one for i=0 and i=1. It follows from this definition that $Y_{N,t}=X_{i^*}\cdot(Y_{N,t}+Y_{S,t})$ and, using Equation (78), this can be rewritten as follows:

(79) $$\frac{f_{N,t}}{f_{S,t}} = \frac{X_{i^*}}{1-X_{i^*}} \cdot \left(\frac{H_{S,t}}{H_{N,t}}\right)^{1-\alpha} \cdot \left(\frac{K_{S,t}}{K_{N,t}}\right)^{\alpha}$$

Equations (78)-(79) jointly determine the pattern of production and trade (i*) and relative factor costs ($f_{N,t}/f_{S,t}$) as a function of spending patterns, industry productivities and factor endowments. Finally, we can use the numeraire rule in Equation (4) to find that:

(80) $$Y_t = \sum_{c\in\{N,S\}} \phi \cdot f_{c,t} \cdot H_{c,t}^{1-\alpha} \cdot K_{c,t}^{\alpha} = (\varepsilon - 1) \cdot \exp\left\{\int_0^{i^*} Z_{N,it} \cdot \sigma_i \cdot di + \int_{i^*}^{1} Z_{S,it} \cdot \sigma_i \cdot di\right\}$$

Having already found the pattern of production and trade (i*) and relative factor costs ($f_{N,t}/f_{S,t}$), Equation (80) can then be used to determine absolute factor costs.

This world is somewhat different form the ones we have seen so far in that we have only two regions. To think about the effects of factor endowments on relative incomes, I consider next a situation in which both regions have symmetric technologies and differ in that North's factor endowments are λ (>1) times larger than South's.[56] Figure 11 depicts this world. The AA and BB lines represent

[56] By symmetric technologies, I mean that if there exists an industry i such that $T_i=\tau$ then there also exists another industry i' such that $T_{i'}=1/\tau$ and $\alpha_i=\alpha_{i'}$, $\beta_i=\beta_{i'}$, $\varepsilon_i=\varepsilon_{i'}$ and $\sigma_i=\sigma_{i'}$.

Equations (78) and (79), respectively. The AA line is non-increasing because T_i is non-increasing in i, while the BB line is non-decreasing because X_i is non-decreasing in i. The existence of a unique crossing point follows since the BB line takes value zero at i=0 and slopes upward towards infinity at i=1.

The top panel of Figure 11 shows the case in which T_i is flat. This case corresponds to a world in which differences in industry productivities are minimal or irrelevant at the margin as in Examples 2.4.1, 2.4.2 and 2.5.1. This allows North to employ its larger factor endowments by producing a larger number of varieties than South. Factor costs are the same in both regions and, as a result, North's income is λ times South's. Relative incomes (after substituting in goods prices) are homogenous of degree one on factor endowments.

The middle panel of Figure 11 shows the opposite case in which T_i is vertical. This case corresponds to a world in which differences in industry productivities are extreme as in Examples 2.5.2. North is forced to employ its larger factor endowments by producing a higher quantity of each of its varieties. Factor costs in North are λ^{-1} times those of South and, as a result, North's income equals that of South. Relative incomes (after substituting in goods prices) are homogenous of degree zero on factor endowments.

The bottom panel shows the intermediate case in which T_i is neither flat nor vertical. Since the slope reflects how strong are differences in industry productivities, we are somewhere in between the two extreme examples considered up to now. North employs its larger factor endowments by producing a larger number of varieties and also a larger quantity of each of them. Factor costs in North are somewhere between λ^{-1} and one times those of South. The degree of homogeneity of relative incomes (after substituting in goods prices) on factor endowments is therefore somewhere between zero and one.

It is possible to generalize Example 2.5.3 in a variety of directions. For instance, one could allow for industry variation in factor intensities and many regions.[57] This is important in empirical applications, of course. But the central message remains. The effects of factor endowments on relative incomes depend on regional differences in industry productivities. If these differences are small, regions with larger factor endowments absorb them mostly through structural transformation: not changing much their production in existing industries and moving into new industries where the region's productivity relative to the rest of the world is similar to existing ones. If differences in industry productivities are large, regions with larger factor endowments absorb them by productivity deepening: substantially increasing their production in existing industries and/or moving into industries where the region's productivity relative to the rest of the world is substantially lower than in existing ones.

One can conclude from this discussion that differences in industry productivities create another force for diminishing returns to physical capital accumulation. As physical capital is accumulated, quantities produced increase and the terms of trade worsen. The result is a reduction in factor prices that lowers wages, savings and capital accumulation. This is a central aspect of the growth process in a world of interdependent regions generates a force towards the stability of the world income distribution.[58]

I argued at the end of section 1 that, if globalization leads to the integrated economy, there is a powerful prescription for economic development: open up and integrate into the world economy. This allows regions to benefit from higher productivity, improved factor allocation and increased market size. Not much has changed here. Naturally, if factor prices are equalized the effects are literally the same as in section 1 since the globalization leads to the integrated economy. If

[57] See Wilson [1980], Eaton and Kortum [1999, 2000], Matsuyama [2000] and Alvarez and Lucas [2004].
[58] See Acemoglu and Ventura [2002] on this point.

factor prices are not equalized, the world economy operates with a lower productivity and a worse factor allocation than the integrated economy. This also means that the size of the world economy will be smaller than that of the integrated economy. As a result, all the benefits from globalization are smaller in the worlds of sub-sections 2.4 and 2.5 than in the world of factor-price equalization. But it is still relatively straightforward to see that coupled with an appropriate transfer scheme globalization constitutes a Pareto improvement for the world economy. Moreover, since all regions gain from trade there exist Pareto-improving transfer schemes that do not require inter-regional transfers.[59] Therefore, the prescription for development remains the same: open up and integrate into the world economy.

We have traveled much already, and the global view of economic growth is starting to take shape. This view is more realistic and rich in details than the views that came out from either the world of autarky or the integrated economy. Despite this progress, we should not rest here yet. We have assumed so far that globalization eliminates all impediments to goods trade. This is obviously an unrealistic assumption. Is it also a crucial one?

3. Transport costs and market size

Despite the already large and growing importance of international trade, there are some important areas of economic activity where the degree of market integration is still relatively low. Surely the clearest case in point is the service sector.[60] As the textbook example of a haircut suggests, many services are

[59] How do we know that all regions have non-negative gains from globalization? Since regions have the choice of not trading, it is therefore possible to achieve the level of income and welfare of the world of autarky after globalization. Realizing these gains might require implementing an appropriate tax-subsidy scheme, though.

[60] In industrial economies, the service sector accounts for more than two thirds of production but only for about one fifth of exports and imports. Moreover, most trade in services is concentrated in activities related to transportation and travel even though these activities only constitute a small component of overall services production.

inherently more difficult to transport than agricultural and manufacturing products. Services also tend to be more vulnerable to various governmental barriers to trade, such as professional licensing requirements that discriminate against foreigners, domestic content requirements in public procurement, or poor protection of intellectual property rights.[61] In addition, there are important examples of weak market integration that go beyond the service sector. Trade in some agricultural and manufacturing products is also severely restricted as a result of protectionist practices in industrial countries.

The goal of this section is to study the effects on the growth process of partial segmentation in goods markets. The new model of globalization that I shall adopt here is as follows: at date t=0 the costs of transporting some (but not all) goods across regions suddenly fall from prohibitive to negligible. In particular, I partition the set of all industries into the sets of tradable and nontradable industries, i.e. T_t and N_t such that $T_t \cup N_t = I$ and $T_t \cap N_t = \varnothing$. The costs of transporting intermediate inputs and final goods fall from prohibitive to negligible at t=0 if $i \in T_t$. But even after t=0, the costs of transporting either the intermediate inputs, or the final goods, or both remain prohibitive if $i \in N_t$.[62] We keep assuming that the costs of transporting factors across regions remain prohibitive after t=0, and that international trade in assets is not possible. Naturally, the model analyzed in section 2 (and formally described in section 2.3) obtains as the special case of this model in which $T_t = I$ and $N_t = \varnothing$ for $t \geq 0$.

[61] There are also signs that this is changing rapidly. Advances in telecommunications technology, the appearance of e-commerce and the development of new and standardized software have all opened up the possibility of trading a wider range of services. Recent multilateral trade negotiations and the process of European integration have also led to the dismantling of various non-tariff barriers to service trade.

[62] The most popular alternative to this model is the "iceberg" cost model whereby all goods are subject to the same proportional transport cost. In particular, a quantity τ (>1) of a good must be shipped from source to ensure that one unit of it arrives to destination. The rest "melts" away in transit. See Matsuyama [2004] for yet another model of transport costs.

A central aspect of the analysis turns out to be whether transport costs apply only to final goods, to intermediate inputs, or to both. Section 3.1 presents the case in which transport costs apply only to final goods. This model neatly generalizes the results obtained in the previous section. Section 3.2 studies the case in which transport costs apply only to intermediate inputs. This gives rise to agglomeration effects that can have a large and somewhat unexpected impact on the world income distribution. Section 3.3 analyzes the case in which transport costs apply to both final goods and intermediate inputs. The interaction between the two types of frictions brings about a new perspective on the role of local markets.

3.1 Nontraded goods and the cost of living

Consider next a world where some final goods are not tradable, although the intermediate inputs required to produce them are always tradable. In particular, the costs of trading intermediate inputs are negligible for all $i \in I$; and the costs of transporting final goods are negligible if $i \in T_t$ but prohibitive if $i \in N_t$. Since prices of final goods can differ across regions, a novel feature of this model is that regions will have different price levels.

I must now revise the formal description of the model. While regional analogues of Equations (1) and (2) continue to apply, one must now recognize that final goods prices in nontradable industries might differ across regions. As a result, the price of consumption and investment will vary across them even if Equation (3) describing spending patterns still applies to all regions. Therefore, we must write the analogues of Equations (1) and (2) as follows:

(81) $$K_{c,t+1} = S_{c,t} \cdot \frac{w_{c,t}}{P_{c,t}} \cdot H_{c,t}$$

(82) $$C_{c,t} = (1 - S_{c,t}) \cdot \frac{w_{c,t}}{P_{c,t}} \cdot H_{c,t} + \frac{r_{c,t}}{P_{c,t}} \cdot K_{c,t}$$

where $P_{c,t}$ is the price level (or cost of living) of region c, i.e. $P_{c,t} = \prod_{i \in I} \left(\frac{P_{c,it}}{\sigma_i} \right)^{\sigma_i}$ for all $c \in C$. A natural choice of numeraire now is the ideal price index for tradable industries:

(83) $$1 = \prod_{i \in T_t} \left(\frac{P_{it}}{\sigma_i} \right)^{\sigma_i}$$

Equation (83) replaces Equation (4). The latter obtains as the special case of the former in which all goods are tradable, i.e. $T_t = I$ and $N_t = \varnothing$. An implication of this choice of numeraire is that the price level of region c is equal to the ideal price index of its nontradable industries:

(84) $$P_{c,t} = \prod_{i \in N_t} \left(\frac{P_{c,it}}{\sigma_i} \right)^{\sigma_i} \qquad \text{for all } c \in C$$

Since now price levels differ across regions it is necessary to distinguish between two concepts of income and factor prices: (1) market-based incomes and factor prices, i.e. $Y_{c,t}$, $w_{c,t}$ and $r_{c,t}$; and (2) real or PPP-adjusted incomes and factor prices, i.e. $Y_{c,t}/P_{c,t}$, $w_{c,t}/P_{c,t}$ and $r_{c,t}/P_{c,t}$. Whenever there is no risk of confusion, I shall refer to the former simply as income and factor prices, and to the latter as real income and real factor prices. As before, Equations (5)-(6) describing technology apply to all regions, with the corresponding factor prices and industry productivities.

After globalization, producers of intermediate inputs in all industries and producers of final goods in tradable industries face a global market and Equations

(7)-(10) describing pricing policies, input demands and the free-entry condition therefore apply only to those regions where the lowest-cost producers are located. But even after globalization, producers of final goods in nontradable industries remain sheltered from foreign competition, and Equations (7)-(8) apply to all regions and not only to the lowest-cost ones. Thus, Equation (44) no longer applies to the producers of final goods in nontradable industries (Equation (43) still stands as a definition, though).

Market clearing conditions are also affected by the presence of transport costs. While Equations (45)-(46) describing market clearing in regional factor markets still apply, Equation (11) describing market clearing in global markets for final goods applies only to tradable industries. In nontradable industries, Equation (11) must be replaced by analogue conditions imposing market clearing in each regional market:

(85) $P_{c,it} \cdot Q_{c,it} = E_{c,it}$ for all $i \in N_t$ and $c \in C$

This completes the formal description of the model. For any admissible set of capital stocks, i.e. $K_{c,0}$ for all $c \in C$; sequences for the vectors of savings, human capital and industry productivities, i.e. $S_{c,t}$, $H_{c,t}$, and $A_{c,it}$ for all $c \in C$ and for all $i \in I$; and a sequence for the set N_t (or T_t); an equilibrium of the world economy after globalization consists of a sequence of prices and quantities such that the equations listed above hold at all dates and states of nature. Although there might be multiple geographical patterns of production that are consistent with world equilibrium, the assumptions made ensure that prices and world aggregates are uniquely determined.

The best way to start the analysis is by asking again whether the assumed trade restrictions matter at all. That is, to ask whether restricting factor mobility and

now goods trade impede the world to achieve the level of efficiency of the integrated economy. Re-define the set FPE_t now as follows:

$$
\begin{aligned}
FPE_t \equiv \Bigg\{ d_t \in D_t \Bigg| \; & \exists x_{c,it}(m) \geq 0,\ x^F_{c,it} \geq 0 \text{ with } \sum_{c \in C} x_{c,it}(m) = 1,\ \sum_{c \in C} x^F_{c,it} = 1 \text{ and} \\
& x_{c,it} = (1-\beta_i) \cdot x^F_{c,it} + \frac{\beta_i}{M_{it}} \cdot \int_0^{M_{it}} x_{c,it}(m) \cdot dm; \text{ such that :} \\
& \text{(R1) } x_{c,it} = 0 \text{ if } Z_{c,it} < \max_{c \in C} \{Z_{it}\}; \\
& \text{(R2) } H_{c,t} = \sum_{i \in I} x_{c,it} \cdot H_{it} \text{ and } K_{c,t} = \sum_{i \in I} x_{c,it} \cdot K_{it}; \\
& \text{(R3) } x_{c,it}(m) \in \{0,1\} \text{ for all } m \in [0, M_{it}] \text{ and } i \in I; \text{ and} \\
& \text{(R4) } x^F_{c,it} \geq (1-\beta_i) \cdot \frac{Y^{IE}_{c,t}}{Y^{IE}_t} \text{ if } i \in N_t \Bigg\}
\end{aligned}
\tag{86}
$$

Comparing Definitions (36) and (86), we observe that the latter contains an additional requirement: each region should be able to produce all the final goods used for its own consumption and investment in nontradable industries. This additional restriction is a direct consequence of transport costs. The presence of this additional restriction reduces the size of FPE_t. In fact, it is now even possible that $FPE_t = \varnothing$. For instance, assume regional differences in industry productivities are such that there exists no region that has the highest possible productivity in all nontradable industries simultaneously. Then, it is not possible to replicate the integrated economy.[63]

If $d_t \in FPE_t$, factor prices are equalized across regions and the world economy operates with the same efficiency as the integrated economy despite factor immobility and goods market segmentation. In this case, the world economy

[63] That one or more regions with the highest possible productivity in all nontradable industries exist is a necessary but not sufficient condition for $FPE_t \neq \varnothing$. Since factor-price equalization requires that all factors be located in these regions, it is also necessary that at least one of these regions have the highest possible productivity for each tradable industry.

behaves exactly as the world of factor-price equalization of section 2.2.[64] If $d_t \notin FPE_t$, the world economy cannot operate at the same level efficiency as the integrated economy. As a result, either market-based factor prices, or real factor prices, or both differ across regions. But even in this case the behavior of the world economy does not depart much from what we observed in the worlds of section 2. To see this, define $H_{c,t}^T$ and $K_{c,t}^T$ as the factor endowments devoted to the production of tradable goods, i.e. all intermediate inputs and the final goods of tradable industries. Straightforward algebra shows that:[65]

$$(87)\quad H_{c,t}^T = \max\left\{0, H_{c,t}\cdot\left(1-\sum_{i\in N_t}(1-\beta_i)\cdot(1-\alpha_i)\cdot\sigma_i\right) - K_{c,t}\cdot\left(\frac{w_{c,t}}{r_{c,t}}\right)^{-1}\cdot\sum_{i\in N_t}(1-\beta_i)\cdot(1-\alpha_i)\cdot\sigma_i\right\} \text{ for all } c\in C$$

$$(88)\quad K_{c,t}^T = \max\left\{0, K_{c,t}\cdot\left(1-\sum_{i\in N_t}(1-\beta_i)\cdot\alpha_i\cdot\sigma_i\right) - H_{c,t}\cdot\frac{w_{c,t}}{r_{c,t}}\cdot\sum_{i\in N_t}(1-\beta_i)\cdot\alpha_i\cdot\sigma_i\right\} \text{ for all } c\in C$$

Equations (87)-(88) show the factor supplies that are left after subtracting from aggregate factor supplies the factors used in the production of final goods in nontradable industries. In the special case in which $N_t = \varnothing$, these factor supplies equal the aggregate factor supplies and are independent of factor prices. But in the general case, these factor supplies depend on factor prices in the usual way. The higher is the wage-rental, the lower is the human to physical capital ratio used for the production of final goods in nontradable industries and, as a result, the higher is the relative supply of human to physical capital that is left after production of final goods in nontradable industries.

[64] Even the price levels would be equalized across regions, i.e. $P_{c,t}=1$ for all $c\in C$. Note however that there is less indeterminacy regarding the patterns of production and trade, since nontradable final goods must now be produced in the same region where they are used for consumption or investment.

[65] To see this, note that the shares of human and physical capital devoted to producing the final good of the i^{th} nontradable industry are $(1-\beta_i)\cdot(1-\alpha_i)$ and $(1-\beta_i)\cdot\alpha_i$. Add over industries and note that the share of spending in the i^{th} industry is $\sigma_i\cdot Y_{c,t}$.

With Equations (87)-(88) at hand, it is straightforward to see that all the results in sections 2.4 and 2.5 regarding incomes and factor prices still go through in the presence of nontradable final goods. Take, for instance, Example 2.4.1. Equations (47)-(48) must be rewritten as follows:

$$(89) \qquad P_{it} = \sigma_i \cdot \frac{\prod_{i' \in T_t} \left(\sum_{c \in C} Q_{c,i't} \right)^{\frac{\sigma_i}{\sum_{i' \in T_t} \sigma_{i'}}}}{\sum_{c \in C} Q_{c,it}} \qquad \text{for all } i \in T_t$$

$$(90) \qquad Y_t = \prod_{i \in T_t} \left(\sum_{c \in C} Q_{c,it} \right)^{\frac{\sigma_i}{\sum_{i' \in T_t} \sigma_{i'}}}$$

while Equations (49)-(52) still apply provided that we write $H^T_{c,t}$ and $K^T_{c,t}$ instead of $H_{c,t}$ and $K_{c,t}$, in Equations (49)-(50). Factor prices and the pattern of trade are determined by these modified versions of Equations (47)-(52) together with Equations (87)-(88). Since factor supplies are well behaved, a brief analysis of this system reveals that all the discussion of the properties of the world income distribution and its dynamics after Equations (58)-(59) still goes through. In fact, all the results and intuitions developed in the examples of sections 2.4 and 2.5 still apply after we remove the assumption that $N_t = \varnothing$.

The major difference between the world of this sub-section and the one in section 2 is that there is a discrepancy between market-based and real incomes and factor prices. To see this, we need to compute regional price levels. Equations (5)-(7) and (83) imply that:

$$(91) \qquad P_{c,t} = \prod_{i \in N_t} \left\{ \frac{1}{\sigma_i} \cdot \left[\frac{1}{Z_{c,it}} \cdot \left(\frac{w_{c,t}}{1-\alpha_i} \right)^{1-\alpha_i} \cdot \left(\frac{r_{c,t}}{\alpha_i} \right)^{\alpha_i} \right]^{1-\beta_i} \cdot \left[\int_0^{M_{it}} p_{it}(m)^{1-\varepsilon_i} \cdot dm \right]^{\frac{\beta_i}{1-\varepsilon_i}} \right\}^{\sigma_i}$$

Since all regions face the same input prices, Equation (91) shows that, ceteris paribus, the price level is high in regions that have high factor prices and low productivity in nontradable industries. This relationship is the first piece of a theory of the price level. The second piece is a relationship between factor prices, factor endowments and industry productivities. The following examples show how to obtain this additional relationship.

Example 3.1.1: Consider a world economy with H- and K-industries, $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume $\alpha_i=\alpha_H$ and $\max_{c\in C}\{Z_{c,it}\} = Z_{Ht}$ if $i\in I^H$, $\alpha_i=\alpha_K$ and $\max_{c\in C}\{Z_{c,it}\} = Z_{Kt}$ if $i\in I^K$, with $\alpha_H \leq \alpha_K$. For simplicity, assume also that $\varepsilon_i=\varepsilon$ and $\beta_i=\beta$ for all $i\in I$. As in section 2.4, we assume that requirement R1 is not binding.[66] The only difference between this world and the one in Example 2.4.1 is the presence of nontradable industries, i.e. $N_t \neq \varnothing$.

Let P_{Ht} and P_{Kt} be the prices of final goods in tradable H- and K-industries. If a region is internationally competitive in tradable H-industries, then the price of final goods of its nontradable H-industries is also P_{Ht}.[67] If a region is not competitive internationally, then the price of final goods in its nontradable H-industries exceeds P_{Ht}. In fact, it follows from Equations (5) and (51)-(52) that the price of the final goods in nontradable H-industries is $\frac{w_{c,t}^{1-\alpha_H} \cdot r_{c,t}^{\alpha_H}}{f_{Ht}} \cdot P_{Ht} \geq 1$. A parallel argument shows that the price of the final goods in nontradable K-industries is $\frac{w_{c,t}^{1-\alpha_K} \cdot r_{c,t}^{\alpha_K}}{f_{Kt}} \cdot P_{Kt} \geq 1$. It then follows from Equations (83)-(84) that the price level of region c is given by:

[66] Note that this implies that all regions have the same productivity in nontradable industries. That is, $Z_{c,it}=Z_{Ht}$ if $i\in N_t \cap I^H$ and $Z_{c,it}=Z_{Kt}$ if $i\in N_t \cap I^K$ for all $c\in C$.

[67] This follows because the technology to produce final goods is the same for all H-industries, and also because the number of input varieties of H-industries does not depend on whether the industry is tradable or nontradable.

(92) $$P_{c,t} = \left[\frac{w_{c,t}^{1-\alpha_H} \cdot r_{c,t}^{\alpha_H}}{f_{Ht}} \cdot \frac{P_{Ht}}{\sigma_H} \right]^{\sum_{i \in N_t \cap I^H} \sigma_i} \cdot \left[\frac{w_{c,t}^{1-\alpha_K} \cdot r_{c,t}^{\alpha_K}}{f_{Kt}} \cdot \frac{P_{Kt}}{\sigma_K} \right]^{\sum_{i \in N_t \cap I^K} \sigma_i} \quad \text{for all } c \in C$$

As in Example 2.4.1, regions with intermediate factor proportions have diversified production structures while regions with extreme factor proportions have specialized production structures. The sets C_{Mt} , C_{Kt} and C_{Ht} are still defined by Equations (53)-(55) provided we write $H_{c,t}^T$ and $K_{c,t}^T$ instead of $H_{c,t}$ and $K_{c,t}$. It follows from Equations (51), (52) and (92) that $P_{c,t} = \left(\frac{P_{Ht}}{\sigma_H} \right)^{\sum_{i \in N_t \cap I^H} \sigma_i} \cdot \left(\frac{P_{Kt}}{\sigma_K} \right)^{\sum_{i \in N_t \cap I^K} \sigma_i}$ if $c \in C_{Mt}$ and $P_{c,t} \geq \left(\frac{P_{Ht}}{\sigma_H} \right)^{\sum_{i \in N_t \cap I^H} \sigma_i} \cdot \left(\frac{P_{Kt}}{\sigma_K} \right)^{\sum_{i \in N_t \cap I^K} \sigma_i}$ if $c \in C_{Kt} \cup C_{Ht}$. All regions within the cone share the same price level, and this is the lowest in the world. The reason, of course, is that these regions are competitive both in H- and K-industries. Regions outside the cone have different price levels. Moreover, it is possible to show that these price levels increase the farther away the regions are from the cone. The reason is that the farther away from the cone, the less competitive a region is in one of the industry types and the more expensive it is to produce the final goods of the nontradable industries of this type.

Example 3.1.1 provides us with a simple theory of why and how the price level varies across regions. But it is difficult to reconcile this theory with the data. The later show that price levels are positively correlated with income, so that regional differences in real incomes are substantially smaller than regional differences in market-based incomes. To obtain this pattern in the world of Example 3.1.1 would require that poor regions be located inside the cone and rich regions outside of it. Although this is not impossible from a theoretical standpoint, it does not seem a

promising starting point for the construction of an empirically successful theory of the price level.

A positive association between incomes and price levels could arise somewhat more naturally in the world of Example 2.4.2 once we remove the assumption that $N_t = \varnothing$. For instance, if nontradable industries tend to be more human-capital intensive than tradable industries the price level would be high in regions that belong to C_{Kt}; intermediate in regions that belong to C_{Mt}; and low in regions that belong to C_{Ht}. Assume then that most of the variation in income levels is due to differences in savings rates, so that rich regions are those that have low human to physical capital ratios. This does not seem implausible, since most nontradable industries tend to be in the service sector and this sector tends to use a higher human to physical capital ratio than other sectors.

More generally, in the worlds of sub-section 2.4 the correlation between income and price levels is positive or negative depending on how factor proportions vary with income and the factor intensities of nontradable industries relative to tradable ones. The central observation is that price levels should be high in regions that have factor proportions that are inadequate to produce nontradable goods. Building an empirically successful theory of the price level around this notion seems promising, although it remains to be done. Most of the existing research on the price level has focused instead on the role of regional differences in industry productivities. The next example presents a world where these differences generate a positive association between income and the price level.

Example 3.1.2: Consider a world where $Z_{c,it} = \pi_{c,Ht}^{1-\alpha_i} \cdot \pi_{c,Kt}^{\alpha_i}$ for all $i \in T_t$ and $c \in C$, and $Z_{c,it}=1$ for all $i \in N_t$, with $\sum_{c \in C} \pi_{c,Ht} \cdot \frac{H_{c,t}}{H_t} = 1$ and $\sum_{c \in C} \pi_{c,Kt} \cdot \frac{K_{c,t}}{K_t} = 1$. The crucial feature

of this example is that productivity differences exist only in tradable industries.[68] This world economy is akin to that in Example 2.5.1. For instance, assume that there are H- and K-industries as in Examples 2.4.1 and 3.1.1. Then, we have that:

$$(93) \quad P_{c,t} = \left[\frac{(\pi_{c,Ht} \cdot \hat{w}_{c,t})^{1-\alpha_H} \cdot (\pi_{c,Kt} \cdot \hat{r}_{c,t})^{\alpha_H}}{\hat{f}_{Ht}} \cdot \frac{P_{Ht}}{\sigma_H} \right]^{\sum_{i \in N_t \cap I^H} \sigma_i} \cdot \left[\frac{(\pi_{c,Ht} \cdot \hat{w}_{c,t})^{1-\alpha_K} \cdot (\pi_{c,Kt} \cdot \hat{r}_{c,t})^{\alpha_K}}{\hat{f}_{Kt}} \cdot \frac{P_{Ht}}{\sigma_H} \right]^{\sum_{i \in N_t \cap I^K} \sigma_i} \quad \text{for all } c \in C$$

where $\hat{f}_{it} = \min_{c \in C} \left\{ \hat{w}_{c,t}^{1-\alpha_i} \cdot \hat{r}_{c,t}^{\alpha_i} \right\}$ for all $i \in I$. Since productivity differences in tradable industries are factor augmenting, regions with higher productivities have higher factor prices. Since there are no productivity differences in nontradable industries, regions with higher factor prices have a higher price level. Note that now a region inside the cone with high productivity in the tradable industries could have a higher price level than a region outside the cone with low productivity in the tradable industries.

In the world of this example, the price level is determined by a combination of two elements: how adequate are the region's factor proportions to produce in the nontradable industries; and how high is the region's productivity in the tradable industries relative to the nontradable ones. In the world of Example 3.1.1, this second force was not present and Equation (93) was reduced to Equation (92). We could also eliminate the first force by assuming that all regions belong to the cone, i.e. by assuming that there is conditional factor-price equalization. In this case, the price level is given by:

$$(94) \quad P_{c,t} = \left[\pi_{c,Ht}^{1-\alpha_H} \cdot \pi_{c,Kt}^{\alpha_H} \cdot \frac{P_{Ht}}{\sigma_H} \right]^{\sum_{i \in N_t \cap I^H} \sigma_i} \cdot \left[\pi_{c,Ht}^{1-\alpha_K} \cdot \pi_{c,Kt}^{\alpha_K} \cdot \frac{P_{Kt}}{\sigma_K} \right]^{\sum_{i \in N_t \cap I^K} \sigma_i} \quad \text{for all } c \in C$$

[68] This assumption makes sense because nontradable industries consist mostly of services, and in the real world productivity differences in services seem small relative to productivity differences in agriculture or manufacturing.

In Equation (94) the only determinant of the price level is the level of productivity in the tradable industries. This special case is known as the Balassa-Samuelson hypothesis of why the price level is positively correlated with income. Higher productivity in the tradable industries is what makes regions both rich and expensive.

In addition to providing a theory of the price level, the world of this section is also useful because it allows us to study a smoother and more realistic version of the globalization process, i.e. a gradual reduction in the size of N_t. This is not only important for quantitative applications of the theory, but it also leads to new insights regarding the effects of globalization on welfare. The next example shows this.

Example 3.1.3: Consider a world economy with H- and K-industries, such that $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume α_i=0 if $i \in I^H$, and α_i=1 if $i \in I^K$; and β_i=0 for all $i \in I$. Within each type there are "advanced" and "backward" industries. A-regions have the highest possible productivity in all industries, regardless of whether they are "advanced" or "backward". B-regions have the highest possible productivity only in "backward" industries. Up this point all the assumptions are as in Example 2.1.2, except that industry factor intensities are more extreme. Assume next that initially some industries are nontradable, i.e. $N_t \neq \varnothing$; and consider a small step in the globalization process: some "advanced" H-industries become tradable, i.e. some elements of the set $N_t \cap I^H$ move into the set $T_t \cap I^H$. What is the effect of this partial reduction in transport costs on regional incomes?

The reduction of transport costs leads to structural transformation: A-regions reduce their production in "backward" H-industries and increase their production in "advanced" H-industries, while B-regions do the opposite.[69] This increases efficiency

[69] Given the extreme assumptions on industry factor intensities, we know that the distribution of production in K-industries will not be affected.

and raises the combined world production of H-industries, lowering the price of their products and therefore wages all over the world. Therefore, a partial reduction of transport costs has two effects: an increase in efficiency that lowers prices and benefits all regions, and a change in relative prices that benefits some regions but hurts others. A-regions with a large enough ratio of human to physical capital are worse off as a result of this partial reduction in transport costs.[70] If coupled with an appropriate transfer scheme, partial globalization still constitutes a Pareto improvement for the world economy. But now this transfer scheme might require inter-regional transfers towards A-regions with large enough human to physical capital ratios.

The world of this sub-section is a simple and yet very useful generalization of the world of section 2. It allows us to study the sources of regional differences in price levels and also permits us to consider smoother versions of the globalization process. Despite this progress, the world of this sub-section fails to capture a central aspect of transport costs because these only affect final goods. When transport costs affect intermediate inputs, they create incentives to agglomerate production in a single location. We study how this works next.

3.2 Agglomeration effects

Consider a world where transport costs apply only to intermediates, and not to final goods. In particular, assume that the costs of transporting inputs are negligible if $i \in T_t$ but prohibitive if $i \in N_t$; while the costs of trading final goods are negligible for all $i \in I$. An implication of this last assumption is that the price level is the same in all regions and market-based and PPP-adjusted incomes coincide. But this

[70] How is it possible that a region have negative gains from globalization? Since relative prices have changed, the region's trade opportunities have changed also and it might no longer be possible to achieve the level of income and welfare that the region enjoyed before the reduction of transport costs in the H-industries.

does not mean that we are back to the worlds of section 2. The inability of trading intermediate inputs creates an incentive to concentrate all the production of an industry in a single region. Only in this way, production of final goods can fully take advantage from the benefits of specialization. This force towards the agglomeration of economic activity has profound effects on the world income distribution and its dynamics.

The formal description of the model is quite similar to that of section 2.3. Regional analogues to Equations (1)-(3) apply. Since all regions share spending patterns and face the same final goods prices, the price of consumption and investment is the same for all, and we keep Equation (4) as the numeraire rule. Equations (5)-(6) describing technology apply to all regions, with the corresponding factor prices and industry productivities. The only difference with the model of section 2.2 is that, even after globalization, producers of intermediate inputs in nontradable industries remain sheltered from foreign competition. As a result, in these industries Equations (9)-(10) apply to producers of intermediates in all regions and not only to the lowest-cost ones. Also Equation (8) applies to each region separately since only the demand from local producers of final goods matters for the producers of intermediate inputs. Thus, Equation (44) no longer applies to the producers of intermediate inputs in nontradable industries, and Equation (43) must be modified as follows:

$$(95)\quad I_{c,t} \equiv \left\{ i \in I \;\middle|\; c \in \underset{c' \in C}{\operatorname{argmin}} \left\{ \left[\frac{1}{Z_{c,it}} \cdot \left(\frac{w_{c,t}}{1-\alpha_i} \right)^{1-\alpha_i} \cdot \left(\frac{r_{c,t}}{\alpha_i} \right)^{\alpha_i} \right]^{1-\beta_i} \cdot \left[\int_0^{M_{c,it}} p_{c,it}(m)^{1-\varepsilon_i} \cdot dm \right]^{\frac{\beta_i}{1-\varepsilon_i}} \right\} \right\} \quad \text{for all } c \in C$$

Equation (95) simply recognizes that the number of intermediate inputs available and their prices can vary across regions.[71] Finally, the market clearing conditions in Equations (11), (45) and (46) apply.

This completes the formal description of the model. For any admissible set of capital stocks, i.e. $K_{c,0}$ for all $c \in C$, and sequences for the vectors of savings, human capital and industry productivities, i.e. $S_{c,t}$, $H_{c,t}$, and $A_{c,it}$ for all $c \in C$ and for all $i \in I$; and a sequence for the set N_t (or T_t); an equilibrium of the world economy after globalization consists of a sequence of prices and quantities such that the equations listed above hold at all dates and states of nature. Like the other worlds we have studied up to this point, there might be multiple geographical patterns of production that are consistent with world equilibrium. Unlike the worlds we have studied up to this point however, there might also be multiple prices and world aggregates that are consistent with world equilibrium. This is, in fact, the most prominent feature of this world.

As usual, we start the analysis by defining the set of factor distributions that allow the world economy to replicate the integrated economy. This set is now as follows:

$$
\begin{aligned}
FPE_t \equiv \Bigg\{ d_t \in D_t \;\Big|\; & \exists x_{c,it}(m) \geq 0,\ x^F_{c,it} \geq 0 \text{ with } \sum_{c \in C} x_{c,it}(m) = 1,\ \sum_{c \in C} x^F_{c,it} = 1 \text{ and} \\
& x_{c,it} = (1-\beta_i) \cdot x^F_{c,it} + \frac{\beta_i}{M_{it}} \cdot \int_0^{M_{it}} x_{c,it}(m) \cdot dm; \text{ such that:} \\
& \text{(R1) } x_{c,it} = 0 \text{ if } Z_{c,it} < \max_{c \in C}\{Z_{it}\}; \\
& \text{(R2) } H_{c,t} = \sum_{i \in I} x_{c,it} \cdot H_{it} \text{ and } K_{c,t} = \sum_{i \in I} x_{c,it} \cdot K_{it}; \text{ and} \\
& \text{(R3) } x_{c,it} \in \{0,1\}\ i \in I \Bigg\}
\end{aligned}
\tag{96}
$$

[71] Equation (95) assumes that regions always produce intermediates with the lowest indices. This simplifies notation a bit and carries no loss of generality.

When comparing this set to those in Definitions (36) and (86), we observe that requirement (R3) is much stronger now. While Definitions (36) and (86) only required that the entire production of each intermediate were located in a single region, Definition (96) requires that the entire production of each industry (i.e. all intermediates plus final goods) be located in a single region. This is a direct implication of the assumption that intermediate inputs are nontradable. Naturally, this strengthening of requirement R3 reduces the size of FPE_t.[72] Therefore, this set is always smaller than the set in Definition (36). But it need not be smaller than the set in Definition (86), since requirement R4 no longer applies when final goods are tradable.

Assume that industries are "small" and regions are "large" so that requirement R3 is not binding. Then, it is straightforward to see that the equilibria studied in section 2 still apply. If $d_t \in FPE_t$, there exists an equilibrium in which factor prices are equalized across regions and the world economy operates at the same level of efficiency as the integrated economy despite factor immobility and goods market segmentation. If $d_t \notin FPE_t$, the world economy cannot operate at the same level efficiency as the integrated economy and factor prices differ across regions. All the equilibria analyzed in sub-sections 2.4 and 2.5 are also equilibria for the world of this section, and all the results and intuitions we learned in these sub-sections remain valid without qualification.

There is however a major difference between this world and the ones we studied in section 2. While the equilibria described in section 2 were unique in the worlds analyzed there, they are only one among many in the world of this section. The next example makes this point very clear:

[72] The set FPE_t is never empty, but it is smaller than the set of all the factor distributions that are equilibria of the integrated economy. The reason is that some of these equilibria split industries across regions.

Example 3.2.1: Consider a world where all industries are nontradable, i.e. $N_t = I$. Then, any collection of sets $I_{c,t}$ (with $I_{c,t} \neq \varnothing$ for all $c \in C$) that constitutes a partition of I is part of an equilibrium of the world economy.[73] This follows immediately from Equations (5) and (8), which now apply to each region, and Equation (95). Equation (5) shows that the cost of production of final good producers in a given region depends on the number of available inputs. But Equation (8) shows the number of inputs produced in a given region depends on the demand by local producers of final goods.

This world economy exhibits a very strong form of agglomeration effects, as a result of backward linkages in production.[74] If there are no input producers in a region, the cost of producing final goods is infinity and no final goods producer will choose to locate in the region. But if there are no final goods producers in a region, there is no demand for inputs and no input producer will choose to locate in the region. In this world economy, these forces for agglomeration are so strong that they dwarf comparative advantage. It is possible that a given industry locates in a region offering cheap factors and high productivity, but it is also possible that it ends up locating in region offering expensive factors and low productivity.

The world income distribution can be written as follows:

(97) $$\frac{Y_{c,t}}{Y_t} = \sum_{i \in I_{c,t}} \sigma_i \qquad \text{for all } c \in C$$

[73] This world economy also has equilibria in which industries are split across regions. In these equilibria, all the regions that host a given industry have the same costs of producing the final goods but possibly different numbers and prices of inputs.

[74] Helpman and Krugman [1985] define a backward linkage as a situation in which a final good producer demands many inputs; and a forward linkage as a situation in which many final good producers demand the same input.

Equation (97) is formally very similar to Equation (76). Remember that the latter described the world income distribution in Example 2.5.2 where differences in industry productivities were so strong so as to single-handedly determine comparative advantage. The formal similarity between these two worlds follows because both exhibit an extreme form of specialization. The difference, of course, is the underlying force that determines this specialization. While in Example 2.5.2 regions specialize in a given industry because of their high productivity, in Example 3.2.1 regions specialize in a given industry only because of luck. While in Example 2.5.2 the shape and evolution of the world income distribution reflects only the distribution of industry productivities, in Example 3.2.1 it reflects only randomness.[75]

Example 3.2.1 is extreme because it assumes all industries are nontradable. Assume instead that $T_t \neq \varnothing$, and let $I_{c,t}^{N_t} = N_t \cap I_{c,t}$. As a result of agglomeration effects, any collection of sets $I_{c,t}^{N_t}$ (with $I_{c,t}^{N_t} \neq \varnothing$ for all $c \in C$) that constitutes a partition of N_t is an equilibrium of the world economy. Let again $H_{c,t}^T$ and $K_{c,t}^T$ be the factor endowments used in the production of tradable goods, i.e. all final goods and the intermediate inputs of tradable industries. It follows that:[76]

$$(98) \qquad H_{c,t}^T = \max\left\{0, H_{c,t} - \sum_{i \in I_{c,t}^{N_t}} (1-\alpha_i) \cdot \sigma_i \cdot \frac{Y_t}{w_{c,t}}\right\} \quad \text{for all } c \in C$$

$$(99) \qquad K_{c,t}^T = \max\left\{0, K_{c,t} - \sum_{i \in I_{c,t}^{N_t}} \alpha_i \cdot \sigma_i \cdot \frac{Y_t}{r_{c,t}}\right\} \quad \text{for all } c \in C$$

[75] Given our assumption of full depreciation of inputs, nothing prevents the pattern of production to shift randomly from generation to generation. This model therefore is consistent with any dynamics for the world income distribution. If inputs depreciated slowly, initial randomness would persist for some time.
[76] Here, I am assuming that industries do not split across regions. As mentioned in an earlier footnote, this is possible too.

Equations (98)-(99) show the factor supplies that are left after subtracting from aggregate factor supplies the factors used in nontradable industries. These Equations are analogous to Equations (87)-(88) of sub-section 3.1. One can use Equations (98)-(99) and a given collection of sets $I_{c,t}^{N}$ to generalize the theory of sections 2.4 and 2.5. For instance, in Example 2.4.1 Equations (47)-(52) still apply provided that we write $H_{c,t}^{T}$ and $K_{c,t}^{T}$ instead of $H_{c,t}$ and $K_{c,t}$.

The effects of this generalization of the theory are hard to assess given the multiplicity of equilibria and the inherent difficulty of finding a "respectable" selection criteria.[77] It is always possible to find perverse equilibria in which regions specialize in the "wrong" industries, i.e. industries in which they do not have comparative advantage. Naturally, all the equilibria of section 2 in which regions specialize in the industries in which they have comparative advantage still apply if requirement R3 is not binding (as we have assumed so far). But there is no compelling reason to choose them over some of the alternatives. Moreover, if requirement R3 is violated or is binding, the equilibria studied in section 2 no longer apply to this world economy. The following example, inspired by Krugman and Venables [1995], relaxes the assumption that industries are "small" and clearly illustrates this point:

Example 3.2.2: Consider a world with two industries I={A,M} and two regions C={N,S}. Assume that both industries have the same factor intensities, i.e. $\alpha_i=\alpha$ for all $i \in I$; but different sizes $\sigma_A<0.5<\sigma_M$ (remember that $\sigma_A+\sigma_M=1$). Also assume that both regions are identical, i.e. they have the same savings, human capital, industry productivities and initial condition. Assume next that the world starts in autarky and globalization proceeds in two stages: in the first one industry A becomes tradable, i.e. N_t={M} for $0 \leq t<T$; and in the second stage also industry M becomes tradable, i.e.

[77] Matsuyama [1991], Krugman [1991] and Fukao and Benabou [1993] study some interesting ways of resolving this indeterminacy.

$N_t = \varnothing$ for $t \geq T$. In the world of autarky, both regions have the same income and the question that I shall address here is: How does globalization affect the world income distribution?

At date t=0, all transport costs disappear except for those that affect the intermediate inputs of industry M. There are two possible patterns of production and trade that can emerge as a result of this. The first one consists of both regions producing the same they did in autarky and not trading between them. Since both regions would have the same goods and factor prices, there would be no incentive for any producer to deviate from this equilibrium. The second possible pattern of production and trade that can emerge consists of each region specializing in a different industry. For instance, assume N specializes in industry M. The absence of other local producers in industry M means that producers in S have no incentive to produce in industry M. Since spending on industry M is more than half of world spending, factor prices are higher in N and therefore producers in N cannot compete in industry A.[78]

It follows from this discussion that the first stage of globalization generates world inequality and world instability. In the world of autarky, both regions had the same income level and income volatility was driven by volatility in fundamentals, i.e. savings, human capital and industry productivities. Globalization generates divergence in incomes because in the equilibrium with specialization the region that "captures" industry M has higher income than the region that is "stuck" producing in industry A. The world income distribution is determined by Equation (97). One effect of this inequality is faster physical capital accumulation in N than in S. Globalization also generates instability, since the pattern of specialization can now change capriciously just as a result of a change in expectations. At any time the specialization pattern can change to the detriment of N and to the advantage of S.

[78] The assumption that industry M is large is crucial in reducing the number of equilibria to three. If there were many "small" M-industries there would also be additional equilibria that split these industries between regions in many different ways.

This constitutes an additional source of income volatility that goes beyond fundamentals.

At date t=T, transport costs for the intermediate inputs of industry M vanish. Although the pattern of production and trade is not uniquely determined, we know that factor prices and incomes are uniquely determined.[79] Moreover, since we have assumed that both industries have the same factor intensities, the world income distribution is now given by Equation (70). It follows that the second stage of globalization starts a slow process of convergence in incomes that eventually restores equality across regions. Throughout this process, expectations no longer play any role and the only sources of income volatility are fluctuations in fundamentals.

This example features a combination of agglomeration effects and "large" industries that underlies most of the work known as economic geography.[80] This research has focused on explaining how income differences can arise among regions that initially have the same fundamentals. The view of globalization and development that arises from this literature is colorful and suggestive, although it has not been subjected yet to serious empirical analysis.

Not surprisingly, globalization might lead to a Pareto-inferior outcome in the world of this section. The following example, which is related to Examples 2.1.2 and 3.1.3, shows this:

[79] When $N_t=\varnothing$, we are back to the world of section 2. The reason why the pattern of production is indeterminate is because I have assumed that industry A and M have the same factor intensities. Otherwise we would be in the case of Example 2.1.1.
[80] See Fujita, Krugman and Venables [1999] and Baldwin, Forslid, Martin, Ottaviano and Robert-Nicaud [2003].

Example 3.2.3: Consider a world economy with H- and K-industries, such that $I^H \cup I^K = I$ and $I^H \cap I^K = \varnothing$. Assume α_i=0 if $i \in I^H$, and α_i=1 if $i \in I^K$; and β_i is small (but not zero) for all $i \in I$. Within each type there are "advanced" and "backward" industries. A-regions have the highest possible productivity in all industries, regardless of whether they are "advanced" or "backward". B-regions have the highest possible productivity only in "backward" industries. Assume next that after globalization all industries are non-tradable. This world is just a special case of Example 3.2.1. We know therefore that there is an equilibrium in which A-regions specialize in "backwards" industries while B-regions specialize in "advanced" industries. This equilibrium can be easily shown to deliver equal or less income and welfare than autarky. Since β_i is small for all $i \in I$, the benefits from an increase in market size are negligible. Since the allocation of production worsens relative to autarky, production and income go down as a result of globalization. Therefore, it is not possible to find a transfer scheme that ensures that globalization benefits all.

Although this is real a theoretical possibility, it is not clear yet how seriously should we take the possibility that globalization worsens the world allocation of production and reduces welfare. How important empirically are these agglomeration effects? What is the relative importance of randomness and comparative advantage in determining the pattern of production and trade? The answers to these questions are critical in determining whether the basic policy prescription that simply opening up to trade leads to development really applies or not. In the worlds of this section, opening up to trade can lead to miracles and disasters alike. A miracle is nothing but a lucky region that attracts a large number of industries exhibiting agglomeration effects. A disaster is an unlucky region that cannot do so. Opening up to trade is therefore a gamble. It opens the door for industries to come into the region and enrich it, but it also opens the door for industries to leave the region and impoverish it. Naturally, the temptation to change the odds of this gamble using industrial policies and protectionism might be overwhelming. The prescriptions for

development are therefore easy to spot but not pleasant. This is a world characterized by negative international spillovers and strong temptations to use "beggar-thy-neighbor" policies.

Despite the presence of transport costs, differences in regional market size still play no role in determining the world income distribution in the worlds of this sub-section and the previous one. If intermediate inputs are tradable, all regions use the same set of specialized inputs and enjoy the same level of industry specialization or technology to produce final goods. If final goods are tradable, industries concentrate their production in one or few regions and all regions buy their final goods at the same prices. The ability to trade intermediates and/or final goods therefore implies that regional differences in market size cannot be a source of regional differences in incomes. We next turn to a world that features some industries in which neither intermediates nor final goods can be traded. This brings back market size effects as a determinant of the world income distribution.

3.3 The role of local markets

We turn next to a world in which the costs of trading intermediate inputs and final goods are prohibitive if $i \in N_t$, but negligible if $i \in T_t$. As in all the worlds considered in this chapter, the benefits of developing specialized inputs depend on the size of the industry's market. For tradable industries, this market is the world economy. For nontradable industries, this market is the region. As a result, regional differences in market size will be translated into regional differences in the degree of specialization or technology of nontradable industries. [81]

[81] There is little empirical evidence that regional differences in market size are an important determinant of income differences. When one interprets the data from the vantage point of the world of autarky, this observation implies that market size effects are weak and sustained growth is not possible. This has led many researchers to spend a substantial effort in developing autarky models where sustained growth is possible without market size effects. Somewhat ironically, once one takes a world equilibrium view of the growth process what requires a substantial effort is to develop models where regional differences in market size do affect the world income distribution.

Formally, this model is very similar to the one in sub-section 3.1. Equations (81)-(82) describe investment and consumption, while Equations (83)-(84) still provide the numeraire rule and the price level. Naturally, Equation (3) describing spending patterns still applies to all regions, and Equations (5)-(6) describing technology apply to all regions, with the corresponding factor prices and industry productivities. The only difference with the model of section 3.1 is when Equations Equations (7)-(10) describing pricing policies, input demands and the free-entry condition apply. For tradable industries, these Equations apply only to those regions where the lowest-cost producers are located. For nontradable industries, these Equations apply to all regions and not only to the lowest-cost ones. Thus, Equation (44) no longer applies to producers in nontradable industries, and Equation (93) must be replaced by Equation (95). Market clearing conditions are also the same as in the model of section 3.1, and consist of Equations (45)-(46) describing market clearing in regional factor markets, Equation (11) describing market clearing in global markets for tradable industries, and Equation (85) describing market clearing in regional markets for nontradable industries.

This completes the formal description of the model. For any admissible set of capital stocks, i.e. $K_{c,0}$ for all $c \in C$; sequences for the vectors of savings, human capital and industry productivities, i.e. $S_{c,t}$, $H_{c,t}$, and $A_{c,it}$ for all $c \in C$ and for all $i \in I$; and a sequence for the set N_t (or T_t); an equilibrium of the world economy after globalization consists of a sequence of prices and quantities such that the equations listed above hold in all dates and states of nature. Like other worlds we have studied up to now, there might be multiple geographical patterns of production that are consistent with world equilibrium. But unlike the world of the previous sub-section (and like the worlds of section 2 and sub-section 3.1), prices and world aggregates are uniquely determined.

In this world economy, the set FPE_t is empty. Since intermediate inputs that are produced in a region cannot be used in another region, the world economy cannot reach the level of efficiency of the integrated economy.[82] Despite this, it is relatively straightforward to analyze this world. Define again $H_{c,t}^T$ and $K_{c,t}^T$ as the factor endowments devoted to the production of tradable goods, i.e. all intermediate inputs and final goods of tradable industries. Straightforward algebra shows that: [83]

$$(100)\quad H_{c,t}^T = \max\left\{0, H_{c,t}\cdot\left(1-\sum_{i\in N_t}(1-\alpha_i)\cdot\sigma_i\right) - K_{c,t}\cdot\left(\frac{w_{c,t}}{r_{c,t}}\right)^{-1}\cdot\sum_{i\in N_t}(1-\alpha_i)\cdot\sigma_i\right\} \quad \text{for all } c\in C$$

$$(101)\quad K_{c,t}^T = \max\left\{0, K_{c,t}\cdot\left(1-\sum_{i\in N_t}\alpha_i\cdot\sigma_i\right) - H_{c,t}\cdot\frac{w_{c,t}}{r_{c,t}}\cdot\sum_{i\in N_t}\cdot\alpha_i\cdot\sigma_i\right\} \quad \text{for all } c\in C$$

Since factor supplies are well behaved, all the results in sections 2.4 and 2.5 regarding market-based incomes and factor prices still go through in the presence of nontradable industries. As in sub-section 3.1, the only important difference between the world of this sub-section and the one in section 2 is that there is a discrepancy between market-based and real incomes and factor prices. In particular, we can write the price level of region c as follows:

$$(102)\quad P_{c,t} = \prod_{i\in N_t}\left\{\frac{1}{\sigma_i}\cdot\left[\frac{1}{Z_{c,it}}\cdot\left(\frac{w_{c,t}}{1-\alpha_i}\right)^{1-\alpha_i}\cdot\left(\frac{r_{c,t}}{\alpha_i}\right)^{\alpha_i}\right]^{1-\beta_i}\cdot\left[\int_0^{M_{c,it}} p_{c,it}(m)^{1-\varepsilon_i}\cdot dm\right]^{\frac{\beta_i}{1-\varepsilon_i}}\right\}^{\sigma_i} \quad \text{for all } c\in C$$

[82] The set FPE_t might be non-empty in the limiting case where $\beta_i\to 0$ (or $\varepsilon_i\to\infty$) for all $i\in I$. But that limiting case brings us to the world of sub-section 3.1.

[83] To see this, note that the shares of human and physical capital devoted to producing the final good of the i^{th} nontradable industry are now $(1-\alpha_i)$ and α_i. Add over industries and note that the share of spending in the i^{th} industry is $\sigma_i\cdot Y_{c,t}$.

The only difference between this Equation and Equation (91) is that the number and price of intermediate inputs varies across regions. Using Equations (6) and (10), we can transform Equation (103) into the following:

$$(103)\quad P_{c,t} = \prod_{i \in N_t} \left\{ \frac{1}{\sigma_i^{\mu_i} \cdot A_{c,it}} \cdot \left(\frac{w_{c,t}}{1-\alpha_i} \right)^{(1-\alpha_i)\cdot\mu_i} \cdot \left(\frac{r_{c,t}}{\alpha_i} \right)^{\alpha_i \cdot \mu_i} \cdot Y_{c,t}^{1-\mu_i} \right\}^{\sigma_i}$$

Basically, this model brings another element to the theory of the price level. To the extent that nontradable industries exhibit increasing returns, regions with larger markets have lower price levels and higher real incomes.

It is straightforward to re-do some of the previous examples in the context of this world. But I shall not do this. The picture that this world generates is clear and unappealing form an empirical standpoint: regional differences in market size are reflected in regional differences in price levels. Ceteris paribus, larger local markets do not lead to higher market-based incomes and factor prices. But they do lead to lower price levels and, as a result, to higher real incomes and factor prices. This is clearly counterfactual.

4. Final remarks

This chapter has developed a unified and yet tractable framework that integrates many key insights of the fields of international trade and economic growth. Its distinguishing feature is that it provides a global view of the growth process, that is, a view that treats different regions of the world as parts of a single whole. This framework incorporates the standard idea that economic growth in the world economy is determined by a tension between diminishing returns and market size effects to capital accumulation. A substantial effort has been made to show how

trade frictions of various sorts determine the shape of the world income distribution and its dynamics.

Despite the length of this chapter, some important topics have been left out. The first and most glaring omission is asset trade. This type of trade allows the world economy to redirect its investment towards regions that offer the highest risk-adjusted return.[84] To the extent that patterns of trade are determined by comparative advantage, these are the regions where capital is scarce and productive and this raises efficiency in the world economy. To the extent that patterns of trade are determined by luck, asset trade magnifies the effect of this randomness and this could either raise or lower the efficiency of the world economy. If this were all there is to asset trade, it would not be too difficult to add to this chapter a section on asset trade in which we endow the world economy with a complete set of asset markets. But asset trade does not seem to work as the standard theory of complete markets would suggest. Empirically asset trade seems both much smaller and much more volatile than it would be warranted by its fundamentals, i.e. savings, human capital and industry productivities. To understand these aspects of asset trade it seems necessary to incorporate to the theory features such as sovereign risk, asymmetric information and asset bubbles. Although this is a very important task, it would require another chapter of this magnitude and must therefore be left for future work.[85]

A second important omission of this chapter is government policy. A central aspect of globalization so far has been its imbalanced nature. While economic integration has proceeded at a relatively fast pace, political integration is advancing at a slower pace or not advancing at all. The world economy today features global (or semi-global) markets but local governments. In this context, globalization can lead to a decline in growth and income through a reduction in the quality of policies.

[84] Naturally, asset trade also allows for a better risk sharing and this raises welfare. Better risk sharing might also increase investment and growth. See Obstfeld [1994].
[85] Among the many papers that study the behavior of financial markets in world equilibrium models, see Gertler and Rogoff [1990], Acemoglu and Zilibotti [1997], Ventura [2002], Matsuyama [2004], Martin and Rey [2002, 2004], Kraay, Loayza, Servén and Ventura [2005] and Broner and Ventura [2005].

International spillovers eliminate the incentives to adopt good but costly policies. Trade also "bails out" regions with bad policies since they can spare some of their costs by specializing in industries where bad policies have little effects. As a result of these forces, globalization could create a "race to the bottom" in policies that lowers savings, human capital, and industry productivities. And this could potentially mitigate or even reverse the benefits from economic integration.[86] Understanding the circumstances under which this "race to the bottom" can happen and the appropriate policy corrections that are required to allow the world economy to take full advantage of globalization is another important task. But this task would also require another chapter of this magnitude and cannot be undertaken here.

At first sight, factor movements might seem a third important omission. But I think it is less so. As mentioned in section 2, the notion that physical and human capital is geographically immobile seems a fair description of reality. Moreover, the benefits of factor mobility might be reaped without factors having to move at all. What is really important about factor movements is that they permit factors located in different regions to work together and produce. Advances in telecommunications technology and the standardization of software allow producers around the world to combine physical and human capital located in different regions in a single production process. We can always think of this situation as one in which the production process has been broken down into intermediate inputs. An increased ability to combine factors located in different regions could therefore be modeled as an increase in the tradability of intermediate inputs, or as an increase in the share of intermediate inputs, or as the development of additional inputs with more extreme factor intensities. All of these possibilities could be (and some have already been) analyzed within the framework developed in this chapter.[87]

---

[86] See Levchenko [2004] for a situation in which globalization leads to a "race to the top" in government policies, though.

[87] An increase in the tradability of inputs corresponds to a gradual increase in T_t in the models of section 3.2 and 3.3. An increase in the share of intermediate inputs corresponds to a gradual increase in β_i, while the development of inputs with more extreme factor intensities corresponds to a gradual change in α_i. I have assumed throughout that industry characteristics are time-invariant only for simplicity. All the formulas in this chapter remain valid if we instead assume that industry characteristics vary, perhaps stochastically, over time.

The goal of this chapter has been to convey a global way of thinking about the growth process. To claim success, you should be persuaded by now that developing and systematically studying world equilibrium models is a necessary condition to gain a true understanding of the growth process. By “true”, I mean the sort of understanding that allows us to frame clear and unambiguous hypotheses about why some countries are richer than others or what are the main forces that drive economic growth in the world economy. To claim success, you should also be convinced by now that much is already known about the structure of world equilibrium models. But you should also be aware that the global view of economic growth that these models reveal is still somewhat fuzzy and blurred. Sharpening this view is a major challenge for growth and trade theorists alike.

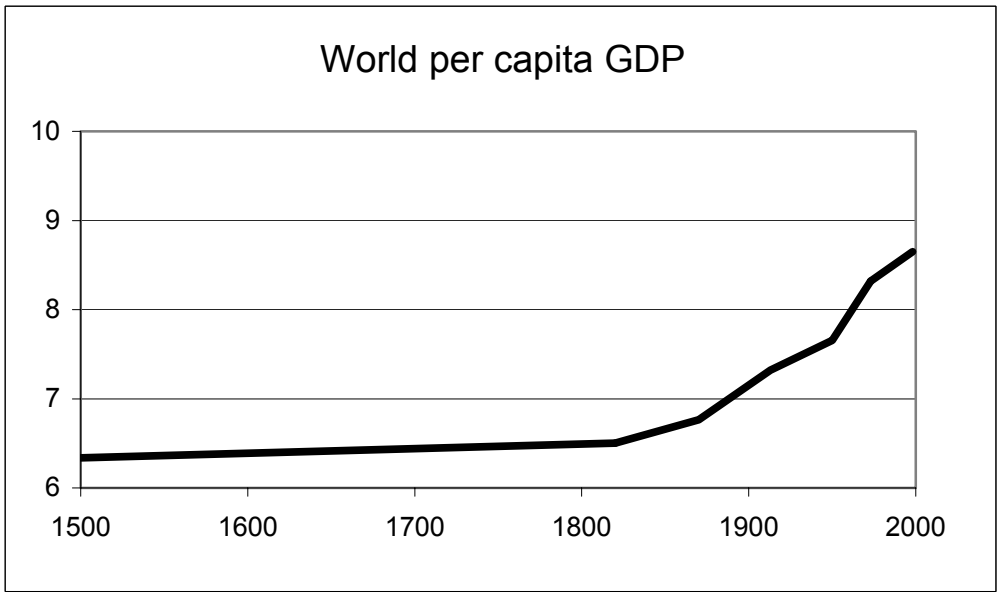
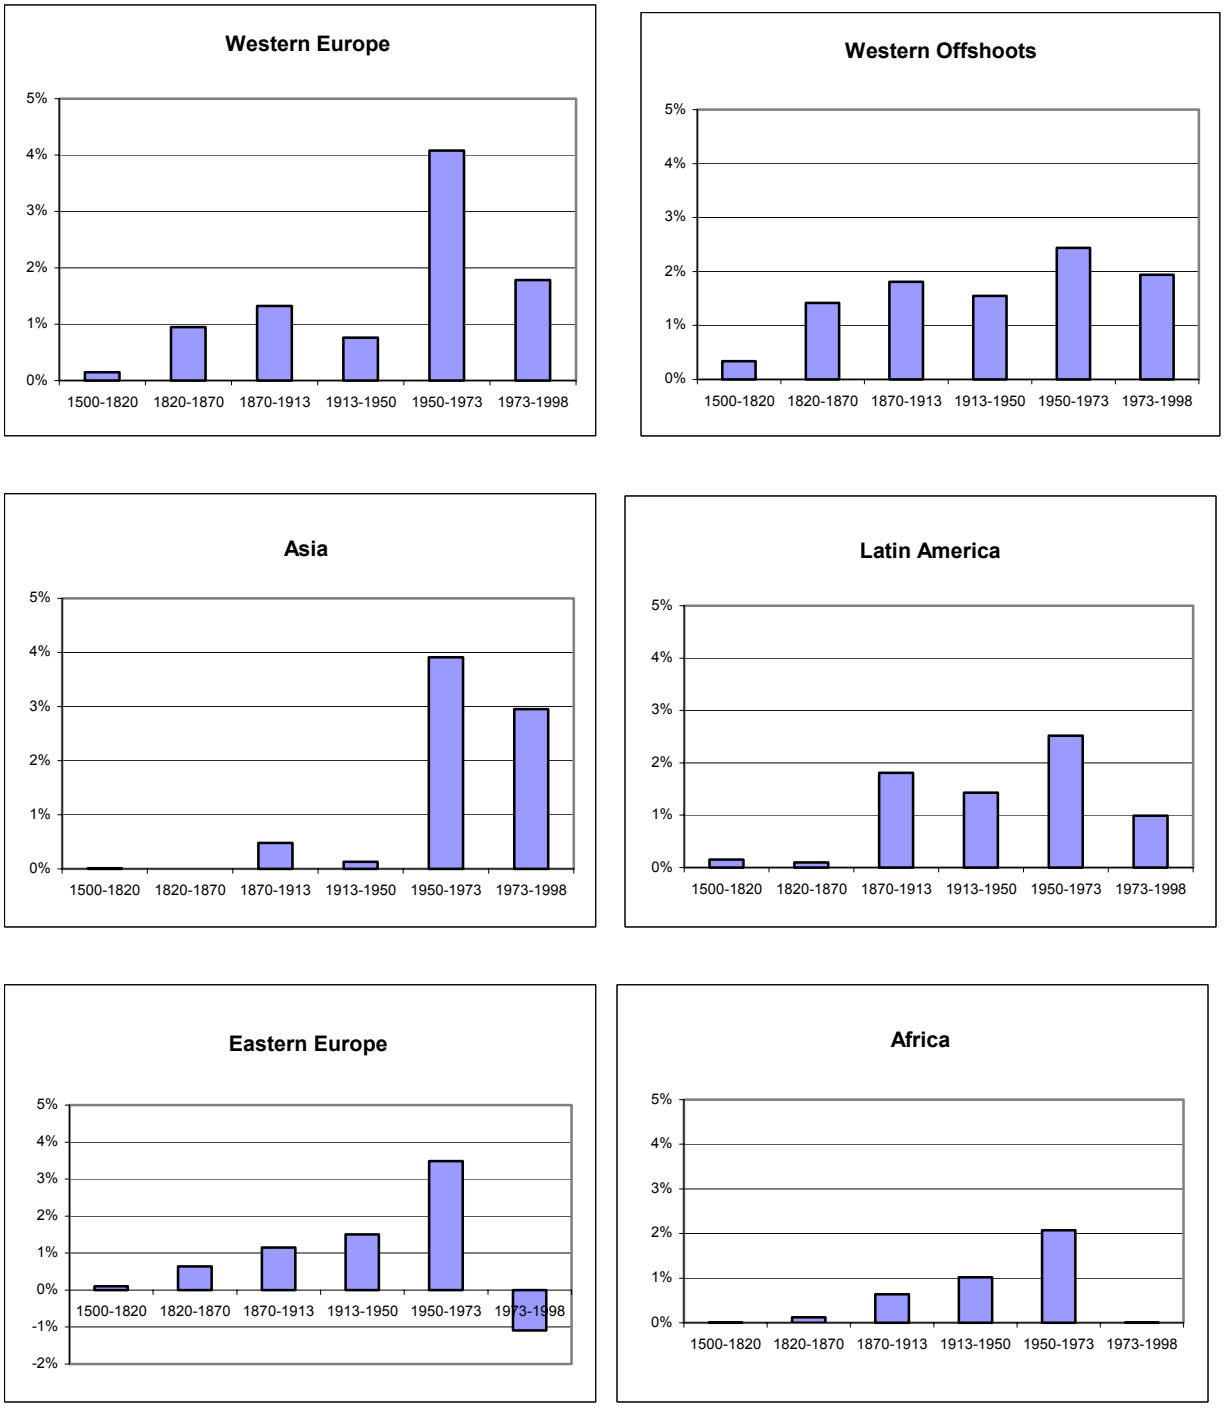
Figure 1



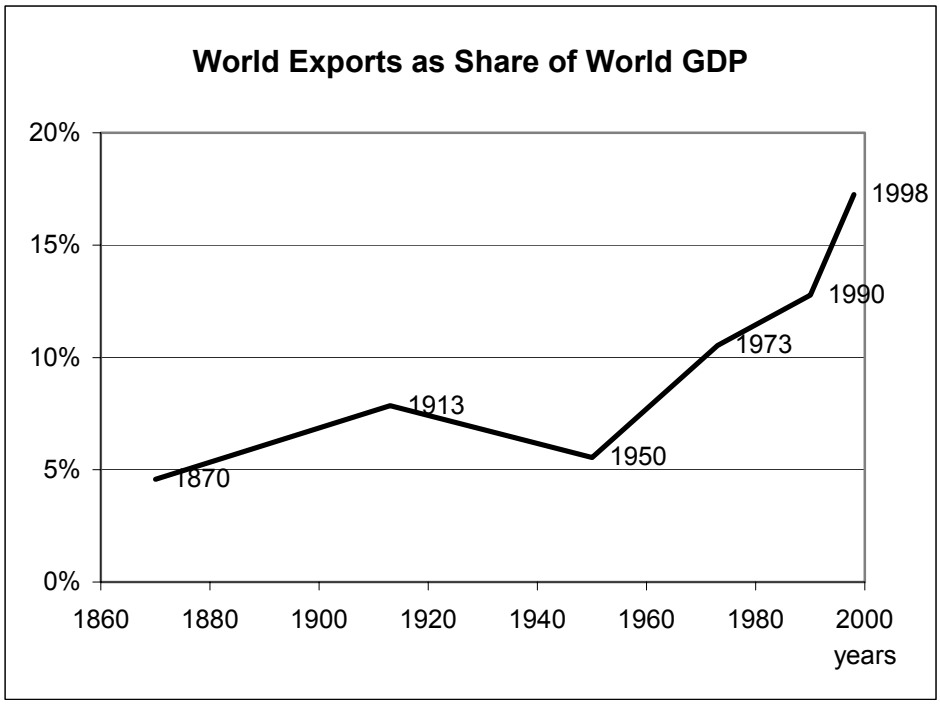
Notes: This figure shows the dynamics of world per capita GDP for the selected years 1500, 1820, 1870, 1913, 1950, 1973, and 1998 (in log of 1990 US$). Data are from Angus Maddison, "The World Economy – A Millennial Perspective" Table 3-1b page126.

Figure 2
Per capita GDP Growth



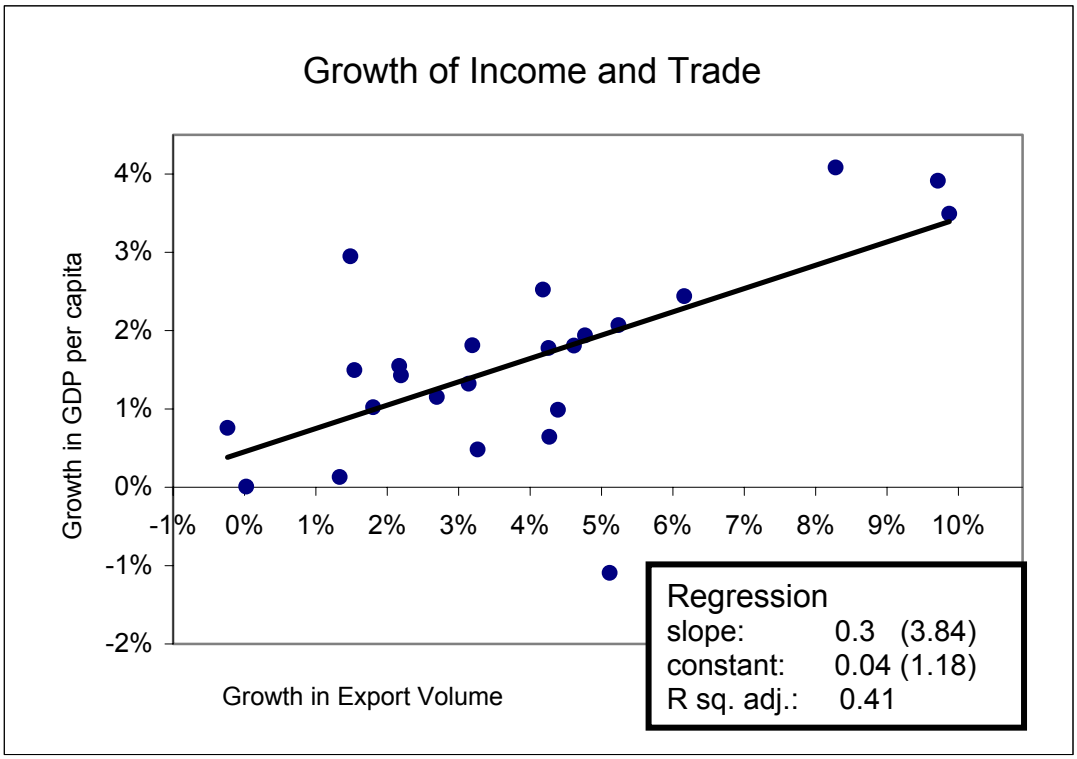
Notes: This figure shows average annual growth rates by major world regions for selected periods. Data are derived from Angus Maddison, "The World Economy – A Millennial Perspective" Table 3-1b page126. (Western Europe contains Austria, Belgium, Denmark, Finland, France, Germany, Italy, Netherlands, Norway, Sweden, Switzerland, UK, Portugal, Spain, Greece and 13 small countries; Western Offshoots are United States, Canada, Australia and New Zealand; Asia is China, India, Japan, Korea, Indonesia, Indochina, Iran, Turkey and Other East and West Asian countries; Latin America includes Brazil, Mexico, Peru, and Others; Eastern Europe contains Albania, Bulgaria, Hungary, Poland, Romania and territories of former Czechoslovakia and Yugoslavia; Africa is Egypt and Others.)

Figure 3



Notes: The figure shows Volume of World Exports over World GDP (in constant US$) for selected dates. Data are from Tables 3-1b, A1-b, A2-b, A3-b, A4-b, pages126, 184, 194, 214, and 223 in Angus Maddison, "The World Economy – A Millennial Perspective".

Figure 4

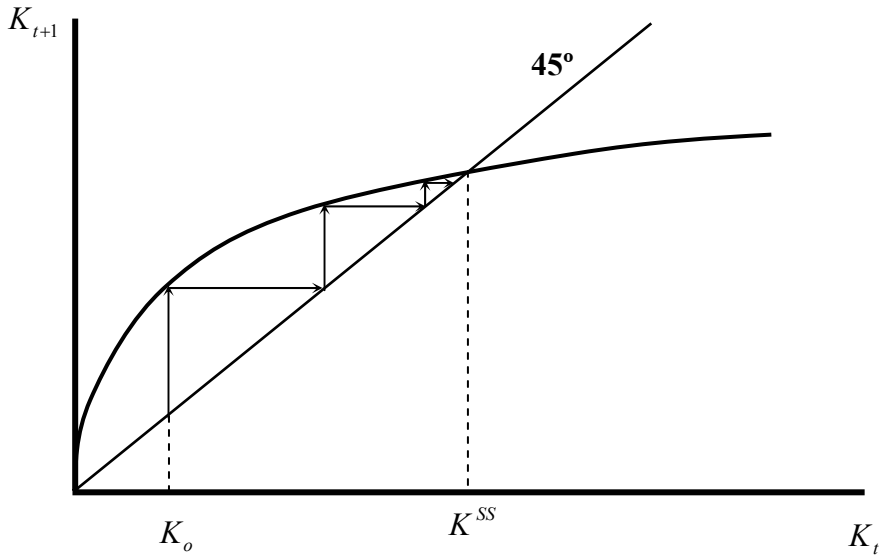


Notes: This figure plots annualized rate of trade growth against annualized rate of per capita GDP growth for major world regions and selected periods. The Regions are Western Europe, Western Offshoots, Eastern Europe and former USSR, Latin America, Asia, and Africa. Periods are 1870-1913, 1913-1950, 1950-1973 and 1973-1998. Each data point stands for one region during one period. The solid line represents the prediction of a linear regression. The estimated regression are reported in the box, t-statistics are in brackets. Data are from Angus Maddison, "The World Economy – A Millennial Perspective". Data for GDP growth are obtained from Table 3-1b page126 and Table B-10 page 241 (to include Japan). Data for export growth are derived from Table F-3 page362 and Tables A1-b, A2-b, A3-b, and A4-b, pages 184, 194, 214 and 223, respectively.

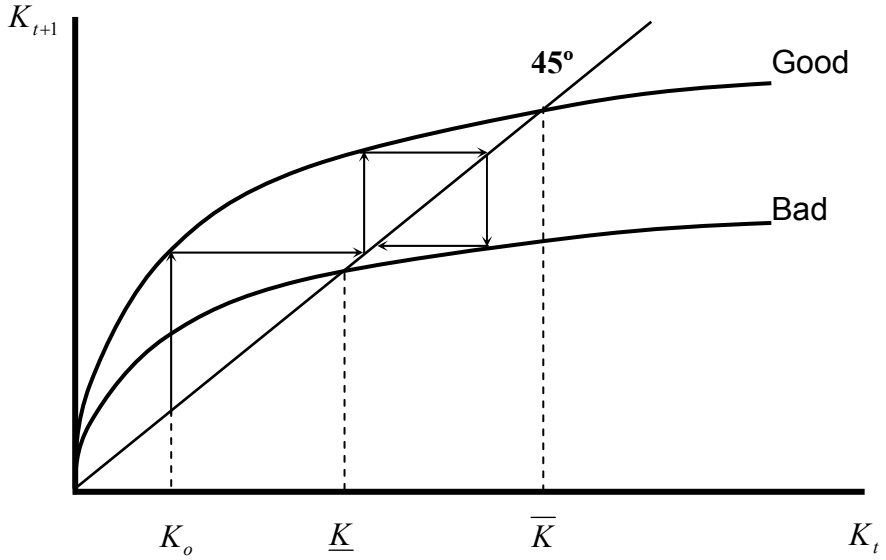
Figure 5

$\alpha\mu + \upsilon < 1$

The “deterministic” case



The “stochastic” case

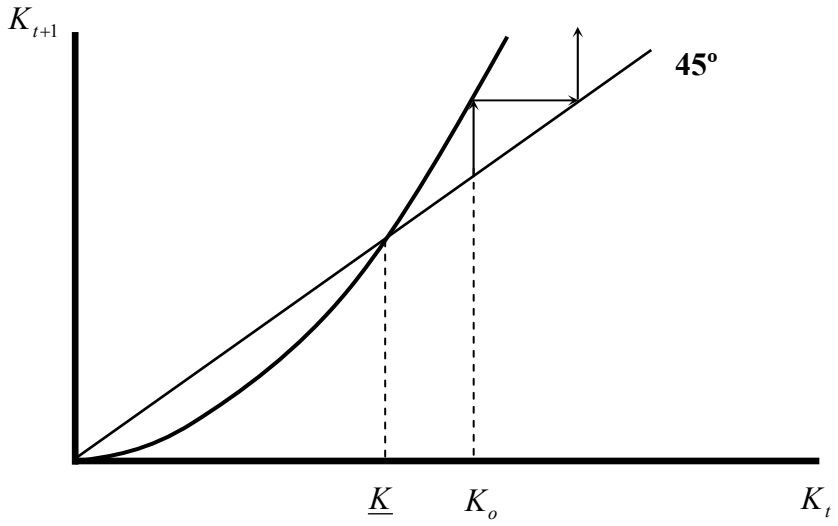


Notes: This figure shows the case of strong deminishing returns and weak market size effects. In the top panel, the stock of physical capital converges monotonically to its unique steady state. The bottom panel shows the stochastic case, where the stock of physical capital converges to the steady state interval $\left[\underline{K}, \overline{K}\right]$ within which it fluctuates according to the states of the world.

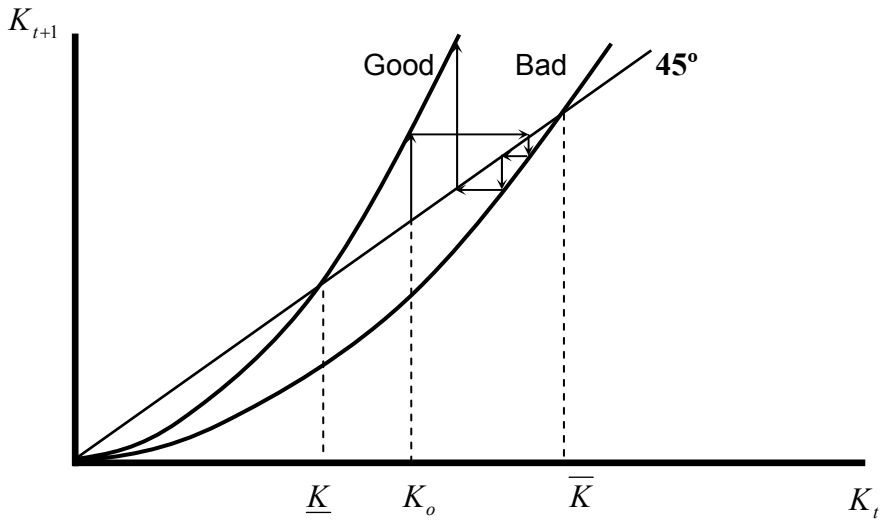
Figure 6

$$\alpha\mu + \upsilon > 1$$

The "deterministic" case



The "stochastic" case

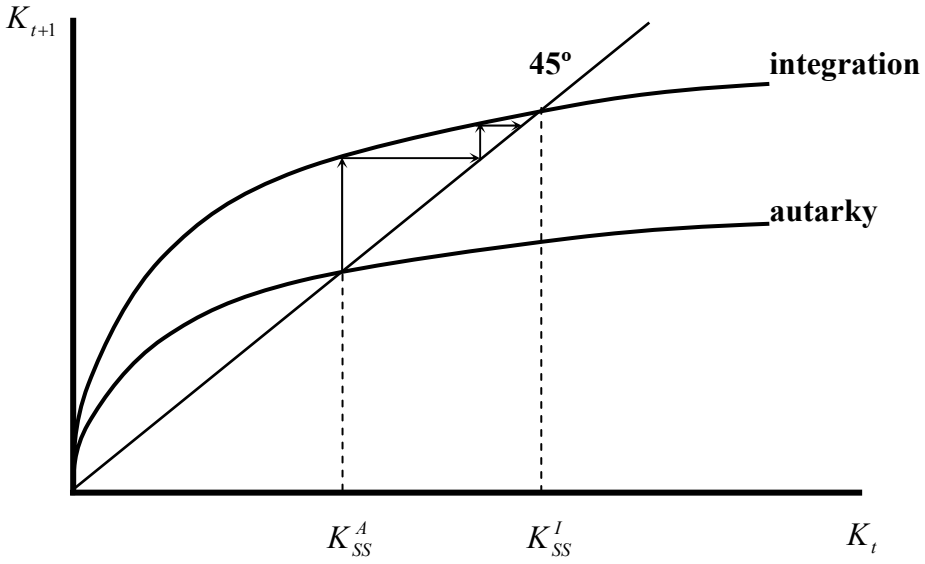


Notes: This figure shows the case of weak diminishing returns and strong market size effects. In the top panel, the stock of physical capital grows at increasing rates since $K_o > \underline{K}$. In the bottom panel the stock of physical capital fluctuates between $\underline{K}$ and $\overline{K}$ according to the states of the world, until it eventually leaves this range.

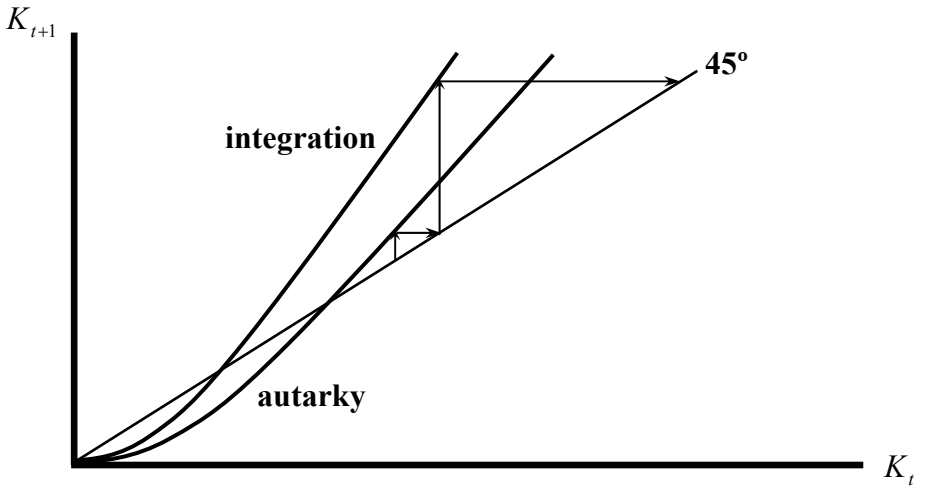
Figure 7

Effects of Economic Integration

$\alpha\mu + \upsilon < 1$

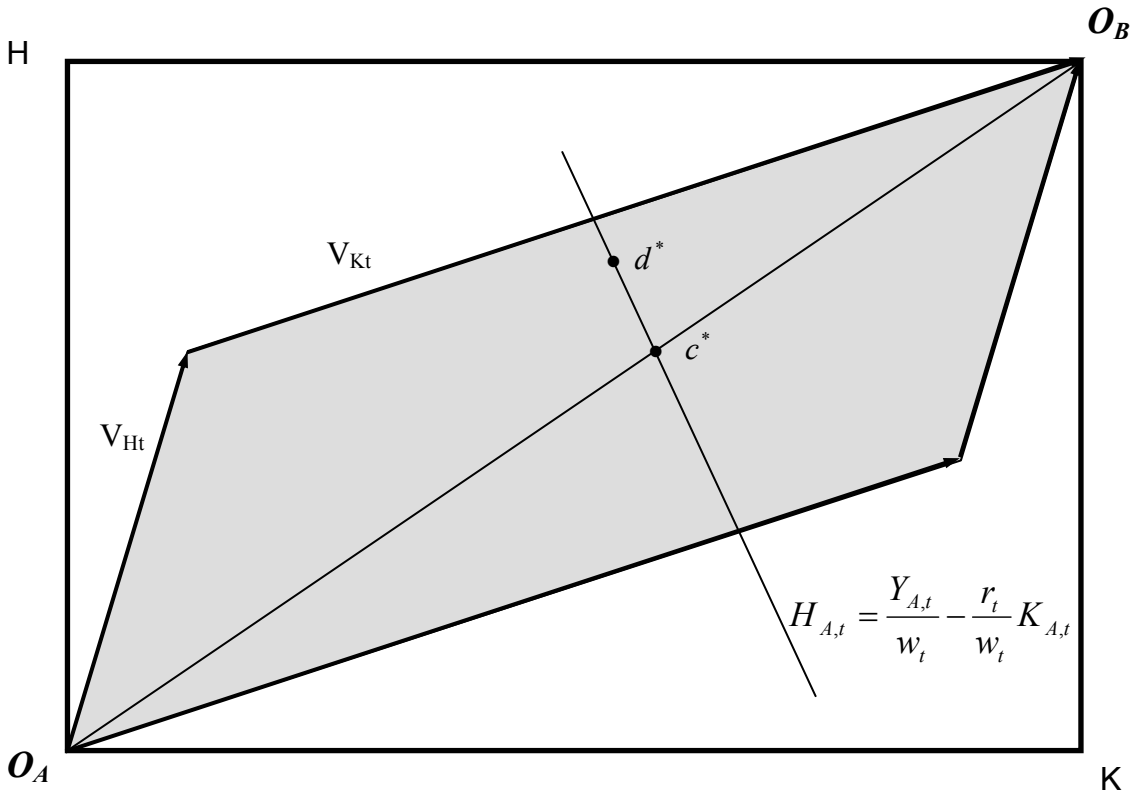


$\alpha\mu + \upsilon > 1$



Notes: This figure illustrates the effects of economic integration. The top panel shows that, if $\alpha \cdot \mu + \upsilon < 1$, economic integration has level effects on income. The bottom panel shows that, if $\alpha \cdot \mu + \upsilon > 1$, economic integration has growth effects on incomes.

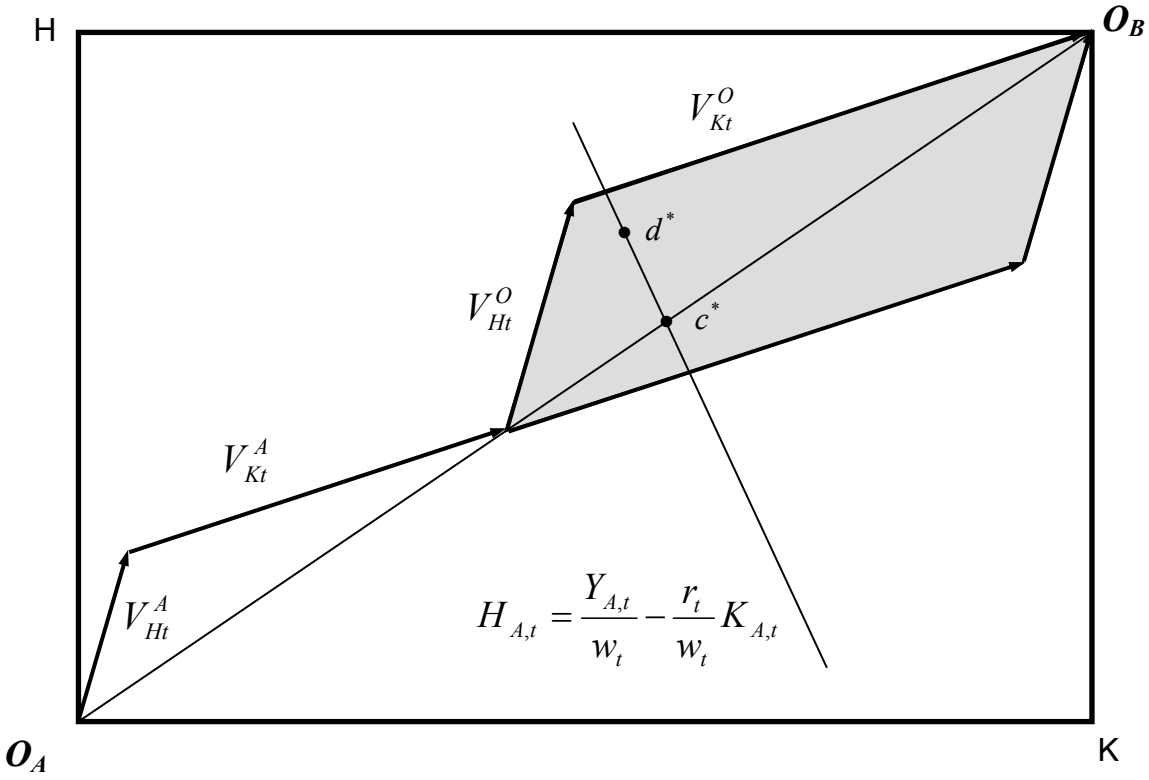
Figure 8



Notes: The box in this figure is a geometrical representation of the set D_t, as each element of this set is a point in the box and vice versa. For instance, d^* is a factor distribution such that A-regions have more human and physical capital than B-regions; but human capital is relatively more abundant in A-regions than in B-regions. The box also contains a set of vectors that represent the factor usage per industry that would apply in the integrated economy. For instance, the vector V_{it} has height H_{it} and width K_{it}. The set FPE_t is the gray area. Since all regions have the same industry productivities, production trivially takes place only in regions with the highest possible productivity (requirement R1). Each of the points in the gray area can be generated as a convex combination of the integrated economy's vectors of factor usage per industry (requirement R2). Since β_i=0, trivially there are no fixed costs of production that are incurred twice (requirement R3). Points outside of the shaded area do not have this property and therefore do not belong to FPE_t.

The factor content of production is given by the regions' factor endowments, i.e. d^*. Since all regions have the same spending shares and use the same techniques to produce all goods, the factor content of consumption lies in the diagonal, i.e. c^*.
In A-regions, the H-industry is a net exporter while the K-industry is a net importer. The opposite occurs in B-regions.

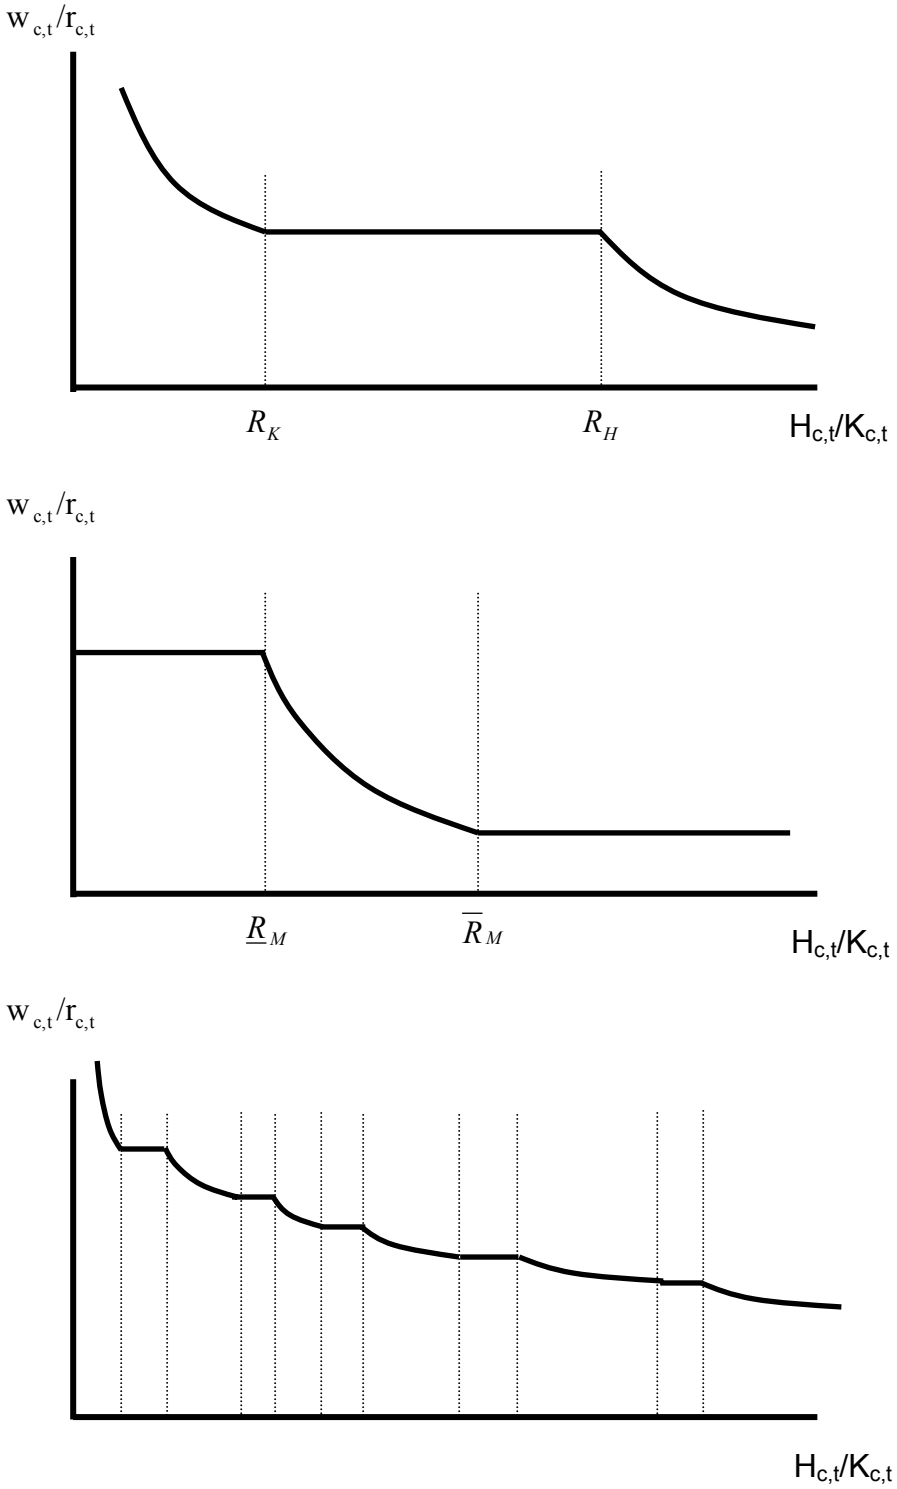
Figure 9



Notes: The box in this Figure is a geometrical representation of the set D_t, as each element of this set is a point in the box and vice versa. For instance, d^* is a factor distribution such that A-regions have more human and physical capital than B-regions; but human capital is relatively more abundant in A-regions than in B-regions. There are four different industries, "advanced" physical (human) capital intensive and "backward" physical (human) capital intensive. The A-countries have a highest productivity in the "advanced" industries; technologies in the "backward" industries are equal in all countries. The vectors V^X_{it} have height H^X_{it} and width K^X_{it} and represent the factor content of the *X*-industries, where *X=A,B* stands for "advanced" or "backward" industries. The set FPE_t is the shaded area. In this set, all "advanced" industries must be located in the A-countries (requirement R1). Once this requirement is satisfied, each of the points in the shaded area can be generated as a convex combination of the integrated economy's vectors of factor usage of the "backward" industries (requirement R2). Since β_i=0, trivially there are no fixed costs of production that are incurred twice (requirement R3). Points outside of the shaded area do not have both properties and therefore do not belong to FPE_t.

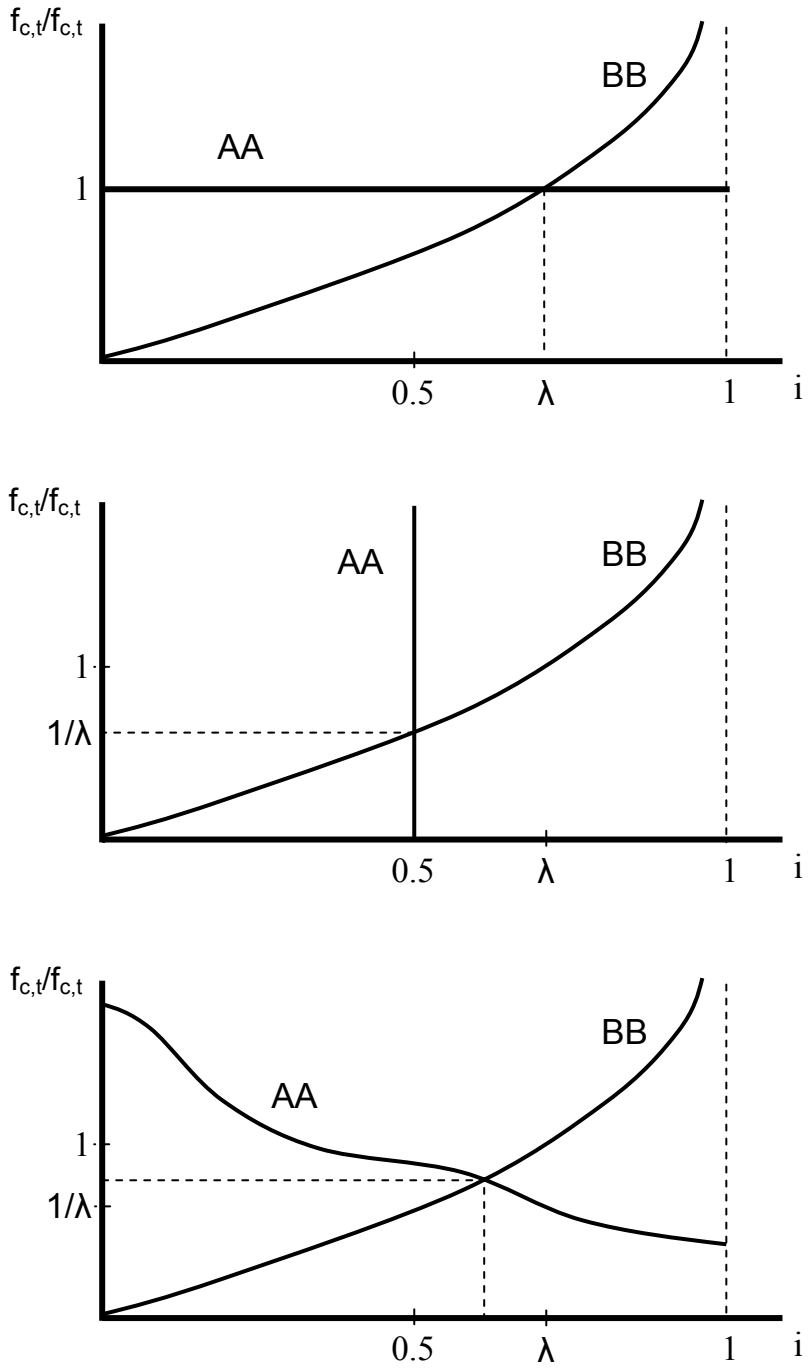
The factor content of production is given by the regions' factor endowments, i.e. d^*. Since all regions have the same spending shares and use the same techniques to produce all goods, the factor content of consumption lies in the diagonal, i.e. c^*. In H-regions, the H-industry is a net exporter while the K-industry is a net importer. The opposite occurs in K-regions.

Figure 10



Notes: This figure shows how the wage-rental ratio varies with the factor proportions. The top panel represents a two-goods, one-cone world where countries with extreme factor proportions are outside the cone (Example 2.4.1). The middle panel represents a three-good, two-cone world where countries with intermediate factor proportions lie outside the cone (Example 2.4.2). The bottom panel shows a world with multiple goods and cones.

Figure 11



Notes: This figure shows how pattern of production and trade (i*) and relative factor costs ($f_{N,t}/f_{S,t}$) are determined in Example 2.5.3. The top panel shows the case of arbitrarily small differences in industry productivities. The middle panel shows the case of arbitrarily large differences in industry productivities. The bottom panel shows the intermediate case.

Trade, Growth and the Size of Countries*

Abstract

Normally, economists take the size of countries as an exogenous variable. Nevertheless, the borders of countries and therefore their size change, partially in response to economic factors such as the pattern of international trade. Conversely, the size of countries influences their economic performance and their preferences for international economic policies - for instance smaller countries have a greater stake in maintaining free trade. In this paper, we review the theory and evidence concerning a growing body of research that considers both the impact of market size on growth and the endogenous determination of country size. We argue that our understanding of economic performance and of the history of international economic integration can be greatly improved by bringing the issue of country size at the forefront of the analysis of growth.

1 Introduction

Does size matter for economic success? Of the five largest countries in the world in terms of population, China, India, the United States, Indonesia and Brazil, only the United States is a rich country.[1] In fact the richest country in the world in 2000, in terms of income per capita, was Luxembourg, with less than 500,000 inhabitants. Among the richest countries in the world, many have populations well below the world median, which was about 6 million people in 2000. And when we consider growth of income per capita rather than income levels, again we find small countries among the top performers. For example Singapore, with 3 million inhabitants, experienced the highest growth rate of per capita income of any country between 1960 and 1990.[2] These examples show that a country can be small and prosper, or, at the very least, that size alone is not enough to guarantee economic success.

In this paper, we discuss the relationship between the scale of an economy and economic growth from two points of view. We first discuss the effects of an economy's size on its growth rate and we then examine how the size of countries evolves in response to economic factors.

The "new growth literature", with its emphasis on increasing returns to scale, has devoted much attention to the question of size of an economy.[3] It is therefore somewhat surprising that the question of the effect of border design and size of the polity as a determinant of economic growth has received limited attention. One reason is that, as we will see below, measures of country size (population or land area) used alone in growth regressions, generally do not have much explanatory power. Even less attention has been devoted to the endogenous determination of borders even from those researchers who have paid attention to the effect of geography on growth. Borders are not exogenous geographical features: they are a man-made institution. In fact, even the geographical characteristics of a country are in some sense endogenous: for instance whether a country is landlocked or not

[1] Throughout this paper we use the word "country", "nation" and "state" interchangeably, meaning a polity defined by borders and a national government and citizens. We are not dealing with the concept of a nation as a people not necessarily identified by borders and a government.

[2] Based on all measures of growth in per capita PPP income in constant prices constructed from the Penn World Tables version 6.1.

[3] However, it is well known that increasing returns are not *necessary* for a positive relationship between market size and economic performance. As we will see in our analytical section, larger markets may entail larger gains from trade and higher income per capita even when the technology exhibits constant returns to scale.

is the result of the design of its borders, which in turn depend upon domestic and international factors.

While economists have remain on the sidelines on this topic, philosophers devoted much energy thinking about country size. Plato, Aristotle and Montesquieu worried that a large polity cannot be run as a democracy. Aristotle wrote in Politics that "experience has shown that it is difficult, if not impossible, for a populous state to be run by good laws". Influenced by Montesquieu, the founding fathers of the United States were preoccupied with the potentially excessive size of the new Federal State. On the other hand, liberal thinkers who in the nineteenth century contributed to defining modern nation-states were concerned that in order to be economically, and therefore politically viable, countries should not be too small. Historians have studied the formation of states and their size and emphasized the role of wars and military technology as an important determinant. In fact, rulers, especially non-democratic ones, have always seen size as a measure of power and tried to expand the size of the territory under their rule. So, while throughout history country size seemed to be a constant preoccupation of philosophers, political scientists and policymakers, economists have largely ignored this subject.

In recent decades the question of borders has risen to the center of attention in international politics. The collapse of the Soviet Union, decolonization, and the break-up of several countries have rapidly increased the number of independent polities. In 1946 there were 76 independent countries, in 2002 there were 193.[4] East Timor was the latest new independent country at the time of this writing.

In this paper, we explore the relatively small recent economics literature dealing with the size of countries and its effect on economic growth. In particular we ask several questions: does size matter for economic success, and if so why and through which channels? What forces lead to changes in the organization of borders, or to put it differently what determines the evolution of the size of countries? Obviously the second question is very broad. Here we focus specifically a narrower version of this question, namely how economic factors, especially the trade regime, influence size.[5]

This paper is organized as follows. Section 2 discusses a general framework for thinking in economic terms about the optimal and the equilibrium

[4] These include the 191 member states of the United Nations, plus the Vatican and Taiwan.

[5] For a broader discussion see Alesina and Spolaore (2003).

size of countries, providing a formal model that focuses on the effect of size on income levels and growth, with special emphasis on the role of trade. Section 3 reviews the empirical evidence on these issues and provides updated and new results. Section 4 briefly explores how the relationship between country size, international trade and growth have played out historically. The last section highlights questions for future research.

2 Size, Openness and Growth: Theory

2.1 The costs and benefits of size

We think of the equilibrium size of countries as emerging from the trade-off between the benefit of size and the costs of preference heterogeneity in the population, an approach followed by Alesina and Spolaore (1997, 2003) and Alesina, Spolaore and Wacziarg (2000).

2.1.1 The Benefits of Size

The main benefits from size in terms of population are the following:

1) There are economies of scale in the production of public goods. The per capita cost of many public goods is lower in larger countries, where more taxpayers pay for them. Think, for instance, of defense, a monetary and financial system, a judicial system, infrastructure for communications, police and crime prevention, public health, embassies, national parks, etc. In many cases, part of the cost of public goods is independent of the number of users or taxpayers, or grows less than proportionally, so that the per capita costs of many public goods is declining with the number of taxpayers. Alesina and Wacziarg (1998) documented that the share of government spending over GDP is decreasing in population; that is, smaller countries have larger governments.

2) A larger country (both in terms of population and national product) is less subject to foreign aggression. Thus, safety is a public good that increases with country size. Also, and related to the size of government argument above, smaller countries may have to spend proportionally more for defense than larger countries given economies of scale in defense spending. Empirically, the relationship between country size and share of spending of defense is affected by the fact that small countries can enter into military alliances, but in general, size brings about more safety. Note that if a small country enters into a military alliance with a larger one, the latter may

provide defense, but it may extract some form of compensation, direct or indirect, from the smaller partner. In this sense, even allowing for military alliances, being large is an advantage.

3) Larger countries can better internalize cross-regional externalities by centralizing the provision of those public goods that involve strong externalities.[6]

4) Larger countries are better able to provide insurance to regions affected by imperfectly correlated shocks. Consider Catalonia, for instance. If this region experiences a recession worse than the Spanish average, it receives fiscal and other transfers, on net, from the rest of the country. Obviously, the reverse holds as well. When Catalonia does better than average, it becomes a net provider of transfers to other Spanish regions. If Catalonia, instead, were independent, it would have a more pronounced business cycle because it would not receive help during especially bad recessions, and would not have to provide for others in case of exceptional booms.[7]

5) Larger countries can build redistributive schemes from richer to poorer regions, therefore achieving distributions of after tax income which would not be available to individual regions acting independently. This is why poorer than average regions would want to form larger countries inclusive of richer regions, while the latter may prefer independence.[8]

6). Finally, the role of market size is the issue on which we focus most in this article. Adam Smith (1776) already had the intuition that the extent of the market creates a limit on specialization. More recently, a well established literature from Romer (1986), Lucas (1988) to Grossman and Helpman (1991) has emphasized the benefits of scale in light of positive externalities in the accumulation of human capital and the transmission of knowledge, or in light of increasing returns to scale embedded in technology or knowledge creation.[9] Murphy, Shleifer and Vishny (1987) focused instead

[6] See Alesina and Wacziarg (1999) for a discussion of this point in the context of Europe. For example, fisheries policy has been centralized in Europe because if each country decided on its own fishing policy, the result would be overfishing and resource depletion. For some policies, such as policies to limit global warming, centralization at the world level might be justified.

[7] Obviously, this argument relies on an assumption that international capital markets are imperfect, so that independenct countries cannot fully self-insure..

[8] See Bolton and Roland (1997) for a theoretical treatment of this point.

[9] A recent critique of some this class of models is due to Jones (1995b). Specifically, Jones pointed out that endogenous growth models generally imply that growth rates should increase with the stock of knowledge. Yet growth rates have been relatively stable or

on the benefits of size in models of "take-off" or "big push" of industrialization, where the take-off phase is characterized by a transition from a slow growth, constant returns to scale technology to an endogenous growth, increasing returns to scale technology. Finally, several papers have stressed the pro-competitive effects of a larger market size: size enhances growth by raising the intensity of product market competition.[10] In these various models, size represents the stock of individuals, purchasing power and income that interact in the market. This market may or may not coincide with the political size of a country as defined by its borders. It does coincide with it if a country is completely autarkic, i.e. does not engage in exchanges of goods or factors of production with the rest of the world. On the contrary, market size and country size are uncorrelated in a world of complete free trade. So in models with increasing returns to scale, market size depends both on country size and on trade openness.

In theory, with no obstacle to the cross-border circulation of factors of productions, goods and ideas, country size should be, at least through the channel of market size, irrelevant for economic success. Thus, in a world of free trade, redrawing borders should have no effect on economic efficiency and productivity. However, a vast literature has convincingly shown that even in the absence of explicit trade policy barriers, crossing borders is indeed costly, so that economic interactions within a country are much easier and denser than across borders. This is true both for trade in goods and financial assets.[11] What explains this border effect, even in the absence of explicit policy barriers, is not completely clear.[12] Whatever the source of the border effect, however, the correlation between the "political size" of a country and its market size does not totally disappear even in the absence of policy-induced trade barriers. Still, one would expect that the correlation between size and economic success is mediated by the trade regime. In a regime of free trade, small countries can prosper, while in a world of trade barriers, being large is much more important for economic prosperity, measured for instance by income per capita.

declining in advanced industrial economies, while the stock of knowledge has increased rapidly. In section 3, we review and discuss this critique in much detail.

[10] See Aghion and Howitt (1998) and Aghion et al. (2002).

[11] On trade see McCallum (1985), Helliwell (1998). For the role of geographical factors in financial flows, see Portes and Rey (1999). For a theoretical discussion of transportation costs across borders and their effects on market integration, see Obstfeld and Rogoff (2000).

[12] A recent literature prompted by Rose (2000) argues that not having the same currency creates large trade barriers. For a review of the evidence see Alesina, Barro and Tenreyro (2002). Other explanatory factors include different languages, different legal standards, difficulties in enforcing contracts across political borders, etc.

2.1.2 The Costs of Size

If size only had benefits, then the world should be organized as a single political entity. This is not the case. Why? As countries become larger and larger, administrative and congestion costs may overcome the benefits of size pointed out above. However, these types of costs become binding only for very large countries and they are not likely to be relevant determinants of the existing countries, many of which are quite small. As we noted above, the median country size is less than six million inhabitants.

A much more important constraint on the feasible size of countries lies in the heterogeneity of individuals' preferences. Being part of the same country implies sharing public goods and policies in ways that cannot satisfy everybody's preferences. It is true that certain policy prerogatives can be delegated to subnational levels of government through decentralization, but some policies have to be national.[13] Think for instance of defense and foreign policy, monetary policy, redistribution between regions, the legal system, etc.

The costs of heterogeneity in the population have been well documented, especially for the case in which ethnolinguistic fragmentation is used a as proxy for heterogeneity in preferences. Easterly and Levine (1997), La Porta Lopez de Silanes, Shleifer and Vishny (1999) and Alesina et al. (2003) showed that ethnolinguistic fractionalization is inversely related to economic success and various measure of quality of government, economic freedom and democracy.[14] Easterly and Levine (1997), in particular, argued that ethnic fractionalization in Africa, partly induced by absurd borders left by colonizers, is largely responsible for the economic failures of this continent. There is indeed a sense in which African borders are "wrong", not so much because there are too many or too few countries in Africa, but because borders cut across ethnic lines in often inefficient ways.[15]

We can think of trade openness as shifting the trade-off between the costs and benefits of size. As international markets become more open, the

[13] In fact, the recent move towards regional decentralization in many countries can be partly viewed as a response of the political system to increasing pressures towards separatism. See Bardhan (2002) for an excellent discussion of this point, and De Figueiredo and Weingast (2002) for a formal treatment. Also, for an excellent review of the literature on federalism, see Oates (1999).

[14] A large literature provides results along the same lines for localities within the United States. For example, see Alesina, Baqir and Easterly (1999). Related to this, Alesina and La Ferrara (2000, 2002) show that measure related to social capital are lower in more heterogeneous communities in the US. Alesina Baqir and Hoxby (2004) show how local political jurisdictions in the US are smaller in more radially heterogeneous areas.

[15] On this point see in particular Herbst (2000).

benefits of size decline relative to the costs of heterogeneity, thus the optimal size of a country declines with trade openness. Or, to put it differently, small and relatively more homogeneous countries can prosper in a world of free trade. With trade restrictions, instead, heterogeneous individuals have to share a larger polity to be economically viable. Incidentally, above and beyond the income effect, this may reduce their utility if preference homogeneity is valued in a polity. While in this paper we focus on preference heterogeneity rather than income heterogeneity, the latter plays a key role as well, a point raised by Bolton and Roland (1997). Poor regions would like to join rich regions in order to maintain redistributive flows, while richer regions may prefer to be alone. There is a limit to how much poor regions can extract due to a non-secession constraint, which is binding for the richer regions. Empirically, often more racially fragmented countries also have a more unequal distribution of income. That is, certain ethnic group are often much poorer than others and economic success and opportunities are associated with belonging to certain groups and not others. These are situations with the highest potential for political instability and violence.

2.2 A Model of Size, Trade and Growth

In this section we will present a simple model linking country size, international trade and economic growth. The model builds upon Alesina and Spolaore (1997, 2003), Alesina, Spolaore and Wacziarg (2000) and Spolaore and Wacziarg (2002).

2.2.1 Production and Trade

Consider a world in which individuals are located on a segment $[0, 1]$. The world population is normalized to 1. Each individual living at location $i \in [0, 1]$ has the following utility function:

$$\int_0^\infty \frac{C_{it}^{1-\sigma} - 1}{1 - \sigma} \, e^{-\rho t} dt \tag{1}$$

where $C_i(t)$ denotes consumption at time t, with $\sigma > 0$ and $\rho > 0$. Let $K_i(t)$ and $L_i(t)$ denote aggregate capital and labor at location i at time t. Both inputs are supplied inelastically and are not mobile. At each location i a specific intermediate input $X_i(t)$ is produced using the location-specific capital according to the linear production function:

$$X_i(t) = K_i(t) \tag{2}$$

Each location i produces $Y_i(t)$ units of the same final good $Y(t)$, according to the production function:

$$Y_i(t) = A\left(\int_0^1 X_{ij}^{\alpha}(t)dj\right)L_i^{1-\alpha}(t) \tag{3}$$

with $0 < \alpha < 1$. $X_{ij}(t)$ denotes the amount of intermediate input j used in location i at time t, and A captures total factor productivity. Intermediate inputs can be traded across different locations in perfectly competitive markets by profit-maximizing firms. Locations belong to N different countries. Country 1 includes all locations between 0 and S_1, country 2 includes all locations between S_1 and $S_1 + S_2$, .., country N includes all locations between $\sum_{n=1}^{N-1} S_n$ and 1. Hence, we will say that country 1 has size S_1, country 2 has size $S_2, ...$, country $N-1$ has size S_{N-1}, and country N has size $S_N = 1 - \sum_{n=1}^{N-1} S_n$.

Political borders impose trading costs. In particular, we make the following two assumptions:

A1). There are *no internal barriers* to trade: Intermediate inputs can be traded across locations that belong to the same country at no cost.

A2). There are barriers to international trade: If one unit of an intermediate good produced at a location within country n' is shipped to a location i'' within a different country n'', only $(1 - \beta_{n'n''})$ units of the intermediate good will arrive, where $0 \leq \beta_{n'n''} \leq 1$.

Consider an intermediate good i produced in country n'. Let $D_{in'}(t)$ denote the units of intermediate input i used domestically (i.e., either at location i or at another location within country n'). Let $F_{in''}(t)$ denote the units of input i shipped to a location within a different country $n'' \neq n'$. By assumption, only $(1 - \beta_{n'n''})F_{in''}(t)$ units will be used for production. In equilibrium, as intermediate goods markets are assumed to be perfectly competitive, each unit of input i will be sold at a price equal to its marginal product both domestically and internationally. Therefore,

$$P_i(t) = \alpha A D_{in'}^{\alpha-1}(t) = \alpha A(1 - \beta_{n'n''})^{\alpha} F_{in''}^{\alpha-1}(t) \tag{4}$$

where $P_i(t)$ is the market price of input i at time t. From equation (2) it follows that the resource constraint for each input i is:

$$S_{n'}D_{in'}(t) + \sum_{n \neq n'} S_n F_{in}(t) = K_{in'}(t) \tag{5}$$

where $S_{n'}$ is the size of country n', while $K_{in'}(t)$ is the stock of capital in location i (belonging to country n') at time t.

By substituting (4) into (5) we obtain:

$$D_{in'}(t) = \frac{K_{in'}}{S_{n'} + \sum_{n \neq n'} S_n (1 - \beta_{n'n})^{\frac{\alpha}{1-\alpha}}} \tag{6}$$

and:

$$F_{in''}(t) = \frac{(1 - \beta_{n'n''})^{\frac{\alpha}{1-\alpha}} K_{in'}}{S_{n'} + \sum_{n \neq n'} S_n (1 - \beta_{n'n})^{\frac{\alpha}{1-\alpha}}} \tag{7}$$

As one would expect, barriers to trade tend to increase the domestic use of an intermediate output and to discourage international trade.

In the rest of this analysis, for simplicity, we will assume that the barriers to trade are uniform across countries, that is:

A3). $\beta_{i'i''} = \beta$ for all i' and i'' belonging to different countries.[16]

We define:

$$\omega \equiv (1 - \beta)^{\frac{\alpha}{1-\alpha}} \tag{8}$$

This means that the lower the barriers to international trade are, the higher is ω. Hence ω can be interpreted as a measure of "international openness". ω takes on values between 0 and 1. When barriers are prohibitive ($\beta = 1$), $\omega = 0$, which means complete autarchy. By contrast, when there are no barriers to international trade ($\beta = 0$), we have $\omega = 1$, that is, complete openness.

Thus, equations (6) and (7) simplify as follows:

$$D_{in'}(t) = \frac{K_{in'}(t)}{S_{n'} + (1 - S_{n'})\omega} \tag{9}$$

and:

$$F_{in''}(t) = \frac{\omega K_{in'}(t)}{S_{n'} + (1 - S_{n'})\omega} \tag{10}$$

[16] For an analysis in which barriers are different across countries and are an endogenous function of size, see Spolaore and Wacziarg (2002).

2.2.2 Capital accumulation and growth

In each location i consumers' net household assets are identical to the stock of capital $K_{in'}(t)$. Since each unit of capital yields one unit of intermediate input i, the net return to capital is equal to the market price of intermediate input P_{it} (for simplicity, we assume no depreciation). From intertemporal optimization we have the following standard Euler equation:

$$\frac{dC_{it}}{dt}\frac{1}{C_{it}} = \frac{1}{\sigma}[P_i(t) - \rho] = \frac{1}{\sigma}\{\alpha A[\omega + (1-\omega)S_{n'}]^{1-\alpha}K_{in'}^{\alpha-1}(t) - \rho\} \quad (11)$$

Hence, the steady-state level of capital at each location i of a country of size $S_{n'}$ will be

$$K_{in'}^{ss} = \left(\frac{\alpha A}{\rho}\right)^{\frac{\alpha}{1-\alpha}}[\omega + (1-\omega)S_{n'}] \quad (12)$$

By substituting (12) into (9) and (10), and using (3), we have the following:

Proposition 1

The steady-state level of output per capita in each location i of a country of size $S_{n'}$ is

$$Y_i^{ss} = A^{\frac{1}{1-\alpha}}\left(\frac{\alpha}{\rho}\right)^{\frac{\alpha}{1-\alpha}}[\omega + (1-\omega)S_{n'}] \quad (13)$$

Hence, it follows that:

1) Output per capita in the steady-state is increasing in openness ω. That is:

$$\frac{\partial Y_i^{ss}}{\partial \omega} > 0 \quad (14)$$

2) Output per capita is increasing in country size $S_{n'}$:

$$\frac{\partial Y_i^{ss}}{\partial S_{n'}} > 0 \quad (15)$$

3) The effect of country size $S_{n'}$ is smaller the larger is ω, and the effect of openness is smaller the larger is country size $S_{n'}$. That is:

$$\frac{\partial^2 Y_i^{ss}}{\partial S_{n'}\partial \omega} < 0 \quad (16)$$

The above results show that openness and size have positive effects on economic performance, but i) openness is less important for larger countries and

ii) size matters less in a more open world.[17] In fact, were there no barriers to trade ($\omega = 1$), output would be independent of country size.

Around the steady-state, the growth rate of output can be approximated by:

$$\frac{dY}{dt}\frac{1}{Y} = \xi e^{-\xi}(\ln Y^{ss} - \ln Y(0)) \tag{17}$$

where $\xi \equiv \frac{\rho}{2}\left[(1+\frac{4(1-\alpha)}{\alpha})^{\frac{1}{2}} - 1\right]$ and $Y(0)$ is initial income.[18] Hence, we will also have:

Proposition 2

The growth rate of income per capita around the steady-state is increasing in size, increasing in openness, and decreasing in size times openness.

These results show how the economic benefits of size are decreasing in openness and the economic benefits from openness are decreasing in size. We will test the empirical implications of this model in Section 4.

2.3 The Equilibrium Size of Countries

So far we have taken the number and size of countries as given. However, in the long-run borders do change, and our model suggests that international openness may play a role in this process. As we have seen, country size affects output and growth when barriers to trade are high, while country size is less important in a world of international integration. Hence, the reduction of trade barriers should reduce the incentives to form larger countries. In what follows we will formalize this insight using the framework of country formation developed by Alesina and Spolaore (1997, 2003).[19]

If there were no costs associated with size, world welfare would be maximized by having only one country, which seems rather unrealistic. Following our previous discussion we model the costs of size as the result of heterogeneity of preferences over public policies and public goods, the collection

[17] The result does not depend on the assumption that barriers to trade are uniform across countries. In particular, one can derive analogous results for the case of non uniform barriers. Moreover, analogous results can be obtained when "openness" is defined as trade over output rather than in terms of trade barriers. See Spolaore and Wacziarg (2002).

[18] For a derivation of this result, see Barro and Sala-i-Martin (1995, chapter 2).

[19] The economics literature on the endogenous formation of political borders, while still in its infancy, has been growing substantially in the past few years. An incomplete list of contributions, besides those cited in the text, includes Friedman (1977), Casella and Feinstein (2001), Findlay (1996), and Bolton and Roland (1997).

of which we label "government". We assume that, for each location, there exists an "ideal" type of government. If individuals in location i belong to a country whose government is different from their ideal type (say $j \neq i$), their utility will be reduced by $h\Delta_{ij}$, where Δ_{ij} is the distance between j and i, and h is a parameter that measures "heterogeneity" costs - that is, the costs of being far from the median position in one's country. The distance from the government that give raise to these costs should be interpreted both as a distance in terms of preferences and in terms of location.[20]

On the other hand, in a country of size S_n the fixed costs of government can be spread through a larger population.[21] For example, if the fixed cost of government is G and it is shared equally by all citizens, each individual in a country of size S_n will have to pay G/S_n - which is obviously decreasing in S_n.

We consider the case in which borders are determined to maximize net income minus heterogeneity costs in steady-state.[22] That is, we assume that each individual at location i in a country n of size S_n is interested in maximizing the following steady-state welfare:

$$W_{in} = Y_{in}^{ss} - t_{in} - h\Delta_{in} \tag{18}$$

where Y_{in}^{ss} is steady-state income, given by $A^{\frac{1}{1-\alpha}} \left(\frac{\alpha}{\rho}\right)^{\frac{\alpha}{1-\alpha}} [\omega + (1-\omega)S_{n'}]$, t_{in} denotes taxes of individual i in country n, Δ_{in} is individual i's "distance from the government".

Country n's budget constraint is:

$$\int_{S_{n-1}}^{S_n} t_{in} di = G \tag{19}$$

How are borders going to be determined in equilibrium? First we consider how borders would be determined *efficiently*, that is, when the sum of everybody's welfare $\int_0^1 W_{in} di$ is maximized. First of all, one can immediately see

[20] This assumption is extreme but allows to have only one dimension. For more discussion see Alesina and Spolaore (2003).

[21] Obviously, not all the costs of government are fixed. Some depend positively on size, such as infrastructure spending or transfers. See Alesina and Wacziarg (1998) for an empirical examination of this point using cross-country data.

[22] The analysis could be extended in order to consider the more complex issue of border changes along the transitional dynamics, in which adjustment costs from changing borders would be explicitly modeled. Here we abstract from such issues and focus on borders in steady-state.

that the efficient solution implies countries of equal size. This is due to the assumption that people are distributed uniformly in the segment $[0,1]$.[23] Second, the government should be located "in the middle" of each country, since the median minimizes the sum of distances. When countries are all of equal size (call it $S = 1/N$, where N is the number of countries), and governments are located "in the middle", the average distance from the government is $S/4$. Hence, the sum of everybody's welfare becomes:

$$\int_0^1 W_{in} di = A^{\frac{1}{1-\alpha}} \left(\frac{\alpha}{\rho}\right)^{\frac{\alpha}{1-\alpha}} [\omega + (1-\omega)S] - \frac{G}{S} - h\frac{S}{4} \tag{20}$$

which is maximized by the following "efficient size":[24]

$$S^* = \sqrt{\frac{4G}{h - 4(1-\omega)A^{\frac{1}{1-\alpha}} \left(\frac{\alpha}{\rho}\right)^{\frac{\alpha}{1-\alpha}}}} \tag{21}$$

Hence,we have that the "efficient size" of countries is:

1) Increasing in the fixed cost of public goods provision (G),

2) Decreasing in heterogeneity costs (h),

3) Decreasing in the degree of international openness (ω),

4) Increasing in total factor productivity (A).

Therefore, in our model, if borders are set efficiently, increasing economic integration and globalization should be associated with a breakup of countries.

Should we expect such a breakup to take place if borders are *not* set optimally? For example, what if, more realistically, borders are set by self-interested governments ("Leviathans") who want to maximize their net rents? We can model the equilibrium of those Leviathans by assuming that a) they want to maximize their rents in steady-state, but) they are constrained in their rent maximization, since they must provide a minimum level of welfare to at least a fraction δ of their population (we can interpret this as a "no-insurrection constraint"). Hence, δ measures the degree to which Leviathans are constrained by their subjects' preferences.

[23] For a formal proof, see Alesina and Spolaore (1997; 2003).

[24] Equation (20) abstracts from the fact that the number of countries $N = 1/S$ must be an integer.

If we assume that each individual in a given country must pay the same taxes (that is, if we rule out inter-regional transfers), we can use t to denote taxes per person in a country of size S. Then, a Leviathan's total rents in a country of size N is given by:

$$tS - G \tag{22}$$

where t is chosen in order to satisfy the constraint:

$$W_{in} = Y_i^{ss} - t - h\Delta_i \geq W_0 \tag{23}$$

for a mass of individuals of size δS.

The Leviathan will locate the government in the middle of his country, as the social planner would do, in order to minimize the costs of satisfying (23). Constraint (23) will be binding for the individual at a distance $\delta S/2$ from the government. Hence, we have:

$$t = Y_i^{ss} - \frac{h\delta S}{2} - W_0 \tag{24}$$

By substituting (24) into (22) and maximizing with respect to S we have the following equilibrium size of countries in a world of Leviathans:

$$S^e = \sqrt{\frac{2G}{h\delta - 2(1-\omega)A^{\frac{1}{1-\alpha}}\left(\frac{\alpha}{\rho}\right)^{\frac{\alpha}{1-\alpha}}}} \tag{25}$$

Again, the size of countries is increasing in the economies of scale in the provision of public goods (G) and in the level of total factor productivity(A), while decreasing in heterogeneity costs (h) and openness (ω).

We can note that $S^e = S^*$ when the Leviathans must provide minimum welfare to exactly half of their population, while countries are inefficiently large ($S^e > S^*$) when Leviathans are really dictatorial, that is, they can stay in power without the need to take into account the welfare of a majority of the population. But even in that case, more openness induces smaller countries.

The comparative statics predict that technological progress, in a world of barriers to trade, should be associated with larger countries. This result is intuitively appealing, since technological progress improves the gains from trade, and barriers to international trade increase the importance of domestic trade, and hence a larger domestic market. However, if technological

progress is accompanied by a reduction in trade barriers, the result becomes ambiguous.[25] Moreover, a reduction in trade barriers (more openness) has a *bigger* impact (in absolute value) on the size of countries at *higher* levels of development - that is, the effect of globalization and economic integration on the size of countries is expected to be larger for more developed societies. Formally:

$$\frac{\partial^2 S^e}{\partial \omega \partial A} < 0 \tag{26}$$

Of course, these comparative statics results are based on the highly simplifying assumption that technological progress is exogenous. An interesting extension of the model would be to consider endogenous links between political borders, the degree of international openness, and technological progress.[26]

Alesina and Spolaore (2003) also analyze the case in which borders are chosen by democratic rule (majority voting). They show that in this case one may or may not obtain the efficient solution depending on the availability of credible transfer programs. When the latter are not available, in a fully democratic equilibrium in which no one can prevent border changes decided by majority rule or prevent unilateral secessions, there would be more countries than the efficient number. *A fortiori* the democratically decided number of countries would be larger that the one chosen by a Leviathan for any value of $\delta < 1$. An implication of this analysis is that democratization should lead to secessions. For the purpose of this paper, even in the case of majority rule choice of borders, the comparative statics regarding trade, size and growth are the same as in the efficient case and in the Leviathan case.

2.4 Summing up

In this section we have provided a model in which the benefits of country size go down as international economic integration increases. Conversely, the benefits of trade openness and economic integration are larger, the smaller the size of a country. Secondly, we have argued that economic integration and political disintegration should go hand in hand. As the world economy becomes more integrated, one of the benefits of large countries (the size of

[25] Another element of ambiguity would be introduced if one were to assume that the costs of government G are decreasing in A.

[26] For example, some authors have suggested that technological progress may be higher in a world with more Leviathans who compete with each other (such as Europe before and after the Industrial Revolution) than in a more centralized environment (such as China in the same period). For a recent formalization of these ideas, see Garner (2001).

markets) vanishes. As a result, the trade-off between size and heterogeneity shifts in favor of smaller and more homogeneous countries. This effect tends to be larger in more developed economies. By contrast, technological progress in a world of *high* barriers to trade should be associated with the formation of *larger* countries.

One can also think of the reverse source of causality: small countries have a particularly strong interest in maintaining free trade, since so much of their economy depends upon international markets. In fact, if openness were endogenized., one could extend our model to capture two possible worlds as equilibrium border configurations: a world of large and relatively closed economies, and one of many more smaller and more open economies. Spolaore (1995, 2001) provides explicit models with endogenous openness and multiple equilibria in the number of countries. Spolaore and Wacziarg (2002) also treat openness as an explicitly endogenous variable, and show empirically that larger countries tend to be more closed to trade. Empirically, both directions of causality between country size and trade openness, which are not mutually exclusive, likely coexist. Smaller countries do adopt more open trade policies (and are consequently more open when openness is measures using trade volumes), so that a world of small countries will tend to be more open to trade.[27] Conversely, changes in the average degree of openness in the world (brought forth for example by a reduction in trading costs) should be expected to lead to more secessions and smaller countries, as we will argue extensively below.

3 Size, Openness and Growth: Empirical Evidence

In this section, we review the empirical evidence on trade openness and growth, as well as the empirical evidence on country size and growth. We then argue that the two are fundamentally linked, because both openness and country size determine the extent of the market. Thus, their impact on growth cannot be evaluated separately. Then we estimate a specification for the determination of growth as a function of market size (itself a function of both country size and trade openness), derived directly from the model presented in Section 2. Our estimates, which are consistent with a growing body of evidence on the role of scale for growth, also provide strong support for our specific model. In particular, we show that the costs of smallness can be avoided by being open. In other words, the impact of size on growth

[27] See Alesina and Wacziarg (1998) and Spolaore and Wacziarg (2002) for cross-country empirical evidence on this point.

is decreasing in openness, or, conversely, the impact of openness on growth falls as the size of countries increases. This evidence suggests that the extent of the market is an important channel for the realization of the growth gains from trade.

3.1 Trade and Growth: A Review of the Evidence

The literature on the empirical evidence of trade and growth is vast and a comprehensive survey is beyond the scope of this article. In this subsection, we simply summarize some of the salient results from recent studies in this literature, in order to set the stage for a discussion of the more specific issue of market size and growth.

The fact that openness to trade is associated with higher growth in post-1950 cross-country data was until recently subject to little disagreement.[28] Whether openness is measured by indicators of trade policy openness (tariffs, non tariff barriers, etc.) or by the volume of trade (the ratio of imports plus exports to GDP), numerous studies document this correlation. For example, Edwards (1998) showed that, out of nine indicators of trade policy openness, eight were positively and significantly related to TFP growth in a sample of 93 countries. Dollar (1992) argued that an indicator of openness based on price deviations was positively associated with growth. Ben-David (1993) demonstrated that a sample of countries with open trade regimes displays absolute convergence in per capita income, while a sample of closed countries did not. Finally, in one of the most cited studies in this literature, Sachs and Warner (1995) classified countries using a simple dichotomous indicator of openness, and argued that "closed" countries experienced annual growth rates a full 2 percentage points below "open" countries in the period 1970-1989. They also confirmed Ben David's result: open countries tend to converge, not closed ones.

These studies focused mostly on the correlation between openness and growth, conditional on other growth determinants. In other words, little attention was typically paid to issues of reverse causation. In contrast, a more recent study by Frankel and Romer (1999) focused on trade as a causal determinant of income levels. Using geographic variables as an instrument for openness, they estimated that a 1 percentage point increase in the trade to GDP ratio causes almost a 2 percent increase in the level of per capita in-

[28] The pre-1990 literature was usefully surveyed in Edwards (1993). We will focus instead on salient papers in this literature since 1990.

come.[29] Wacziarg (2001) also addressed issues of endogeneity by estimating a simultaneous equations system where openness affects a series of channel variables which in turn affect growth. Results from this study suggest that a one standard deviation increase in the portion of the trade to GDP ratio attributable to formal trade policy barriers (tariffs, non tariff barriers, etc.) is associated with a 1 percentage point increase in annual growth across countries.

These six studies were recently scrutinized by Rodríguez and Rodrik (2000), who argued that their basic results were sensitive to small changes in specification, or that the measurement of trade policy openness captured other bad policies rather than trade impediments.[30] While it is true that cross-country empirical analysis is fraught with data pitfalls, specification problems and issues of endogeneity, these authors do recognize that it is difficult to find a specification where indicators of openness actually have a negative impact on growth.[31] In other words, they essentially conclude that the range of possible effects is bounded below by zero. One could argue that by the standards of the cross-country growth literature, this is already a huge achievement: it constitutes an important restriction on the range of possible estimates. Moreover, Rodríguez and Rodrik (2000) argue that one of the problems associated with estimating the impact of trade on growth is that protectionism is highly correlated with other growth-reducing policies, such as policies that perpetuate macroeconomic imbalances. This suggests that trade restrictions are one among a "basket" of growth-reducing policies. Since Rodriguez and Rodrik (2000), the literature on trade and growth has proceeded apace. Using a new measure of the volume of trade, Alcalá and Ciccone (2004) revisit the issue of trade and growth, and argue that "in contrast to the marginally significant and non-robust effects of trade on productivity found previously, our estimates are highly significant and robust even when we include institutional quality and geographic factors in the empirical analysis". The difference stems for these authors' use of a

[29] A crucial assumption is that the instrument (constructed as the sum of predicted bilateral trade shares, where only gravity/geographical variables are used as predictors of bilateral trade) be excludable from the growth regression, i.e. that it affects growth only through its impact on trade volumes.

[30] For another critical view of this literature, in particular of the Sachs and Warner (1995) study, see Harrison and Hanson (1999). Pritchett (1996) showed that various measures of policy openness were not highly correlated among themselves, suggesting that relying on any single measure was unlikely to capture the essence of trade policy.

[31] They state that "we know of no credible evidence–at least for the post-1945 period– that suggests that trade restrictions are systematically associated with higher growth rates.", p.317.

measure of "real openness" defined as a US dollar value of import plus export relative to GDP in PPP US dollars, as further detailed below. The same authors argue that their results are robust to controlling for institutional quality, a point disputed by Rodrik, Subramanian and Trebbi (2003). In a within-country context, Wacziarg and Welch (2003) show that episodes of trade liberalization are followed by an average increase in growth on the order of 1 to 1.5 percentage points per annum.

An important drawback of the literature on trade and growth is that it does not generally focus on the channels through which trade openness affects economic performance.[32] This makes it difficult to assess whether the dynamic effects of trade openness are mediated by the extent of the market. There are many reasons that could explain a positive estimated coefficient in a regression of trade openness (however measured) on growth or income levels. Such effects could stem from better checks on domestic policies, an improved functioning of institutions, technological transmissions that are facilitated by openness to trade, increased foreign direct investment, scale effects of the type discussed in Section 2, traditional comparative advantage-induced static gains from trade, or all of the above. Few studies attempt to discriminate between these various hypotheses. Hence, while there is a general sense that trade openness increases growth and income levels, and while this creates a presumption that market size may be important, the accumulated evidence on trade and growth does not directly answer the question of whether it is market size that is good for growth, as opposed to some other aspect of openness.

3.2 Country Size and Growth: A Review of the Evidence

We now turn to the empirical evidence on the effects of country size on economic performance. There is a vast microeconometric literature on estimating the returns to scale in economic activities and how they relate to firm or industry productivity. This literature is beyond the scope of this paper, but a general sense is that, at least in some manufacturing sectors or industries, scale effects are present. It may therefore come as a surprise that the conventional wisdom seems to be that scale effects are not easily detected at the aggregate (country) level. The macroeconomic literature on country size and growth is much smaller than the microeconometric literature, but a common claim is that the size of countries does not matter for

[32] An exception is Wacziarg (2001). Alcala and Ciccone (2004) also examine whether the effect of openness works through labor productivity or capital accumulation (in its various forms).

economic growth, either in a time-series context for individual economies, or in a cross-country context.

In a time-series context, Jones (1995a, 1995b) made a simple point. Several endogenous growth models predict that the rate of long-run growth of an economy is directly proportional to the number of researchers, itself a function of population size.[33] Hence, as the population of the United States increased (and in particular the number of scientists and researchers), so should have growth. Yet while the number of researchers exploded, rates of growth in industrial countries have been roughly constant since the 1870s. This simple empirical fact created difficulties for first-generation endogenous growth models. In particular, it was taken as indicative of the absence of scale effects in long-run growth. However, while it contributed to the conventional wisdom that scale is unrelated to aggregate growth, this finding in no way precludes the existence of scale effects when it comes to income levels, which is the focus both of the theory presented in Section 2 and of our empirical estimates presented below.[34] Hence, Jones's objection applies neither to our theory nor to our evidence. Several recent theoretical papers have sought to extend and preserve the endogenous growth paradigm while eliminating scale effects on growth. See for instance Young (1998), Howitt (1999) and Ha and Howitt (2004).

In a cross-country context, some of the most systematic empirical tests of the scale implications of endogenous growth models appeared in Backus, Kehoe and Kehoe (1992). They showed empirically, in a specification where scale was defined as the size of total GDP, that scale and aggregate growth were largely unrelated. In their baseline regression of growth on the log of total GDP, the slope coefficient was positive but statistically insignificant.[35]

[33] As suggested by Jones (1999), such models include Romer (1990), Grossman and Helpman (1991) and Aghion and Howitt (1992).

[34] Scale effects in our theory come purely from the border effect - namely the fact that it is more costly (in the iceberg cost sense) to conduct trade across borders than within. This allows us to combine scale effects with a neoclassical model of growth. Our theory has standard neoclassical implications as far as transitional growth is concerned. Thus, scale may affect growth in the transition to the steady-state, since it is a determinant of steady-state income *levels*. But scale has no impact on long-run growth, which is exogenous in our model.

[35] According to the authors, this univariate regression implies that "a hundredfold increase in total GDP is associated with an increase in per capita growth of 0.85". One could argue that this is a sizeable effect, but the t-statistic on the slope coefficient is only 1.64 and the regression contains no other control variables. In a multivariate setting, the authors show that when "standard" growth regressors (but *not* trade openness) are controlled for, the coefficient estimate on total GDP remains essentially identical, but the

Moreover, the number of scientists per countries was not found to be a significant predictor of growth, and the scale of inputs into the human accumulation process (meant to capture the extent of human capital spillovers) similarly did not help predict aggregate growth. The authors also showed that scale effects were present in the data when confining attention to the manufacturing sector (i.e. regressing manufacturing growth on total manufacturing output), and suggest that this is consistent with microeconometric studies, which typically focus on manufacturing. But the set of regressions relating to the aggregate economy is often cited as evidence that there are no effects of scale on growth at the country level.

A major problem with this approach is that variables defined at the national level may be poor proxies for the total scale of the economy, the extent of R&D activities or the importance of human capital externalities. Scale effects do not stop at the borders of countries. Since small countries adopt more open trade policies, and likely also import more technologies, a coefficient on size in a regression of growth on size that omits openness is going to be biased towards zero.[36] The authors do recognize (and show empirically) that imports of specialized inputs to production can lead to faster growth. They also mention that "by importing specialized inputs, a small country can grow as fast as a larger one". But they do not empirically examine variations in the degree of openness of an economy and how it might impact the effect of size on growth.[37] In other words, they examine separately whether country size on the one hand, and imports of specialized inputs on the other, affect growth. We propose instead to examine openness and country size jointly as determinants of market size and thus growth.

t-statistic falls considerably.

[36] See Alesina and Wacziarg (1998) and Spolaore and Wacziarg (2002) for empirical evidence that small countries tend to be more open to trade, when trade openness is measures by the trade to GDP ratio. Perhaps more surprisingly, such a relationship also holds when openness is measured by average weighted tariffs, i.e. by a direct measure of trade policy restrictiveness.

[37] Another shortcoming of the literature linking economic growth to country size is its failure to examine whether size might have different effects on growth at different levels of development. Growth may have different sources at different stages of development, and country size may affect these sources differently. For instance, scale effects may be more present in the increasing returns, endogenous growth phase that characterizes advanced industrialized countries, and have a smaller effect in the capital deepening phase that perhaps characterizes less advanced economies.

3.3 Summing up

The literature on trade and growth indicates that trade openness has favorable effects on growth and income levels, but for the most part does not inform us as to whether these effects are attributable to the extent of the market, or to other channels. The literature on scale and growth typically considers measures of scale that have to do with domestic market size (i.e. the size of a country or a national economy), and generally fails to consider that openness can substitute for a large domestic market. In what follows, we bring these literatures together to focus on the impact of market size on growth.

3.4 Trade, Size and Growth in a Cross-Section of Countries

In this subsection, we bring Propositions 1 and 2 of Section 2 to the data. If small countries tend to be more open to trade, and if trade openness is positively related to growth, then a regression of growth on country size that excludes openness will understate the effect of scale. Moreover, our theory suggests that the effects of size become less important as an economy becomes more open, i.e. the coefficient on an interaction term between openness and country size is predicted to be negative. Ades and Glaeser (1999), Alesina, Spolaore and Wacziarg (2000) and Spolaore and Wacziarg (2002) have examined how country size and openness interact in growth regressions, and have confirmed the pattern of coefficients on openness, country size and their interaction predicted by our theory. In this section, we update and expand upon these results. We focus on growth specifications of the form:

$$\begin{aligned} \log \frac{y_{it}}{y_{it-\tau}} &= \beta_0 + \beta_1 \log y_{it-\tau} + \beta_2 \log S_{it} + \beta_3 O_{it} + \beta_4 O_{it} \times \log S_{it} \\ &\quad + \beta_5' Z_{it} + \varepsilon_{it} \end{aligned} \tag{26}$$

where y_{it} denotes per capita income in country i at time t, S_{it} is a measure of country size, O_{it} is a measure of openness, and Z_{it} is a vector of control variables. In this specification, the parameter estimates on openness, country size and their interaction will be our main focus. In the context of the theory presented in Section 2, these variables as well as the Z_{it} variables are to be interpreted as determinants of the steady-state *level* of per capita income.[38]

[38] Alesina, Spolaore and Wacziarg (2000) present direct evidence on the effects of market size based on levels regressions where initial income does not appear on the right hand

3.4.1 Descriptive Statistics

Tables 1 through 3 display summary statistics for our main variables of interest, averaged over the period 1960-2000. The data on openness, investment rates, growth and income levels, government consumption, and population come from release 6.1 of the Penn World Tables (Heston, Summers and Aten, 2002), which updates their panel of PPP-comparable data to the year 2000. The rest of the data we use in this paper comes from Barro and Lee (1994, subsequently updated to 2000) or from the CIA (2002). Country size is measured by the log of total GDP or by the log of total population, in order to capture both economic size and demographic size. Throughout, we define trade openness in two ways: as the ratio of imports plus exports in current prices to GDP in current prices, and as the ratio of imports plus exports in exchange rate US$ to GDP in PPP US$. We label the first variable "nominal openness" and the second one "real openness".

Recently, Alcalá and Ciccone (2003, 2004) have criticized the widespread use of the first measure, have advocated the use of the second, finding that the latter leads to more robust effects of openness on growth. The key difference between the two measure stems from the treatment of non tradable goods. Suppose that trade openness raises productivity, but does so more in the tradable than in the nontradable sector (a plausible assumption). This will lead to a rise in the relative price of nontradables, and a fall in conventionally measured openness under the assumptions that the demand for nontradables is relatively inelastic, as it may raise the denominator of the conventional measure of openness more than the numerator. So one may observe trade-induced productivity increases going hand in hand with a decline in conventional measures of openness. "Real openness" will address the problem, since the denominator now corrects for international differences in the price of nontradable goods. We show results based on both measures, in order to simultaneously address Alcalá and Ciccone's points and to allow comparability with past results.

Table 2 reveals that both measures of openness are closely related, with a correlation of 0.87. While high, this correlation justifies examining differences in results obtained using each measure. The correlation between our two measures of country size is also high, equal to 0.85. The correlation between openness and country size is negative, whatever the measures

side. These regressions were consistent with the predictions of the theory presented in Section 2. We have repeated these levels regressions using the new cross-country data that extends to 1999, with little changes in the results.

of openness and size, and in three out of four cases is of a magnitude between 0.33 and 0.54, confirming past results that small countries are more open, and suggesting that an omission of openness in a regression of growth on country size would understate the effect of size. Finally, while the simple correlation between growth and size is 0.33 when size is measured by the log of total GDP, and the correlation between openness and growth is equal to 0.21 or 0.33 (when openness is measured in current or "real terms" respectively).

Preliminary evidence on Propositions 2 and 3 can be gleaned from conditional correlations displayed in Table 3. This table presents correlations of openness and growth conditional on country size being greater or lower than the sample median, and correlations of country size and growth conditional on openness being greater or lower than the sample median. For the sake of illustration, let us focus on the log of population as a measure of size and on current openness as a measure of openness (the results are qualitatively unchanged when using the other measures). The correlation between openness and growth is 0.51 for small countries (those smaller than 6.7 million inhabitants), and only 0.10 for large countries. Similarly, the correlation between country size and growth is 0.11 for open countries, and 0.43 for closed ones. This provides suggestive evidence that openness and country size are substitutes, and that the correlation between size and growth falls with the level of openness. To fully evaluate this claim, we now turn to panel data growth regressions.

3.4.2 Growth, Openness and Size: Panel Regressions

Tables 4 through 6 present Seemingly Unrelated Regression (SUR) estimates of regressions of growth on openness, country size and their interaction, as well as additional controls. The SUR estimator amounts to a flexible form of the random-effects panel estimator, which allows for different covariances of the error term across time periods.[39] Its use in cross-country work is now widespread (see for example Barro and Sala-i-Martin (1995)). The panel consists of four periods of 10 year-averages (1960-69, 1970-79, 1980-89 and 1990-99), and up to 113 countries. The estimation procedure is to formulate one equation per decade, constrain the coefficients to equality across periods,

[39] In contrast, the random-effects estimator imposes that the covariance between the error terms at time t and time t+1 be equal to the covariance between the error terms at time t+1 and time t+2.

and run SUR on the resulting system of equations.[40]

Table 4 present estimation results when the measure of country size is the log of population and the measure of openness involves variables in current prices. In all specifications, the parameter estimates on our three variables of interest (openness, country size and their interaction) are of the predicted sign and all are significant at the 5% level (and often at the 1% level). This holds whether we enter these variables alone (column 1), whether we control for initial income (column 2), whether we control for a long list of common growth regressors (column 3) and whether we include time specific effects in addition to all the controls (column 4). Moreover, Table 5 shows that the results change little when size is measured by the log of total GDP, although the level of significance is reduced somewhat in the specifications that include many control variables. Finally, Table 6 shows that using "real openness" does not modify the overall pattern of coefficients. In fact our results are generally stronger (in the sense of the estimated coefficients being larger in magnitude) when using this measure of openness. Similar estimates in Alcalá and Ciccone (2003, written after first draft of this paper) lend further support to our results. They show how controlling for a host of additional variables including institutional quality does not change the nature of these results and that the use of "real openness" leads to coefficients that are larger and more robust than when using "nominal openness".

3.5 Endogeneity of Openness: 3SLS estimates

Openness, especially when defined as the volume of trade divided by GDP (however deflated), may be an endogenous variable in growth regressions. As described above, in an important paper Frankel and Romer (1999) have developed a innovative instrument to deal with potential endogeneity bias in growth and income level regressions. We use our own set of geographic variables as well as Frankel and Romer's instrument to address potential endogeneity. Our panel data IV estimator relies on a three stage least squares (3SLS) procedure. This estimator achieves consistency through instrumentation, and efficiency through the estimation of cross-period error covariance terms. Table 7 presents parameter estimates of our basic specification when the list of instruments includes geographic variables, namely dummy variables for small countries, islands, small islands, landlocked countries and the

[40] We use the term constrained SUR to refer to the fact that slope coefficients are constrained to equality across periods.

interaction term between each of these measures and country size.[41] Again, the results are consistent with previous observations, namely the pattern of coefficients suggested by theory is maintained. In the specification with all the controls, the statistical significance of the coefficients of interest is reduced slightly when real openness is used instead of current openness (Table 9), though all remain significant at the 10% level. The signs of the main coefficients of interest are maintained and the magnitude of the openness coefficient is raised in all specifications, confirming the results of Alcalá and Ciccone (2003, 2004).[42]

Finally, Table 11 show the same results using the geography-based instrument from Frankel and Romer (1999), as well as the interaction term between this variable and country size. In all specifications, the signs and basic magnitudes of the coefficients of interest are unchanged (although when openness is entered in "real" terms, the estimates cease to be statistically significant at the 5% level). Spolaore and Wacziarg (2002) present more evidence on this type of regression, by treating estimating a simultaneous equations system for the endogenous determination of openness and growth jointly. Their results are similar in spirit to those presented here.

Alcalá and Ciccone (2003) present further results along the same lines, and also explicitly consider institutional quality variables in addition to performing further sensitivity tests. Their empirical results are very consistent with ours, suggesting that predictions on the relationship between trade, country size and growth implied by our model are confirmed when the "real" measure of openness is used instead of nominal openness.

3.5.1 Magnitudes and Summary

While the pattern of signs and the statistical significance of the estimates presented above is consistent with our theory, the effects could still be small in magnitude. However, they are not. To illustrate the extent of the substitutability between country size and openness, let us choose a baseline

[41] This is the same list of instruments as was used in Alesina, Spolaore and Wacziarg (2000). Unsing Hausman tests, this paper showed that this set of instruments was statistically excludable from the growth regression, and first stage F-tests suggested that they were closely related to openness and the interaction term.

[42] Tables 8 and 10 present F-tests for the first stage of the 3SLS procedure. They test the joint significant of the instruments in regressions of the endogenous variables (openness and its interaction with country size) on all the exogenous variables in the system. These F-tests show that our instruments are closely related to the variables they are instrumenting for, limiting the potential for weak instruments, especially in the specifications with many controls.

regression. Consider column 4 of Table 4 - this involves using the log of population as a measure of size, current openness as a measure of openness, and a wide range of controls in the growth regression. Consider a country with the median size. In our sample, when the data on log population are averaged over the period 1960-2000, the median country turns out to be Mali (where the log of population is 8.802 - this corresponds to an average population of 6.6 million over the sample period). The effect of a one standard deviation change in openness (a change of 42 percentage points) on Mali's annual growth is estimated to be 0.419 percentage points. In contrast, in the smallest country in our sample (the Seychelles), the same change in openness would translate into an increase in growth of 1.40 percentage points. The effect of a marginal increase in openness on growth becomes zero when the log of population is equal to 10.8, which is the size of France (in our sample, only 13 countries are larger).

Conversely, the effect of size at the median level of openness, which is attained by South Korea (with a trade to GDP ratio of 54% on average between 1960 and 1999), the effect of multiplying the country's size by 10 would be to raise annual growth by 0.33 percentage points. In contrast, a relatively closed country such as Argentina (with a trade to GDP ratio of 15% on average between 1960 and 1998) would experience an increase in growth of 0.78 percentage points from decupling its population. The effect of size on growth attains zero when openness reaches 82.4% (in our sample, 26 countries had a higher level of average openness over the 1960-1999 period). Using the results obtained with "real" measures of openness the magnitude of our results would typically be even larger.

Whether one "believes" these actual magnitudes or not, the signs and statistical significance of our variables of interest are very robust features of the data and independently confirmed and reinforced by Alcalá and Ciccone (2003). When evaluating the effects of scale on growth, it is essential to view scale as attainable either through a large domestic market, or through trade openness. Ignoring either would lead to underestimating scale effects in income. This section and the literature from which it is inspired has sought to bring together the research on the impact of trade on growth and the research on the impact of economic scale on growth, and in doing so has empirically established a substitutability between openness and country size.

4 Country Size and Trade in History

To what extent the size of countries respond to the economic "incentives" that we discussed above? Is there a sense that in the long-run the size of countries responds to economic forces? Our answer is yes, even though, of course, the determination of borders is driven by a highly complex web of politico-economic forces. The point of this section is simply to highlight the relationship between country size and trade in a brief historical excursion. We certainly we do not aim to discuss the entire history of state formation and their size. For a more extensive discussion we refer the reader to Alesina and Spolaore (2003), and to the voluminous literature cited therein.

4.1 The City-States

The city-states of Italy and the Low Countries of the Renaissance in Europe represent a clear example of a political entity that could prosper even if very small because they were taking advantage of world markets. Free trade was the key to prosperity of these small states. A contemporary observer described Amsterdam as a place were "commerce is absolutely free, absolutely nothing is forbidden to merchants, they have no rule to follow but their own interest. So when an individual seems to do in his own commercial interest something contrary to the state the state turns a blind eye and pretends not to notice".[43] The other reason why city-states could afford to be small is that the state did not provide many public goods, so that not much was lost in terms of tax burden from being small. Thus, the combination of a small states who provided very few public goods and complete freedom of trade allowed for the city state to reach unprecedented level of wealth based on trade.

4.2 The Absolutist Period

The emergence of centralized states from the consolidation of feudal manors was driven by three main forces. One is technological innovations in military technology that increased the benefits of scale in warfare. Secondly, there was a need to enforce property rights and to create markets above and beyond the maritime commerce of the city-states. Finally bellicose rulers needed vast populations in order to extract levies to finance wars and luxurious courts. Territorial expansion and fiscal pressure went hand in hand and city-states could not survive in this changed world. Italian city-states

[43] From Braudel (1992, page 206). Also cited in Alesina and Spolaore (2002).

lost predominance. The Low Countries survived longer because of their role as Atlantic traders. While the small-city states blossomed on trade, as Wilson (1967) writes regarding France "by the second half of the sixteenth century primitive ideas about trade had already given rise to a corpus of legislation ... aimed at national self-sufficiency". Similarly, English policy turned quite protectionist in the early seventeenth century. From the small and open city-states with low taxation, the western world became organized in large countries, pursuing inward looking policies. So economic predominance switched from small open economies with cheap governments to large relatively closed economies with a heavier burden of taxation to service war.

Outside the core of Europe, absolutist regimes were based on heavy taxation raised without the parenthesis of city-states. This is the case, for instance of the Ottoman Empire, but also of India and China. The Ottoman empire for instance, was largely based on extracting rents from its population. In India the level of taxation was extraordinarily high for that period. In the sixteenth century the estimated tax revenue of the central government was about 20% of GNP.

4.3 The Birth of the Modern Nation-State

The nineteenth century marks the birth of the nation-state in modern forms, both in Europe and North America. It also marks the beginning of industrialization and the growth take-off, which likely transformed the relationship between country size and economic performance, raising the importance of scale effects. The liberal philosophers of these times viewed the "optimal size" of a nation-state as emerging from the trade-off between homogeneity of language and culture and the benefit of economic size. In fact, following the work of Adam Smith, they were well aware that with free trade a market economy can easily prosper even without a heavy central government. Nevertheless, the view was that there existed an minimum size that made an economy viable. For instance, certain regions, like Belgium, Ireland and Portugal were considered too small to prosper, but free trade was regarded as a way of allowing even relatively small countries to prosper. Giuseppe Mazzini, an architect of the Italian unification, suggested that the optimal number of states in Europe was 12. His argument was precisely based on the consideration of a trade-off between the economically viable size of country and nationalistic aspiration of various groups. A famous political economy treaty of the time argues that it was "ridiculous" that Belgium and Portugal should be independent because there economies were too small to be

economically viable.[44]

The unification of Germany can in fact be viewed along similar lines. The German nation-state started as a customs union (the Zollverein) which was viewed as necessary to create a sufficiently large market. As Merriman (1996, page 629) notes, before the customs union "German merchants and manufacturers began to object to the discouraging complexity of custom tariffs that created a series of costly hurdles... many businessmen demanded an end to these unnatural impediments faced by neither of their French or British rivals". Clearly market size was a critical determinant of the birth of Germany. The external threat of a war with France was a second one, as emphasized by Riker (1964). The establishment of a common market free of trade barriers was also one of the motivating factor behind the creation of the United States.

4.4 The Colonial Empires

In the period between 1848 and early 1870's the share of international trade in GDP quadrupled in Europe.[45] From 1870 to the First World War trade grew much more slowly despite a drastic reduction of transportation costs, as documented in Estevadeordal, Frantz and Taylor (2003). In fact the extent of the reduction of trade amongst European powers in the half century between 1870 and 1915 is a matter of dispute amongst historians. Bairoch (1989) has probably the most sanguine view on one side of the argument when he writes that the introduction of new large tariff by Germany in 1879 marks the "death" of free trade. While many historians may find this view a bit extreme, it is fairly non controversial that without the sharp reduction in trading costs international trade would have probably greatly suffered in this period, which was certainly associated with an increase in protectionism.

The last two decades of the nineteenth century witnessed the expansion of European (and North American) powers over much of the "less developed" world. One motivation of this expansionary policy was certainly the opening of new markets. As reported by Hobsbawn (1987, p. 67), in 1897 the British Prime Minister told the French ambassador to Britain that "if you [the French] were not such persistent protectionists, you would not find us so keen to annex new territories". Needless to say, the British were just as protectionist as the French and the British navy was heavily used to protect trade routes. Similar considerations apply to the expansionary acquisitions

[44] See Hobsbawn (1987).

[45] See Estevadeordal, Frantz and Taylor (2002) for a more detailed discussion.

of the United States in the late nineteenth and early twentieth centuries, namely Alaska, Hawaii, Samoa, Cuba and the Philippines. At the same time, in response to European protectionism, the United States also turned protectionist in this period.

In summary, from the point of view of the colonizers, Empires were a brilliant solution to the trade-off between size and heterogeneity. Large empire guaranteed large markets, especially necessary when protectionism was on the rise, but at the same time, by not granting citizenship to the inhabitants of the colonies, the problem of having a heterogeneous population with full political rights was reduced.

4.5 Borders in the Interwar Period

Figure 1 shows all the countries created and eliminated in five years periods from 1870 until today.[46] The dip at the beginning of the figures highlights the unification of Germany. This figure shows that in the interwar period after the Treaty of Versailles, borders remained essentially frozen, despite the fact that many nationalistic aspiration had been left unanswered by the peace treaty. In fact, a common view amongst historians is that the Treaty of Versailles vastly mishandled the border issue. Nevertheless, borders remained virtually unchanged, in a period in which free trade collapsed. No decolonization occurred. Amongst the new country creations, at least one, Egypt (independent in 1922) is merely an issue of classification: it was largely independent from Britain, but its status switched from a protectorate to a semi-independent country. Leaving aside the Vatican City, the only other countries created between 1920 and the Second World War were Ireland (1921), Mongolia (1921), Iraq (1932), and Saudi Arabia (1932).

The interwar period was characterized by a collapse of free trade, the emergence of dictatorships, and by a belligerent state of international relationships. The Great Depression completed the gloomy picture and precipitated the rise of protectionism. These are all factors that, according to our analysis, should *not* be associated with the creation of new countries, in fulfillment of nationalistic aspirations. In addition, these elements (lack of democracy, international conflicts, protectionism) would make colonial powers hold on to their empires and repress independent movements. In fact, all the colonial powers were adamant in refusing self-determination of colonies during this period. This combinations of events, protectionism and

[46] This figure exclude Sub-Saharan Africa, given the difficulty of identifying borders before the colonization period.

maintenance of large countries and empire, stands in sharp contrast with what happened in the aftermath of the Second World War.

4.6 Borders in the Post-Second World War period

In the fifty years that followed the Second World War, the number of independent countries increased dramatically. There were 74 countries in 1948, 89 in 1950, and 193 in 2001. The world now comprises a large number of relatively small countries: in 1995, 87 of the countries in the world had a population of less than 5 million, 58 had a population of less than 2.5 million, and 35 less than 500 thousands. In the same 50 years, the share of international trade in world GDP increased dramatically. The volume of imports and exports in a sample of about 60 countries has risen by about 40 percent.

We should stress that the increase in international trade in the last half-century, as documented in Figure 2, is not the simple result of an accounting illusion. In fact, if two countries were to split, their resulting trade to GDP ratios would automatically increase, as former domestic trade is now counted as international trade. But Figure 2 only features the average trade to GDP ratio for a set of countries *whose borders did not change since 1870.* Furthermore, Figure 3 uses average tariffs on foreign trade for a selection of countries with available data, a more direct reflection of trade policy, to display a similar historical pattern. Obviously, such policy measures are not subject to the accounting illusion either.

The correlation between the number of countries and trade liberalization is captured by Figure 4 and 5 which plot the detrended number of independent countries against the detrended trade to GDP ratio, including Sub-Saharan Africa from 1905 onward, and without it from 1870 to 1905.[47] In both cases the correlation is very strong. Since both variables are detrended, this positive correlation is not simply due to the fact that both variables increase over time. In Figure 2, note the sharp drop in the number of countries between 1870 and 1871, due to the unification of Germany. While 1871 is on the "regression line", 1870 is well above it, suggesting that there were "too many" countries before the German unification, relative to the average level of openness.

Not only have the recent decades witnessed an increase in the number of countries, but many regions have demanded and often obtained more

[47] All these figures are take from Alesina, Spolaore and Wacziarg (2000).

autonomy from their central governments. In fact, decentralization is very popular around the world. The case of Québec is especially interesting. The push for independence in Québec was revamped by the implementation of the North American Free Trade Agreement (NAFTA). The freer trade in North America, the easier it would be for a relatively small country, like Québec, to prosper. As we discussed above, at least for Canada, national borders still matter, so that trade among Canadian provinces is much easier than trade between Canadian provinces and US states. As shown by McCallum (1988), two distant Canadian provinces trade much more with each other than US states and Canadian provinces bordering each other, even though distance is a strong determinant of trade flows. This implies that there might be a cost for Québec in terms of trade flows if it were to become independent and such arguments were made by the proponents of the "no" in the self-determination referendum of 1996. As the perceived economic costs of secession fall with greater North American economic integration, the likelihood of Québec gaining independence can be expected to increase. In fact, the development of a true free-trade area in North America might reduce these costs and make Québec separatism more attractive.

4.7 The European Union

Fifteen European countries have created a union which has several supranational institutions, such as the Parliament, a Court system, a Commission and a Council of Ministers and have delegated to them substantial policy prerogatives. We have argued that more economic integration should have lead toward political separatism. How does the European Union "fit" into this picture?

First of all, the European Union is not a state, not even a federation since it does not have the critical determinant of what a state is: the monopoly of coercion over its citizens. Thus, the European Union does not satisfy the Weberian notion of what constitutes a "sovereign state". The newly proposed draft Constitution for Europe states clearly in its article 2 that the European Union is indeed a union of independent countries and not a Federal State. Secondly, as economic integration is progressing at the European level, regional separatism is more and more vocal in several member countries of the Union, such as the UK, Spain, Belgium, Italy and even France. So much so, that many have argued that Europe will (and, perhaps should) become a collection of regions (Brittany, the Basque Region, Scotland, Catalonia, Wales, Bavaria, etc.) loosely connected within a European confederation of independent regions. In fact, ethnic and cultural

minorities feel that they would be economically "viable" in the context of a truly European common market, thus they could "safely" separate from the home country. This argument is often mentioned in the press. For an example pertaining to Scotland, see the Financial Times, September 16, 1998: "...the existence of the European Union lowers the cost of independence for small countries by providing them with a free trade area... and by creating a common currency which will relieve the Scots of the need to create one for themselves".

One way of thinking about the EU is as a supranational union of countries that have merged certain functions needed to guarantee the functioning of a common market and take advantage of economies of scale. Whether or not the attribution of responsibilities and policy prerogatives between the EU and the national government is appropriate or not is an intricate subject which is beyond the scope of this paper.[48]

5 Conclusion

This paper has argued that size matters for economic performance and that country size is endogenous and depends on economic factors such as free trade, public goods provision and preference heterogeneity. We have reviewed and extended a recent literature that has discussed country formation and secession in the context of the theory of economic growth. The econometric and historical evidence is broadly consistent with the implications of these models

Much remains to be done. On the theoretical side, we have shown how scale effects could be derived in a simple neoclassical growth model, without appealing to increasing returns technologies, endogenous R&D or human capital spillovers, but simply by appealing to the existence of a border effect driven by trading frictions. However, whether the scale effects that we observe in the data come from the border effect, technology or spillovers remains to be investigated.

The models that we discussed are based on the assumption that heterogeneity within a country has negative effects on average utility. However, heterogeneity may also bring about some benefits. In fact, the gains from trade in our model do stem from a kind of heterogeneity - the production of different intermediate goods by different regions - and this is why a larger country, for given barriers to trade, brings net economic gains through the

[48] For a discussion of this point, see Alesina and Wacziarg (1999).

trade channel. By "heterogeneity" costs here we mean the specific costs associated with disagreements over the basic characteristics of a government (including policies about official languages, religion, etc.). A richer discussion of the pros and cons of heterogeneity is certainly called for.

On the empirical side, debates are still raging. Even the literature on the effect of trade on economic performance is now subject to debates on the nature and extent of this effect. The literature on the effect of country size is even more contentious. Yet the existence of both of these effects is important to the argument that we proposed about the role of trade openness in the endogenous determination of country size. We have shown that a simultaneous consideration of an economy's openness and of its size led to estimating strong effects of both size and openness on growth in a sample of countries since 1960.

Finally, in a broad historical sweep, we have suggested that the types of trade-offs identified by our framework have been at play at various stages in modern history. In a way, current developments provide an ideal setting for observers of country creation. Since the Second World War, increasing globalization has threatened nation-states "from above", while rising regionalism and decentralizing forces have threatened them "from below". The construction of the European Union epitomizes this tension, as a fundamental redrawing of the distribution of political prerogatives is being orchestrated. Powers are being transferred down through decentralization, and up through the European construction. It is likely that if globalization proceeds apace, so will regionalism. If the backlash against globalization succeeds, however, large centralized nation-states could initiate a comeback.

Table 1 - Descriptive Statistics (1960-2000 averages)

	No. Obs.	Mean	Standard Deviation	Minimum	Maximum
Average Annual Growth	104	1.669	1.374	-1.259	5.515
Openness Ratio (Current)	114	64.098	41.871	14.373	322.128
Openness Ratio (Real)	114	37.363	35.376	4.350	244.631
Log per capita GDP 1960	110	7.730	0.889	5.944	9.614
Log total GDP	113	23.905	1.943	19.723	29.165
Log population	114	15.763	1.678	11.019	20.670
Fertility rate	156	4.569	1.797	1.733	7.597
Female human capital	103	1.116	1.067	0.024	4.923
Male human capital	103	1.523	1.225	0.096	5.467
Investment Rate (% GDP)	114	15.653	7.880	2.023	41.252
Government consumption (% GDP)	114	19.869	9.439	4.297	48.635

Table 2 - Pairwise Correlations for the Main Variables of Interest (1960-2000 averages)

	Average Annual Growth	Log total GDP	Log per capita GDP 1960	Log Population	Openness Ratio (current)
Average Annual Growth	1.000				
Log total GDP	0.338	1.000			
Log per capita GDP 1960	0.172	0.436	1.000		
Log population	0.125	0.853	-0.058	1.000	
Openness Ratio (Current)	0.216	-0.334	0.135	-0.537	1.000
Openness Ratio (Real)	0.331	-0.042	0.382	-0.348	0.870

Table 3 - Conditional Correlations – 1960-2000

Variable	Conditioning Statement	Correlation with Growth	Number of Obs.
Openness (current)	Log pop>median=8.807	0.104	54
Openness (current)	Log pop<=median=8.807	0.511	50
Openness (current)	Log GDP> median=16.700	0.301	52
Openness (current)	Log GDP<=median=16.700	0.462	52
Openness (real)	Log pop>median=15.715	0.131	54
Openness (real)	Log pop<=median=15.715	0.579	50
Openness (real)	Log GDP> median=23.607	0.223	52
Openness (real)	Log GDP<=median=23.607	0.474	52
Log population	Openness (current)>median=53.897	0.107	50
Log population	Openness (current)<=median=53.897	0.426	54
Log GDP	Openness (current)>median=53.897	0.324	50
Log GDP	Openness (current)<=median=53.897	0.563	54
Log population	Openness (real)>median=26.025	-0.089	51
Log population	Openness (real)<=median=26.025	0.587	53
Log GDP	Openness (real)>median=26.025	0.137	51
Log GDP	Openness (real)<=median=26.025	0.625	53

Medians computed from individual samples, while correlations are common sample correlations.
Growth: Average annual growth, 1960-2000

Urbanization and Growth[*†]

J. Vernon Henderson

Brown University

August 11, 2004

[*] I thank Diego Puga for very helpful comments on a preliminary draft of this chapter.

[†] Draft chapter prepared for Handbook of Economic Growth, Volume 1, P. Aghion and S. Durlauf (eds.), North Holland.

The study of urbanization and growth focuses on a set of five inter-linked sets of questions. First, why do cities form and why is economic activity so geographically concentrated? In the USA, only 2% of the land area is covered by the urban built environment. This incredible geographic concentration is the central focus of economic geographers. Economists dating from Marshall (1890) have answered the question by saying urban agglomerations are based on technological externalities – the information spill-over benefits in input and output markets of having economic agents in close spatial proximity, where information decay over space is very rapid. In addition the new economic geography develops the idea that close spatial proximity involves pecuniary externalities – reduces the costs of intermediate and final good trade. Agglomeration benefits are specified typically as applying within industries or sets of inter-related industries; there is considerable debate empirically about their application across industries. That issue, as we will see later, is related to the second set of questions.

How do cities interact with each other, at any instant in time? What are the trade patterns across cities in final and intermediate outputs and how does that correspond to the roles of big and small cities? In what ways are cities specialized by either products or functions, and why? How do these patterns of specialization and diversification relate to city labor force compositions and human capital accumulations?

Given the role of cities at a point in time, the third set of questions asks how urban growth intersects with, or even defines national economic growth? The close connection between urban and national economic growth was recognized by Lucas (1988) and inspired by the development of endogenous growth models. To the extent endogenous growth is based on knowledge spillovers and sharing, given the role of close spatial proximity in spillovers, much of the interaction and sharing must occur at the level of individual cities. Given that, there must also be a close connection between economic development and urbanization. How are the two tied together? In addition the stochastic forces that shock production processes, invention, and technological progress must also play out in an urban form. How does that occur?

The fourth set of questions asks how governance, institutions, and public policy affect urbanization, which then in turn affect economic efficiency and growth. Apart from the long standing analysis of provision and financing of local public goods, there are three issues of interest specific to the urbanization process. First, public infrastructure investments in cities are enormous and the internal structure of cities affects not just the resources devoted to urban living such as commuting and congestion costs, but also affects production efficiency – the extent to which information and knowledge spillovers are fully realized and exploited. Second, institutions governing land markets, property rights, local government autonomy, and local financing including local public debt accumulation affect the city formation process, city sizes, and national economic growth. Finally, national government policies

concerning migration, trade policy, national investment in communications and transport infrastructure have profound impacts on the urban system, migration patterns, regional economic development and the like.

The final set of questions has to do with where cities locate and the economic geography of urbanization. In what regions do cities cluster and why are some regions so sparsely populated? What first nature forces of location of natural resources, including rivers and natural harbors drive the location of economic activity? How do transport costs and technological change in transport costs affect the extent to which coastal versus hinterland regions are inhabited? And what is the role of second nature forces and history on location – how does the accumulation of economic activity based on historical market forces affect the current spatial patterns of economic activity?

This handbook chapter reviews evidence on all these questions and then turns to models that focus on aspects of the middle three questions – how do cities interact with each other; what is the relationship among urbanization, urban growth, national economic growth, and economic development; and what is the role of institutions and public policy in shaping urbanization? In terms of the first question on why cities form, there is a splendid handbook paper by Duranton and Puga (2004) reviewing models of the micro-foundations of agglomeration economies and another by Rosenthal and Strange (2004) reviewing empirical evidence on the subject. In terms of the where question, there is little in the way of models that look at the location patterns of individual cities. There are the core-periphery models of economic geography that analyze the allocation of economic activity within a country between a core and periphery region. We will discuss how these models may inform the where question for cities. But they are a topic unto themselves with excellent general handbook coverage in Overman, Venables, and Redding (2001) and coverage specific to regional issues in Ottaviano and Thisse (2004), with a review of empirical evidence in Head and Mayer (2004).

The first section reviews data and empirical evidence on aspects of the five questions. The second presents a simple system of cities model, which illustrates the basic organization of the urban sector and the interaction between economic and urban growth. The model serves as a platform to discuss issues of institutions and policy. In the third section, the model in Section 2 is adapted to analyze rural-urban transformation and urbanization as part of economic development; policy issues for developing countries are analyzed.

1. Facts and Empirical Evidence

This section reviews basic facts and a body of empirical evidence on systems of cities. We start by looking at evidence based primarily on either the world as a whole or on large developed countries.

We look at the evolution of the size distribution of cities, Zipf's Law and related topics. Then we turn to what cities do – evidence on urban specialization and geographic concentration – and where they locate. Finally we turn to evidence that is more specific to the urbanization process in developing countries and issue surrounding that process.

1.1 The Size Distribution of Cities and Its Evolution

Work by Eaton and Eckstein (1997) on France and Japan and by Dobkins and Ioannides (2001) on the USA, with later work by Black and Henderson (2003) and Ioannides and Overman (2003) on the USA, establish some basic facts about urban systems and their development in France, Japan, and the USA over the last century or so. Foremost is that there is a wide relative size distribution of cities in large economies that is stable over time. Big and small cities coexist in equal proportions over long periods of time. Second, within that relative size distribution, individual cities are generally growing in population size over time; and what is considered a big versus small city in absolute size changes over time. Third, while there is entry of new cities and rapid growth and relative decline of cities nearer the bottom of the urban hierarchy, at the top city size rankings are remarkably stable over time. Finally, size distributions of cities within countries, at least at the upper tail are well approximated by a Pareto distribution, with Zipf's Law applying in many cases. Establishing these facts raises a variety of issues and different methodological and technical approaches.

1.1.1 What is a City?

The empirical work in Eaton and Eckstein (1997) and subsequent work typically looks at the decade by decade development of urban systems. In doing so, there are critical choices researchers must make when assembling data. First is to define geographically what consists of the generic term "city". The usual definition is the "metro area", where large metro areas like Chicago comprise over 100 municipalities, or local political units. The idea in defining metro areas is to cover the entire local labor market and all contiguous manufacturing, service and residential activities radiating out from the core city, until activity peters out into farm land or very low density development. A second choice concerns how to accommodate changes in geographic definitions over time. One can use whatever contemporaneous definitions the country census/statistical bureau uses; however metro area definitions only start to be applied after World War II. Another approach is to take current metro area definitions and follow the same geographic areas back in time, focusing on non-agricultural activity.

A third problem concerns how to define "consistently" over time the threshold population size at which an agglomeration becomes a metro area, especially since the economic nature, population density, and spatial development of metro areas have changed so much over the last century. Some authors use an absolute cut-off point (e.g., urban population of 50,000 or more); some use a relative cut-off point (e.g., the minimum size city included in the sample should be .15 mean city size); and others

look at a set number (e.g., 50 or 100) of the largest cities. The relative cut-off point approach is attractive because it attempts to hold constant the area of the relative size distribution which is examined over time, as illustrated below. In presenting evidence on the topics to follow, whatever choices researchers make can strongly affect specific results. Nevertheless there are a variety of findings that are consistent across studies.

1.1.2 Evolution of the Size Distribution

In the research, one focus has been to study the evolution of the size distribution of cities, applying techniques utilized by Quah (1993) in examining cross-country growth patterns. Cities in each decade are divided by relative size into, say, 5-6 discrete categories, with fixed relative size cut-off points for each cell (e.g., < .22 of mean size, .22 to.47 of mean size, ... > 2.2 mean size). A first order Markov process is assumed and a transition matrix calculated. In many cases, stationarity of the matrix over decades can't be rejected, so cell transition probabilities are based on all transitions over time. If M is the transition matrix, i the average rate of entry of new cities in each decade (in a context where in practice there is no exit), Z the (stationary) distribution across cells of entrants (typically concentrated on the lowest cell), and f the steady-state distribution, then

$$f = \left[I - (1-i)\ M \right]^{-1}\ iZ \qquad (1)$$

In the data, relative size distributions are remarkably stable over time and steady-state distributions tend to be close to the most recent distributions. In the studies on the USA, Japan, and France, there is no tendency of distributions to collapse and concentrate in one cell, or for all cities to converge to mean size; nor generally is there a tendency for distributions to become bipolar. Distributions are remarkably stable. I illustrate this based on a world cities analysis (although conceptually distributions may better apply to "countries", within which population is relatively mobile).

Table 1 gives the size distribution of world metro areas over 100,000 population in 2000. Details on the data are available on-line.[1] Note that much of the world's population in cities over 100,000 are in small-medium size metro areas. 56% are in cities under 2 million, while only 17% are in cities over 8 million. Moreover all these cities only account for 62% of the world's urban population; the rest live in cities smaller than 100,000. So overall 73% of the world's urban population lives in cities under 2 million in population. While the popular press may focus on mega-cities, only a small part of the action is there.

Figure 1 plots the relative size distribution of the approximately 1200 metro areas worldwide over 100,000 in 1960 against the relative size distribution of the approximately 1700 metro areas over 200,000

[1] http://www.econ.brown.edu/faculty/henderson/worldcities.html.

in 2000. Relative sizes are actual sizes divided by the world average size in the corresponding year. The 100, 000 versus 200,000 cut-off points for minimum size are relative ones based on a constant minimum to mean size ratio. Using an absolute cut-off point in this case has little impact on the figure. The figure plots the histogram for 20 cells on a log scale. The 1960 versus 2000 distributions for all cities worldwide (Figure 1a) and for those in developing and transition economies (Figure 1b) almost perfectly overlap. Relative size distributions are stable. Similarly performing transition analysis on world cities for 1960-1970-1980-1990-2000 and calculating the steady state distributions, starting with 5 cells and shares in each of .351, .299, .151, .100, .0991 in 1960, as we move up the urban hierarchy the steady state shares are .324, .299, .138, .122, and .117. Again, this indicates rock stablility of distributions over time.

An alternative way of expressing this is to calculate spatial Gini's (Krugman, 1991b). For a spatial Gini rank all cities from smallest to largest on the x-axis and on the y-axis calculate their Lorenz curve -- the cumulative share of total sample population. The Gini is the share of the area below the 45° line, between that line and the Lorenz curve. The greater the Gini, the "less equal" the size distribution. The world Gini in 1960 versus 2000 is .59 versus .56 for developed countries, .57 versus .56 for less developed countries, and .52 versus .45 for transition economies as noted in Table 2 columns 1-4. Table 2 also lists Gini's for 1960 versus 2000 for 14 countries. Note apart from transition economies (and Nigeria), the lack of change; and note also that transition economies are distinctly "more equal". Transition economies have forestalled the growth of mega-cities through explicit and implicit (housing availability in cities) migration restrictions, as discussed in Section 3.3.1.

A second finding in examining city size distributions is that, for larger cities, over time there is little change in relative size rankings. In Japan and France, the 39-40 largest cities in 1925 and 1876 respectively all remain in the top 50 in 1985 and 1990 respectively; and, at the top, absolute rankings are unchanged (Eaton and Eckstein, 1997). The USA displays more mobility due to substantial entry of new cities. However, while smaller cities do move up and down in rank, the biggest cities tend to remain big over time. So, for example, cities in the top decile of ranking stay in that decile indefinitely, with newer cities joining that decile as the total number of cities expands. Alternatively viewed, based on the Markov transition process, the mean first passage time for a city to move from the top to bottom cell is thousands of years (Black and Henderson, 2003). In the world cities data, as in the USA data, the probability in the transition matrix of moving out of the top cell to the next cell is very small: .038 in a decade time frame. Why do big cities stay big? A common answer is physical infrastructure (see Section 3.3.2). Large cities have huge historical capital stocks of streets, buildings, sewers, water mains and parks that are cheaply maintained and almost infinitely lived in, that give them a persistent comparative advantage over cities without that built-up stock. A second answer is modeled in Arthur (1990) and Rauch (1993) where, with localized scale externalities in production, large cities with a particular set of industries have a

comparative advantage in attracting new firms, relative to cities with a small representation of those industries. Large cities have an established scale, offering high levels of scale externalities, which smaller cities can only achieve quickly if they are able to co-ordinate mass in-migration of firms into their location, something which may be institutionally difficult to do.

1.1.3 Growth in City Numbers and Sizes

For any steady state size distribution of cities, as urbanization and growth proceed, both the absolute sizes and numbers of cities have grown historically, as a country's urban population expands through rural-urban migration and overall population growth. City sizes in the USA, Japan, and France over the past century have grown at average annual rates of 1.2 - 1.5%, depending on the country and exact time interval, rates which involve city sizes rising 3.3 - 4.5 fold every century. A small city today which is 250,000 would have been a major center in 1900.

In the world city data set, for comparable sets of countries the numbers of metro areas grew by 62% from 1960-2000 using a relative cut-off point (approximately 100,000 in 1960 versus 170,000 for this sample in 2000). Average sizes grew by about 70%. Decade by decade figures are given in Table 3. Using an absolute cut-off point of 100,000, numbers have about doubled and average sizes grown by 36% over 40 years. However we count cities, it is clear they have grown in population and numbers on an on-going basis over the decades.

The theory section will model city size growth and numbers in developed, or fully urbanized countries in Section 2 and in urbanizing economies in Section 3, as related to technological change induced by knowledge accumulation and demographic changes. There is empirical work relating city size increases to changes in knowledge levels. Glaeser, Scheinkman, and Shleifer (1995) in a cross-section city growth framework estimate that controlling for 1960 population, in the USA, cities in 1990 are 7% larger if they had a one-standard deviation higher level of median years of schooling in 1960. Black and Henderson (1999) place the issue in a panel context for 1940-1990 for the USA controlling for city fixed effects and examining the impact of percent college educated (which has enormous time variation). They find a one-standard deviation higher level of percent college educated leads to a 20% larger city.

1.1.4 Zipf's Law

In considering the size distribution of cities, especially in a cross-sectional context, there is a large literature on what is termed Zipf's Law (e.g., Rosen and Resnick 1980, Clark and Stabler 1991, Mills and Hamilton 1994, and Ioannides and Overman 2003). City sizes are postulated to follow a Pareto distribution, where if R is rank from smallest, r, to largest, 1, and n is size

$$R(n) = An^{-a} \tag{2}$$

given the Prob $(\tilde{n} > n) = An^{-a}$ and relative rank is $R(n)/r$, or the proportion of cities with size greater than n. Under Zipf's Law $a = 1$, or we have the rank size rule where, for every city, rank times size is a constant, A. Putting (2) in log-linear form, empirical work produces a's that vary across countries, samples, and times but many are "close" to one. This empirical regularity has drawn considerable attention and is often used to characterize spatial inequality, using (2) as a first approximation of the true size distribution. We list sample a coefficients for 2000 for fifteen countries in Table 2, column 5. Note however while people often say that an exponent of .74 or 1.34 is "close to" one, such coefficients produce very different city size distributions, than if the coefficient is one.[2] As a declines, or the slope of the rank size line gets flatter, urban concentration is viewed as increasing: for given size changes, rank changes more slowly, or cities are "less equal". In Table 2, the a coefficients and the Ginis are in fact strongly negatively correlated, as one would expect. But we note that typically the log version of equation (2) is better approximated by a quadratic form than linear one. However one looks at it, Zipf's Law is just an approximation that does well in some circumstances and not so well in others. If one wants to compare measures of urban concentration across countries, rather than compare estimated *a*'s in eq. (2), a more non-parametric measure such as a Gini might be more reliable.

If Zipf's Law holds even approximately, why is that? In an interesting development, Gabaix (1999a, 1999b) starts to formalize the underlying stochastic components which might lead to such a relationship, building on Simon (1955). Gabaix shows that if city growth rates obey Gabaix's Law where growth rates are random draws from the same distribution,[3] so growth rates are independent of current size, Zipf's Law emerges as the limiting size distribution. Growth is scale invariant, so the final distribution is; and we have a power law with exponent 1. Gabaix sketches an illustrative model, based on on-going natural amenity shocks facing cities of any size, which leads to Zipf's Law for the size distribution of cities. More comprehensive formulations in Duranton (2004) and Rossi-Hansberg and Wright (2004) are discussed in the theory section.

While Gibrat's Law is a neat underlying stochastic process, does it hold up empirically? Black and Henderson (2003) test whether in the relationship, $\ln n_{it} - \ln n_{it-1} = a + \delta t + \alpha \ln n_{it-1} + \varepsilon_{it}$, $\alpha = 0$ as hypothesized under the Law. The Law requires ε_{it} to be i.i.d., so simple OLS suffices. Black and Henderson find $\alpha < 0$ under a variety of circumstance and sub-samples, under appropriate statistical criteria, which rejects Gibrat's Law. Ioannides and Overman (2003) examine the issue more thoroughly in a non-parametric fashion, characterizing the mean and variance of the distribution from which growth

[2] I don't report standard errors since OLS estimates of standard errors are biased downwards. See Gabaix and Ioannides (2004).

[3] Actually the requirement is that they face the same mean and variance in the drawing.

rates are drawn. The mean and variance of growth rates do seem to vary with city size but bootstrapped confidence intervals are fairly wide generally, allowing for the possibility of (almost) equal means.

1.2 Geographic Concentration and Urban Specialization

Geographic concentration refers to the extent to which an industry k is concentrated at a particular location or, more generally concentrated at a few versus many locations nationally. A common measure of concentration of industry k at location i is $l_{ik} = X_{ik} / \sum_i X_{ik}$. X_{ik} is location i 's employment or output of industry k. Thus l_{ik} is location i 's share of, say, national employment in industry k. In contrast to geographic concentration, specialization refers to how much of a location's total employment is found in industry k, or $s_{ik} = X_{ik} / \sum_k X_{ik}$. As Overman, Redding and Venables (2001) demonstrate, if we normalize l_{ik} by location i 's share of national employment $(s_{ik} \equiv \sum_k X_{ik} / \sum_k \sum_i X_{ik})$ and s_{ik} by industry k 's share of national employment $(s_k \equiv \sum_i X_{ik} / \sum_k \sum_i X_{ik})$ we get the same measure -- a location quotient, or

$$q_{ik}^k = X_{ik} \frac{(\sum_k \sum_i X_{ik})}{\sum_k X_{ik} \sum_i X_{ik}} \tag{3}$$

The distribution of q_{ik} across industries, k, compared over time for a city would tell us about how city i 's specialization patterns are changing over time. And the distribution of q_{ik} across locations, i, over time would tell us whether industry k is becoming more or less concentrated over time at different locations. In a practical applications looking at many industries and cities over time or across countries, the issue concerns how to produce summary measures to describe either how overall concentration varies across industries or how one city's specialization compares with another's. Another issue concerns how to factor in the different forces that cause specialization or concentration phenomena. The literature uses a variety of approaches. We start by looking at urban specialization.

1.2.1 Urban Specialization

Evidence on countries such as Brazil, U.S.A., Korea, and India (Henderson 1988, and Lee 1997) indicate that cities are relatively specialized. The traditional urban specialization literature going back to Bergsman, Greenston and Healy (1972) uses cluster analysis to group cities into categories based on similarity of production patterns -- correlations (or minimum distances) in the shares of different industries in local employment, s_{ik}. Cluster analysis is an "art form" in the sense that there is no optimal set of clusters, and it is up to the researcher to define how fine or how broad the clusters should be and there are a variety of clustering algorithms.

Using 1990 data for the U.S.A., Black and Henderson (2003) group 317 metro areas into 55 clusters, "defining" 55 city types based on patterns of specialization for 80 2-digit industries. They define textile, primary metals, machinery, electronics, oil and gas, transport equipment, health services, insurance, entertainment, diversified market center, and so on type cities, where anywhere from 5-33% of local employment is typically found in just one industry. They show that production patterns across the types are statistically different and that average cities and educational levels by type differ significantly across many of the types. Specialization especially among smaller cities tends to be absolute. At a 3-digit level many cities have absolutely zero employment in a variety of categories. So in the 1992 Census of Manufactures for major industries like computers, electronic components, aircraft, instruments, metal working machinery, special machinery, construction machinery, and refrigeration machinery and equipment, respectively, of 317 metro areas 40%, 17%, 42%, 15%, 77%, 15%, 14% and 24% have absolutely zero employment in these industries.

Kim (1995) in looking at the USA examines how patterns of specialization have changed over time, by comparing for pairs (i, j) of locations $\sum_k |s_{ik} - s_{jk}|$ and by estimating spatial Gini's for industry concentration. He finds that states are substantially less specialized in 1987 than in 1860, but that localization, or concentration has increased over time. For Korea, as part of the deconcentration process noted earlier, Henderson, Lee, and Lee (2001) find that from 1983 to 1993, city specialization as measured by a normalized Hirschman-Herfindahl index

$$g_j = \sum_k (s_{jk} - s_j)^2 \qquad (4)$$

rises in manufacturing, while a provincial level index declines. Cities become more specialized and provinces less so. Clearly the geographic unit of analysis matters, as do the concepts. City specialization as envisioned in the models presented below is consistent with regional diversity, when large regions are composed of many cities of different types.

Henderson (1997) for the USA and Lee (1997) for Korea show that the g_j index of specialization in manufacturing declines with metro area size. Smaller cities are much more specialized than larger cities in their manufacturing production. More generally, Kolko (1999) demonstrates that larger cities are more service oriented and smaller ones more manufacturing oriented. For six size categories (over 2.5 million, 1 - 2.5 million, ... < .25 million, non-metro counties) Kolko shows that the ratio of manufacturing to business service activity rises from .68 to 2.7 as size declines, where manufacturing and business services account for 35% of local private employment. The other 65% of local employment is in "non-traded" activity whose shares don't vary across cities – consumer services, retail, wholesale, construction, utilities.

1.2.2 Geographic Concentration

What about concentration of industry -- the extent to which a particular industry is found in a few versus many locations? In an extremely important paper Ellison and Glaeser (1999) model the problem using USA data, to determine the extent of clustering of plants within an industry due to either industry-specific natural advantages (e.g., access to raw materials) or spillovers among plants. Plants locate across space so as to maximize profits and profits depend on area specific natural advantage, spillovers, and an i.i.d. drawing from Weibul distribution. The idea is to explain the joint importance of spillovers and natural advantage in geographic concentration.

Geographic concentration for industry j is $G_j = \sum_i (s_{ji} - x_i)^2$, where s_{ji} is the share of industry j in employment in location i and x_i is location i's share in total national employment (to standardize for location size). Where $0 \leq \gamma^{na} \leq 1$ represents the importance of natural advantage (where the variance in relative profitability of a location is proportional to γ^{na}) and γ^S represents the fraction of pairs of firms in an industry between which a spillover exists, under their assumptions, Ellison and Glaeser show that

$$E\left[G_j\right] = (1 - \sum_i x_i^2)\,(\gamma_j + (1-\gamma_j)\,H_j)$$
$$\gamma \equiv \gamma^{na} + \gamma^s - \gamma^s\gamma^{na} \qquad (5)$$

where H_j is the standard Hirschman-Herfindahl index of plant industrial concentration in industry j. So $E\left[G_j\right]$ adjusts γ_j for variations in location size $(1 - \sum x_i^2)$ and industry concentration H. Using (5) and estimates of G_j, H_j, and $(1 - \sum x_i^2)$, the empirical part of their paper calculates γ_j for all 3- or 4-digit manufacturing industries across states and countries. They show for 4-digit industries that $G > (1 - \sum x_i^2)H$ in 446 of 459 industries, where $G \leq (1 - \sum x^2)H$ only if $\gamma \leq 0$. That is, almost all industries display some degree of spatial concentration due to either natural advantage or spillovers. Second they argue that 25% of industries are highly concentrated $(\gamma > .05)$ and 43% are not highly concentrated $(\gamma < .02)$. In a later article, Ellison and Glaeser (1999) argue that, based on econometric results relating location choices to natural advantage measures, 10-20% of γ in eq. (5) is accounted for by natural advantage. The rest is due to intra-industry spillovers, a rather critical finding in urban analysis indicating the importance of understanding the nature of scale externalities.

In an important working paper, Duranton and Overman (2004), look at geographic concentration using British data. Rather than model the underlying stochastic process of industrial location under

specific assumptions to yield a specific index, Duranton and Overman take a non-parametric approach, where they also focus on how to test statistically whether industries are significantly concentrated. They calculate the distribution of all pair-wise distances between plants in an industry. Distributions shifted to the left have a greater concentration of short pair-wise distances and are more spatially concentrated. The authors have the advantage of knowing "exact" plant locations (basically within a city block or so), rather than having to rely on, say, county locations which in the US can cover vast distances. They develop a framework to test observed industry distributions against the "counterfactual" of what distributions would look like if firms choose locations randomly, given (a) the set of locations in the UK for industrial plants is limited, (b) bilateral distances between all possible points are not independent, and (c) industry sizes or numbers of plants differ. The framework involves repeated sampling for an industry without replacement from the set of national industrial sites with the sample size equal to industry size. Following that procedure, they construct 95% confidence intervals to test if observed distributions depart from randomness. Compared to Ellison-Glaeser

In practical applications their approach captures a nuanced aspect of spatial clustering. For relatively concentrated industries, the Ellison and Glaeser index is typically dominated by the county with the highest share (given squared shares in the index), telling us the extent to which an industry is concentrated in just one place. The Duranton-Overman approach tells us more generally about spatial clustering over the whole country. So in Ellison and Glaeser, an industry which has a high concentration in one county but is otherwise very dispersed across the 3000 USA counties may look more concentrated than an industry which is concentrated in, say 3-4 nearby counties, with little representation elsewhere. But the latter would be well represented in Duranton and Overman.

1.2.3 Geography

A variety of recent studies have examined the role of geography, primarily natural features, in the spatial configuration of production and growth of cities. Rappaport and Sacks (2001) building on Sacks' general geography program herald the role of coastline location in the U.S.A., as a factor promoting city growth. In a related study, Beeson, DeJong and Troeskan (2001) look at USA counties from 1840-1990. They show that iron deposits, other mineral deposits, river location, ocean location, river confluence, heating degree days, cooling degree days, mountain location, and precipitation all affect 1840 county population significantly. However for 1840-1990 growth in county population, only ocean location, mountain location, precipitation, and river confluence matter, controlling for 1840 population. That is, first nature items strongly affected 1840 and hence indirectly 1990 populations; but growth from 1840-1990 is independent of many first nature influences. Ocean location as Sacks' suggests has persistent growth effects.

Both these studies ignore the geography of markets and the role of neighbors in influencing city evolution. Dobkins and Ioannides (2001) show that growth of neighboring cities influence own city growth and cities with neighbors are generally larger than isolated cities. Black and Henderson (2003) put neighbor and geographic effects together. They calculate normalized market potential variables (sum of distance discounted populations of all other counties in each decade, normalized across decades). They find climate and coast affect relative city growth rates; but market potential has big effects as well, although they are non-linear. Bigger markets provide more customers, but also more competition, so marginal market potential effects diminish as market potential increases. High market potential helps explain why North-East cities in the USA maintain reasonable growth given it is the most densely populated area from history, despite the hypothesized natural advantages of the West.

1.3 Urbanization in Developing Countries

Urbanization, or the shift of population from rural to urban environments, is typically a transitory process, albeit one that is socially and culturally traumatic. As a country develops it moves from labor-intensive agricultural production to labor being increasingly employed in industry and services. The latter are not land-intensive and are located in cities because of agglomeration economies. Thus urbanization moves populations from traditional rural environments with informal political and economic institutions to the relative anonymity and more formal institutions of urban settings. That in itself requires institutional development within a country. It spatially separates families, particularly intergenerationally as the young migrate to cities and the old stay behind.

Urbanization is a spatial transition process. By upper middle income ranges, countries become "fully" urbanized, in the sense that the percent urbanized levels out at 60-90% of the national population living in cities. The actual percent urbanized with full urbanization varies with geography, the role of modern agriculture in the economy, and national definitions of urban. This idea of a transitory phenomenon is illustrated Figure 2, comparing different regions of the world in 1960 versus 1995. While urbanization increased in all regions of the world over those 35 years, among developed countries there is little change since 1975. By 1995 Soviet bloc and Latin American countries had almost converged to developed country urbanization levels. Only sub-Saharan African and Asian countries still face substantial urbanization in the future. Although urbanization is transitory, given the total spatial transformation and accompanying institutional and social transformation involved, as a policy issue urbanization is very important to developing countries. Here we review some basic facts and issues about the process.

1.3.1 Issues Concerning Overall Urbanization

As noted above, urbanization is the consequence of changes in national output composition from rural agriculture to urbanized modern manufacturing and service production. As such, Renaud (1981) makes the basic point that government policies bias, or influence urbanization through their effect on national sectoral composition. So policies affecting the terms of trade between agriculture and modern industry or between traditional small town industries (textiles, food processing) and high tech large city industries affect the rural-urban or small-big city allocation of population. Such policies include tariffs, and price controls and subsidies. The idea that government policies affect urbanization primarily through their effect on sector composition is a key point of empirical studies of urbanization by Fay and Opal (1999) and Davis and Henderson (2003). These studies show that, indeed, urbanization which occurs in the early and middle stages of development is determined largely by changes in national economic sector composition and in technology, and government policies tend to affect urbanization only indirectly through their effect on sector composition.

Urbanization promotes benefits from agglomeration such as localized information and knowledge spillovers and thus efficient urbanization promotes economic growth. Writers such as Gallup, Sacks and Mellinger (1999) go further to suggest that urbanization may "cause' economic growth, rather than just emerge as part of the growth process. The limited evidence so far suggests urbanization doesn't cause growth per se. Henderson (2003) finds no econometric evidence linking the extent of urbanization to either economic or productivity growth or levels. That is if a country were to enact policies to encourage urbanization per se, typically that wouldn't improve growth.

Finally on urbanization, there is an informal notion (Mills and Becker 1986 and World Bank 2000) that the transitory urbanization process follows the same stages as population growth (the "demographic" transition between falling death rates and falling fertility rates) – an S-shaped relationship where urban population growth is slow at low levels of development, then there is a period of rapid acceleration in intermediate stages, followed by a slowing of growth. However the data suggest otherwise at least over the last 35 years. Figure 3 illustrates after parceling out the effect of national population, or country size, based on pooled country data every 5 years from 1965-1995. In Figure 3 the log of national urban population is an increasing concave function of the log of income per capita, indicating the *growth* rate of urban population is a concave increasing function of income levels (Davis and Henderson, 2003).

1.3.2 The Form of Urbanization: The Degree of Spatial Concentration

In 1965, Williamson published an innovative paper based on cross-section analysis of 24 countries in which he argued that national economic development is characterized by an initial phase of internal regional divergence, followed by a phase of later convergence. That is, a few regions initially experience accelerated growth relative to other (peripheral) regions, but later the peripheral regions start

to catch up. Barro and Sala-i-Martin (1991 and 1992) present extensive evidence on this for the USA, Western Europe, and Japan, by examining the evolution of inter-regional differences in per capita incomes. While inter-regional out-migration from poorer regions plays a role in catch-up, it may not be critical. For Japan, the authors argue that later convergence of backward regions occurred through improved productivity in backward regions.

The urban version of this divergence-convergence phenomenon looks at urban primacy. Following Ades and Glaeser (1995), conceptually the urban world is collapsed into two regions -- the primate city versus the rest of the country, or at least the urban portion thereof. The basic question concerns to what extent urbanization is concentrated, or confined to one (or a few) major metro areas, relative to being spread more evenly across a variety of cities. Primacy is commonly measured by the ratio of the population of the largest metro area to all urban population in the country (Ades and Glaeser 1995, Junius 1999, and Davis and Henderson 2003). A more comprehensive measure might use either a spatial Gini or a Hirschman-Herfindal index [HHI] from the industrial organization literature.

Corresponding to Williamson's hypothesis, these papers find an inverted U-shape relationship, where relative urban concentration first increases, peaks, and then declines with economic development. Despite different concentration measures and methods, Wheaton and Shishido (1981) examining a HHI using cross-section non-linear OLS and Davis and Henderson (2003) examining primacy using panel data methods and IV estimation find that concentration rises, peaks in the $2000-4000 range (1985 PPP dollars), and then declines. As Figure 4 illustrates, without conditioning on other variables affecting primacy, the inverted $U-$ relationship of primacy against income is noisy and only apparent in the raw data in earlier time periods (cf. 1965-75 in part (a) with 1985-95 in part (b)).

Lee (1997) explores the relationship between changes in urban concentration and industrial transformation for Korea. The idea is that manufacturing is also first very concentrated in primate cities at early stages of development and then decentralizes to such an extent that at the other end of economic development it is relatively more concentrated in rural areas, as in the USA today as noted earlier. Seoul's urban primacy peaked around 1970 and while Seoul's absolute population has continued to grow, its share has declined steadily. At the urban primacy peak in 1970, Seoul had a dominant share of national manufacturing although the other major metro areas, Pusan and Taegu, also had large shares. During the next 10-15 years, manufacturing suburbanized from Seoul to satellite cities in the rest of Kyonggi province (its immediate hinterland), as well as to satellite cities surrounding Pusan and Taegu. Such suburbanization of manufacturing has been documented also for Thailand (Lee, 1988), Colombia (Lee, 1989), and Indonesia (Henderson, Kuncoro and Nasution, 1996). But the key development following the early 1980's in Korea is the spread of manufacturing from the three major metro areas (Seoul, Pusan, and Taegu) and their satellites to rural areas and other cities. The share of rural areas and other cities in

manufacturing rose from 26% in 1983 to 42% in 1992, in a time period when national manufacturing employment is fairly stagnant and rural areas and other cities actually continue to experience modest absolute population losses. That is, manufacturing deconcentrated both relatively and absolutely to hinterland regions. This deconcentration coincided with economic liberalization, enormous and widespread investment in inter-regional transport and infrastructure investment, and fiscal decentralization (Henderson, Lee, and Lee, 2001) and is consistent with core-periphery reversal in the new economic geography literature discussed later.

Given the urban primacy relationships, the immediate issue is the "so-what" question. How is urban concentration important to growth? For example, is there an optimal degree of urban primacy with each level of development, where significant deviations from this level detract from growth? Conceptually there should be an optimal degree of primacy, where optimal primacy involves a trade-off of the benefits of increasing primacy-- enhanced local scale economies contributing to productivity growth-- against the costs -- more resources diverted away from productive and innovative activities to shoring up the quality of life in congested primate cities. In the first econometric examination of this so-what question, Henderson (2003), using panel data and IV estimation for 1960-1990, finds that there is an optimal degree of primacy at each level of development that declines as development proceeds. Optimal primacy is the level that maximizes national productivity growth. Initial high relative agglomeration is important at low levels of development when countries have low knowledge accumulation, are importing technology, and have limited capital to invest in widespread hinterland development. However the desirability of high relative agglomeration declines with development. Error bands about optimal primacy numbers are quite tight. Second, large deviations from optimal primacy strongly affect productivity growth. An 33% increase or decrease in primacy from a typical best level of .3 reduces productivity growth by 3% over five years. There is some tendency internationally to excessive primacy, with the usual suspects such as Argentina, Chile, Peru, Thailand, Mexico, and Algeria having extremely high primacy.

Why would countries significantly deviate from desired levels of concentration? There is a considerable literature of government policies and institutions in fostering excessive concentration. In Ades and Glaeser (1995), the basic idea is that national policy makers favor the national capital (or other seat of political elites such as São Paulo in Brazil) for reasons of personal gain. For example, direct restraints on trade for hinterland cities such as inability to access capital markets or to get export or import licenses favor firms in the national capital. Policy makers and bureaucrats may gain as shareholders in such firms, or they may gain rents from those seeking licenses or other exemptions to trade restraints (see Henderson and Kuncoro, 1996, on Indonesia). Indirect trade protection for the primate city can also involve under-investment in hinterland transport and communications infrastructure.

Whether as true beliefs or as a justification to cover rent-seeking behavior, policy makers in different countries often articulate a view that large cities are more productive and thus should be the site for government-owned heavy industry (e.g., São Paulo or, Beijing-Tianjin historically). Later we will point out that it may be that output per worker in heavy industries is higher in the productive external environment of large metro areas. It just isn't high enough to cover the higher opportunity costs of land and labor in those cities, which is one reason why those state-owned heavy industries lose money in such cities.

Favoritism of a primate city creates a non-level playing field in competition across cities. The favored city draws in migrants and firms from hinterland areas, creating an extremely congested high cost-of-living metro area. Local city planners can try to resist the migration response to primate city favoritism by, for example, refusing to provide legal housing development for immigrants or to provide basic public services in immigrant neighborhoods. Hence the development of squatter settlements, bustees, kampongs and so on. But still, favored cities tend to draw in enormous populations.

Is there econometric evidence indicating that politics plays a role in increasing sizes of primate cities? Ades and Glaeser (1995) based on cross-section analyses find that if the primate city in a country is the national capital it is 45% larger. If the country is a dictatorship, or at the extreme of non-democracy, the primate city is 40-45% larger. The idea is that representative democracy gives a political voice to the hinterland regions limiting the ability of the capital city to favor itself. Apart from representative democracy, fiscal decentralization helps to level the playing field across cities, by giving political autonomy for hinterland cities to compete with the primate city.

Davis and Henderson (2003) explore these ideas further, examining in a panel context the impact upon primacy of democratization and fiscal decentralization from 1960-1995. Using a panel approach with IV estimation, they find smaller effects than Ades and Glaeser but still highly significant ones. Examining both democratization and fiscal decentralization together, they find moving from the extreme of least to most democratic form of government reduces primacy by 8% and from the extreme of most to least centralized government reduces primacy by 5%. Primate cities which are national capitals are 20% larger and primate cities in planned economies with migration restrictions are 18% smaller. Finally they find transport infrastructure investment in hinterlands which opens up international markets to hinterland cities reduces primacy, as the core-periphery models of the new economic geography tend to predict. A one-standard deviation increase in roads per sq. kilometer of national land area or in navigable inland waterways per sq. kilometer each reduce primacy by 10%.

2. Cities and Growth

To establish the links between cities, growth, urbanization, urban concentration and policy, we look at models in which cities are a defined unit, endogenous in number and size. These are systems of cities models which date to Henderson (1974), with a variety of substantial contributors to further development (Hochman 1977, Kanemoto 1980, Henderson and Ioannides 1981, Abdel-Rahman and Fujita 1990, Helsley and Strange 1990, Duranton and Puga 2000, and Rossi-Hansberg and Wright 2004, to name a few). Here I outline the model in Black and Henderson (1999a) which is an endogenous growth model of cities, examining the growth-urban connection. The analysis is broken into several parts. The first reviews the traditional static model, focused on city formation and the determination of the sizes, numbers, and industrial composition of cities in an economy at a point in time. A thorough review of static models is in Abdel-Rahman and Anas (2004), so our treatment focuses on what we need to analyze growth and later urbanization and development. We then turn to the growth part, focusing first on steady-state growth and a variety of extensions covering stochastic processes and analysis of functional specialization. Section 3 turns to rural-urban transformation, or urbanization under economic development. That section also discusses issues of city debt finance and land market institutions.

2.1 The Systems of Cities at a Point in Time

Consider a large economy composed of two types of cities, where there are many cities of each type and each type is specialized in the production of a specific type of traded good. We will show why (when) there is specialization momentarily; the generalization to many types of goods and cities is straightforward. To simplify the growth story, each firm is composed of a single worker. In a city type 1, in any period, the output of firm i in a type 1 city is

$$X_{1i} = D_1 \ (n_1^{\delta_1} h_1^{\psi_1}) \ h_{1i}^{\phi_1}, \ 0 < \delta_1 < \frac{1}{2} \qquad (6)$$

h_{1i} is the human capital of the worker and is his input in the production process. A worker-firm is subject to two local externalities. First is own industry localization economies, the level of which depends on the total number of worker-firms, n_1, in this representative type 1 city. There is a large literature on micro-foundations of localization economies, with an excellent analysis and review in Duranton and Puga (2004). While the concepts are discussed in Marshall (1890), the formal literature dates to Fujita and Ogawa (1982) who model micro-foundations as exogenous information spillovers that enhance productivity but decay with spatial distance between plants. Such spillovers can be made endogenous (Kim, 1988) with the volume of costly "contacts" being a firm choice variable. But the modern literature

on micro-foundations as reviewed in Duranton and Puga moves on to try to model why contacts matter, rather than just assuming they matter.

In this section spatial decay is all or nothing – no decay within the city's; 100% across cities. As such in (6), n_1 could represent the total volume of local spillover communications, where δ_1 is the elasticity of firm output with respect to n_1. The restriction $\delta_1 < 1/2$ ensures a unique solution in an economy composed of many type 1 cities. A larger δ_1 results in all X_1 production crowding into one city. Note the production process ignores land, collapsing the central business district [CBD] to a point. There is a recent literature building upon Fujita and Ogawa where firm density is endogenous in a spatial CDB with information spillover decay. There market equilibrium density is non-optimal because firms in making location decisions don't recognize that choices leading to greater densities would enhance information spillovers (Lucas and Rossi-Hansberg, 2002 and Rossi-Hansberg, 2004). The issue of central city design and zoned density is an important one in the design of cities in developing countries. But this review focuses on other issues.

The second externality in (6) derives from h_1, the average level of human capital in the city, which represents local knowledge spillovers. $h_1^{\psi_1}$ could be thought of as the richness of information spillovers $n_1^{\delta_1}$, so that knowledge enhances (multiplies) local information spillovers, or gives better information. Alternatively it could just represent the level of local technology, which increases as average education increases locally.

Given this simple formulation the wage of worker i in city type 1 is

$$W_{1i} = X_{1i} \tag{7}$$

In an economy of identical individual workers in type 1 cities, individuals will all have the same human capital level (either exogenously in a static context, or endogenously in a growth context). Thus total city output is

$$X_1 = D_1 h_1^{\phi_1 + \psi_1} n_1^{1+\delta_1} \tag{8}$$

2.1.1 Equilibrium City Sizes

Equations (6) and (8) embody the scale benefits of increases in local employment, where output per worker is an increasing function of local own industry scale. Determinant city sizes arise because of scale diseconomies in city living, including per capita infrastructure costs, pollution, accidents, crime, and

commuting costs. In Henderson (1974) those are captured in a general cost of housing function, but most urban models consider an explicit internal spatial structure of cities. As noted all production occurs at a point, the CBD. Surrounding the CBD in equilibrium in local land markets is a circle of residents each on a lot of unit size. People commute back and forth at a constant cost per unit (return) distance of τ. That cost can be from working time, or here an out-of-pocket cost paid in units of X_1. Equilibrium in the land market is characterized by a linear rent gradient, declining from the center to zero at the city edge where rents (in agriculture) are normalized to zero. Standard analysis dating to Mohring (1961) gives us expressions for total city commuting and rents, in terms of city population where[4]

$$\text{total commuting costs} = bn_1^{3/2} \tag{9}$$

$$\text{total land rents} = 1/2\ bn_1^{3/2} \tag{10}$$

$$\text{b} \equiv 2/3\ \pi^{-\frac{1}{2}}\tau.$$

Equation (9) is the critical resource costs, where marginal commuting costs are increasing in city population. Rents are income to, potentially, a city developer.

How do cities form and how are sizes determined? We start with a specific mechanism and discuss how it generalizes below, and what happens if such a mechanism isn't present. There is an unexhausted supply of identical city sites in the economy, each owned by a land developer in a nationally competitive urban land development market. A developer for an occupied city collects local land rents, specifies city population (but there is free migration in equilibrium), and offers any inducements to firms or people to locate in that city, in competition with other cities in order to maximize profits. Population is freely mobile.

The land developer maximizes

[4] An equilibrium in residential markets requires all residents (living on equalize size lots) to spend the same amount on rent, $R(u)$, plus commuting costs, τu, for any distance u from the CBD. Any consumer then has the same amount left over to invest or spend on all other goods. At the city edge at a radius of u, rent plus commuting costs are τu_1 since $R(u_1) = 0$; elsewhere they are $R(u) + \tau u$. Equating those at the city edge with those amounts elsewhere yields the rent gradient $R(u) = \tau(u_1 - u)$. From this, we calculate total rents in the city to be $\int_0^{u_1} 2\pi u R(u) du$ (given lot sizes of one so that each "ring" $2\pi u du$ contains that many residents) or $1/3\pi\tau u_1$. Total commuting costs are $\int_0^{u_1} 2\pi u\ (\tau u)\ du = 2/3\pi r u_1^3$. Given a city population of n and lot sizes of one, $n_1 = \tau u_1^2$ or $u_1 = \pi^{-\frac{1}{2}} n^{\frac{1}{2}}$. Substitution gives us eqs. (9) and (10).

$$\max_{n_1,\ T_1} \ profit_1 = 1/2\ bn_1^{3/2} - T_1 n_1$$
$$\text{subject to } W_1 + T_1 - 3/2\ bn_1^{\frac{1}{2}} = I_1 \tag{11}$$

where T_1 is the per firm subsidy (e.g., in practice, in a model with local public goods, a tax exemption). I_1 is the real income per worker available in equilibrium in national labor markets under free mobility, which a single developer takes as given. In the constraint, I_1 equals wages in (7), plus the subsidy, less per worker rents plus commuting costs paid from (9) and (10). Maximizing with respect to T_1 and n_1 and imposing perfect competition in national land markets so $profit_1 = 0$ ex post, yields

$$T_1 = 1/2\ bn_1^{\frac{1}{2}} \tag{12}$$

$$n^* = (\delta_1 2b^{-1} D_1)^{2/(1-2\delta_1)} h_1^{2\varepsilon_1} \tag{13}$$

$$\varepsilon_1 \equiv \frac{\phi_1 + \psi_1}{1 - 2\delta_1} \tag{14}$$

This solution has a variety of properties heralded in the urban literature. First it reflects the Henry George Theorem (Flatters, Henderson, and Mieszkowski 1974, Stiglitz 1977), where the transfer per worker/firm exactly equals the gap $(\delta_1 W_1)$ between social and private marginal of labor to the city, and that subsidy which prices externalities is exactly financed out of collected land rents at efficient city size. That is, total land rents cover the cost of subsidies needed to price externalities, as well as the costs of local public goods in a model where good goods are added in. Second the efficient size in (13) is the point where real income, I_1, peaks, as an inverted $U-$shape function of city size, as we will illustrate later in Figure 5. If $\delta_1 < 1/2$, we can show that I_1 is a single-peaked function of n_1, so n_1^* is the unique efficient size. If $\delta_1 > 1/2$, in essence there will only be one type 1 city in the economy, because net scale economies are unbounded. Given n_1^* is the size where I_1 peaks, n_1^* is a free mobility equilibrium -- a worker moving to another city would lower real income in that city and be worse off. Finally city size is increasing in technology improvements: τ declining, δ_1 rising, D_1 rising, or local knowledge accumulation (h_1) rising.

By substituting in the constraint in (11), we can define relationships among real income, wages, and human capital. Substituting in first for T_1 and then n_1 we get

$$I_1 = W_1 - bn^{1/2} = (1-2\delta)\ W_1 = Q_1 h_1^{\varepsilon_1} \tag{15}$$

where Q_1 is a parameter cluster. Note real income is wages deflated by urban living costs; and that real income rises with human capital.

Institutions and City Size. I have specified the equilibrium in national land markets, given competitive developers. Helsley and Strange (1990) put this in proper context, specifying the city development game, determining how many cities will form and what their sizes (n^*) will be. Henderson and Becker (2001) show that the resulting solutions (with multiple factors of production) are (1) Pareto efficient, (2) the only coalition proof equilibria in the economy, (3) unique under appropriate parameters, and (4) free mobility ones where the developer specified populations are self-enforcing. They also show that, under appropriate conditions, such outcomes arise (1) in a self-organized economy with no developers where city governments can exclude residents ("no-growth" restrictions) to maximize the welfare of the representative local voter, (2) in a growing economy where developers form new cities and old cities are governed by local governments. Note for developing countries the key ingredients: either national land markets must be competitive with developers free to form new cities or atomistic settlements can arise freely and local autonomous governments can limit their populations as they grow.

Absent such institutions, cities only form through "self-organization". In the model here with perfect mobility of resources, the result is potentially enormously oversized cities (Henderson 1974, Henderson and Becker 2001). Nash equilibrium city size in atomistic worker migration decisions lies between efficient size, n^*, and a limit size to the right, $n_{\max}$, where city size is so large with such enormous diseconomies that the population is indifferent between being in a rural settlement of size 1 (the size of a community formed by a defecting migrant) and $n_{\max}$ That is, given an inverted-U shape to real income I_1, self organization has cities at the right of the peak n^*, potentially at $n_{\max}$ where where $I_1\ (n=1) = I_1\ (n=n_{\max})$. The problem is one of co-ordination failure.

Consider a large economy with growing population, where, in size, all cities are at or just beyond n^*. Timely formation of the next city to accommodate this population growth requires en mass movement of population from existing cities into a new city of size, n^*. Without co-ordination in the form of developers or city governments, no such en mass movement is possible, so people wait to migrate from existing cities to a new city until existing cities have all grown to $n_{\max}$, where it pays individual

migrants to exit to a cities to set up their own tiny "city". Of course at that "bifurcation point" (Krugman, 1991a), in equilibrium these milling migrants coalesce into 1 or more new cities of size greater than or equal to n^*, at which point, again, all then existing cities start to grow again with national population growth until they too hit the bifurcation point $n_{\max}$. This dismal process is what faces countries where local autonomy and national markets are poorly functioning, so that there are no market or institutional mechanisms to co-ordinate en mass movements of people. However the process we have outlined involving population swings across cities and potentially enormously over-populated cities may not be consistent with the data. In Section 3 we will outline a model with immobile capital, where self-organization can involve "commitment" given irreversibility of investment decisions. In that context outcomes, while still inefficient, are not so dismal.

2.1.2 Other City Types

In Black and Henderson, X_1 city type 1 is an input into production of the single final good in the economy, X_2 (from which, hence in a growth context human capital is also "produced"). In many models all outputs of specialized city types are final consumption goods. But here we follow Black and Henderson, without loss of generality. X_2 is produced in type 2 cities where the output for worker/firm j is correspondingly

$$X_{2j} = D_2 \ (n_2^{\delta_2} h_2^{\psi_2}) \ h_{2j}^{\theta_2} \ X_1^{1-\alpha} \tag{16}$$

As in type 1 cities, per worker output is subject to own industry local scale externalities and to local knowledge spillovers. However now there is an intermediate input, X_{1j}, which is the numeraire good with X_{2j} priced at P in national markets. The analysis of city sizes and formation for type 2 cities proceeds as for city type 1, with corresponding expressions, other than the addition of an expression for P in n_2^* and I_2 and a restriction for an inverted $U-$shape to I_2 that $\delta_2 < \alpha/2$.

In a static context the model is closed by utilizing the national full employment constraint

$$m_1 n_1 + m_2 n_2 = N \tag{17}$$

where m_1 and m_2 are the numbers of each type of city and N is national population. The second equation (to solve the 3 unknowns P, m_1 and m_2) equates real incomes as in equation (15) across cities $(I_1 = I_2)$, where individual workers move across cities to equalize real incomes. Finally there is an

equation where national demand equals supply in either the market. That is, the supply, $m_1 X_1$, equals the demand for X_1 as an intermediate input, $m_2 n_2 x_{1,}$ and for producing commuting costs $(m_1\ (bn_1^{3/2}) + m_2\ (bn_2^{3/2}))$ from eq. (9). In this specific model, the solution yields values of m_1, m_2 and *P* that are functions of parameters and h_1 and h_2. In a static context of identical workers, one would impose $h = h_1 = h_2$. We will discuss momentarily the solution for h_1 and h_2 and the model in the growth context. Later in section 3, we will detail solutions for prices and numbers of cities in a simpler but related two sector model. Here given log-linear production functions and a single final consumption good, as Black and Henderson show, X_1 and m_1 / m_2 will be constant over time, independent of *h.*

In the static context where, labor mobility requires $I_1 = I_2$, in the larger type of city, say type 1, commuting and land rent costs will be higher. Thus, if real incomes are equalized, from (15) , $W_1 > W_2$ as a compensating differential for higher living costs. Firms in type 1 cities are willing to pay higher wages because type 1 cities offer them greater scale benefits. Empirical evidence shows as cities move from a small size (say, 50,000) to very large metro areas, the cost-of-living typically doubles (Thomas 1978, Henderson, 2002), explaining the fact that nominal wages also double.

Another issue discussed at length in section 1.3 is that policy makers may favor large cities because they view them as "more productive". Indeed for an industry found in smaller towns, it may be that the externalities they face in equations (6) or (16) may be higher in a larger city. However that doesn't mean they locate there. Although externalities may be higher, in order for them to locate there, it must be sufficiently relatively higher to afford the higher wage and land rents, compared to a smaller city. If not, their profit maximizing or cost minimizing location is the smaller city.

Specialization. This analysis presumes cities specialize in production. That is an equilibrium outcome under a variety of conditions. In the model described so far, there are no costs of inter-city trade: no costs of shipping X_1 as inputs to X_2 type cities and shipping X_2 back as retail goods in X_1 type cities. All transport costs are internal to the city, given the relative greater importance of commuting costs in modern economies. Given that and given scale economies are internal to the industry, any specialized city (formed by a developer) out-competes any mixed city. The heuristic argument is simple. Consider any mixed city with $\tilde{n}_1$ and $\tilde{n}_2$ workers in industry 1 and 2. Split that city into two specialized cities, one with just $\tilde{n}_1$ people and the other with just $\tilde{n}_2$. Scale economies are undiminished ($\tilde{n}_1^{\delta_1}$ and $\tilde{n}_1^{\delta_2}$ in both cases in industries 1 and 2 respectively) but per worker commuting costs are lower in the specialized cities compared to the old larger mixed cities, so real incomes are higher in each specialized city compared to the old city.

Having own industry, or localization economies is a sufficient but not necessary condition for specialization. Industries can instead all have "urbanization" economies where scale depends on total local employment. However if the degree of urbanization economies differs across industries then each industry has a different efficient local scale and is better off in a different size specialized city than any mixed city. Mixed cities occur more in situations where each good has localization economies enhanced by separate spillovers from the other industry or sharing of some common public infrastructure (Abdel-Rahman 2000).

A basic problem in these urban models is the lack of nuance on transport costs. Either transport costs of goods across cities is zero ($X_1$and X_2) or infinite (housing, and potentially other non-tradables). A recent innovation is to have generalized transport costs (without a specific geography) where the cost of transporting a unit of X_1 to an X_2city is t_1 and the cost of shipping X_2 back to an X_1 city is t_2, an innovation due to Abdel-Rahman (1996) in a model similar to the one used here (one intermediate and one final good) and then generalized by Xiong (1998) and Anas and Xiong (1999). Now whether there are specialized as opposed to diversified cities depends on the level of t_1 and t_2. At appropriate points as t_1 or t_2 or both rise from zero, X_1 and X_2 will collocate (in developer run cities). More generally with a spectrum of, say, final products, we would expect that some products with low enough t 's will always be produced in specialized cities, some high enough t 's will be in all cities, and some with middle range t 's will be produced in some cities (ones with bigger markets) but not others (with smaller markets). No one has yet simulated this more complex outcome.

2.1.3 Replicability and National Policy

At the national level in a large economy with many cities, at the limit, there are constant returns to scale, or replicability. If national population doubles, the numbers of cities of each type and national output of each good simply doubles, with individual city sizes, relative prices and real incomes unchanged .[5] With two goods and two factors, basic international trade theorems (Rybczynski, factor price equalization, and Stolper-Samuelson) hold (Hochman 1977, Henderson 1988). This gives an urban flavor to national policies (Renaud 1981, Henderson, 1988). For example trade protection policies favoring industry X_1 produced in relatively large size cities over industry X_2 produced in smaller type cities will alter national output composition towards X_1 production and increase the number of large relative to small cities. National urban concentration will rise. Similarly subsidizing an input such as

[5] Here with h_1 and h_2 yet to be solved we would need to double the numbers of people with h_1 and h_2 respectively. Below we will see the solution with growth to h_1 and h_2 is national scale invariant.

capital for a high tech product, X_1, again, say, produced in a larger type of city will cause the numbers of that type of city to increase, raising urban concentration.

2.2 Growth in a System of Cities

Black and Henderson (1999a) specify a dynastic growth model where dynastic families grow in numbers at rate g over time starting from size 1. If c is per person family consumption, the objective function is $\int_0^{\infty} \frac{c(t)^{1-\sigma}-1}{1-\sigma} e^{-(\rho-g)t} dt$ where $\rho(>g)$ is the discount rate. Dynasties can splinter (as long as they share their capital stock on an equal per capita basis) and the problem can be put in an overlapping generations context with equivalent results (Black, 2000), under a Galor and Zeira (1993) "joy of giving" bequest motive.

The only capital in the model is human capital and as such there is no market for it. Intra-family behavior substitutes for a capital market. Specifically families allocate their total stock of human capital (H) and members across cities, where Z proportion of family members go to type 1 cities (taking $Z\ h_1 e^{gt}$ of the H with them) and $(1-Z)$ go to type 2 cities taking $(1-Z)\ \mathrm{h}_2 e^{gt}$ with them). Additions to the family stock come from the equation of motion where the cost of additions, PH, equals family income $Ze^{gt} I_1 + (1-Z)\ e^{gt} I_2)$ less the value of family consumption of X_2, or $Pc\ e^{gt}$. Constraints prohibiting consumption of human capital, non-transferability except to newborns, and non-transferability within families across city types (either directly or indirectly through migration) are non-binding on equilibrium paths.

Families allocate their populations across types of cities, with low human capital types (say h_1) "lending" some of their share $(h = H / e^{gt})$ to high human capital types (say h_2). High human capital types with higher incomes $(I_2 > I_1$ if $h_2 > h_1)$ repay low human capital types so $c_1 = c_2 = c$ (governed by the family matriarch). This in itself is an interesting development story, where rural families diversify migration destinations (including the own rural village) and remittances home are a substantial part of earnings. In Black and Henderson if capital markets operate perfectly for human capital (i.e., we violate the "no slavery" constraint) or capital is physical and capital markets operational, one dynastic family could move entirely to, say, type 1 cities and lend some of their human capital to another dynastic family in type 2 cities. With no capital market, each dynastic family must operate as its own informal capital market and spread itself across cities.

In this context Black and Henderson show that, regardless of scale or point in the growth process, h_1 / h_2 and I_1 / I_2 are fixed ratios, dependent on θ_i eq. (6) and (16). As θ_1 / θ_2 (the relative returns to capital) rises, h_1 / h_2, I_1 / I_2 and also n_1 / n_2 rise. Z and m_1 / m_2 are all fixed ratios of parameters θ_i, δ_i, and α under

equilibrium growth. Equilibrium and optimal growth differ because the private returns to education in a city, θ_i, differ from the social returns, $\theta_i + \psi_i$. But local governments can't intervene successfully to encourage optimal growth. Why? With free migration and "no slavery", if a city invests to increase its citizens' education, a person can take their human capital ("brain drain") and move to another city (be subsidized by another city to immigrate, given that city then need not provide extra education for that worker). This model hazard problem discourages internalization of education externalities.

2.2.1 Growth properties: Cities

From eq. (13), equilibrium (and efficient) city size in type 1 cities is a function of the per person human capital level, h_1, in type 1 cities. After solving out the model (for P), the same will be true of type 2 cities. City sizes grow as h_1 and h_2 grow, where, under equilibrium growth given h_1 / h_2 is a fixed ratio, $\dot{h}_1 / h_1 = \dot{h}_2 / \dot{h}_2$ where a dot represents a time derivative. Then

$$\frac{\dot{n}_2}{n_2} = \frac{\dot{n}_1}{n_1} = 2\varepsilon_1 \frac{\dot{h}}{h} \tag{18}$$

where $\dot{n}_i / n_i$ is the growth rate of efficient sizes n_i^*.

For the number of cities, the issue is whether growth in individual sizes absorbs the national population growth, or more cities are needed. Given

$$\frac{\dot{m}_1}{m_1} = \frac{\dot{m}_2}{m_2} = g - \frac{\dot{n}_i}{n_i} = g - 2\varepsilon_1 \frac{\dot{h}}{h}, \tag{19}$$

the numbers of cities grow if $g > \dot{n}_i / n_i$. Note growth in numbers and sizes of cities is "parallel" by type, so the relative size distribution of cities is constant over time. Parallel growth with a constant relative size distribution of cities as reviewed in Section 1.1 is what is observed in the data. This result generalizes to many types of cities under certain conditions. For example, with the log linear production technologies we assumed and with many varieties of output consumed under unitary price and income elasticities of log-linear preferences, parallel growth results.

2.2.2 Growth properties: Economy

Ruling out explosive or divergent growth, there are two types of growth equilibria. Either the economy converges to a steady state level, or it experiences endogenous steady-state

growth. Convergence to a level occurs if $\varepsilon \equiv \varepsilon_1 \ (1-(\gamma - 2\delta_2)) + \varepsilon_2 \ (\gamma - 2\delta_2) < 1,$ where ε is a weighted average of the individual city type. In that case at the steady-state $\bar{h}$, $\dot{n}_i / n_i = 0$ and $\dot{m}_i / m_i = g$, or only the numbers but not sizes of cities grow just like in exogenous growth (Kanemoto 1980, Henderson and Ioannides, 1981). If $\varepsilon = 1$ then there is steady-state growth, where $\bar{\gamma}^h = \dot{h}/h = \frac{A-\rho}{\sigma}$ (where the transversality condition requires $A > \rho$). In that case $\dot{n}_i / n_i = 2\varepsilon_1^{\left(\frac{A-\rho}{\sigma}\right)}$, or cities grow at a constant rate. and their numbers also increase if $g > 2\varepsilon_1^{\left(\frac{A-\rho}{\sigma}\right)}$. This "knife-edge" result of whether there is endogenous growth or not dependent on the value of ε is not essential. For example in Rossi-Hansberg and Wright (2004) endogenous growth can occur more generally in a context where human capital accumulation involves worker time and the growth rate of human capital is a log-linear function of the fraction of time devoted to human capital accumulation, as opposed to production.

2.3 Extensions

There are three major extensions to the basic systems of cities models. First people may differ in terms of inherent productivity or in terms of endowments. Second, while we have discussed the issue of city specialization versus diversification we haven't developed insights into a more nuanced role of small highly specialized cities versus large diversified metro areas in an economy.

2.3.1 Different Types of Workers

Turning to the first extension, Henderson (1974) has physical capital as a factor of production owned by capitalists who needn't reside in cities. Equilibrium city size reflects a market trade-off between the interests of city workers who have an inverted U-shape to utility as a function of the size of the city they live in and capitalists whose returns to capital rise indefinitely with city size (for the same capital to labor ratio). There is a political economy story, where capitalists collectively in an economy have an incentive to limit the number of cities, thus forcing larger city sizes. Helsley and Strange (1990) have a matching model between the attributes of entrepreneurs and workers and Henderson and Becker (2001) a related two class model. Again the two class model yields a conflict between the city sizes that maximize the welfare of one versus another group, which is resolved in competitive national land development markets.

In a different approach Abdel-Rahman and Wang (1997), Abdel-Rahman (2000) and later Black (2000) look at high and low skill workers who are used in differing proportions in production of different goods. Black has one traded good produced with just low skill labor and a second traded good produced with high skill workers and inputs of a local non-traded good produced with just low skill workers. High skill workers generate production externalities in the form of knowledge spillovers for all traded goods. In Black, urban specialization with all high skill workers (and some low skill workers) concentrated in one

type of city producing the first type of good is efficient; but a separating equilibrium that would sustain this pattern, where low skill workers and low tech production stay in their own type of city (rather than trying to cluster with high tech production) is not always sustainable. Black characterizes conditions under which a separating equilibrium will emerge.

It is important to note that there is a much more developed literature on inequality induced by neighborhood selection, where the characteristics of neighbors affect skill acquisition (e.g. average family background in the classroom affects individual student performance). That leads to segregation of talented or wealthier families by neighborhood (Benabou 1993, Durlauf, 1996) and can help transmit economic status across generations, promoting inter-generational income inequality.

2.3.2 Metro Areas.

Simple indices of urban diversity indicate that smaller cities are very specialized and larger cities highly diversified. So the question is what is the role of large metro areas in an economy and their relationship to smaller cities. Henderson (1988) and Duranton (2004) have a first nature - second nature world, where every city has a first nature economic base and footloose industries cluster in these different first nature cities. In general the largest centers are those attracting the most footloose production to their first nature center. The Duranton paper is discussed in detail in Section 2.3.3. However, it seems that today few metro areas have an economic base of first nature activity. Accordingly recent literature has focused on the role of large metro areas as centers of innovation, headquarters, and business services (Kolko, 1999).

The Dixit-Stiglitz model opened up an avenue to look at large metro areas as having a base of diversified intermediate service inputs, which generate scale-diversity benefits for local final goods producers. That initial idea was developed in Abdel-Rahman and Fujita (1990) and has led to a set of papers focused on the general issue of what activities, under what circumstances are out-sourced. Theory and empirical evidence (Holmes, 1999 and Ono 2000) suggest that as local market scale increases, final producers will in-house less of their service functions. The resulting increased out-sourcing encourages competition and diversity in the local business service market, encouraging further out-sourcing.

In terms of incorporating this into the role of metro areas versus smaller cities, Davis (2000) has a two-region model, a coastal internationally exporting region and an interior natural resource rich region. There are specialized manufacturing activities which, for production and final sale, require business service activities, summarized as headquarters functions. Headquarters purchase local Dixit-Stiglitz intermediate services such as R&D, marketing, financing, exporting, and so on. Headquarters' activity is in port cities in the coastal region. The issue is whether manufacturing activities are also in these ports versus in specialized coastal hinterland cities versus in specialized interior cities. Scale economies in

manufacturing and headquarters activities are different and independent of each other, so that, based on scale considerations, these activities would be in separate specialized cities. However if the costs of interaction (shipping manufactured goods to port and transactions costs of headquarters-production facility communication) between headquarters and manufacturing functions are extremely high, then both manufacturing and headquarters activities can be found together in coastal port cities. Otherwise they will be in separate types of cities. In that case, manufacturing cities will be in coastal hinterlands if costs of headquarters-manufacturing interaction are high relative to shipping natural resources to the coast. However if natural resource shipping costs are relatively high, then manufacturing cities will be found in the interior. Duranton and Puga (2001) have a very similar model of functional specialization, without the regional flavor. If there is specialization, then there are headquarter cities where headquarters outsource local services in diversified large metro areas, while production occurs in specialized manufacturing cities.

In a different paper Duranton and Puga (2000) develop an entirely different and stimulating view of large metro areas. In an economy there are m types of workers who have skills each specific to producing one of m products. Specialized cities have one type of worker producing the standardized product for that type of worker subject to localization economies. Diversified cities have some of all types of workers. Existing firms at any instant die at an exogenously given rate; and, in a steady-state, new firms are their replacement. New firms don't know "their type" -- what types of workers they match best with and hence what final product they would be best off producing. To find their type they need to experiment by trying the different technologies (and hence trying different kinds of workers). New firms have a choice. They can locate in a diversified city with low localization economies in any one sector. In a diversified city they can experiment with a new process each period until they find their ideal process. At that point they relocate to a city specialized in that product, with thus high localization economies for that product. Alternatively new firms can experiment by moving from specialized city to specialized city with high localization economies, but face a relocation cost each time. If relocation costs are high, the advantage during their experimental period is to be in a diversified city. This leads to an urban configuration of experimental diversified metro areas and other cities which are specialized in different standardized manufacturing products.

The Duranton and Puga model captures a key role of large diversified metro areas consistent with the data. They are incubators where new products are born and where new firms learn. Once firms have matured then they typically do relocate to more specialized cities. This also captures the product-life cycle for firms in terms of location patterns. Fujita and Ishii (1994) document the location patterns of Japanese and Korean electronics plants and headquarters. In a spatial hierarchy mega-cities house headquarters activities (out-sourcing business services) and experimental activity. Smaller Japanese or

Korean towns have specialized, more standardized high tech production processes and low tech activity is off-shore.

2.3.3 Stochastic Process and Zipf's Law

Gabaix (1999a, 1999b) argues that if, there is a stochastic process where individual city growth rates follow Gibrat's Law—the growth rate in any period is unrelated to initial size -- then the size distribution the emerges will follow Zipf's Law. Beyond specifying a stochastic process where shocks to productivity or preferences follow a random walk, to get the result in a model where there is an endogenous number of cities of efficient sizes, as opposed to just fixing the number of cities (Gabaix 1999a, and Duranton 2004) requires considerable structure, with a variety of such issues being analyzed in Cordoba (2004). We follow Rossi-Hansberg and Wright (2004) who adapt the model we have presented. In their base case there is only human capital; and technology and preferences are log-linear. They have many final output industries and hence types of specialized cities. They group industries and specialized city types into sets, where within each set industries and city types have the *same* technology but each industry draws its own permanent shock each instant. In terms of the shock they assume that $D_1(t)$ in the equivalent of eq. (6) follows a finite order Markov process. Finally and critically to have Gibrat's Law lead to Zipf's Law, they must impose an arbitrary lower bound on the sizes that cities can fall to (Gabaix (1999a). These assumptions lead to Zipf's Law holding for each set of industries and they show one can aggregate across sets of industries to get Zipf's Law in aggregate. It goes without saying many of the assumptions imposed to get Zipf's Law are very strong, a key point made in Cordoba (2004).

In a recent paper, Duranton (2004) tries to model "micro-foundations" for the stochastic process affecting city sizes and as a result ends up modeling an important overlooked aspect of city evolution. Duranton has "first nature" (immobile given natural resource location) production and "second nature" (mobile, or footloose) production in m cities, where m is given by the number of immobile natural resource products, each needing their own city. So, in contrast to Rossi-Hansberg and Wright the number of cities is fixed; but given that restriction a lot is accomplished. In the paper there are $(n >> m)$ products, in a Grossman-Helpman (1991) product quality ladder model. The latest innovation in each product is produced by the monopolist holding the patent and only this top quality is marketed for any product. Investment in innovation to try to move the next step up in the quality ladder in industry k and get the next patent in k, can also lead to the next step up in a different industry -- i.e., there can be cross-industry innovation. For footloose industries, to partake of a winning innovation occurring for industry k in city i, requires industry k production to locate in city i where the innovator is. Presumably co-location of the inventor and production makes the information needed for the transition to mass production cheaper to exchange (e.g., the workers in the innovative firm take over production). Innovation follows a stochastic process where innovation probabilities depend on R&D expenditures. Industry jumps from city to city

according to where the latest innovation is, and city growth also follow a stochastic process. The resulting stochastic process of city growth and decline results in steady state size distributions that are similar to Zipf's Law. Adding in considerations of urban scale economies in the innovation process helps explain the long right tails in actual city size distributions, as they differ from Zipf's Law.

Duranton's formulation has the nice feature that cities have patterns of production specialization which change over time. This seems to fit the data; and Duranton's paper in fact models the evolution of industry structure of cities. We know from Black and Henderson (1999b) and Ellison and Glaeser (1999) that industries move "rapidly" across cities, with city specialization changing over time for cities. Any city is very slow to gain a high share of any particular industry's production (given there are many possible industries to gain a share from) and is very quick to lose a high share (given many competitor cities).

3. Urbanization and Growth

The previous section examined a fully urbanized economy where all production occurs in cities. City sizes grow with improvements in technology but, absent stochastic elements, individual cities grow in parallel, with the relative numbers of different types of cities and the relative size distribution of cities time invariant. Here we examine a non-steady state world in which an economy has an agriculture sector that is shrinking with economic development and an urban sector that is growing. We briefly review traditional dual sector models and the new economic geography models, both of which examine sectoral transformation, but without cities per se and generally without real economic growth. Then we present an endogenous growth model in which there is sectoral change with cities.

3.1 Two Sector Approaches, Without Cities

Urbanization involves resources shifting from an agricultural to an urban sector. The dual economy models dating back to Lewis (1954) look at sectoral change but are really static models. They focus on the question of urban " bias", or the effect of government policies on the urban-rural divide, and the efficient rural-urban allocation of population at a point in time. These two sector models have an exogenously given "sophisticated" urban sector and a "backward" rural sector (Rannis and Fei 1961, Harris and Todaro 1970, and others as now well exposited in textbooks (e.g., Ray 1998)).

In these models, the marginal product of labor in the urban sector is assumed to exceed that in the rural sector. Arbitrage in terms of labor migration is limited by inefficient (and exogenously given) labor allocation rules such as farm workers being paid average rather than marginal product or artificially limited absorption in the urban sector (e.g., formal sector minimum wages). The literature focuses on the effect on migration from the rural to urban sector of policies such as rural-urban terms of trade, migration

restrictions, wage subsidies, and the like.

The final and most complex versions of dual sector models are in Kelley and Williamson (1984) and Becker, Mills, and Williamson (1992), which are fully dynamic CGE models. They have savings behavior and capital accumulation, population growth, and multiple economic sectors in the urban and rural regions. Labor markets within sector and across regions are allowed to clear. The models analyze the effects of a wider array of policy instruments, including sector specific trade or capital market policies for housing, industry, services and the like. However the starting point is again an exogenously given initial urban-rural productivity gap, sustained initially by migration costs and exogenous skill acquisition. On-going urbanization is the result of exogenous forces -- technological change favoring the urban sector or changes in the terms of trade favoring the urban sector.

As models of urbanization, these dual economy ones are a critical step but they suffer obvious defects. First how the dual starting point arises is never modeled. Second, and related to the first, there are no forces for agglomeration that would naturally foster industrial concentration in the urban sector. Finally although the models have two sectors there is really little spatial or regional aspect to the problem. There is a new generation of two-sector models, the core-periphery models, which attempt to address some of these defects. The core-periphery models ask under what conditions in a two-region country, industrialization, or "urbanization" is spread over both regions versus concentrated in just one region.

Compared to the dual economy models, Krugman's (1991a) paper explicitly has scale economies that foster endogenous regional concentration. Second, while there are two regions, no starting point is imposed, where one region is assumed to start off ahead of the other. Industrialization may occur in both regions or in only one region. One region can become "backward" (under certain assumptions), or, if not backward (lower real incomes) at least relatively depopulated (Puga, 1999). But these are outcomes solved for in the model. Third the models have some notion of space represented as transport costs of goods between regions.

The models are focused on a key developmental issue -- the initial development of a core (say, coastal) region and a periphery (say, hinterland) region, as technology improves (transport costs fall) from a situation starting with two identical regions. As such they do relate to the earlier discussion in Section 1.3 of urban concentration in a primate city versus the rest of the urban sector. Some work (Puga 1999, Fujita, Krugman, and Venables 1999, Chapter 7, Helpman 1998, and Tabuchi 1998) also analyzes how under certain conditions, with further technological improvements, there can be reversal. Some industrial resources leave the core; and the periphery also industrializes/urbanizes. However core-periphery models have limited implications for urbanization per se, since in many versions including Krugman's (1991a) initial paper, the agricultural population is fixed.

Unfortunately, to date core-periphery models have been almost exclusively uni-dimensional in focus, asking what happens to core-periphery development as transport costs between regions decline. They are not focused on other forms of technological advance, let alone endogenous technological development. With a few exceptions, Fujita and Thisse (2002) and Baldwin (2001), the models are static. But even in these exceptions, there is still the focus on exogenous changes in transport technology. Compared to the older dual economy literature, generally core-periphery models have no policy considerations of interest to development economists, such as the impact of wage subsidies, rural-urban terms of trade, capital market imperfections. An exception is that some papers have examined the impact on core-periphery structures of reducing barriers to international trade, such as tariff reduction, and papers are starting to explore issues of capital market imperfections. The core-periphery model is an important innovation in bringing back the role of transport costs, largely ignored in urban systems work, to the forefront. Excellent summaries of the key elements include Neary (2001), Fujita and Thisse (2000) and Ottaviano and Thisse (2004), with the latter two developing many extensions. Fujita, Krugman and Venables (1999) stands as a basic reference on detailed modeling.

The dual economy and core-periphery models are regional models, with limited urban implications. Urban models are focused on the city formation process, where the urban sector is composed of numerous cities, endogenous in number and size. Efficient urbanization and growth require timely formation of cities. As policy issues the extent of market completeness in the national markets in which cities form, the role of city governments and developers, the role of inter-city competition, and the role of debt finance and taxation are critical. In the next section we analyze an urbanization process in which there are cities. Then we turn to a discussion of some key policy issues.

3.2 Urbanization With Cities

Here I present a simple two sector model of urbanization with cities, adapting the model in part 2 following Henderson and Wang (2005, 2004). The urban sector is exactly like the X_1 type of city sector earlier with production technology given in (6). The other sector is food produced in the agriculture sector, which we make now the numeraire (since there may initially be no urban sector). As a result, for type 1 cities in the urban sector, equation (7) for wages, equations (9) and (10) for commuting costs and rents, and equation (15) for income are all redefined to be multiplied by the price of X_1, p. The city size equation is the same, invariant to relative prices. Critical here is

$$I_1 = W_1 \ (1 - 2\delta_1) = pQ_1 h_1^{\varepsilon_1} \qquad (15^1)$$

for Q_1 a parameter cluster.

Agriculture. Rural output per worker is $D_a h_a^{\psi_a} h_a^{\theta_a}$, or $D_a h_a^{\varepsilon_a}$, so rural wages and real income are

$$W_a = D_a h_a^{\varepsilon_a} \qquad \varepsilon_a \equiv \psi_a + \theta_a \tag{20}$$

As such the rural sector is very simple: no commuting costs, no agglomeration economies and no diminishing returns to land. As in the urban sector, productivity is affected by individual human capital accumulation, $h_a^{\theta_a}$, and by sector knowledge spillovers, $h_a^{\psi_a}$.

Preferences and Urbanization. To have sectoral transformation we need to move away from the world of unitary price and income elasticities in Section 2, so growth between sectors is not parallel. Here we assume preferences have the form

$$V = (x + a^{\gamma})^{\alpha}, \qquad \gamma, a < 1 \tag{21}$$

where *a* is consumption of agricultural products. In (21) agricultural demand is income inelastic, with a demand function

$$a = \gamma^{\frac{1}{1-\gamma}} \rho^{\frac{1}{1-\gamma}}. \tag{22}$$

3.2.1 Human Capital Market, Migration, Savings.

The urbanization process as a "transitory" phenomenon is not a steady state process. To simplify, following much of the literature, we introduce an explicit market for human capital, as though human capital investments were not embodied. And we assume an exogenous savings rate, s. For the former, now each person in the economy has a human capital level, h, which can be used in production or can be loaned out. I now flesh out the equations of the model, that in Section 2 were skimmed over. The capital market equalizes capital returns across sectors so $r = p\ \theta_1\ D_1\ h_1^{\theta_1+\psi_1-1}\ n_1^{\delta_1} = \theta_a\ D_a\ h_a^{\theta_a+\psi_a-1}$. Substituting in for n_1 from (13)

$$p = Q_2\ h_a^{\varepsilon_a} h_1^{1-\varepsilon_1} \tag{23}$$

recalling $\varepsilon_a \equiv \psi_a + \theta_a$ and $\varepsilon_1 \equiv (\theta_1 + \psi_1)/(1 - 2\delta_1)$. Q_2 is a parameter cluster.

Free migration requires urban incomes defined to be gross human capital returns to equal the same for agriculture, or $I_1 + r\ (h - h_1) = W_a + r\ (h - h_a)$. Utilizing (15)

$$W_1 - W_a = pbn^{1/2} + r\ (h_1 - h_a) \tag{24}$$

With free migration equalizing real incomes across sectors, urban wages exceed rural wages by (commuting) cost-of-living differences (the first term on the RHS of (24)), and by a factor compensating if human capital requirements in the urban sector exceed those in the rural, as I assume.

If we substitute in (24) for $W_1,\ W_a,\ p$ and r and rearrange, we get

$$h_a = h_1\ \frac{\theta_a}{\theta_1}\ \left(\frac{1-\theta_1-2\delta}{1-\theta_a}\right) \tag{25}$$

A sufficient condition for $h_1 > h > h_a$, or the urban sector to be human capital intensive, is that $\theta_1 > \theta_a$, as assumed.

To close the model requires three relationships. First is national full employment of capital and labor so

$$n_a h_a + n_1 m_1 h_1 = hN \tag{26a}$$

$$n_a + m_1 n_1 = N \tag{26b}$$

where m_1,as before, is the number of type 1 cities and N is the national population. The third equation equates the demand for food equal to its supply. But that requires a digression on how human capital is produced and nature of savings. Since we want to be able to start with a purely rural economy, we don't want to have it produced just from X_1 as in Section 2.

We assume human capital production in each sector is made from goods from that sector (where an equal expenditure in any sector results in the same human capital), which is almost like assuming, for a fixed savings rate, a fixed fraction of working time in any sector is needed to produce a unit of human capital. Second, we assume savings at the rate s are from wage income net of rental costs, or from $I_1 - rh_1,$ and $W_a - rh_a$, which magnitudes are equalized by migration. Thus in the food market total production $n_a D_a h_a^{\varepsilon_a}$ equals food consumption demand $N\ (\rho\gamma)^{\frac{1}{1-\gamma}}$ (see 22) plus agricultural savings,

or $n_a D_a h_a^{\varepsilon_a} = N\ (p\gamma)^{\frac{1}{1-\gamma}} + sn_a\ (W_a - rh_a)$. Substituting in for r, for p from (22), W_a from (20) and for h_a from (25) we get

$$n_a / N = Q_3 h_1^{\frac{\gamma\varepsilon_a - \varepsilon_1}{1-\gamma}} \tag{27}$$

with Q_3 a parameter cluster. We assume $\gamma\varepsilon_a - \varepsilon_1 < 0$, so the social returns to human capital in the urban sector exceed those in the rural sector discounted by γ. With economic growth in human capital, the rural sector diminishes. Note in (27) for there to be an urban sector, h_1 must be large enough so $n_a / N < 1$, as we explain below. Of course h_1 is linked to h through (26a) where with substitutions

$$h_1 \left(1 - Q_4\ h_1^{\frac{\gamma\varepsilon_a - \varepsilon_1}{1-\gamma}}\right) = h \tag{28}$$

where given $\gamma\varepsilon_a - \varepsilon_1 < 0,\ dh_1 / dh > 0$, once there is an urban sector. Q_4 is a parameter cluster.

3.2.2 Urban Growth and Transformation

Once an urban sector exists, city growth is as in section 2: $\dot{n}_1 / n_1 = 2\varepsilon_1 \dot{h}_1 / h_1$, so cities grow with human capital accumulation. The growth in number of cities now depends on the rate of urbanization, as well. Combining (26a) and (26b), with differentiation $\dot{m}_1 / m_1 = (N / m_1 n_1)\ g - \dot{n}_1 / n_1 - (n_a / m_1 n_1)\ \dot{n}_a / n_a$. If we differentiate (27) for $\dot{n}_a / n_a$ and combine this becomes

$$\dot{m}_1 / m_1 = g - \dot{n}_1 / n_1 + \frac{n_a}{m_1 n_1}\ \frac{\gamma\varepsilon_a - \varepsilon_1}{1-\gamma}\ \dot{h}_1 / h_1 \tag{29}$$

As before the rate of growth of numbers of cities is increased by national population growth, g, and reduced by growth in individual city sizes. Now it is also enhanced by economic growth which increases relative demand for urban products and draws labor out of agriculture, as captured by the last term in (29).

3.2.3 Economic Growth

Given the savings rule, total human capital increases by $\dot{H} = s\left[m_1 n_1\ (I_1 - rh_1) + n_a\ (W_a - rh_a)\right]$ each instant so per person change in capital is $\dot{h} / h = \dot{H} / H - g$. Given $I_1 - rh_1 = W_a - rh_a$, with substitutions we have

$$\dot{h}/h = sQ_5 h_1^{\varepsilon_a - 1} \left(1\text{-}Q_6 h_1^{\frac{\gamma\varepsilon_a - \varepsilon_1}{1-\gamma}} \right)^{-1} - g \qquad (30)$$

where $Q_6 < Q_4$, for parameter clusters. In terms of growth, if $\varepsilon_a < 1$ and urbanization occurs, we have steady state levels given $\dot{h}/h$ declines with increases in h_1, and hence *h*. If $\varepsilon_a = 1$, we approach steady state growth once h_1 gets large so $n_a N \to 0$ and the expression in parentheses in (30) approaches 1. However in either case at low levels of development in (27) n_a / N is bounded at 1 where equation (27) defines a critical h_1 and hence h in (28), say h_c, below which $n_a / N = 1$. To have steady state levels with urbanization given we start at $n_a / N = 1$ with $\dot{h}/h = \dot{h}_a / h_a = -g + (1-\theta_a)\, h_a^{\varepsilon_a - 1}$, requires $h_c < (g/(1\text{-}\theta_a))^{\frac{1}{\varepsilon_a - 1}}$, so we pass the critical h at which urbanization starts before hitting the potential steady state value of *h* without urbanization. Otherwise the economy can be stuck with no urbanization. Details of this and issues of multiple equilibria are discussed in Henderson and Wang (2005).

3.3 Extensions and Policy Issues

There are three general sets of policy issues. First concerns whether in the context of the models in section 2 and 3.2, the national composition of cities of different types is efficient. We have already discussed this issue: in many contexts asking whether the national composition of cities is efficient is like asking if national output composition is efficient. If there are national policy biases such as trade policies favoring steel products over textile products, with urban specialization, if steel is produced in bigger types of cities than textiles, the numbers of larger cities relative to smaller ones and hence urban concentration will increase. The second set of policy issues concerns whether, in general, city sizes are likely to be efficient and we discuss this in Section 3-3-1.

The second general set of issues deals with factors we have ignored. In particular the modeling in sections 2 and 3.2 assumes a nice smooth process where (i) all factors of production are perfectly mobile and malleable, (ii) city borrowing and debt accumulation have no role, (iii) "lumpiness" problems that arise in city formation when economies are small are ignored: while m must be an integer in reality, in the analysis it is treated as any positive number where the number of cities grows at a rate $\dot{m}/m$, rather than by 0, 1 or 2. A model that incorporates these features is outlined in section 3.3.2, which brings to the forefront a variety of policy issues.

3.3.1 City Sizes

A perpetual debate in particular developing countries is whether certain mega-cities are oversized, squandering national resources that must be allocated to commuting, congestion, and transport

in those cities and resulting in low quality of life in the polluted, unsanitary and crowded slums of such cities. In other countries especially former planned economies the debate goes the other way: are cities too small? The growth connection is straightforward. Either squandered resources in over-sized cities or too small cities with unexploited scale economies mean lower income levels, potentially lower savings, lower capital accumulation and thus lower growth rates. While calculations are tedious, in the steady state growth in section 2.2.2 where $\gamma^h = \dot{h}/h = (A-\rho)/\sigma$, A depends on urban parameters (for example, increasing with human capital returns) and will be lowered if city sizes are inefficient.

Using a simple, partial equilibrium diagram, it is possible to illustrate both issues: the mega-city "problem" and the planned economy problem. The diagrams point to first order effects. For the mega-city problem, suppose there are a variety of type 1 cities in an economy with free mobility of labor and institutions supporting efficient city formation. In Figure 5a, the representative city has a size n_1^*, where real income as function of city size peaks at I_1^*, tangent to the perfectly elastic national supply curve of labor to the city. Suppose one particular type 1 city is favored relative to the rest, where the various types of favoritism are discussed in Section 1.3.2. For example it may have special public services compared to other cities financed out of national taxes. Those favors raise the utility, or real income that residents in the favored city potentially receive, shifting up the inverted-U real income curve. That upward shift draws migrants into the city expanding its size to n_{mega}. But at n_{mega}, the net income generated by the city, ignoring its nationally financed favors, is only net I_m. The gap, $I_1^* - I_m$, times the population represents "squandered resources". Of course, such squandering would in general equilibrium affect prices, lowering the height of the population supply curve and the inverted-U's.

A second issue in city formation concerns poor institutions in national land markets and in local governance which limit the number of cities that can form. Suppose that, in villages which might become cities, local governments by institutional restrictions can't expand infrastructure (see next section), can't rezone and build on urban fringe land, and can't offer subsidies to incoming firms. And suppose developers can't assemble large tracts of land for development because property rights are ill-defined. These villages can't grow into cities; nor can entirely new cities form. If the number of cities is bindingly limited, so there are too few cities, all existing cities under free migration are too big. In Figure 5a, suppose we reconsider the figure ignoring the representative city curve and assume all cities have inverted-U's like the favored city. Then, in this reinterpretation of the figure, I_F is the potentially attainable real income in all cities (ignoring general equilibrium effects) if cities could freely form. Given restricted numbers, rather than operating at I_F (with size n_1^*), cities are overcrowded; and in equilibrium

they operate at I_1^* (with size n_{mega}), with the same national supply curve of labor as labeled in the figure. The restrictions result in losses related to the gap $I_F - I_1^*$.

The planned economy problem is entirely different. Former "planned" economies like China have formal migration restrictions limiting the visas given for rural people to move to cities and limiting migrants access to jobs, housing, medical care and schooling in destination cities to reduce the incentive to migrate. Some former planned economies (as well as China) limited migration through housing provision and land development. If the state provides and allocates all housing assignments, migrants can't move unless housing is provided in the destination. As we saw in Table 2, countries like China and Russia have very low urban concentration compared to other large countries. Figure 5b captures the essence of the problem. While the representative city has an inverted-U where real income is maximized at n_1^*, migration restrictions for cities a and b restrict sizes to n_a and n_b and real incomes to I_a and I_b. Au and Henderson (2002) estimate these inverted-U's for different types of cities in China in 1997 and find that 30% of cities are significantly undersized – below the lower 95% confidence interval on their equivalent to n_1^*. The productivity losses from being undersized are enormous: 30-50% or more loss in GDP per capita for many cities.

3.3.2 Sequential City Formation and Governance

In a working paper, Henderson and Venables (2004) take a new approach to city formation. They assume a context where (1) there is a steady-flow of migrants from rural to urban areas, and (2) urban residence requires a fixed investment in non-malleable, immobile capital (housing, sewers, water mains, etc.). Cities form sequentially without population swings, so migrants all flow first into city 1 until its equilibrium size is reached (abstracting from any on-going technological change), and then all future migrants all go to a second city until its equilibrium size is reached, and so on. This is a very different process than when all resources are mobile: in the usual models in a small economy, when the second city forms, it takes half the population of the first at that instant, and when the third forms it takes one third of the then population of the first two. Cities grow way past $\overset{*}{n}_1$, shrink back to $\overset{*}{n}_1$, and then grow again, shrink, and on so. With fixed capital, such population swings would mean periods of abandoned housing. With sufficiently high required capital investments all population swings are eliminated in equilibrium. Each new city starts off tiny with no accumulated scale effects and low productivity. It grows steadily absorbing all new rural-urban migrants until its growth interval is complete and it reaches steady state size; then a new city starts off growing from a tiny size.

With sequential city formation without population swings, given discounting of the future, efficient city size requires cities to grow past the equivalent of $\overset{*}{n}_1$ to their steady state size, n_{opt}, at which

point real income per worker is declining. Intuitively, growing past n_1^*, with declining but still high real income, postpones the formation of a new city with tiny population, no scale effects and very low incomes. The paper then looks at equilibrium city formation in two contexts.

First is a situation with no "large agents" in national land markets – no developers and no city governments. In a model with perfect mobility of resources as discussed in Section 2, city formation with atomistic agents is a disaster due to coordination failure. A new city can only form when old cities are so big that the income levels they offer have fallen to the point where they equal what a person can earn in a city of size one. Having immobile capital presents a commitment device (Helsley and Strange, 1996), so individual, sequentially rational builders switch from building in an old city to building in a new one at a "reasonable time". Real incomes are still equalized across cities through migration. Given big old cities have high nominal incomes and the tiny new one low nominal income, housing rents adjust in old cities to equalize real incomes. Housing rents in old cities change over the growth cycle of a new city, starting very high and then declining (see also Glaeser and Gyourko, 2003). In this context, equilibrium sizes may even be smaller than optimal ones. The deviation from optimum has not to do with coordination failure which is solved despite the absence of "large" agents, but with the present value of externalities from a migrant in an old versus a new city.

With developers or full empowered local governments, externalities are appropriately internalized and city sizes are n_{opt}. However, apart from financing the housing and infrastructure capital, to induce new migrants to move to a new city with its low real income and scale economies in a timely fashion, large agents must subsidize in-migration of worker-firms. To do this they must borrow and, in fact, public debt accumulates over the entire growth interval of a city and only starts to be paid off once it reaches steady state size. Debt ceilings, or limits for cities which are common in many countries curtail subsidies to in-migrants and postpone new city formation. Debt limited cities are too big. The paper also explores the effects of limits on local tax property tax powers.

4. Some Issues For a Research Agenda

A handbook paper is a place to offer research suggestions, as well as summarize the state of knowledge. While various avenues of needed research are noted throughout, here I summarize three key suggestions. In all the spatial and urban work, transport costs are either absent or treated as a technology parameter that may exogenously change. In an actual development and growth context, transport costs reflect public infrastructure investment decisions, subject to political influence. Core-periphery models need to endogenize transport costs and urban models consider them, so spatial structures across regions

and cities are an outcome of investment decisions. A similar comment involves mobility costs of workers, which are related to both transport and communication infrastructure investments.

A second key research issue involves spatial inequality as it evolves with growth in a context where workers have different ability endowments and choose different human capital levels. In most spatial and urban models, workers are identical, except for their degree of mobility. But with urbanization, it may be that it is higher ability rural folks who urbanize and acquire modern skills, increasing real income gaps between high and low ability people. We have no models that directly address these issues and provide a comprehensive framework to evaluate spatial inequality, or cross-space income differences.

Finally we don't really have models that address the evolution of city production patterns with on-going technological change. While we have looked at parallel growth and urbanization, we know city functions also change over time. In less developed countries, bigger cities may be focused on manufacturing, but somehow with growth and technological change, big cities tend to specialize more in service functions, purchased by manufacturers and retailers in smaller cities. While we have models of functional specialization , we haven't modeled this evolution in city roles over the development process.

Abstract

The distribution of human capital and income lies at the center of a nexus of forces that shape a country's economic, institutional and technological structure. I develop here a unified model to analyze these interactions and their growth consequences. Five main issues are addressed. First, I identify the key factors that make both European-style "welfare state" and US-style "laissez-faire" social contracts sustainable.; I also compare the growth rates of these two politico-economic steady states, which are no Pareto-rankable. Second, I examine how technological evolutions affect the set of redistributive institutions that can be durably sustained, showing in particular how skill-biased technical change may cause the welfare state to unravel. Third, I model the endogenous determination of technology or organizational form that results from firms' tailoring the flexibility of their production processes to the distribution of workers' skills. The greater is human capital heterogeneity, the more flexible and wage-disequalizing is the equilibrium technology. Moreover, firms' choices tend to generate excessive flexibility, resulting in suboptimal growth or even self-sustaining technology-inequality traps. Fourth, I examine how institutions also shape the course of technology; thus, a world-wide shift in the technology frontier results in different evolutions of production processes and skill premia across countries with different social contracts. Finally, I ask what joint configurations of technology, inequality and redistributive policy are feasible in the long run, when all three are endogenous. I show in particular how the diffusion of technology leads to the "exporting" of inequality across borders; and how this, in turn, generates spillovers between social contracts that make it more difficult for nations to maintain distinct institutions and social structures.

Keywords: inequality, welfare state, technical change, skill bias, human capital, redistribution, social contract, political economy.

JEL classification: D31, O33, J3, H10.

Introduction

The distribution of human capital and income lies at the center of a nexus of forces that shape a country's economic, institutional and technological structure. This chapter develops a unified model to analyze these interactions and their implications for growth, emphasizing in particular the mechanisms that allow different socioeconomic structures to perpetuate themselves, and those pushing toward convergence.[1] The analysis centers around five main questions.

1. *Why do countries at similar levels of development choose widely different social contracts?* Redistribution –through taxes and transfers, unemployment and health insurance, education finance and labor market regulation– displays remarkable variations even among countries with similar economic and political fundamentals. I thus ask what makes both European-type welfare states and US-type, more laissez-faire social contracts sustainable in the long run, together with their respective levels of inequality.[2] I then examine the efficiency and growth properties of these two regimes (which cannot be Pareto ranked) and ask what shocks might cause each one to unravel. The model also sheds light on the contrasting historical development paths of North and South America, and on the more recent experience of East Asia versus Latin America.

2. *How does skill-biased technical and organizational change impact the viability of redistributive institutions?* Over the last twenty-five years, most industrialized countries experienced a considerable rise in wage inequality.[3] This trend is generally attributed to three main factors: skill-biased technical change, international trade (which lies outside the scope of this chapter), and institutional change, such as the erosion of the minimum wage and the decline of unions. But minimum wages, labor market legislation and union power are endogenous outcomes, to the same extent as social insurance and education policy; and indeed, they evolved quite differently in Continental Europe or Canada and in the United States.[4] Analyzing redistributive institutions as a whole, I show how skill-biased technical change can cause the welfare state to unravel, and examine more generally how technological evolutions affect the set of social contracts that can be sustained in the long run.

The previous questions aim to explain differences in redistributive policies (together with their economic implications) and the role of technology in their evolution. The next two take the reverse perspective.

[1] The main channels through which inequality and redistributive institutions can in turn affect growth were exposited in Bénabou (1996).

[2] I shall limit my scope here to politico-economic persistence mechanisms that reflect differences in agents' economic interests and political power (Bénabou (2000), Saint Paul (2001), Hassler et al. (2003), Alesina, Glaeser and Sacerdote (2002)) rather than social norms (Lindbeck (1995)) or differences in beliefs about the mobility process and the determinants of individual income (Piketty (1995), Bénabou and Tirole (2002), Alesina and Angeletos (2003)).

[3] See, e.g. Autor, Katz and Krueger (1997) or Berman, Bound and Machin (1997).

[4] See, e.g., Freeman (1995), Fortin and Lemieux (1997), Lee (1999), or Acemoglu, Aghion and Violante (2001).

3. *What determines the types of technologies and organizational forms used by firms?* Production processes –and in particular their degree of skill bias– are themselves endogenous, adapting over time to the skills of the labor force.[5] I develop here a new and very tractable model of technology choice, based on the idea that firms tailor the *flexibility* of their production processes (substitutability between different labor inputs) to the distribution of human capital in the workforce. The main prediction is that the more heterogenous are workers' skill levels, the more flexible and wage-disequalizing the equilibrium technology will be. In a country like Japan, by contrast, production will involve much tighter complementarity between workers' tasks. Integrating this model with the previous analysis of human capital dynamics, I also show that firms' choices involve externalities that tend to result in excessive flexibility and a suboptimal growth rate, or even in self-sustaining technology-inequality traps.

4. *What types of societies and institutions are most conducive to the emergence of skill-biased technologies and organizational forms?* Through their influence on the distribution of human capital, public policies in the fiscal, labor market and especially educational arenas are important determinants of what innovations can be profitably developed and adopted; the same is true for immigration. One notes, for instance, that skill-biased technical change and reorganization occurred first, and to a greater extent, in the United States compared to Europe –and within the latter, more so in England than on the Continent. Combining the technology and policy components of the model, I show how a world-wide shift in the technological frontier leads to different evolutions of production processes and skill premia across countries with different social contracts.

Two extensive but essentially disconnected literatures have examined the economic determinants and consequences of redistributive policies on the one hand, those of biased technical change on the other.[6] Yet in reality both are endogenous, and jointly determined. The ability to conduct a unified analysis of human capital dynamics, technology and institutions is a novel and key feature of the framework developed in this chapter. It makes it possible to address important questions such as the second, fourth and especially fifth ones on the list:

5. *What "societal models" –joint configurations of technology, inequality, and policy– are feasible in the long run? In particular, how does the diffusion of technology affect nations' ability to maintain their own redistributive institutions and social structures?* Analyzing the case of two countries linked by the (endogenous) diffusion of their domestically developed technologies, I show how inequality

[5] See, e.g., Kremer and Maskin (1996), Acemoglu (1998), Kiley (1999), Lloyd-Ellis (1999), and Vindigni (1992). Relatedly, Grossman and Maggi (2000) show how the skill distribution matters for international specialization, and Legros and Newman (1996) how the wealth distribution affects the organization of firms.

[6] See the previously cited references, as well as the other ones given throughout the paper.

tends to be "exported" to the less heterogeneous one. This mechanism, in turn, generates spillovers between the social contracts of different nations, transmitting even purely political shocks and potentially triggering "chain reactions" that can cause major shifts towards a common, and generally inegalitarian, outcome.

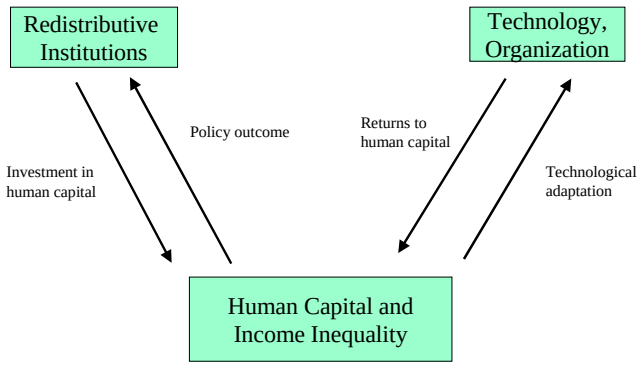

Figure 1: The links between inequality, technology and redistributive institutions

The chapter is organized in two main parts, corresponding respectively to the left- and right-hand sides of Figure 1.[7] The first of these two feedback loops centers on political-economy interactions. I thus present in Sections I and II a model of inequality, growth and redistributive policy in a context of imperfect credit and insurance markets (based on Bénabou (2000)). I first analyze how macro and distributional dynamics are affected by redistributive policies, then how the latter are themselves determined from the preferences and political power of different social classes. Finally, I identify the conditions under which a single or multiple politico-economic steady states arise.

The second and most novel part of the chapter incorporates the role of technology and its interactions with redistributive institutions. I first consider in Section III the impact of exogenous skill-biased technical change on inequality and the political equilibrium. I then study how technology responds to the composition of the labor force, through firms' choice of their degree of flexibility. In Section IV both sides of Figure I are brought together to analyze the long-run determination of institutions, technologies and the distribution of human capital. In Section V, finally, I show how technology diffusion leads to the "exporting" of inequality and international spillovers between social contracts. Section VI concludes. All proofs are gathered in the appendix.

[7] Each arrow on the diagram actually corresponds to a specific equation or proposition in the model. From left to right, these are (11), Proposition 3, (1) or later (28), and Proposition 8.

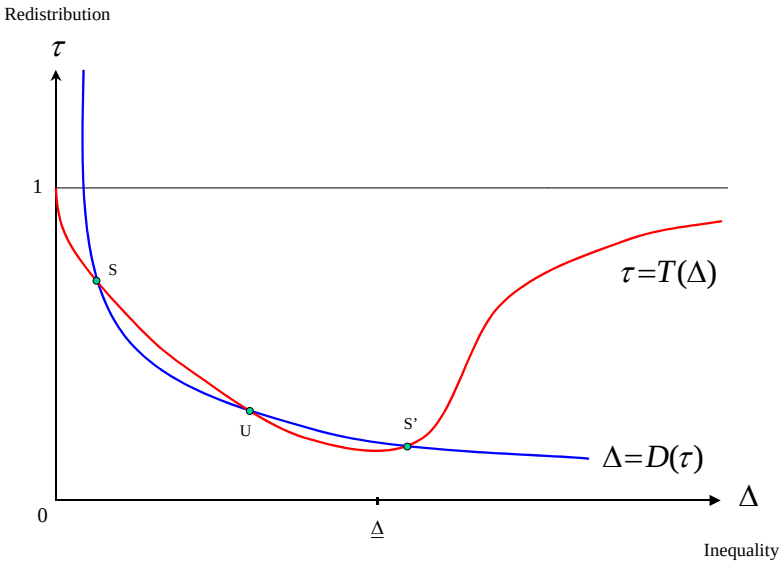

Figure 2: The two key relationships between inequality and redistribution.

I Inequality, Redistribution, and Growth

The model presented in this section (drawing on Bénabou (2000)) can be summarized by *two key relationships* between inequality and redistribution; both arise from imperfections in credit and insurance markets, and are illustrated on Figure 2.

The first locus summarizes the *political mechanism:* in each period, the equilibrium rate of redistribution chosen by voters is a U-shaped function $\tau = T(\Delta)$ of inequality in human capital, measured here as the variance of a lognormal distribution. The downward-sloping part of this curve, which is the crucial one, reflects a very general intuition: while asset market imperfections create a scope for efficient redistributive institutions (to provide social insurance and relax credit constraints), these institutions command much less support in an unequal society than in a relatively homogeneous one. Thus, starting from $\Delta = 0$, where there is unanimous support for the ex-ante efficient degree of redistribution, growing inequality increases the fraction of agents rich enough to lose from, and therefore oppose, all but relatively low levels of τ. The upward-sloping part of the curve, in contrast, is shaped by the standard skewness effect, which eventually dominates: rising numbers of poor will eventually impose more redistribution, well beyond the point where it ceases to be efficient.[8]

The second curve on Figure 2 represents the *accumulation mechanism:* since redistribution relaxes the credit constraints bearing on the poor's human capital investments, long-run inequality is a declining

[8] See, e.g., Alesina and Rodrik (1994) or Persson and Tabellini (1994) for models leading to such a positive slope. The empirical evidence (discussed at the end of this section) for both countries and US states provides little support for the standard view of a positive relationship between inequality and redistribution.

function $\Delta = T(\tau)$ of the rate of redistribution. When the two curves have several intersections, as illustrated on the figure, these correspond to *multiple politico-economic steady states* that are sustainable under the same fundamentals. One, with low inequality and high redistribution, corresponds to a European-type welfare state; the other, with the reverse configuration, to a US-type, more laissez-faire society.

In this and the next section I will derive the two loci from an explicit dynamic model, and identify the configurations of economic and political parameters under which alternative social models can coexist. In later sections I shall investigate how the two curves, and therefore the equilibrium set, are affected by exogenous technical change, then ultimately extend the analysis to the case where technology itself adapts endogenously to the distribution of skills in the population.

A *Production, Preferences and Policy*

The economy is populated by overlapping-generations families, $i \in [0,1]$. In generation t, adult i combines his human capital k_t^i with effort l_t^i to produce output, subject to a productivity shock z_t^i :

$$y_t^i = z_t^i \left(k_t^i\right)^\gamma \left(l_t^i\right)^\delta . \tag{1}$$

At this point the technology is exogenous and does not explicitly involve interactions among workers. Later on I will introduce a richer production structure, where agents with different skill levels perform complementary tasks and the degree of substitutability between them is optimally chosen by firms. The return to human capital γ and the mean of the productivity shocks z_t^i will then be endogenous functions of the current distribution of human capital. From the point of view of an individual worker-voter, however, this richer structure will retain an earnings function very similar to (1), so all the results obtained with this unconstrained reduced form will remain directly applicable.

Public policy or labor market institutions redistribute income through taxes and transfers, or a wage-equalization scheme, that transform each agent's gross earnings (or marginal revenue product) y_t^i into a disposable income $\hat{y}_t^i$, as specified further below. These resources finance both the adult's consumption, c_t^i, and his investment or educational bequest, e_t^i :

$$\hat{y}_t^i = c_t^i + e_t^i \tag{2}$$

$$k_{t+1}^i = \kappa\, \xi_{t+1}^i \left(k_t^i\right)^\alpha \left(e_t^i\right)^\beta, \tag{3}$$

where ξ_{t+1}^i represents the child's unpredictable ability, or simply luck, and $\alpha+\beta\gamma \leq 1$. There is thus no loan market for financing individual investments (e.g., children cannot be held responsible for the debts of their parents), and no insurance or securities market where the idiosyncratic risks z_t^i and ξ_{t+1}^i could be diversified

away.[9] Both shocks are i.i.d. and lognormal with mean one, and initial endowments are also lognormally distributed across families: thus $\ln z_t^i \sim \mathcal{N}(-v^2/2, v^2)$, $\ln \xi_t^i \sim \mathcal{N}(-w^2/2, w^2)$ and $\ln k_0^i \sim \mathcal{N}(m_0, \Delta_0^2)$.

Agents' preferences over their own consumption, effort, and child's human capital are defined recursively over their lifetime. Once he has learned his productivity z_t^i, agent i chooses his effort and consumption to maximize:

$$\ln V_t^i \equiv \max_{l_t^i,\, c_t^i} \left\{ (1-\rho)[\ln c_t^i - (l_t^i)^\eta] + \rho \ln E_t[k_{t+1}^i] \right\}. \tag{4}$$

The disutility of effort is measured by $\eta > 1$, which corresponds to an intertemporal elasticity of labor supply of $1/(\eta - 1)$. The discount factor ρ defines the relative weights of the adult's own felicity and of his bequest motive.[10]

At the beginning of period t, however, when evaluating and voting over redistributive policies, the agent does not yet know his lifetime productivity z_t^i. The resulting uncertainty over his *ex–post* utility level V_t^i is reflected in his *ex–ante* preferences, with a risk–aversion coefficient of a :

$$U_t^i \equiv \ln \left(E_t[(V_t^i)^{1-a} \mid k_t^i]^{1/(1-a)} \right), \tag{5}$$

This recursive specification allows a to parametrize the insurance value of redistributive policies, just as the labor supply elasticity $1/(\eta - 1)$ parametrizes the effort distortions.[11]

The redistributive policies over which agents vote are represented by simple, progressive schemes that map a market income y_t^i (marginal revenue product) into a disposable income $\hat{y}_t^i$, according to:

$$\hat{y}_t^i \equiv (y_t^i)^{1-\tau_t} (\tilde{y}_t)^{\tau_t}. \tag{6}$$

The break–even level $\tilde{y}_t$ is determined by the balanced-budget constraint, which requires that net transfers sum to zero. Thus, denoting per capita income by y_t, it must be that:

$$\int_0^1 (y_t^i)^{1-\tau_t} (\tilde{y}_t)^{\tau_t} \, di = y_t \,. \tag{7}$$

The elasticity τ_t measures the degree of *progressivity,* or equalization, of redistributive institutions.[12]

[9] The absence of any intertemporal trade is clearly an oversimplified (but quite common) representation of asset market incompleteness, making the model analytically tractable. Zhang (2004) extends a simplified version of the present model (with a zero-one policy variable and no political-economy mechanism) to allow for physical capital and financial bequests. He obtains similar results for the effects of inequality, plus new ones on convergence speeds to the steady-state.

[10] His (relative) risk–aversion with respect to the child's endowment k_{t+1}^i at that stage is normalized to zero, but this plays no role in any of the results. A dynastic specification of preferences (Bénabou (2002)) also leads to similar aggregate and distributional dynamics, but is less simple to work with.

[11] When $a \neq 1$ these recursive preferences are not time-separable (see, e.g., Kreps and Porteus (1979)), as risk-aversion differs from the inverse of the intertemporal elasticity of substitution in consumption, which by (4) remains fixed at one. This last assumption, common to many papers in the literature, helps make the model analytically solvable.

[12] When $\tau_t > 0$ the marginal rate rises with pretax income, and agents with average income are made better off: $\tilde{y}_t > y_t$. The elasticity of aftertax to pretax income is indeed the "right" measure of equalization: the posttax distribution induced by a fiscal scheme Lorenz–dominates the one induced by another (for all pretax distributions), if and only if the first scheme's elasticity is everywhere smaller (Fellman (1976)).

Three types of redistributive mechanisms can be considered here, being close to formally equivalent in this model. The first one, on which the exposition will generally focus, is that of fiscal policy, which equalizes disposable incomes through *taxes and transfers.* A second is *wage or earnings compression* through labor market institutions and policies favorable to workers with relatively low skills: minimum wage laws, union-friendly or right-to-strike regulations, firing costs, public sector pay and employment, etc.[13] The third one is *education finance,* where τ_t now applies only to human capital expenditures e_t^i, as opposed to all of income y_t^i. This may be achieved through a policy of school funding equalization across local communities, the presence of a centrally financed public-education system, or more generally by subsidizing differentially the education of rich and poor students.[14] Under either of the three above interpretations of τ_t, incentive compatibility requires that $\tau_t \leq 1$; on the other hand a regressive policy $\tau_t < 0$ cannot be ruled out a priori, and indeed one does observe such policies, typically in countries characterized by high inequality and a powerful ruling class.

B *Distributional Dynamics and Aggregate Growth*

Taking policy as parametrically given for the moment, I first consider the resulting economic decisions of individual agents, then the economy-wide dynamics of human capital and income.

Proposition 1 *Given a rate of redistribution τ_t, agents in generation t choose a common labor supply and savings rate: $l_t = \chi\,(1-\tau_t)^{1/\eta}$ and $e_t^i = s\,\hat{y}_t^i$, where $\chi^\eta \equiv (\delta/\eta)(1-\rho+\rho\beta)/(1-\rho)$ and $s \equiv \rho\beta/(1-\rho+\rho\beta)$.*

The fact that savings are unaffected is due to the imperfect-altruism assumption made regarding preferences.[15] Labor supply, on the other hand, declines in τ_t with an elasticity of $1/\eta$, and this single distortion will suffice to demonstrate how the efficiency costs and benefits of redistributive institutions shape the set of politico-economic equilibria.

Given Proposition 1, and substituting (6) into (3), the law of motion for human wealth is loglinear:

$$\begin{aligned} \ln k_{t+1}^i &= \ln \xi_{t+1}^i + \beta(1-\tau_t)\ln z_t^i + \ln\kappa + \beta \ln s \\ &\quad +(\alpha + \beta\gamma(1-\tau_t))\ln k_t^i + \beta\delta(1-\tau_t)\ln l_t + \beta\tau_t \ln \tilde{y}_t. \end{aligned} \tag{8}$$

[13] With the "autarkic" production function (1) the equivalence between the wage-income-equalization and the fiscal-redistribution interpretations of τ_t is immediate. It continues to hold when we move in Section III.B to a richer production structure with interacting agents.

[14] See Bénabou (2000) for this version of the model. Some of the formulas change slightly from those presented here for fiscal policy, but without affecting the qualitative nature of any of the results. There are, on the other hand, important quantitative differences between the growth and welfare implications of the two policies; see Bénabou (2002) and Sheshadri and Yuki (2004) for comparative analyzes. Previous models of redistribution centering on education finance include Becker (1964), Loury (1981), Glomm and Ravilkumar (1992), Saint-Paul and Verdier (1993), Bénabou (1996b) and Fernandez and Rogerson (1996). On the empirical side, see Krueger (2002) for a comprehensive summary and discussion of the evidence on targeted education and training policy interventions, from preschool to the college level.

[15] In Bénabou (2002) I develop and calibrate a version of the present model with dynastic preferences, where τ_t does affect the savings rate. On the other hand, agents are then able (and will indeed want) to use additional policy instruments, such as consumption taxes and investment subsidies, to alleviate this distortion.

This linearity reflects the absence of any non-convexities in the model, making clear that the multiplicity of equilibria will arise solely through the general-equilibrium feedback from the income distribution onto the political determination of τ_t.[16] These simple conditional dynamics also imply that human capital and income always remain lognormally distributed across agents:

$$\ln k_t^i \sim \mathcal{N}(m_t, \Delta_t^2), \tag{9}$$

$$\ln y_t^i \sim \mathcal{N}(\gamma m_t + \delta \ln l_t - v^2/2, \gamma^2 \Delta_t^2 + v^2), \tag{10}$$

where m_t and Δ_t^2 evolve according to two simple linear difference equations obtained by taking means and variances in (8), and given in the appendix. Since the growth of mean income y_t is of more direct economic interest than that of mean log-income m_t, I present here the equivalent characterization of the economy's dynamic path in terms of two linear difference equations in Δ_t^2 and $\ln y_t = m_t + \Delta_t^2/2$.

Proposition 2 *The distributions of human capital and income at time t are given by (9)-(10), where* $l_t = \chi(1-\tau_t)^{1/\eta}$. *The evolution of inequality across generations is governed by*

$$\Delta_{t+1}^2 = (\alpha + \beta\gamma(1-\tau_t))^2 \Delta_t^2 + \beta^2 (1-\tau_t)^2 v^2 + w^2, \tag{11}$$

and the growth rate of aggregate income by:

$$\ln(y_{t+1}/y_t) = \ln\tilde{\kappa} - (1-\alpha-\beta\gamma)\ln y_t + \delta(\ln l_{t+1} - \alpha \ln l_t) - \mathfrak{L}_v(\tau_t) v^2/2 - \mathfrak{L}_\Delta(\tau_t)\gamma^2\Delta_t^2/2, \tag{12}$$

where $\ln\tilde{\kappa} \equiv \gamma(\ln\kappa + \beta\ln s) - \gamma(1-\gamma)w^2/2$ *is a constant and*

$$\mathfrak{L}_v(\tau) \equiv \beta\gamma(1-\beta\gamma)(1-\tau)^2 \geq 0,$$

$$\mathfrak{L}_\Delta(\tau) \equiv \alpha + \beta\gamma(1-\tau)^2 - (\alpha + \beta\gamma(1-\tau))^2 \geq 0.$$

Equation (11) shows how inequality in the next generation stems from three sources: the varying abilities of children (w^2), shocks to family income (v^2), and differences in parental human capital (Δ_t^2), which matter both through family income and at-home transmission. Redistribution equalizes the disposable resources available to finance educational investments (but not social backgrounds), thus limiting both cross-sectional inequality and the *persistence* of family wealth, $\alpha + \beta\gamma(1-\tau_t)$; conversely, it increases *social mobility.*

Equation (12) makes apparent the growth losses from inequality due to credit constraints, and how redistribution's impact on growth involves a tradeoff between incentive and investment-allocation effects.[17]

[16] Or / and a feedback from the distribution onto the technology γ, once it is endogenized later on. By contrast, nearly all models in the literature that feature multiple equilibria rely on investment thresholds (e.g., Galor and Zeira (1993), Banerjee and Newman (1993)), indivisibilities in effort (Piketty (1997)), or non-homotheticity in preferences (e.g., Moav (2002)). For a discussion of indivisibilities, see also Mookerjee and Ray (2003).

[17] See Bénabou (1996b) for an overview of the literature on the relationship between inequality and growth, which is not the main focus of the present paper. In particular, inequality can also have positive effects on growth when there are non-

The effort distortion corresponds to the term in δ, which declines with parallel increases in τ_t and τ_{t+1}. The reallocation of human capital investments across differentially wealth-constrained agents is captured by the terms in $\mathfrak{L}_v(\tau_t)$ and $\mathfrak{L}_\Delta(\tau_t)$. When $\alpha = 0$ both are equal, and proportional to the concavity $\beta\gamma(1-\beta\gamma)$ of the common accumulation technology facing all families: differences in parental human capital and productivity shocks simply combine into variations in disposable income, $(1-\tau_t)^2\left(\gamma^2\Delta_t^2 + v^2\right)$, which credit constraints then translate into inefficient variations in investment, reducing overall growth proportionately. When $\alpha > 0$, however, disparate family backgrounds k_t^i represent complementary inputs that generate differential returns to investment, thus reducing the desirability of equalizing resources. Thus $\mathfrak{L}_\Delta(\tau)$ now differs from $\mathfrak{L}_v(\tau)$, and is minimized for $\tau = (1-\alpha-\beta\gamma)/(1-\beta\gamma)$, which decreases with α.

The term in $-\ln y_t$ in the growth equation, finally, reflects the standard convergence effect. It disappears under constant aggregate returns, namely when $\alpha + \beta\gamma = 1$, or when the constant κ in (3) is replaced by a knowledge spillover such as

$$\kappa_t \equiv \left(\int_0^i (k_t^i)^\gamma\right)^{(1-\alpha-\beta\gamma)/\gamma}. \tag{13}$$

This last variant yields an *endogenous-growth* version of the model, where all the predictions obtained with a constant κ in (12) now directly transpose from short-run growth and long-run per capita income to *long-term growth rates.*

Are the potential growth-enhancing effects of redistributive policies in the presence of credit constraints significant, or trivial compared to the standard deadweight losses? While the answer must ultimately come from empirical studies of specific policy programs or experiments, recent quantitative models suggest very important long-run effects, ranging from several percentage points of steady-state GDP to several percentage points of long-run growth, depending on the presence of accumulated factors, such as physical capital or knowledge spillovers, that complement individual human capital. Calibrating to US data a model with neither effort distortions nor complementarities, Fernandez and Rogerson (1998) find that complete school finance equalization raises long-run GDP by 3.2 %. In a model with both educational and financial bequests, Sheshadri and Yuki (2004) find that a mix of fiscal and educational redistribution that approximates current US policies raises long-run income by 13.5%, relative to laissez-faire. This more substantial impact primarily reflects the induced adjustment of physical capital, but it remains a level effect due to decreasing returns to the two types of capital together. In a dynastic-utility version of the present model with endogenous growth (Bénabou (2002)) I find that the growth-maximizing value for fiscal redistribution is $\tau_{fisc} = 21\%$, which corresponds to a share of redistributive transfers in GDP of 6%; in spite of reduced labor supply this raises the long-run growth rate by 0.5 percentage points. Under

convexities in either the investment technology (e.g., Galor and Zeira (1993)) or in preferences (e.g., Galor and Moav (1999)). For recent contributions to the empirical debate, see Forbes (2000) and Banerjee and Duflo (2003).

the alternative policy of progressive education finance, the growth-maximizing equalization rate for school expenditures is $\tau_{educ} = 62\%$, which raises long-run growth by 2.4 percentage points. In both cases, the efficient policy involves the top 30% of families subsidizing the bottom 70%, whether through the fiscal or the education system.

C Voter Preferences, Political Power, and Equilibrium Policy

I now turn to the determination of policy, which reflects both individual citizens' preferences and the allocation of power in the political system. In each generation, before the productivity shocks z_t^i are realized, agents vote on the rate of redistribution τ_t to which they will be subject; again, this could be through the fiscal system, labor market regulation, or education finance. Applying Propositions 1 and 2 to equations (4)-(5), an individual i's intertemporal welfare U_t^i can be computed from (5) as a function of the proposed policy τ_t, his endowment k_t^i, and the overall distribution of human capital (m_t, Δ_t), which is the system's state variable.[18] Defining the composite efficiency parameter

$$B \equiv a + \rho(1-a)(1-\beta) \geq 0, \tag{14}$$

whose interpretation is is given below, the resulting first-order condition for agent i's ideal tax rate takes the form:

$$\frac{\partial U_t^i}{\partial \tau_t} = (1-\rho+\rho\beta)\left[\gamma(m_t - \ln k_t^i) - \frac{\delta}{\eta}\left(\frac{\tau}{1-\tau}\right) + (1-\tau)(\gamma^2\Delta_t^2 + Bv^2)\right] = 0. \tag{15}$$

The first term inside the brackets, which disappears when summing across agents, reflects the basic redistributive conflict: since τ_t reallocates resources (spent on both consumption and children's education) from rich to poor households, the latter want it to be high, and the former, low. The next two terms represent the *aggregate welfare cost* and *aggregate welfare benefit* of a marginal increase in τ_t. First, there is the deadweight loss due to the distortion in effort: it is proportional to the labor supply elasticity $1/\eta$, and vanishes at $\tau = 0$. Second, the term $(1-\tau_t)(\gamma^2\Delta_t^2 + Bv^2)$, which is maximized for $\tau_t = 1$, embodies the (marginal) efficiency gains that arise from better insurance and the redistribution of resources towards more severely credit-constrained investments. Indeed it is clear from (14) that the composite parameter B multiplying the variance of adults' income shocks v^2 is monotonically related to both *risk–aversion* a and to the extent of *decreasing returns* in human-capital investment, $1-\beta$.[19] As to initial income inequality,

[18] See the appendix. Note that due to the model's overlapping–generations structure, voting involves no intertemporal strategic considerations.

[19] More specifically, under constant returns ($\beta = 1$) the term $(1-\rho+\rho\beta)Bv^2$ reduces to $a(1-\tau)v^2$, which is the insurance value of a marginal reduction in the lifetime resource risk $(1-\tau)^2v^2/2$ faced by agents. Conversely, for risk–neutral agents who care only about their offspring ($a = 0,\ \rho = 1$) that same term becomes $\beta(1-\beta)(1-\tau)v^2$, which is the gain in expected (and aggregate) human capital growth resulting from a marginal decrease in the variability of post-tax resources $(1-\tau)^2v^2/2$, given the concavity of the investment technology.

the term $\gamma^2\Delta_t^2$ reflects two motives for redistribution.[20] First, relaxing preexisting credit constraints tends to increase overall growth (see the last term in (12)), and therefore also average welfare. Second, with concave (logarithmic) utility functions, average welfare increases whenever individual consumptions (of c_t^i and k_{t+1}^i) are distributed more equally. Equivalently here, this captures the effect of skewness: given m_t, a higher Δ_t^2 implies a higher per capita income $\ln y_t = m_t + \Delta_t^2/2$, making redistribution more attractive for the median voter, and more generally at any given level of k_t^i.

From this analysis it easily follows that agent i's preferred tax rate, obtained as the unique solution $\tau_t^i < 1$ to the quadratic equation (15), decreases with his endowment k_t^i and increases with the ex-ante benefits from redistribution Bv^2. Similarly, $\left|\tau_t^i\right|$ decreases with $1/\eta$, as a more elastic labor supply magnifies the distortions that result from redistributive policies –whether progressive, $\tau > 0$, or regressive, $\tau < 0$.

I now turn from the preferences of different classes of voters to their political power or influence over the process that determines the actual τ_t. Even in advanced democracies, poor and less educated individuals have a lower propensity to register, turn out to vote and give political contributions, than better-off ones. For voting itself the tendency is relatively moderate, whereas for contributing to campaigns it is drastic. Even for political activities that are time- rather than money-intensive, such as writing to Congress, attending meetings, trying to convince others, etc., the propensity to participate rises sharply with income and education. These facts are documented for instance in Rosenstone and Hansen (1993), while Bartels (2002) provides a striking study of how they translate into disproportionate political influence. Studying the roll calls of US senators in three Congresses he finds that their votes are more responsive, by a factor ranging from 3 to 15, to the views of their constituents located the 75^{th} income percentile than to those of the 25^{th}; and again more responsive, by a factor of 2 to 3, to the views of the 99^{th} percentile than to those of the 75^{th}. In less developed countries there is also extensive vote-buying, clientelism, intimidation and the like, which are likely to result in even more bias.

To summarize this political influence of human and financial wealth in a simple manner I shall assume that *the pivotal voter is located at the* $100 \times p^*$ *-th percentile* of the distribution, where the critical level p^* can be any number in $[0, 1]$. A perfect democracy corresponds to $p^* = 1/2$, while an imperfect one where participation or influence rises with social status corresponds to $p^* > 1/2$.[21] Given that k_t^i is here log-normally distributed, an equivalent but more convenient measure of the political system's departure from the democratic ideal is

[20] See Bénabou (2000) for the exact decomposition.

[21] Since individual preferences are single-peaked and the preferred policy is monotonic in k_t^i, it is easy to show that such a critical p^* is a sufficient statistic for any *ordinal* weighing scheme where each agent's opinion is affected by a weight, or relative probability of voting, ω^i (with $\int_0^1 \omega^j \, dj = 1$), that increases with his *rank* in the distribution of human capital or income. Alternatively, political influence may depend on individuals' income *levels*. Thus, with ω^i proportional to $(y^i)^\lambda$ it can be shown that the pivotal voter has rank $p^* = \Phi(\lambda\Delta)$, so that λ in (16) is simply replaced by $\lambda\Delta$. As intuition suggests, this alternative formulation only reinforces the key result that efficient redistributions may decline with inequality, since it implies that the political system tends to becomes more biased towards the wealthy as inequality rises.

$$\lambda \equiv \Phi^{-1}(p^*), \tag{16}$$

where $\Phi(\cdot)$ denotes the c.d.f. of a standard normal. I shall refer to λ as the degree of *wealth bias* in the political system, and focus on the empirically relevant case where $\lambda > 0$.[22] Given the location of the pivotal voter, the policy outcome is simply obtained by setting $\ln k_t^i - m_t = \lambda \Delta_t$ in the first-order condition $\partial U_t^i / \partial \tau = 0$. This yields the quadratic equation:

$$\frac{1}{1-\tau_t} = \frac{1}{\lambda}\left[\frac{\gamma^2 \Delta_t^2 + Bv^2}{\gamma \Delta_t} - \frac{\tau_t}{\eta \gamma \Delta_t (1-\tau_t)^2}\right]. \tag{17}$$

When labor supply is inelastic ($1/\eta = 0$), it is immediately apparent that this equilibrium tax rate is U–shaped in Δ_t, and minimized where $\gamma^2 \Delta^2 = Bv^2$. This is true more generally.

Proposition 3 *The rate of redistribution $\tau_t = T(\Delta_t)$ chosen in generation t is such that:*

1) τ_t increases with the ex–ante efficiency gain from redistribution Bv^2, and decreases with the political influence of wealth, λ.

2) $|\tau_t|$ decreases with the elasticity of labor supply $1/\eta$.

3) τ_t is U-shaped with respect to inequality Δ_t. It starts at the ex–ante optimal rate $T(0) > 0$, declines to a minimum at some $\underline{\Delta} > 0$, then rises back towards $T(\infty) = 1$. The larger Bv^2, the wider the range $[0, \underline{\Delta})$ where $\partial \tau_t / \partial \Delta_t < 0$.

The first two results show that equilibrium policy depends on the costs and benefits of redistribution and on the allocation of political influence in a sensible manner. The third one confirms the key insight that efficient redistributions may *decrease* with inequality; more specifically, it yields the U-shaped function $\tau = T(\Delta)$ shown on Figure 2. The underlying intuition is simple, and very general: a) when distributional conflict $\gamma \Delta$ is small enough relative to the ex-ante efficiency gains Bv^2, there is widespread support for the redistributive policy, so its equilibrium level is high; b) as inequality rises, so does the proportion of agents rich enough to be net losers from the policy, who will *block* all but relatively low levels of τ_t; c) at still higher levels of inequality, the standard skewness effect eventually dominates: there are so many poor that they *impose* high redistribution, even when it is very inefficient.[23]

It is now well-recognized that the standard median-voter model's prediction of a positive effect of inequality on redistribution fails to explain the empirical patterns actually observed, both across countries (see, e.g., Perotti (1996), Bénabou (1996a, 2000), Alesina et al. (2002)) and within them (see Rodriguez

[22] Recent papers that aim to endogenously explain the allocation of political power in a country (corresponding here to the parameter λ) include Bourguignon and Verdier (2000), Pineda and Rodriguez (2000), Acemoglu and Robinson (2000), and Baland and Robinson (2003).

[23] A similar form of non-monotonicity (U-shape, or even declining throughout for λ high enough) is obtained with a Pareto distribution by Lee and Romer (1998).

(1999) for panel-data tests on US states). Among developed countries, in particular, the relationship is in fact negative (Pineda and Rodriguez (2000). The present framework explains how and when greater inequality will indeed *reduce* redistribution, or even result in *regressive* policies –both in the short run (Proposition 3) and in the long-run, when both are endogenous (Proposition 4 below). Furthermore, the distinctive *non–monotonic* relationship predicted by the model turns out to have empirical support: in tests using cross-country data, Figini (1999) finds in a significant U-shaped effect of income inequality on the shares of tax revenues and government expenditures in GDP; De Mello and Tiongson (2003) find a similar pattern for government transfers.

II Sustainable Social Contracts

A *Dynamics and Steady States*

The joint evolution of inequality and policy is described by the recursive dynamical system:

$$\left\{ \begin{array}{lcl} \tau_t & = & T(\Delta_t) \\ \Delta_{t+1} & = & \mathfrak{D}(\Delta_t, \tau_t) \end{array} \right. \tag{18}$$

where $T(\Delta_t)$ is given by Proposition 3 and $\mathfrak{D}(\Delta_t, \tau_t)$ by (11). Under a time–invariant policy, in particular, long–run inequality decreases with redistribution:

$$\Delta_\infty^2 = \frac{w^2 + \beta^2(1-\tau)^2 v^2}{1-(\alpha+\beta\gamma(1-\tau))^2} \equiv D^2(\tau). \tag{19}$$

A steady-state equilibrium is an intersection of this downward-sloping locus, $\Delta = D(\tau)$, with the U-shaped curve $\tau = T(\Delta)$, as illustrated in Figure 2. The following key proposition identifies the conditions under which multiple intersections occur.

Proposition 4 *Let $1-\alpha < 2\beta\gamma$. When the normalized efficiency gain B is below some critical value $\underline{B}$ there is a unique, stable, steady–state. When $B > \underline{B}$, on the other hand, there exist $\underline{\lambda}$ and $\bar{\lambda}$ with $0 < \underline{\lambda} < \bar{\lambda}$, such that:*

1) For each λ in $[\underline{\lambda}, \bar{\lambda}]$ there are (at least) two stable steady states.[24]

2) For $\lambda < \underline{\lambda}$ or $\lambda > \bar{\lambda}$ the steady–state is unique.

These results can shed light on a number of important issues and puzzles raised in the introduction.

First, they explain how countries with similar economic and political fundamentals can nonetheless sustain very different redistributive institutions, such as a *European-style welfare state* and a *US-style*

[24] See Bénabou (2000) for additional results on the number of stable steady-states ($n \leq 4$), including conditions ensuring that $n = 2$.

laissez-faire social contract. Notably, these two societies cannot be Pareto ranked. Recall also that τ_t can be equally interpreted as describing tax-and-transfer policy, labor market regulation, or (with some minor changes) education finance policy. Moreover, it is clear that the model's key mechanism makes these multiple dimensions of policy complementary, so that they will tend to covary positively across countries, as indeed they do empirically. A more egalitarian education system, for instance, tends to reduce income inequality, which in turn increases political support for fiscal redistribution or labor-earnings compression –and vice-versa. Summarizing a large collective research project on Sweden, Freeman (1995) emphasizes the presence of such complementarities, describing *"a highly interrelated welfare state and economy in which many parts fit together (be they subsidies, taxes, wage compression etc.)".*

Second, the two conditions required for multiplicity embody *very general intuitions* that are easily understood in the context of Figure 2. To start with, the ex-ante welfare benefits of redistribution must be high enough, relative to the costs.[25] Otherwise the T curve will be upward-sloping except over a very narrow initial range, and consequently have a unique intersection with the D curve; economically speaking, we would be close to the standard, complete-markets case. In addition, the political power of the wealthy must lie in some intermediate range, otherwise the T curve will lie too high or too low relative to the D curve, and again there will be a unique intersection, with high inequality and low redistribution, or vice-versa.

Third, while in the short-run the relationship is non-monotonic, there emerges in the long–run a *negative* correlation between inequality and redistribution, as indeed one observes between the United States and Europe, or among advanced countries in general (Pineda and Rodriguez (2000)).

Fourth, *history matters* in an important and plausible way: temporary shocks to the distribution of wealth (immigration, educational discrimination, demand shifts) as well as to the political system (slavery, voting rights restrictions) can permanently move society from one equilibrium to the other, or more generally have long-lasting effects on inequality, growth, and institutions. In particular, the model provides a formalization of Engerman and Sokoloff's (1998) thesis about the historical origins of South and North America's very different development paths, which they trace back to the former set of New World colonies having had much higher initial inequality Δ_0, and a much more concentrated power structure λ_0, than the latter.[26]

Finally, the model also shows that *different sources of inequality* have different effects on redistributive institutions –which, in particular, sheds doubt on the possibility of empirically estimating a catch-all relationship between inequality and redistribution, or inequality and growth. Indeed, one can show (provided

[25] The claim with respect to the benefits is clear from Proposition 4; with respect to the costs one can show, under additional technical assumptions, that the threshold $\underline{B}$ shifts up as the labor supply elasticity $1/\eta$ rises.

[26] This, in turn, was due to reasons linked to the technologies required for the different goods these colonies were producing –a point I shall come back to in Section III.A.

$1/\eta$ is not too large) that the threshold for multiplicity $\underline{B}$ is a decreasing function of the variance ratio v^2/w^2, with $\lim_{v/w\to 0}(\underline{B}) = +\infty$ and $\lim_{v/w\to+\infty}(\underline{B}) = 0$. Quite intuitively, income *uncertainty* interacts with the incompleteness in insurance and credit markets in generating ex ante efficiency gains from redistribution, as reflected by the term Bv^2 in (17). By contrast, a greater variance w^2 of the endowments that agents receive *prior* to choosing policy increases the distributional conflict between *identifiable losers and gainers* from the policy. Thus, whereas an increase in the variability of sectoral shocks (similar to v^2) will lead to an expansion of the welfare state, a surge in immigration that results in a greater heterogeneity of the population (similar to a rise in w^2) can easily lead to cutbacks, or even a large–scale dismantling. We shall observe similar effects when studying the political implications of skill-biased technical change.

B *Which Societies Grow Faster?*

As mentioned earlier, the steady states corresponding to different social contracts are not Pareto–rankable: rich enough agents always prefer a more laissez-faire society, while those who are poor enough always want more of a welfare state. One may still ask, however, how these two social models compare in terms of aggregate growth. This question is important first for its policy content, and second to know whether one should expect any empirical relationship between inequality and growth, when account is taken of the fact that *both* are endogenous. The answer hinges on the basic tradeoff, discussed earlier, between the distortions induced by redistribution and its beneficial effect on credit–constraints (magnified, in the long run, by the fact that it also reduces income inequality $\gamma\Delta_\infty$). This is made clear by the following results, which apply equally in the short and in the long run.[27]

Proposition 5 *Compared to a more laissez-faire alternative τ', a more redistributive social contract $\tau > \tau'$ is associated with lower inequality, and*

1) has higher growth when tax distortions are small $(1/\eta \approx 0)$ relative to those induced by credit constraints on the accumulation of human capital $(\beta\gamma < 1)$;

2) has lower growth when tax distortions are high $(1/\eta > 0)$ and the credit–constraint effect is weak $(\beta\gamma \approx 1)$.

The first scenario, of *"growth-enhancing redistributions",* seems most relevant for developing countries, where capital markets are less well-functioning, and for redistribution through public investments in human capital and health. One may contrast here the paths followed by East Asia and Latin America in those respects. The result may also help understand why regression estimates of the effects of social and educational transfers on growth are often significantly positive, or at least rarely significantly negative.

[27] See Section I.B for the simple correspondence between the stationary and the endogenous-growth versions of the model, where policy affects growth in the short and the long-run respectively.

The second, *Eurosclerosis"* scenario can account for why Europeans consistently choose more social insurance than Americans –at the cost of higher unemployment and slower growth –even though they are not necessarily more risk-averse. The intuition is that, in more homogenous societies, there is less erosion of the consensus over social insurance mechanisms which, ex–ante, would be valued enough to compensate for lesser growth prospects.[28]

Putting the two cases together, finally, Proposition 5 can also be related to the empirical findings of Barro (2000) that inequality tends to be negatively associated with subsequent growth in poor countries, but positively associated with it in richer ones. To the extent that poor countries are also those where credit markets are least developed, Proposition 5 predicts that inequality-reducing policies will give rise to just such a dichotomy.

III Technology and the Social Contract

I shall now extend the model to analyze how technology and redistributive institutions both affect inequality and respond to it, and consequently how they *influence each other* –as described on Figure 1. Of particular interest are the following questions. First, how does technical change impact the sustainability of welfare-state and laissez-faire social contracts? Second, what types of societies are likely to be leaders or early adopters in developing or implementing flexible, skill-biased technologies or organizational forms? More generally, how do the skill distribution among workers and the production side of the economy shape each other, through human capital investments and technology choices? Finally, what happens in the long run when technological and institutional factors evolve interdependently –within a country, and possibly even across countries?

A *Exogenous Technical Change and the Viability of the Welfare State*

I first examine here how technical or organizational change that increases the return to human capital affects redistributive institutions. This policy response represents an additional channel through which technological evolutions affect the income distribution, in addition to their direct impact via the wage structure.

Figure 3 illustrates the effects of an increase in γ, the coefficient on human capital in the production and earnings function (1). As will from now on be made explicit in the notation, this affects both of the key curves describing the inequality-redistribution nexus:

[28] For the specific case of unemployment insurance, Hassler et al. (1999) provide a complementary explanation, based on interactions with workers' specialization (or lack thereof) that can result in multiple equilibria.

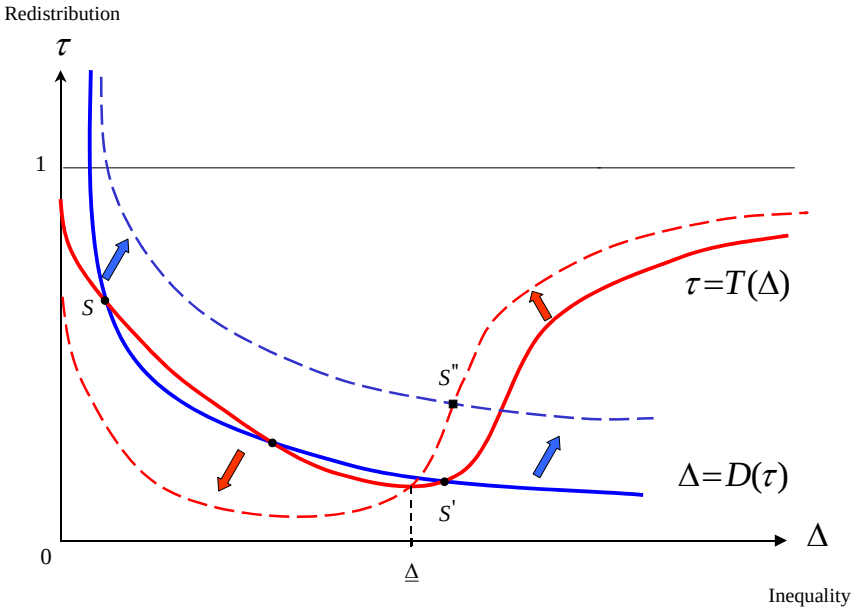

Figure 3: The effects of an increase in the returns to human capital, $\gamma = (\sigma - 1)/\sigma$.

i) The intergenerational-transmission locus $\Delta = D(\tau; \gamma)$ shifts up, and becomes less steep: for given human capital inequality Δ_t and policy τ there is more inequality in incomes $\gamma\Delta_t$, hence also in investments, and consequently more inequality of human capital (and of course income) in all subsequent periods.[29]

ii) The policy locus $\tau = T(\gamma\Delta)$ shifts down over $[0, \underline{\Delta})$, and up over $(\underline{\Delta}, +\infty)$: since what matters for the political outcome is *income* inequality $\gamma\Delta$ (see (17), an increase in γ for given Δ has the same U-shaped effect on redistribution as an increase in Δ for given γ –initially lowering τ, then raising it.

Figure 3 directly yields a local analysis of the more egalitarian, welfare-state equilibrium –and more generally, of any steady state that occurs along the declining portion of the T locus.[30]

Proposition 6 *Let (Δ, τ, γ) be such that (Δ, τ) is a stable steady state under the technology γ, with $\Delta < \underline{\Delta}(Bv^2; \gamma)$. A marginal increase in γ results in higher long run human capital and income inequality, as well as in less redistribution.*

[29] Recall that a worker's human capital reflects his individual ability, family background, and parental investment in education: $k_t^i = \kappa\, \xi_t^i\, (k_{t-1}^i)^\alpha\, (e_{t-1}^i)^\beta$. The kind of technical change considered here raises the return to all three components of k_t^i equally. In Galor and Tsiddon (1997) by contrast, major innovations raise the relative return to pure ability, while subsequent learning-by-doing innovations raise the relative return to inherited human capital. In Galor and Moav (2000) human capital is also sector-specific, and therefore eroded by new technologies, to an extent that decreases with individual ability. In these models technological innovations can thus raise as well as lower integenerational mobility.

[30] For steady-states that occur on the rising part, local comparative statics are ambiguous. Note, however, that in versions of the model where power inequality rises with income or human wealth inequality –meaning that λ increases with Δ (see footnote 21)– the declining portion of the locus is wider and the increasing portion reduced, making it easier to rule out such equilibria. For instance, if political power ω_i is proportional to $(y_i)^\lambda$ –e.g., "one dollar, one vote" for $\lambda = 1-$ then λ is simply replaced by $\lambda\Delta$ everywhere. As seen from (17), for $1/\eta = 0$ the $T(\gamma\Delta)$ curve is then decreasing throughout.

The policy response thus amplifies the direct effect of skill-biased technical progress on disposable incomes –and, over time, on the distributions of human capital and earnings. Figure 3 also suggests that it can have, in the long run, much more drastic consequences for redistributive institutions: starting from a situation with multiple steady states, an increase in γ tends to undermine the sustainability of the "Welfare State" equilibrium. Similarly, we shall see that starting from a configuration with a single "Welfare-State" it can make a second, "Laissez-Faire" equilibrium appear. Such a *global* analysis is potentially quite complicated, however, since in general there may be more than two stable equilibria, and some may also occur in the upward-sloping portion of the $\tau = T(\gamma\Delta)$ locus, where the policy response has a dampening rather than an amplifying effect on inequality. To demonstrate the most interesting insights, I shall therefore impose some simplifying assumptions. First, I restrict voters to a choice between only two policies:

• A generous *"Welfare State"* social contract, corresponding to a relatively high rate of redistribution $\bar{\tau} \in (0, 1)$;

• A more *"Laissez Faire"* social contract, corresponding to a relatively low rate of redistribution $\underline{\tau} \in (0, \bar{\tau})$.

Once again, τ can be interpreted as corresponding to either fiscal redistribution, wage compression through labor market regulation, or education finance progressivity. To further simplify the problem I abstract from labor supply distortions ($1/\eta = 0$) and assume that B is large enough that both potential steady states are always on the downward-sloping part of the $\tau = T(\Delta\gamma)$ curve, which is the one of most interest.[31]

Given an initial distribution of human capital Δ_t, the more redistributive policy $\tau_t = \bar{\tau}$ is adopted over $\tau_t = \underline{\tau}$ if $U_t^i(\bar{\tau}) > U_t^i(\underline{\tau})$ for at least a critical fraction $p^* \equiv \Phi(\lambda)$ of the population. Note from (15) that with $1/\eta = 0$, $\partial U_t^i/\partial\tau_t$ is linear in τ_t, so the preceding inequality evaluated at $\ln k_t^i = m_t + \lambda\Delta_t$ takes the form:

$$(\bar{\tau} - \underline{\tau})\left[\gamma\lambda\Delta_t + (1 - \underline{\tau})\left(\gamma^2\Delta_t^2 + Bv^2\right)\right] < (\bar{\tau} - \underline{\tau})^2\left(\gamma^2\Delta_t^2 + Bv^2\right)/2, \quad \text{or:}$$

$$\lambda < \left(1 - \frac{\bar{\tau} + \underline{\tau}}{2}\right)\left(\gamma\Delta_t + \frac{Bv^2}{\gamma\Delta_t}\right). \tag{20}$$

We first see that the *political influence of wealth* must not be too large, compared to the *aggregate welfare gain* from redistribution relative to laissez faire (net of the deadweight loss, which I am here abstracting from). Second, preexisting income inequality *raises the hurdle* that public policy must overcome, as the ex-ante benefit term Bv^2 is divided by $\gamma\Delta_t$. This effect impedes the adoption of more redistributive

[31] The required condition appears in Proposition 7. It is thus not inevitably the case that skill-biased technical progress leads to a retrenchment of redistributive institutions; the model allows for the reverse case, for steady-states that occur on the rising part of the T locus. The case on which I focus, however, appears to be the most relevant for recent trends, and in any case is the more robust, since: i) when multiple steady-states exist, there is always at least one the declining part; ii) in simple and plausible variants of the model, the T locus is decreasing throughout (see footnote 30).

institutions ($\tau = \bar{\tau}$) where they had not previously been in place, because of the greater divergence of interests that results over time from a more laissez-faire system ($\tau = \underline{\tau}$). Pushing in the other direction – namely, intensifying the demand for redistribution as inequality rises– are the effects of skewness and initial credit-constraints, reflected in the additive term $\gamma\Delta_t$. As a result of these offsetting forces, the right-hand side of (20) is U-shaped in $\gamma\Delta_t$. To focus on the long–run, let us now replace human capital inequality Δ_t with its asymptotic value under a technology γ and a constant policy τ –namely, by (11):

$$D(\tau,\gamma) \equiv \sqrt{\frac{w^2+\beta^2(1-\tau)^2v^2}{1-(\alpha+\beta\gamma(1-\tau))^2}}, \tag{21}$$

which is the long-run inequality in human capital resulting from a constant policy τ and technology γ. Given γ, the policy-inequality pair $(\bar{\tau}, D(\tau,\gamma))$ is thus a politico-economic steady state if:

$$\lambda < \left(1-\frac{\bar{\tau}+\underline{\tau}}{2}\right)\left(\gamma D(\tau,\gamma)+\frac{Bv^2}{\gamma D(\tau,\gamma)}\right) \equiv \bar{\lambda}(\gamma;B). \tag{22}$$

Conversely, the laissez-faire configuration $(\underline{\tau}, D(\underline{\tau},\gamma))$ is a politico-economic steady state given γ if:

$$\lambda > \left(1-\frac{\bar{\tau}+\underline{\tau}}{2}\right)\left(\gamma D(\underline{\tau},\gamma)+\frac{Bv^2}{\gamma D(\underline{\tau},\gamma)}\right) \equiv \underline{\lambda}(\gamma;B). \tag{23}$$

The two regimes coexist if and only if $\underline{\lambda}(\gamma;B) < \bar{\lambda}(\gamma;B)$, or:

$$\frac{\bar{\lambda}(\gamma;B)-\underline{\lambda}(\gamma;B)}{\gamma D(\underline{\tau},\gamma)-\gamma D(\bar{\tau},\gamma)} = \left(1-\frac{\bar{\tau}+\underline{\tau}}{2}\right)\left(\frac{Bv^2}{\gamma^2 D(\bar{\tau},\gamma)D(\underline{\tau},\gamma)}-1\right). \tag{24}$$

We thus obtain here the analogue, for a discrete policy choice, of Proposition 4: multiplicity requires that B be large enough compared to income inequality (and, in general, to $1/\eta$),

$$B > \left(\gamma^2/v^2\right)\cdot D(\bar{\tau},\gamma)\cdot D(\underline{\tau},\gamma) \equiv \underline{B}(\gamma), \tag{25}$$

and that the wealth bias λ be neither too high nor too low, given the technology $\gamma : \lambda \in \left[\underline{\lambda}, \bar{\lambda}\right]$, defined by (22)-(23).[32] Now, furthermore, we shall see that (under appropriate conditions) the *skill bias* γ must also be neither too high nor too low, given λ. This result is illustrated in Figure 4.

Proposition 7 *Let $1/\eta = 0$ and $Bv^2 > \gamma_{\max}\cdot D(\underline{\tau},\gamma_{\max})$, where $\gamma_{\max} \equiv (1-\alpha)/\beta$. There exist two skill-bias thresholds $\underline{\gamma}(\lambda;B) < \bar{\gamma}(\lambda;B)$, both decreasing in λ and increasing in B, such that:*

[32] Note also that as B increases both $\underline{\lambda}$ and $\bar{\lambda}$ rise, but (24) shows that the interval $[\underline{\lambda},\bar{\lambda}]$ widens. When (25) does not hold, on the other hand, we have $\bar{\lambda} < \underline{\lambda}$. For $\lambda \notin [\bar{\lambda},\underline{\lambda}]$ there is a unique steady–state, but for $\lambda \in [\bar{\lambda},\underline{\lambda}]$ the economy can instead be shown to cycle between the two regimes, as in Gradstein and Justman (1997). This feature reflects the restriction of policy to a binary choice.

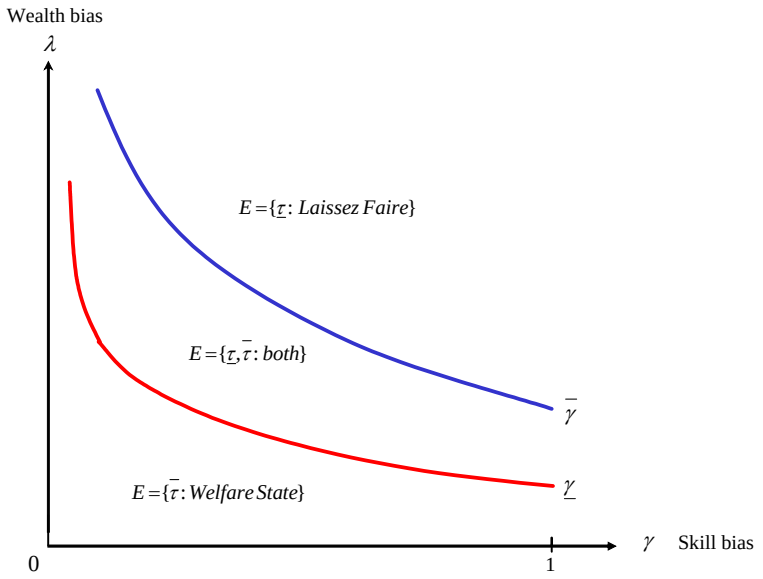

Figure 4: Technology, political influence, and the social contract. E denotes the set of stable steady-states.

i) for $\gamma < \underline{\gamma}(\lambda; B)$, *the unique steady state corresponds to the welfare-state outcome* $(\bar{\tau}, D(\bar{\tau}, \gamma))$;
ii) for $\gamma \in \left[\underline{\gamma}(\lambda; B), \bar{\gamma}(\lambda; B)\right]$, *both* $(\bar{\tau}, D(\bar{\tau}, \gamma))$ *and* $(\underline{\tau}, D(\underline{\tau}, \gamma))$ *are stable steady states;*
iii) for $\gamma \in [\bar{\gamma}(\lambda; B), \gamma_{\max}]$, *the unique steady state is laissez-faire,* $(\underline{\tau}, D(\underline{\tau}, \gamma))$.

These results have a number of important implications.

First, they confirm that *the Welfare State becomes unsustainable* when technology becomes too skill-biased; and, conversely, that multiple social contracts can coexist only when γ is in some intermediate range.[33] We see here again at work the general insight that sources of heterogeneity that are predictable on the basis of of initial endowments –a greater variance of abilities, w^2, as discussed earlier, or greater skill bias γ, as here– push equilibrium institutions towards less redistribution.

Second, Proposition 7 also reveals interesting interactions between *the production and political "technologies".* As seen on Figure 4, in a country with relatively little wealth bias the welfare state is –for better of for worse– much more "immune" to skill-biased technical change than in one where λ is high. Similarly, a given change in the political system will have very different effects on redistributive institutions, depending on how skill-biased the technology is. Finally, the "surest way" to set out on a course of persistently high inequality and inefficiently regressive (or insufficiently progressive) institutions is to start out with *both* a production structure that generates high wage inequality, and a political system marked by a high

[33] Hassler et al. (2003) also show that the "welfare-state" equilibrium in their model no longer exists above a certain level of skill bias. The mechanism is quite different, however: it is the *anticipation* of a higher skill premium that causes more agents to invest in education –to the point where, ex-post, a majority of them end up with high incomes (the distribution is negatively skewed), and therefore oppose redistribution.

degree of bias. As demonstrated by Engerman and Sokoloff (1995), such were the initial conditions found in the plantation-based and natural-resource based colonies of Central and South America in the 16^{th} and 17^{th}centuries –in contrast to those of North America, where agriculture was not subject to significant increasing returns to scale, and initial institutions were much less oligarchic.

Third, our result can also be related to that of Acemoglu, Aghion and Violante (2001), who show that skill-biased technical progress may cause a decline in unionization. While their model is quite different, it shares the two key features emphasized in previous sections. First, relatively rich agents –namely skilled workers– are pivotal, in the sense that it is their willingness to leave or avoid the unionized sector that limits the extent of wage compression. Second, in making this mobility decision –voting with their feet– they trade off redistributive losses (unions redistribute towards unskilled workers, who are a majority in the unionized sector) against ex-ante efficiency benefits: unions provide insurance through wage-sharing and / or a safeguard against the "holdup" by firms of workers' specific human capital investments; even when they play no such role, leaving the unionized sector involves mobility costs. Consequently, when skill-biased technical change makes the interests of the two classes of workers too divergent, redistributive institutions –here, union participation– will decline. Moreover, this can happen inefficiently.[34]

B *Skills, Technology, and Income Inequality*

I now turn to the reverse mechanism and examine how inequality itself *feeds back* onto the nature of technical change, making γ endogenous. Recognizing that individuals do not produce in isolation, I model production interactions with a simple specialization structure where workers perform complementary tasks.[35] Final output is produced by competitive firms, using a continuum of differentiated intermediate inputs:

$$y_t = A_t \cdot \left(\int_0^\infty z_t(s) \cdot x_t(s)^{\frac{\sigma-1}{\sigma}} \, d\, s \right)^{\frac{\sigma}{\sigma-1}} , \ \sigma \geq 1, \tag{26}$$

where $x_t(s)$ denotes the quantity of input s, $z_t(s)$ an i.i.d. sectoral shock, and A_t a TFP parameter. Workers specialize in a single good, which they produce using their human capital and labor. Since they face downward-sloping demand curves each selects a different task, $s(i) = i$, and produces $x_t^i = k_t^i \, l_t^i$ units, where l_t^i is endogenously chosen. The unit price for his output is thus:

$$p_t^i = A_t^{\frac{\sigma-1}{\sigma}} \cdot z_t^i \cdot (k_t^i \, l_t^i / y_t)^{-\frac{1}{\sigma}} \ . \tag{27}$$

The corresponding hourly wages are $\omega_t^i = p_t^i \, k_t^i$, and the resulting incomes

[34] Relatedly, note from Figure 4 that a minor change in γ can trigger a significant decline in redistribution from $\bar{\tau}$ to $\underline{\tau}$, and recall from Proposition 5 that the latter can easily lead to lower aggregate growth. The same is clearly true for average welfare, e.g. when $1/\eta = 0$.

[35] Building on those in Bénabou (1996) and Tamura (1992), themselves based on Romer (1987).

$$y_t^i = \omega_t^i \, l_t = z_t^i \cdot \left(k_t^i \, l_t^i\right)^{\frac{\sigma-1}{\sigma}} \times A_t^{\frac{\sigma-1}{\sigma}} (y_t)^{\frac{1}{\sigma}} \equiv \tilde{A}_t \cdot z_t^i \cdot \left(k_t^i\right)^{\gamma} (l_t^i)^{\delta}. \tag{28}$$

This earnings function is exactly the same as in previous sections (see (1)), with

$$\gamma = \delta \equiv \frac{\sigma - 1}{\sigma}, \tag{29}$$

except for the extra TFP factor $\tilde{A}_t \equiv A_t^{\frac{\sigma-1}{\sigma}} (y_t)^{\frac{1}{\sigma}}$, which acts as a shift in the mean of the productivity shocks z_t^i. While $\tilde{A}_t$ varies endogenously with the economy's state variables (m_t, Δ_t^2), individual workers and voters take it as given in their decisions over (l_t^i, c_t^i) and their votes over τ_t.[36] Consequently, the entire analysis of earlier sections still applies, with the simple substitution of $\tilde{A}_t \cdot z_t^i$ wherever z_t^i previously appeared. Conditional on γ, distributional dynamics and the political equilibrium thus remain essentially unchanged, and so do the corresponding $\Delta = D(\tau, \gamma)$ and $\tau = T(\gamma\Delta)$ loci.

I now consider firms. Recall that in equilibrium all workers supply the same effort $l_t^i = l_t$ and the distribution of human capital remains lognormal, $\ln k_t^i \sim \mathcal{N}(m_t, \Delta_t^2)$. The output of a representative firm is thus:

$$y_t = A_t \cdot l_t \cdot \left(\int_0^1 \left(k_t^i\right)^{\frac{\sigma-1}{\sigma}} \, di \right)^{\frac{\sigma}{\sigma-1}} = A_t \cdot l_t \cdot e^{-\Delta_t^2/2\sigma} \cdot \left(\int_0^1 k_t^i \, di \right). \tag{30}$$

Keeping average human capital constant, the loss $e^{-\Delta_t^2/2\sigma}$ makes apparent the productivity costs imposed by (excessive) *heterogeneity of the labor force:* poorly educated, insufficiently skilled production and clerical workers drag down the productivity of engineers, managers, scientists, etc. We also see that a production technology with greater substitutability between the tasks performed by different types of workers reduces these costs of skill disparities (Bénabou (1996), Grossman and Maggi (2000)). Indeed, this greater *flexibility* allows firms to more easily substitute towards the more productive workers, and conversely reduce their dependence on low-skill labor. This may be achieved by internal retooling, reorganization, or by outsourcing certain activities to competitive subcontractors.[37] One can also think of a higher σ as a more discriminating search technology, resulting in more assortative matching between workers –that is, in a more *segregated* production structure (Kremer and Maskin (1996), (2003)).[38]

Naturally, production processes with less complementarity between workers of different skills result in greater inequality of wages and incomes, as they have the effect of *uncoupling* their marginal products:

[36] Note again the role of the overlapping-generations structure with "imperfect" altruism in simplifying the voting problem. Observe also that τ_t can now, as claimed earlier, be interpreted as the extent of *wage income compression,* i.e. the degree of progressivity in the mapping (defined by (6)) from workers' true marginal revenue products y_t^i (given by (28)) to the labor earning they actually receive, $\hat{y}_t^i$.

[37] For evidence on organizational change, see for instance Caroli and Van Reenen (1999).

[38] When labor supply is endogenous, $1/\eta > 0$, a higher σ also induces workers to increase their labor supply, as they face a less elastic demand curve: by Proposition 1, $l_t = \chi (1 - \tau_t)^{1/\eta}$, with now $\gamma = (\sigma - 1)/\sigma$. This effect is independent of any issues of skill heterogeneity or wage inequality, however.

$$\text{Var}\left[\ln y_t^i\right] = \left(\frac{\sigma_t - 1}{\sigma_t}\right)^2 \Delta_t^2 = \gamma_t^2 \Delta_t^2. \tag{31}$$

C *Technological Choice and Endogenous Flexibility*

More flexible technologies and production processes require costly investments or reorganizations. Moreover, their benefits to an individual firm are endogenous even in the short run (i.e., given the skill composition of the labor force), as they depend on the decisions of other firms, which affect the wage structure.

I therefore now model firms' choices of technology or organizational form, proposing a new and very simple formulation that highlights the roles of heterogeneity and flexibility. In every period, firms have access to a menu of potential technologies with *different elasticities of substitution* $\sigma \in [1, +\infty)$ and associated costs $c(\sigma)$; the latter result in a TFP factor $A(\sigma) = e^{-c(\sigma)}$, with $c' > 0$ and $c'' > 0$.[39] Given the distribution of workers' human capital $\ln k_t^i \sim \mathcal{N}(m, \Delta_t^2)$ and the technology σ_t used by its competitors, each firm chooses its own technology $\hat{\sigma}$ as a best response. This results in a marginal cost of

$$A(\hat{\sigma})^{-1} \left(\int_0^1 \left(z_t^i\right)^{\hat{\sigma}} \left(p_t^i\right)^{1-\hat{\sigma}} di \right)^{\frac{1}{1-\hat{\sigma}}}. \tag{32}$$

Substituting from (27) for the equilibrium input prices p_t^i, and normalizing by the other firms' marginal cost (see the proof of Proposition 8), the firm's relative marginal cost is equal to:

$$mc(\hat{\sigma}|\sigma_t) = \left(\frac{A(\sigma_t)}{A(\hat{\sigma})}\right) \cdot \left(\int_0^1 \left(k_t^i\right)^{\frac{1-\hat{\sigma}}{\sigma_t}} di \right)^{\frac{1}{1-\hat{\sigma}}} \cdot \left(\int_0^1 \left(k_t^i\right)^{\frac{1-\sigma_t}{\sigma_t}} di \right)^{\frac{-1}{1-\sigma_t}},$$

or:

$$mc(\hat{\sigma}|\sigma_t) = \exp\left[c(\hat{\sigma}) - c(\sigma_t) + \frac{\Delta_t^2}{2} \left(\frac{\sigma_t - \hat{\sigma}}{\sigma_t^2}\right) \right]. \tag{33}$$

The first-order condition for this convex minimization problem is

$$c'(\hat{\sigma}) = \frac{\Delta_t^2}{2\sigma_t^2}. \tag{34}$$

Intuitively, the marginal benefit of flexibility rises with the variability of skills in the labor force, but decreases with the degree to which other firms choose technologies that allow them to more easily substitute toward better workers, since in doing so they drive up the skill premium.

[39] I thus abstract here from the intertemporal (investment) aspects of innovation that would be part of a more complete (but also more complicated) model of technological change; see, e.g., Acemoglu (1998), Kiley (1999), Lloyd-Ellis (1999), or Aghion (2002).

Proposition 8 *There is a unique symmetric equilibrium in technology choice. The more heterogenous the workforce, the more flexible and skill-biased the technology used by firms:* $\sigma_t = \sigma^*(\Delta_t)$ *is the solution to* $c'(\sigma^*) = \Delta^2/2(\sigma^*)^2$, *with* $0 < \partial \ln \sigma^*/\partial \ln \Delta < 1$.

This result has several interesting implications.

A first one is the *magnification of wage inequality:* the return to human capital $\partial \ln \omega_t^i/\partial \ln k_t^i = (\sigma_t - 1)/\sigma_t$ is higher where the labor force is more heterogenous, further amplifying wage differentials across educational levels. This simple prediction could be tested empirically across countries and / or time periods.[40]

A second implication is the potential for *"immiserizing technological choices".* Proposition 8 states that σ increases with Δ; conversely, because of credit constraints, human capital heterogeneity itself rises over time with $\gamma = (\sigma - 1)/\sigma$, and in the long-run $\Delta = D(\tau, \gamma)$, which is increasing in γ. Could these two mechanisms reinforce each other to the point of resulting in multiple steady states *even under a fixed policy* –whether activist or laissez-faire– and even though, once again, there are no non-convexities in the model? The idea is that a high degree of skill bias results in very low wages for unskilled workers, severely limiting the extent to which they can invest in human capital (for themselves or their children). This, in turn, leads firms to again choose a very flexible, skill-biased technology in the next period, and so on. Conversely, a less skilled-biased technology and a less dispersed distribution of human wealth could be self-sustaining. To examine this possibility, note first that:

$$\frac{\partial \ln \sigma^*}{\partial \ln \Delta} = \left(1 + \frac{1}{2}\frac{c''(\sigma_t)}{c'(\sigma_t)}\right)^{-1} < 1 \tag{35}$$

by Proposition 8, while (21) yields

$$\frac{\partial \ln D(\tau, \gamma)}{\partial \ln \sigma} = \frac{\beta(1-\gamma)(1-\tau)(\alpha + \beta\gamma(1-\tau))}{1 - (\alpha + \beta\gamma(1-\tau))^2} \tag{36}$$

where, as usual, $\gamma = (\sigma - 1)/\sigma$. If the product of these two derivatives is everywhere less than 1, there is a unique equilibrium. If it exceeds 1 for some value of σ, on the other hand, there may be multiplicity. It is easily verified that $\partial D(\tau, \gamma)/\partial \ln \sigma < 1$ if and only if

$$(\alpha + \beta\gamma(1-\tau))(\alpha + \beta(1-\tau)) < 1. \tag{37}$$

The first term is always less than one (or else inequality explodes; moreover, this can never occur when τ is

[40] Kremer and Maskin (1996) present evidence for a related intervening mechanism (similar to $\partial\sigma^*/\partial\Delta > 0$ in this model), although not for how educational returns and wage inequality are ultimately affected. They show that in US states characterized by greater human capital inequality, there is more segregation of workers by skills (the ratio of within- to between-plant skill dispersion is lower).

endogenously chosen), but the second need not be, especially if $\tau < 0$. We can thus conclude that the kind of *"technology-inequality trap"* described above becomes a real possibility under *regressive or insufficiently progressive* policies. In particular, education systems that result in significant resource disparities between students, such as private financing or local (property-tax based) school funding as in the United States, are fertile ground for the joint emergence of highly skill-biased production processes and a persistently skewed skill distribution. Furthermore, as we shall see below, endogenizing τ only increases the likelihood of such outcomes, since the degree of redistribution tends to fall with inequality.

A third point is that even under the less extreme conditions where no such trap exists, firms' decisions involve a *dynamic externality* that tends to result in *excessively skill-biased* or flexible technologies. Indeed, each takes the distribution of skills it faces as given but neglects the effects of its own flexibility on workers' human capital investments, and therefore on subsequent distributions. More specifically, while a marginal change in σ_t has only second-order effects on the current production costs faced by firms, it has three first-order effects on growth.[41] First, a lower σ_t would reduce current income inequality $\gamma_t \Delta_t$, which is growth-enhancing given the presence of credit constraints. This would in turn lower the skill disparities Δ_{t+k} that firms will face in the future, as well as the costs $c\left(\sigma^*(\Delta_{t+k})\right)$ they will bear to adapt to this heterogeneity. Although $\gamma_t = (\sigma_t - 1)/\sigma_t$ also affects in a somewhat complex way the concavity of educational investment (where it interacts with α, β and τ_t), it is easy to identify cases where growth *in every period* would be higher if firms collectively chose less skill-biased technologies.

For instance, let $\alpha = 0$, $\beta = 1$, and $1/\eta = 0$ (inelastic labor supply), and fix any constant policy τ; the interactions of technology choice and policy decisions will be examined in the next section. In the resulting steady state, the degree of flexibility and the dispersion in skills are given by the two equations $\sigma_\infty = \sigma^*(\Delta_\infty)$ and $\Delta_\infty = D(\tau, \gamma_\infty)$, where $\gamma_\infty \equiv (\sigma_\infty - 1)/\sigma_\infty$.[42] The corresponding asymptotic growth rate is computed in the appendix, and equals:

$$g_\infty = \ln \kappa + \ln s - c(\sigma_\infty) - \frac{D(\tau, \gamma_\infty)^2}{2\sigma_\infty}. \tag{38}$$

A marginal reduction in σ from its equilibrium value, if it were permanently implemented by all firms, would then increase steady-state growth, since:

$$\left.\frac{\partial g_\infty}{\partial \sigma}\right|_{\sigma=\sigma_\infty} = -c'\left(\sigma_\infty\right) + \frac{\Delta_\infty^2}{2\sigma_\infty^2} - \frac{1}{2\sigma_\infty} \cdot \left.\frac{\partial D^2(\tau, \gamma_\infty)}{\partial \sigma}\right|_{\sigma=\sigma_\infty} = -\frac{1}{2\sigma_\infty^3} \cdot \frac{\partial D^2(\tau, \gamma_\infty)}{\partial \gamma} < 0. \tag{39}$$

In this expression the first two terms cancel out by the first-order condition (34), while the last one reflects

[41] As explained in footnote 38, when $1/\eta > 0$ a higher σ_t also raises the return to labor supply $\delta_t = (\sigma_t - 1)/\sigma_t$, inducing all agents to work more.

[42] I assume here that (37) holds, so that this steady-state is unique (given τ), although this is inessential to the argument.

the dynamic externality. The above result holds more generally for any equilibrium path that is either near the steady state, or such that σ_t converges to its long-run value from above (see the appendix).

Inefficient choices of technology or firm organization arise in a number of models where market imperfections create an excessive role for the distribution of financial or human wealth to shape the structure of production, with the result of exacerbating inequality and making it more persistent. In Banerjee and Newman (1993) and Newman and Legros (1998), for instance, the moral-hazard problem affecting entrepreneurship combines with an unequal wealth distribution in forcing too many agents to work for low wages in large firms, rather than setting up their own. In Vindigni (2002) an extreme example of the technology trap studied above occurs, as firms' decisions (choosing the arrival rate of exogenously skill-biased innovations) can permanently confine some dynasties of workers below the fixed income threshold required to invest in human capital.[43] In Grossman (2004), a high variance of human capital in the labor force increases the incentives of the most skilled agents to work in sectors where individual productivity is observable, rather than in those where output is team-determined; because they fail to internalize the spillovers they would have on team productivity, the resulting occupational segregation is inefficiently high.

IV Endogenous Institutions and Endogenous Technology

Combining the main mechanisms analyzed in previous sections yields a model where the distribution of human capital, the technologies used by firms and the policy implemented by the state are all endogenous –as they are in reality. The dynamical system governing the economy's evolution remains recursive:

$$\left\{ \begin{array}{rcl} \gamma_t & = & \Gamma(\Delta_t) \\ \tau_t & = & T(\Delta_t \gamma_t) \\ \Delta_{t+1} & = & \mathcal{D}(\Delta_t, \tau_t; \gamma_t) \end{array} \right. , \tag{40}$$

where $\Gamma(\Delta) \equiv (\sigma^*(\Delta) - 1)/\sigma^*(\Delta)$ represents the technology outcome given by Proposition 8, $T(\gamma\Delta)$ the policy outcome given by Proposition 3, and $\mathcal{D}(\Delta, \tau, \gamma)$ the transmission of human capital inequality given in Proposition 2. The resulting aggregate growth rate, $\ln(y_{t+1}/y_t) = g(\tau_t, \Delta_t, \gamma_t)$, follows from Proposition 2. Finally, steady states are solutions to the fixed-point equation

$$\Delta = \mathcal{D}(\Delta, T(\Delta; \Gamma(\Delta)), \Gamma(\Delta)). \tag{41}$$

[43] A more benign form of multiplicity (with greater wage inequality now going together with more, rather than less, total human capital) occurs in Acemoglu (1998). In his model, a relative abundance of skilled workers makes it more profitable for firms to develop skill-biased technologies; this then raises the wage premium, encouraging more workers to become skilled.

This structure makes clear the presence of important *multiplier effects:* a transitory shock affecting inequality (e.g., more idiosyncratic uncertainty v^2) or the political system (a higher λ) will be amplified through technology decisions, the policy choice, and the intergenerational transmission mechanism, and may thus have considerable long-term consequences.[44] Most importantly, in accounting for changes in inequality *one can no longer treat technological and institutional factors as separate,* competing explanations: both are jointly determined, and complementary. The model thus shows how, in the words of Freeman (1995), one needs to think of *"the Welfare State as a system".*

To demonstrate these points I shall assume from here on a piecewise-linear technological frontier. Flexibility is free up to σ_L, then has a marginal cost of $M > 0$, up to a maximum level $\sigma_H > \sigma_L$:

$$c(\sigma) = \begin{cases} 0 & \text{for} \quad \sigma < \sigma_L \\ M(\sigma - \sigma_L) & \text{for} \quad \sigma \in [\sigma_L, \sigma_H] \\ +\infty & \text{for} \quad \sigma > \sigma_H \end{cases} . \tag{42}$$

I will denote $\gamma_i = (\sigma_i - 1)/\sigma_i$, $i \in \{L, H\}$. The analogue of Proposition 8 in this case is very simple, as the first order condition in a symmetric equilibrium involves the comparison:

$$M \gtrless \frac{\Delta_t^2}{2\sigma_t^2}. \tag{43}$$

The unique symmetric outcome is thus $\sigma_t = \sigma_L$ when $\Delta_t^2/2M < \sigma_L^2$, and $\sigma_t = \sigma_H$ when $\Delta_t^2/2M > \sigma_H^2$. When $\Delta_t^2/2M \in (\sigma_L^2, \sigma_H^2)$, on the other hand, firms mix between σ_L and σ_H, in proportions such that the resulting factor prices make each one indifferent; this equilibrium will be denoted σ_{LH}.[45] Focussing now on technology-inequality steady states, for any $\tau \leq 1$ and $\sigma \geq 1$ the *marginal benefit of flexibility* (right-hand-side of (43)) equals

$$R(\tau, \sigma) \equiv \frac{D(\tau; (\sigma - 1)/\sigma)^2}{2\sigma^2},$$

where $D(\tau, \gamma)$ is the asymptotic variance under the policy τ and return to skill γ, given by (21). Thus, under any time-invariant policy τ, whether exogenous or endogenous:

- For $M > \max\{R(\tau, \sigma_L), R(\tau, \sigma_H)\}$, the unique technological steady state is σ_L;
- For $M < \min\{R(\tau, \sigma_L), R(\tau, \sigma_H)\}$, it is σ_H;
- If $R(\tau, \sigma_L) > R(\tau, \sigma_H)$, then for $M \in [R(\tau, \sigma_H), R(\tau, \sigma_L)]$ it is the mixed-strategy outcome σ_{LH};
- If $R(\tau, \sigma_L) < R(\tau, \sigma_H)$, then for $M \in [R(\tau, \sigma_L), R(\tau, \sigma_H)]$ there are three technological steady states:

[44] The long-run multiplier for any shock to the $\mathcal{D}$ function (e.g., a change in w^2) is $\mu \equiv \left(1 - \mathcal{D}_1 - \mathcal{D}_2\left(\frac{\partial T}{\partial \Delta} + \frac{\partial T}{\partial \Gamma}\frac{\partial \Gamma}{\partial \Delta}\right) - \mathcal{D}_3\frac{\partial \Gamma}{\partial \Delta}\right)^{-1}$. Similarly, the long-run effects on inequality of a shock to the T function (e.g., a change in λ) its is $\mu \cdot \mathcal{D}_2(\partial T/\partial \lambda)$.

[45] It is not necessary to provide here the full characterization of this mixed-strategy equilibrium.

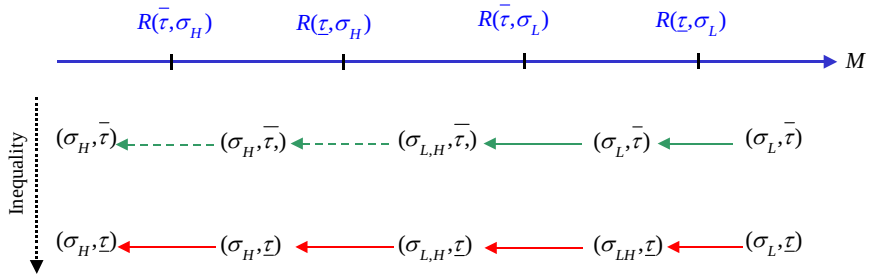

Figure 5: The response of technology and policy to a decline in the cost of flexibility (case (i)). Under each range of M appears the unique (σ,τ) such that $(\sigma,\Delta=D(\tau;1-1/\sigma))$ is a stable steady state given τ and M. The subset reached via solid lines corresponds to the stable steady-states in (σ,Δ,τ) jointly, when policy is endogenous as well.

σ_L, σ_H, and σ_{LH}; the first two are stable, the third one unstable.

Furthermore, since $R(\tau,\sigma)$ is decreasing in τ, we have:

Proposition 9 *More skill-biased technologies appear first in, and less skill biased technologies disappear first from, countries that have less redistributive fiscal, educational or labor market institutions. For any* $M>0$:

1) If σ_H *is a steady state equilibrium technology under a constant redistributive policy* τ, *this remains true under any less progressive policy* $\tau'<\tau$.

2) If σ_L *is a steady state equilibrium technology under a constant redistributive policy* τ', *this remains true under any more progressive policy* $\tau<\tau'$.

These results are illustrated in Figures 5 and 6 for two cases where: i) $R(\underline{\tau},\sigma_H)<R(\bar{\tau},\sigma_L)$, implying that for each M there is a unique technology compatible in the long-run with each policy $\tau\in\{\underline{\tau},\bar{\tau}\}$;[46] ii) $R(\underline{\tau},\sigma_L)<R(\bar{\tau},\sigma_H)$, implying that for either policy $\tau\in\{\underline{\tau},\bar{\tau}\}$ there is a range of M's where multiple technologies are sustainable. The message is essentially the same in both cases, showing how a *world-wide shift* in the set of feasible technologies can result in *different evolutions* of both production processes and the skill premium across countries. In particular, the model can help explain why skill-biased technical change and reorganization occurred first, and to a greater extent, in the United States compared to Europe –and within Europe, more so in England than on the Continent.[47]

[46] For instance, under condition (37), $\partial\ln\Delta_\infty/\partial\ln\sigma<1$, so $R(\underline{\tau},\sigma_H)<R(\underline{\tau},\sigma_L)$ provided σ_H and σ_L are close enough. If $\underline{\tau}$ and $\bar{\tau}$ are also not too different, then $R(\bar{\tau},\sigma)\precsim R(\underline{\tau},\sigma)$ for $\sigma=\sigma_H,\sigma_L$, so the thresholds rank as illustrated on Figure 5.

[47] Acemoglu (2003) proposes a different mechanism, based on imperfectly competitive labor markets, through which the wage-compression policies of continental European countries may have caused technological progress there to be less skill-biased than in the United States. In his model, a binding minimum wage makes low-skill workers' compensation a fixed price, whereas for high-skill workers the binding constraint for the firm is rent-sharing (due to search market frictions), which acts as a tax on productivity improvements. As a result, firms in high minimum-wage countries have greater incentives to invest in technologies that are complementary to low-skill labor than high-skill labor. In both Acemoglu's and the present model, the effects of policy on technology are indirect, operating through either the distribution of skills or equilibrium wages. In

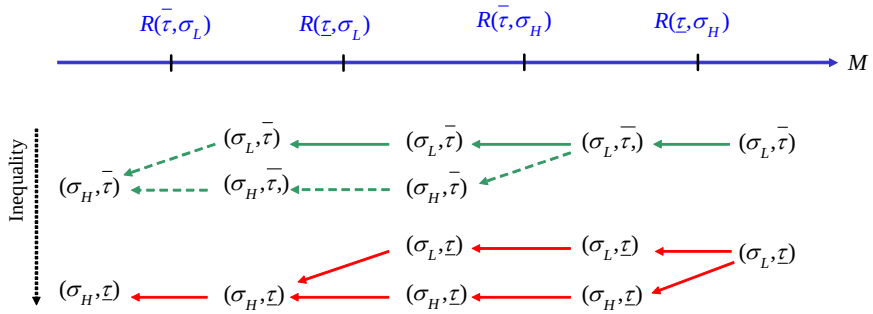

Figure 6: The response of technology and policy to a decline in the cost of flexibility (case (ii)). Under each range of M appear the values of (σ,τ) such that $(\sigma,\Delta=D(\tau;1-1/\sigma))$ is a stable steady state given τ and M. The subset reached via solid lines corresponds to the stable steady-states in (σ,Δ,τ) jointly, when policy is endogenous as well.

Indeed, consider two countries, C_1 and C_2, that are initially identical in all respects, including both using the technology σ_L, except that one is in a laissez-faire equilibrium, $\tau=\underline{\tau}$, and the other in a welfare state, $\tau=\bar{\tau}$. Suppose now that the technological frontier gradually flattens (M declines), meaning that flexibility becomes cheaper to achieve. As shown on Figures 5-6, the more skill-biased technology σ_H becomes (all or part of) another feasible equilibrium in C_1 before it does in C_2; similarly, σ_L first ceases to be viable (by itself or as part of a mixed equilibrium) in the laissez-faire country, while it is still sustainable in the more redistributive one.

Going further, there are in fact *reciprocal interactions* between the economy's *technology response* and *policy response* to shocks. Proposition 9 and Figures 5-6 show that feasible new technologies are not implemented unless institutions are sufficiently inegalitarian. But, conversely, the occurrence of technical change alters these same institutions, as seen in Proposition 7. Indeed, suppose that:

$$\underline{\lambda}(\gamma_L;B)<\lambda<\bar{\lambda}(\gamma_L;B), \tag{44}$$

where $\bar{\lambda}$ and $\underline{\lambda}$ were defined in (22)-(23). These inequalities imply that: i) under the technology σ_L, both social contracts $\underline{\tau}$ and $\bar{\tau}$ are political steady states; ii) under σ_H, $\bar{\tau}$ is a political steady state, while $\underline{\tau}$ is one if and only if we also have $\lambda<\bar{\lambda}(\gamma_H;B)$.

When this last inequality holds, the set of stable politico-economico-technological steady states (with endogenous τ,Δ and σ) is the same as described on Figures 5-6. When $\lambda>\bar{\lambda}(\gamma_H;B)$, however, the more redistributive social contract $\bar{\tau}$ is not *politically* sustainable under the amount of inequality that results, in the long run, from the technology σ_H. Therefore one must remove from the set of steady states on each figure the "branches" corresponding to this outcome; these are indicated by the dashed lines. The

Krusell and Rios-Rull (1996), by contrast, agents with different vintages of human capital vote directly on whether or not to allow the adoption of new technologies by firms.

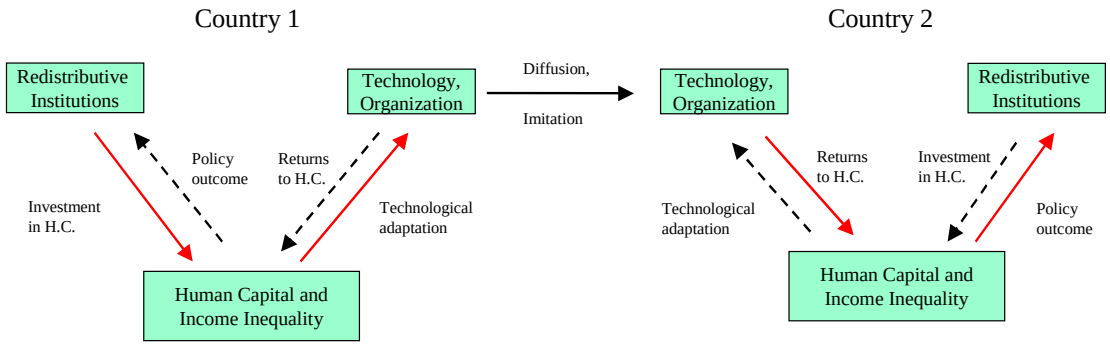

Figure 7: International spillovers between social contracts

remaining solid lines then indicate that *only certain politico-technological configurations* can be observed in the long run: a) for low values of M, e.g. for $M < R(\bar{\tau}, \sigma_L)$ on the first figure, the only feasible social contract is $\underline{\tau}$, together with the technology σ_H; b) on the second figure, for $M \in (R(\bar{\tau}, \sigma_L), R(\underline{\tau}, \sigma_L))$ only the egalitarian social contract and the egalitarian technology, or the inegalitarian social contract and inegalitarian technology, are mutually compatible.

V Exporting Inequality: Spillovers Between Social Contracts

The model also allows us to think about spillovers between national policies or institutions, operating via technological and organizational diffusion. The basic idea is illustrated in Figure 7, which shows how the social contract in Country 2 can, over time, be affected by technological or even purely political shifts in Country 1, propagated along the channels indicated by the solid lines on the diagram.

As seen in the previous section, firms operating in countries with more laissez-faire fiscal, educational or labor market policies have greater incentives to develop and adopt low-complementarity production processes. Suppose now that the cost of imitating, adapting or copying a more flexible technology or organizational form, once it has been developed and implemented elsewhere, is lower than the cost of innovation; in terms of the model, it is $m < M$. This lower marginal cost may for instance reflect, as in Acemoglu (1998), an imperfect international enforcement of property rights over technological or organizational innovations. As we shall see, redistributive institutions in one country will then be significantly affected, perhaps even completely undermined, by technological or political changes occurring in another.[48]

[48] As mentioned earlier I abstract here from international trade, which could be yet another channel of transmission. See Grossman and Maggi (2000), Grossman (2004) or Thoenig and Verdier (2003) for papers that study the effects of trade openness on technical and organizational change, although not their political economy implications.

A *A Shift in One Country's Technological Frontier*

I shall focus here on parameter configurations that satisfy the following conditions:

$$\max\left\{\underline{\lambda}(\gamma_L;B),\bar{\lambda}(\gamma_H;B)\right\} < \lambda < \bar{\lambda}(\gamma_L;B), \tag{45}$$

$$\max\left\{R(\underline{\tau},\sigma_L),R(\underline{\tau},\sigma_H)\right\} < M, \tag{46}$$

$$m < R(\bar{\tau},\sigma_L) < M' < \min\left\{R(\underline{\tau},\sigma_L),R(\underline{\tau},\sigma_H)\right\}, \tag{47}$$

which imply in particular that $M > M' > m$. As shown as part of Proposition 10 below, these conditions also ensure that the technology σ_L allows for both social contracts $\underline{\tau}$ and $\bar{\tau}$, and conversely that σ_L is an equilibrium technology under both social contracts (no firm wants to switch to σ_H).

Proposition 10 *Assume that conditions (45)–(47) are satisfied, and consider two countries, C_1 and C_2, that both start in steady state, with the same technology σ_L. Suppose now that the cost of flexibility in country C_1 declines from M to M'.*
1) If both C_1 and C_2 were initially in the more egalitarian of the two regimes compatible with σ_L nothing happens, in the sense that $(\bar{\tau},\gamma_L,D(\bar{\tau},\gamma_L))$ remains a stable steady state for both countries.
2) If C_1 was initially in the more inegalitarian regime $(\underline{\tau},\gamma_L,D(\underline{\tau},\gamma_L))$, the unique long run outcome is for both countries to switch to the technology σ_H, and for country C_2 to also adopt the more unequal social contract $\underline{\tau}$: the unique steady state for the two countries is now $(\underline{\tau},\gamma_H,D(\underline{\tau},\gamma_H))$.

The intuition is as follows. Even as M declines to M', firms faced with the skill distribution $D(\bar{\tau},\gamma_L)$ resulting from $\bar{\tau}$ do not find it profitable to switch technology. Given the higher dispersion $D(\underline{\tau},\gamma_L)$ that prevails under $\underline{\tau}$, however, if country C_1 starts in this regime all firms there will eventually switch to technology σ_H.[49] Next, given the lower cost of flexibility m to which firms in C_2 now have access through imitation, σ_L is no longer viable there even under $\bar{\tau}$. And, in turn, with the higher income inequality that results in the long run from technology σ_H, the only politically sustainable social contract is $\underline{\tau}$.

These results make clear how technological change (a shift in the frontier) has significant effects only when it is *mediated* through specific institutions –namely, which social contract C_1 had adopted; and, conversely, how under such conditions it will then affect institutions in other countries, namely here in C_2.

B *A Shift in One Country's Political Institutions*

I consider now a second scenario, namely the transmission of *a political shock.* Having seen earlier how the mere fact of being in different institutional steady states (say, for historical reasons) can lead to

[49] I leave aside the dynamics here, but they are straightforward: since (45) implies that (25) holds for $\gamma = \gamma_L$, γ_H, we always operate on the portion of the $T(\gamma\Delta)$ curve where increases in inequality imply decreases in the tax rate.

very different technological trajectories, I shall assume here that C_1 and C_2 both start in the egalitarian steady state, $(\bar{\tau}, \gamma_L, D(\bar{\tau}, \gamma_L))$, with the same technology σ_L. Let C_1 now experience an increase in the political influence of wealth, from λ to λ'. This may reflect a rising importance of *lobbying and campaign contributions*, an exogenous *decline in unionization,* or a lower *electoral turnout* by the poor. It may even simply represent the political outcome during a particular period in which the electorate stochastically shifted to the right.[50] I shall assume here the following conditions:

$$\bar{\lambda}(\gamma_H; B) < \lambda < \bar{\lambda}(\gamma_L; B) < \lambda', \tag{48}$$

$$m < R(\bar{\tau}, \sigma_L) < M < \min\left\{R(\underline{\tau}, \sigma_L), R(\underline{\tau}, \sigma_H)\right\}. \tag{49}$$

Proposition 11 *Assume that conditions (48)–(49) are satisfied. Consider two countries, C_1 and C_2, that both start in the egalitarian steady state, $(\bar{\tau}, \gamma_L, D(\bar{\tau}, \gamma_L))$, with the same technology σ_L. Suppose now that the political influence of wealth in country C_1 rises from λ to λ'. The unique long run outcome is for <u>both</u> countries to switch to the technology σ_H <u>and</u> the more unequal social contract $\underline{\tau}$, thus ending up at the steady state $(\underline{\tau}, \gamma_H, D(\underline{\tau}, \gamma_H))$.*

As a result of the initial political shift, redistribution τ_1 (fiscal, educational, or via labor-market institutions) in country C_1 declines. This leads over time to a rise in human capital inequality Δ_1, to which firms respond by adopting more flexible, wage-disequalizing technologies, switching from σ_L to σ_H and further precipitating the shift from $\bar{\tau}$ to $\underline{\tau}$. Their counterparts in C_2, which would not have developed such technologies by themselves, now find it profitable to copy them from C_1. This results in a rise in income inequality $\gamma_2\Delta_2$ in C_2 (and, over time, in human-capital inequality Δ_2 itself) that ultimately leads to the unravelling of the Welfare State in that country as well.

VI Conclusion

This chapter offers a new, unified model to analyze the reciprocal interactions between the distribution of human wealth, technology, and redistributive institutions. It identifies in particular certain core mechanisms that allow alternative societal models to persist, as well as powerful forces pushing towards uniformization. Key among the former is the interplay of imperfections in asset markets and in the political system that can lead to multiple steady states where inequality and redistribution are negatively correlated. Among the latter is skill-biased technical change, which can potentially lead to the unravelling of the Welfare State. When technological or organizational form is endogenous, moreover, firms respond to greater human capital heterogeneity with more flexible technologies, further exacerbating income inequal-

[50] Indeed, the political shock need not be permanent, provided the speed at which λ reverts to its previous value is low enough, relative to those of human capital adjustment and technological or organizational evolution.

ity. The possibility for firms in different countries to thus choose technologies adapted to the local labor force can also make it easier to sustain multiple social models. The international diffusion of technology, however, implies that the more flexible, skill-biased technologies profitably developed in nations with greater inequality and less redistributive institutions may then be imitated by firms in other countries, thereby triggering a "chain reaction" that moves the whole system towards a common outcome that is more inegalitarian –technologically, economically, and politically speaking. Such international spillovers between national social contracts are important concerns in the debate over globalization, and warrant further research.

Appendix

Proofs of Propositions 1-5. See Bénabou (2000); I shall only provide here:

(i) the formula for the break-even income level $\tilde{y}_t$ where $\hat{y}_t^i = y_t^i$,

$$\ln \tilde{y}_t = \gamma m_t + \delta \ln l_t + (2-\tau_t)\gamma^2 \Delta_t^2/2 \; + (1-\tau_t)v^2/2; \tag{A.1}$$

(ii) the laws of motion for (m_t, Δ_t^2) that underlie Proposition 2,

$$\begin{aligned} m_{t+1} &= (\alpha+\beta\gamma)\, m_t + \beta\delta \ln l_t + \beta\, \tau_t\, (2-\tau_t)\, (\gamma^2\Delta_t^2 + v^2)/2 + \ln\left(\kappa s^\beta\right) - (w^2+\beta v^2)/2 \quad \text{(A.2)} \\ \Delta_{t+1}^2 &= (\alpha+\beta\gamma(1-\tau_t))^2\, \Delta_t^2 + \beta^2(1-\tau_t)^2\, v^2 + w^2; \quad \text{(A.3)} \end{aligned}$$

(iii) and the formula for each agent's intertemporal welfare that underlies Proposition 3: under a rate of redistribution τ_t,

$$U_t^i = \bar{u}_t + A(\tau_t)(\ln k_t^i - m_t) + C(\tau_t) - (1-\rho+\rho\beta)(1-\tau_t)^2 \left(\gamma^2\Delta_t^2 + Bv^2\right)/2, \tag{A.4}$$

where $\bar{u}_t$ is independent of the policy τ_t, $B \equiv a + \rho(1-a)(1-\beta)$ was defined in (14) and:

$$\begin{aligned} A(\tau) &\equiv \rho\alpha + (1-\rho+\rho\beta)\gamma(1-\tau), \quad \text{(A.5)} \\ C(\tau) &\equiv (1-\rho)(\delta \ln l(\tau) - l(\tau)^\eta) + \rho\beta\delta \ln l(\tau), \quad \text{(A.6)} \end{aligned}$$

The first-order condition (15) readily follows. ■

Proof of Proposition 7. Because $D(\tau,\gamma)$ is increasing in γ for all τ the functions $\bar{\lambda}(\gamma;B)$ and $\underline{\lambda}(\gamma;B)$ are both U-shaped in γ, and minimized at the point where $\gamma D(\tau,\gamma) = v\sqrt{B}$, for $\tau = \bar{\tau},\ \underline{\tau}$ respectively. Furthermore, the minimum of $\bar{\lambda}(\gamma;B)$ occurs to the right of that of $\underline{\lambda}(\gamma;B)$. Under the assumption that $v\sqrt{B} > \gamma_{\max}\, D(\underline{\tau}, \gamma_{\max})$ we have $\gamma D(\bar{\tau},\gamma) < \gamma D(\underline{\tau},\gamma) < v\sqrt{B}$ for all $\gamma \leq \gamma_{\max}$, implying that both $\bar{\lambda}(\gamma;B)$ and $\underline{\lambda}(\gamma;B)$ are decreasing in γ over $[0, \gamma_{\max}]$; they are obviously increasing in B. Inverting these functions with respect to γ yields the claimed properties of $\underline{\gamma}(\lambda;B)$ and $\bar{\gamma}(\lambda;B)$. ■

Proof of Proposition 8. Consider a firm $\hat{\imath} \in [0,1]$ with technology $\hat{\sigma}$ and associated productivity factor $\hat{A} \equiv A(\hat{\sigma})$. Its marginal cost is:

$$MC(\hat{\sigma}|\sigma_t) \equiv \min_{\{\hat{x}_t^i\}} \left\{ \int_0^1 p_t^i\, \hat{x}_t^i\, di \;\middle|\; \hat{A} \cdot \left(\int_0^1 z_t^i \; \left(\hat{x}_t^i\right)^{\frac{\hat{\sigma}-1}{\hat{\sigma}}} \, ds \right)^{\frac{\hat{\sigma}}{\hat{\sigma}-1}} = 1 \right\}. \tag{A.7}$$

The first-order condition for cost-minimization is:

$$
\begin{aligned}
p_t^i &= \hat{\mu}_t\ \hat{A}\ z_t^i\ \left(\hat{x}_t^i\right)^{\frac{-1}{\hat{\sigma}}} \cdot \left(\int_0^1 z_t^i\ \left(\hat{x}_t^i\right)^{\frac{\hat{\sigma}-1}{\hat{\sigma}}}\ d\,s\right)^{\frac{1}{\hat{\sigma}-1}} = \hat{\mu}_t\ \hat{A}\ z_t^i\ \left(\hat{x}_t^i\right)^{\frac{-1}{\hat{\sigma}}} \cdot \left(\hat{A}\right)^{-\frac{1}{\hat{\sigma}}}, \quad \text{or:} \\
\hat{x}_t^i &= \hat{\mu}_t^{\hat{\sigma}}\ \hat{A}^{\hat{\sigma}-1} \left(\frac{p_t^i}{z_t^i}\right)^{-\hat{\sigma}}.
\end{aligned}
$$

Therefore:

$$
\begin{aligned}
\hat{\mu}_t &= \int_0^1 p_t^i\, \hat{x}_t^i\, di = \hat{\mu}_t^{\hat{\sigma}}\ \hat{A}^{\hat{\sigma}-1} \left(\int_0^1 z_t^i\ \left(p_t^i/z_t^i\right)^{1-\hat{\sigma}}\, di\right), \quad \text{or:} \\
\hat{\mu}_t &= \hat{A}^{-1} \left(\int_0^1 \left(z_t^i\right)^{\hat{\sigma}} \left(p_t^i\right)^{1-\hat{\sigma}}\, di\right)^{\frac{1}{1-\hat{\sigma}}}, \qquad \text{(A.8)}
\end{aligned}
$$

which establishes (32). Now, replacing the equilibrium prices from equation (27) yields:

$$
\hat{\mu}_t = \hat{A}^{-1} A_t^{\frac{\sigma_t-1}{\sigma_t}} \left(\frac{y_t}{l_t}\right)^{\frac{1}{\sigma_t}} \left(\int_0^1 z_t^i\ \left(k_t^i\right)^{\frac{\hat{\sigma}-1}{\sigma_t}}\, di\right)^{\frac{1}{1-\hat{\sigma}}} = \hat{A}^{-1} A_t^{\frac{\sigma_t-1}{\sigma_t}} \left(\frac{y_t}{l_t}\right)^{\frac{1}{\sigma_t}} \left(\int_0^1 \left(k_t^i\right)^{\frac{\hat{\sigma}-1}{\sigma_t}}\, di\right)^{\frac{1}{1-\hat{\sigma}}},
$$

since the z_t^i's and k_t^i's are independent. We now eliminate the terms common to all firms by computing firm $\hat{\imath}$'s relative marginal cost:

$$
mc(\hat{\sigma}|\sigma_t) \equiv \frac{\hat{\mu}_t}{\mu_t} = \left(\frac{A_t}{\hat{A}}\right) \cdot \left(\int_0^1 \left(k_t^i\right)^{\frac{\hat{\sigma}-1}{\sigma_t}}\, di\right)^{\frac{1}{1-\hat{\sigma}}} \cdot \left(\int_0^1 \left(k_t^i\right)^{\frac{\sigma_t-1}{\sigma_t}}\, di\right)^{\frac{-1}{1-\sigma_t}}.
$$

Finally, using the fact that $\ln \int_0^1 \left(k_t^i\right)^{\chi} di = \exp\left[\chi m_t + \chi^2 \Delta_t^2/2\right]$ for all χ, this yields:

$$
mc(\hat{\sigma}|\sigma_t) = \left(\frac{A(\sigma_t)}{A(\hat{\sigma})}\right) \exp\left[\frac{\Delta_t^2}{2}\left(\frac{1-\hat{\sigma}}{\sigma_t^2} - \frac{1-\sigma_t}{\sigma_t^2}\right)\frac{\Delta_t^2}{2}\right] = \left(\frac{A(\sigma_t)}{A(\hat{\sigma})}\right) \exp\left[\frac{\Delta_t^2}{2}\left(\frac{\sigma_t-\hat{\sigma}}{\sigma_t^2}\right)\right]. \qquad \text{(A.9)}
$$

The (necessary and sufficient) first-order condition for firm $\hat{\imath}$ is therefore: $c'(\hat{\sigma}) = \Delta_t^2/2\sigma_t^2$. Evaluating it at $\hat{\sigma} = \sigma_t$ yields the technology-equilibrium condition $\sigma_t^2 c'(\sigma_t) = \Delta_t^2/2$, which by convexity of $c(\cdot)$ has a unique solution $\sigma^*(\Delta_t)$, increasing in Δ_t. Finally, the result that $\partial \ln \sigma^*/\partial \ln \Delta \in (0,1)$ is established in equation (35). ■

Proof of Section III.C's claims concerning growth with endogenous technology. In the general growth formula (12), $\delta \ln l_t$ is now replaced everywhere (according to (28)) by

$$
\ln \tilde{A}_t + \delta_t \ln l_t = \ln l_t + \ln\left(A_t^{\frac{\sigma_t-1}{\sigma_t}} (y_t)^{\frac{1}{\sigma_t}}\right) = \delta_t \ln l_t + \gamma_t \ln A(\sigma_t) + (1-\gamma_t) \ln y_t.
$$

This leads to:

$$\begin{aligned}\gamma_t \ln(y_{t+1}/y_t) &= \gamma_t \left[\ln\kappa + \beta \ln s + \delta_{t+1} \ln l_{t+1} - \alpha\delta_t \ln l_t + \ln A\left(\sigma_{t+1}\right) - \alpha \ln A\left(\sigma_t\right)\right] \\ &\quad -\gamma_t(1-\gamma_t)w^2/2 - \beta\gamma_t(1-\beta\gamma_t)(1-\tau_t)^2 v^2/2 \\ &\quad - \left[\alpha + \beta\gamma_t(1-\tau_t)^2 - (\alpha + \beta\gamma_t(1-\tau_t))^2\right]\gamma_t^2\Delta_t^2/2. \end{aligned} \tag{A.10}$$

For $\alpha = 0$ and $\beta = 1$, this simplifies to:

$$\begin{aligned}\gamma_t \ln(y_{t+1}/y_t) &= \gamma_t \left[\ln\kappa + \ln s + \delta_{t+1} \ln l_{t+1} + \ln A\left(\sigma_{t+1}\right)\right] \\ &\quad -\gamma_t(1-\gamma_t)\left[w^2/2 + (1-\tau_t)^2 v^2/2 + (1-\tau_t)^2\gamma_t^2\Delta_t^2/2\right] \\ &= \gamma_t \left[\ln\kappa + \ln s + \ln l_{t+1} + \ln A\left(\sigma_{t+1}\right)\right] \\ &\quad -\gamma_t(1-\gamma_t)\left[w^2/2 + (1-\tau_t)^2 v^2/2 + (1-\tau_t)^2\gamma_t^2\Delta_t^2/2\right], \end{aligned} \tag{A.11}$$

or, finally, since $\Delta_{t+1}^2 = \gamma^2(1-\tau_t)^2\,\Delta_t^2 + (1-\tau_t)^2\,v^2 + w^2$:

$$\begin{aligned}\ln(y_{t+1}/y_t) &= \ln\kappa + \ln s + \delta_{t+1}\ln l_{t+1} + \ln A\left(\sigma_{t+1}\right) - (1-\gamma_t)\Delta_{t+1}^2/2 \\ &= \ln\kappa + \ln s + \ln l_{t+1} - c(\sigma_{t+1}) - \frac{\Delta_{t+1}^2}{2\sigma_t}. \end{aligned} \tag{A.12}$$

Substituting for Δ_{t+1}^2 from (11), the growth rate between t and $t+1$ is thus:

$$g_t = \ln\kappa + \ln s + \delta_{t+1}\ln l(\tau_{t+1}) - c(\sigma_{t+1}) - \frac{\mathcal{D}(\Delta_t, \tau_t; \gamma_t)^2}{2\sigma_t}.$$

Therefore, with fixed labor supply ($1/\eta = 0$), if all firms are forced to use technology $\sigma_t - d\sigma$ instead of σ_t in every period the impact on growth will be $d\sigma$ times

$$\begin{aligned}\left.\frac{\partial g_t}{\partial\sigma}\right|_{\sigma=\sigma_t} &= -c'\left(\sigma_{t+1}\right) + \frac{\Delta_{t+1}^2}{2\sigma_t^2} - \frac{\Gamma'(\sigma_t)}{2\sigma_t}\cdot\frac{\partial\mathcal{D}^2(\Delta_t,\tau_t;\gamma_t)}{\partial\gamma} \\ &= -\frac{\Delta_{t+1}^2}{2}\left(\frac{\sigma_t^2}{\sigma_t^2} - 1\right) - \frac{\Gamma'(\sigma_t)}{2\sigma_t}\cdot\frac{\partial\mathcal{D}^2(\Delta_t,\tau_t;\gamma_t)}{\partial\gamma}, \end{aligned}$$

where we have used the condition for equilibrium technology choice in Proposition (8). The growth impact is thus positive in all periods provided that either $\sigma_{t+1}^2 \approx \sigma_t^2$ (we start in or near the steady state), or $\sigma_{t+1}^2 \leq \sigma_t^2$ (we start with "excessive" heterogeneity with respect to the steady state). ■

Proof of Proposition 10. We begin with some preliminaries. Given a technology σ and associated $\gamma = (\sigma-1)/\sigma$, recall from (22)-(23) that the tax rate $\bar{\tau}$ is a steady-state political equilibrium, which we shall denote as $\bar{\tau} \in \mathcal{P}(\sigma;\lambda)$, if and only if $\lambda \leq \bar{\lambda}(\gamma, B)$. Similarly, $\underline{\tau} \in \mathcal{P}(\sigma;\lambda)$ if and only if $\lambda \geq \underline{\lambda}(\gamma, B)$.

Conversely, given a tax rate τ we see from (43) that the technology σ_L and associated $\gamma_L = (\sigma_L - 1)/\sigma_L$ is a technological steady state when the slope of the technology frontier is M, which we denote as $\sigma_L \in T(\tau; M)$, if and only if:

$$M \geq \frac{D(\tau; \gamma_L)^2}{2\sigma_L^2} \equiv R(\tau, \sigma_L). \tag{A.13}$$

Conversely, the technology σ_H and associated $\gamma_H = (\sigma_H - 1)/\sigma_H$ is a technological steady state, which we denote as $\sigma_H \in T(\tau; M)$, if and only if:

$$M \leq \frac{D(\tau; \gamma_H)^2}{2\sigma_H^2} \equiv R(\tau, \sigma_H). \tag{A.14}$$

A policy-technology combination $(\tau, \sigma) \in \{\bar{\tau}, \underline{\tau}\} \times \{\sigma_L, \sigma_H\}$ is then a full steady-state if and only if $\tau \in P(\sigma; \lambda)$ and $\sigma \in T(\tau; M)$. Clearly, there are at most four stable steady-states (we restrict attention here to cases where the technology equilibrium is in pure strategies). We now proceed through a sequence of three claims, which together establish the proposition.

Claim 1: for a country facing the technological frontier M, the only steady states are $(\bar{\tau}, \sigma_L)$ and $(\underline{\tau}, \sigma_L)$. Indeed, the first inequality in (45) states that $\sigma_L \in T(\underline{\tau}; M)$ and this is easily seen to imply that $\sigma_L \in T(\bar{\tau}; M)$. Conversely, the second inequality states that $\sigma_H \notin T(\underline{\tau}; M)$ and this is easily seen to imply that $\sigma_L \in T(\bar{\tau}; M)$. Finally, the fact that $\underline{\lambda}(\gamma_L; B) < \lambda < \bar{\lambda}(\gamma_L; B)$ due to (45) means that $\underline{\tau} \in P(\sigma_L; \lambda)$ and $\bar{\tau} \in P(\sigma'_L; \lambda)$.

Claim 2: for a country facing the technological frontier M', the only steady states are $(\bar{\tau}, \sigma_L)$ and $(\underline{\tau}, \sigma_H)$. Indeed, note first from (47) that $R(\bar{\tau}, \sigma_L) < M'$ means that we still have $\sigma_L \in T(\bar{\tau}; M')$; by contrast, $M' < \min\{R(\underline{\tau}, \sigma_L), R(\underline{\tau}, \sigma_H)\}$ means that $\sigma_H \in T(\underline{\tau}; M)$ but $\sigma_L \notin T(\bar{\tau}; M)$. The only possible equilibria are thus $(\bar{\tau}, \sigma_L)$, $(\underline{\tau}, \sigma_H)$ and $(\underline{\tau}, \sigma_H)$. Turning now to (45), the fact that $\lambda < \bar{\lambda}(\gamma_L; B)$ means that $\bar{\tau} \in P(\sigma'_L; \lambda)$; the fact that that $\bar{\lambda}(\gamma_H; B) < \lambda$, on the other hand, means that $\underline{\tau} \in P(\sigma_H; \lambda)$ but $\underline{\tau} \notin P(\sigma_H; \lambda)$. So only the first two of the three preceding configurations are full equilibria.

Claim 3: *for a country facing the technological frontier m, the only steady state is $(\underline{\tau}, \sigma_H)$.* Observe from (47) that m satisfies all the same inequalities as M', except that $m < R(\bar{\tau}, \sigma_L)$ whereas $R(\bar{\tau}, \sigma_L) < M'$. This means that whereas we had $\sigma_L \in T(\bar{\tau}; M')$, we now have $\sigma_L \notin T(\bar{\tau}; M')$. This rules out the equilibrium $(\bar{\tau}, \sigma_L)$, leaving only $(\underline{\tau}, \sigma_H)$. ■

Proof of Proposition 11.

Claim 1: in the initial parameter configuration, $(\bar{\tau}\ , \sigma_L)$ is a steady state (and even the only steady-state with policy $\bar{\tau}$). Indeed, the fact that $\bar{\lambda}(\gamma_H; B) < \lambda < \bar{\lambda}(\gamma_L; B)$ means that $\bar{\tau} \in \mathcal{P}(\sigma_L; \lambda)$, whereas $\bar{\tau} \notin \mathcal{P}(\sigma_H; \lambda)$. The rest of the claim follows from the fact $\sigma_L \in \mathcal{T}(\bar{\tau}; M)$, since $M > R(\bar{\tau}, \sigma_L)$.

Claim 2: After the political shift in C_1, $(\underline{\tau}, \sigma_H)$ is the only steady-state for that country. First, since $\lambda' > \bar{\lambda}(\gamma_L; B) > \bar{\lambda}(\gamma_H; B)$ we now have $\bar{\tau} \notin \mathcal{P}(\sigma_L; \lambda')$ and $\bar{\tau} \notin \mathcal{P}(\sigma_H; \lambda')$, so there is no steady-state with policy $\bar{\tau}$. Moreover, since $M < R(\underline{\tau}, \sigma_L)$ we have $\sigma_L \notin \mathcal{T}(\underline{\tau}; M)$, so the only possible equilibrium is $(\underline{\tau}, \sigma_H)$. It is indeed an equilibrium, as $M < R(\underline{\tau}, \sigma_H)$ means that $\sigma_H \in \mathcal{T}(\underline{\tau}; M)$, while $\bar{\lambda}(\gamma_H; B) < \lambda'$ means that $\underline{\tau} \in \mathcal{P}(\sigma_H; \lambda')$.

Claim 3: After C_1 has switched to the technology σ_H, so that C_2 faces the technology frontier m, the only steady-state for C_2 is $(\underline{\tau}, \sigma_H)$. First the fact $m < R(\bar{\tau}, \sigma_L) < R(\underline{\tau}, \sigma_L)$ implies that $(\bar{\tau}, \sigma_L)$ is no longer a technological equilibrium, and a fortiori neither is $(\underline{\tau}, \sigma_L)$. Second, the fact $m < \min\{R(\underline{\tau}, \sigma_L), R(\underline{\tau}, \sigma_H)\}$ means that the only technological equilibrium under policy $\underline{\tau}$ is σ_H. Finally, since $\lambda > \bar{\lambda}(\gamma_H; B)$, $\underline{\tau} \in \mathcal{P}(\sigma_H; \lambda)$ whereas $\bar{\tau} \notin \mathcal{P}(\sigma_H; \lambda)$, which concludes the proof. ■

Social Capital

Abstract

This paper surveys research on social capital. We explore the concepts that motivate the social capital literature, efforts to formally model social capital using economic theory, the econometrics of social capital, and empirical studies of the role of social capital in various socioeconomic outcomes. While our focus is primarily on the place of social capital in economics, we do consider its broader social science context. We argue that while the social capital literature has produced many insights, a number of conceptual and statistical problems exist with the current use of social capital by social scientists. We propose some ways to strengthen the social capital literature.

> ...in every community there seems to be some sort of justice, and some type of friendship, also. At any rate, fellow-voyagers and fellow-soldiers are called friends, and so are members of other communities. And the extent of their community is the extent of their friendship, since it is also the extent of the justice found there...What is just...is not the same for parents towards children as for one brother towards another, and the same for companions as for fellow-citizens, similarly with the other types of friendship...what is unjust towards of these is also different, and become more unjust as it is practiced on closer friends. It is more shocking, e.g., to rob a companion of money than to rob a fellow-citizen, to fail to help a brother than a stranger, and to strike one's father than anyone else. What is just also naturally increases with friendship, since it involves the same people and extends over an equal area.

I. Introduction

Social capital represents one of the most powerful and popular metaphors in current social science research. Broadly understood as referring to the community relations that affect personal interactions, social capital has been used to explain an immense range of phenomena, ranging from voting patterns to health to the economic success of countries. Literally hundreds of papers have appeared throughout the social science literature arguing that social capital matters in understanding individual and group differences and further that successful public policy design needs to account for the effects of policy on social capital formation.

This paper is designed to survey research on social capital. We will give primary focus to the role of social capital in economic growth and development as suggested by the presence of this paper in the Handbook of Economic Growth. That being said, this survey will discuss social capital in general as there is no part of the social capital literature that may plausibly be treated as orthogonal to the issues that arise in relating social capital to economic growth. Our objectives are threefold. First, we provide an overview of conceptual issues that underlie social capital studies. Second, we identify

some general flaws we see in the empirical social capital literature. While we would hardly claim that every social capital study suffers from these problems, we do claim that they are prevalent in the literature. Third, we make a number of recommendations on how to strengthen the social capital literature. In assessing empirical work, we will focus almost exclusively on statistical analyses of social capital. This is not because we regard qualitative studies as unimportant (we will in fact advocate their greater use in the course of our discussion) but because such studies raise very distinct conceptual and interpretative questions from their quantitative counterparts.

Much of our discussion is critical. We argue that empirical social capital studies are often flawed and make claims that are in excess of what is justified by the statistical exercises reported. However, this should not be taken as an indictment of research on social capital per se. In our judgment the role of social factors in individual and group outcomes is of fundamental importance in most of the contexts in which social capital has been studied. Hence we regard the empirical social capital literature as addressing major outstanding issues in many areas of social science. Our intent in this survey is to evaluate what is currently known and to make suggestions on how to improve future research.

The paper is organized as follows. Section II contains a discussion of how economists and other social scientists have attempted to define social capital. The section also reviews some of the contexts in which social capital has been argued to play an important causal role in various sociological outcomes. Section III discusses efforts to theorize about social capital; both heuristic and conceptual arguments are discussed as well as formal analyses. Section IV discusses econometric issues that arise in the efforts to develop empirical evidence of the role of social capital as a determinant of socioeconomic outcomes. Section V reviews the empirical literature on social capital; while this literature is far too large to cover comprehensively we believe our survey captures the range of contexts in which social capital effects have been evaluated. Section VI reviews empirical studies that analyze the determinants of social capital. Section VII contains some suggestions for improving social capital research. Section VIII concludes.

II. Social capital: basic concepts

II.i. Defining social capital

Since Loury (1977) introduced it into modern social science research and Coleman's (1988) seminal study placed it at the forefront of research in sociology, the term social capital has spread throughout the social sciences and has spawned a huge literature that runs across disciplines. Despite the immense amount of research on it, however, the definition of social capital has remained elusive. From a historical perspective, one could argue that social capital is not a concept but a *praxis*, a code word used to federate disparate but interrelated research interests and to facilitate the cross-fertilization of ideas across disciplinary boundaries. The success of social capital as a federating concept may result from the fact that no social science has managed to impose a definition of the term that captures what different researchers mean by it within a discipline, let alone across fields.[1]

While conceptual vagueness may have promoted the use of the term among the social sciences, it also has been an impediment to both theoretical and empirical research of phenomena in which social capital may play a role.[2] In order to anchor our discussion of social capital, we need a substantive definition. We begin our search by listing a number of definitions that have been proposed by some of the most influential researchers on social capital. We begin with Coleman (1990) who defines social capital as:

[1]Even if a precise definition of social capital were attempted, it is likely to be no less vague than other similar concepts. The term capital, for instance, is used to describe different things – from finance to machinery to infrastructure. Human capital similarly has many different meanings, such as education, nutrition, health, vocational skills, and knowledge. This kind of vagueness, however, is less problematic as long as researchers agree on some basic principles.

[2] Criticisms of the vagueness and inconsistency of various definitions of social capital may be found in Dasgupta (2000), Durlauf (2000), Manski (2000) and Portes (1998). Arrow (2000) goes so far as to suggest that the term social capital be abandoned.

> ...social organization constitutes social capital, facilitating the achievement of goals that could not be achieved in its absence or could be achieved only at a higher cost. (pg. 304)

Putnam *et al* (1993) provides a similar characterization,

> ...social capital...refers to features of social organization, such as trust, norms, and networks that can improve the efficiency of society... (pg. 167)

Both definitions emphasize the beneficial effects social capital is assumed to have on social aggregates. According to these definitions, social capital is a type of positive group externality. Coleman's definition suggests that the externality arises from social organization. Putnam's definition emphasizes specific *informal* forms of social organization such as trust, norms and networks. In his definition of social capital, Fukuyama (1997) argues that only certain shared norms and values should be regarded as social capital:

> Social capital can be defined simply as the existence of a certain set of informal rules or norms shared among members of a group that permits cooperation among them. The sharing of values and norms does not in itself produce social capital, because the values may be the wrong ones... The norms that produce social capital... must substantively include virtues like truth-telling, the meeting of obligations, and reciprocity. (pp. 378-379)

Other definitions characterize social capital not in terms of outcome but in terms of relations or interdependence between individuals. In later research, Putnam (2000) defines social capital as

> ...connections among individuals - social networks and the norms of reciprocity and trustworthiness that arise from them. (pg. 19)

Ostrom (2000) writes

> *Social capital* is the shared knowledge, understandings, norms, rules and expectations about patterns of interactions that groups of individuals bring to a recurrent activity. (pg. 176)

In a similar vein Bowles and Gintis (2002) state

> Social capital generally refers to trust, concern for one's associates, a willingness to live by the norms of one's community and to punish those who do not. (pg. 2)

Finally, one finds in a recent book-length treatment, Lin (2001)

> ...social capital may be defined operationally as *resources embedded in social networks and accessed and used by actors for actions.* Thus, the concept has two important components: (1) it represents resources embedded in social relations rather than individuals, and (2) access and use of such resources reside with actors. (pp. 24-25)

From these definitions, we can distinguish three main underlying ideas: (1) social capital generates positive externalities for members of a group; (2) these externalities are achieved through shared trust, norms, and values and their consequent effects on expectations and behavior; (3) shared trust, norms, and values arise from informal forms of organizations based on social networks and associations. The study of social capital is that of network-based processes that generate beneficial outcomes through norms and trust.

By this definition social capital is always desirable since its presence is equated with beneficial consequences. This formulation is quite unsatisfactory from the perspective of policy evaluation (e.g., Durlauf (1999,2002b), Portes (1998)): if one denies the appellation of social capital to contexts where strong social ties lead to immoral or unproductive behaviors, there is nothing nontrivial to say in terms of policy. Presumably it is social structures, not their consequences, which can be influenced by policymakers.

Unless we know under what conditions social structures generate beneficial outcomes, we cannot orient policy. We also note that the benefits that social capital generates for one group may disadvantage another, so that the combined effect on society need not be positive. We come back to this issue later.

The three main ideas outlined above often appear intertwined in the mind of their proponents so that one in isolation would probably not be considered social capital. For instance, there are many phenomena that generate positive (or negative) externalities. According to the definitions listed here, they would probably not be considered social capital unless they involve norms or trust. There appears to be more confusion as to whether all three parts of the definition are required for social capital. Norms and trust can be based on formal institutions such as laws and courts without reference to social networks. Yet the literature sometimes has referred to such generalized trust as social capital (e.g., Knack and Keefer (1997)). It is also unclear whether (1) and (3) alone constitute social capital. In his seminal work on job markets, for instance, Granovetter (1975) discusses how social networks are activated to share job market information, thereby speeding job search and raising the efficiency of the job matching process. This process does not, by itself, require shared norms or values. Fafchamps and Minten (2002) use the phrase 'social network capital' to describe this phenomenon.

From the perspective of empirical work, a definition of social capital limited to (1) and (2) is problematic. Things like 'norms' and 'shared values' are notoriously difficult to measure. This has led some of the less rigorous work in this area to present evidence of a beneficial group effect as evidence of social capital itself, and consequently to conclude that social capital is good. This kind of circular reasoning is of course not satisfactory since it is ultimately tautological and is not falsifiable.

A definition of social capital suitable for rigorous empirical work must identify observable variables that can be used as proxies for social capital (Portes (2000)). Norms, trust, and expectations of behavior are very broad ideas that encompass no end of phenomena. Identifying a commonly acceptable set of proxies for social capital has therefore proved a formidable task and many different variables have appeared in empirical papers purportedly to measure it. Another problem has to do with the extent to which the variables used identify well defined social influences – part (3) of our

definition. Adherence to norms can be induced for many reasons, including many that cannot be reasonably construed as social. Consequently, evidence of adherence to norms does not, by itself, constitute evidence of the importance of social networks. To the extent that social networks and associations are part of the definition of social capital, evidence must also be provided that trust and shared norms are achieved via social interaction based on interpersonal networks and associations.

II.ii The efficiency of social exchange

Perhaps a more fruitful approach for our purpose is to proceed by example, that is, to select one specific phenomenon and use it to illustrate how research on social capital can be organized. Much of the commonality in definitions of social capital and in examples given by respective authors is the focus on interpersonal relationships and social networks and their effect on the efficiency of social exchange – whether the provision of a public good, as in Coleman's work, or the better organization of markets, as in Granovetter's. At the heart of the concept of social capital is the idea that positive externalities cannot be achieved without some kind of coordination, i.e., there is coordination failure. Much of the interest in social capital stems from efforts to understand how socially efficient outcomes can occur in environments in which the sorts of conditions necessary for the classical First Welfare Theorem are not fulfilled. Efficiency of social exchange is thus a good vantage point around which to organize our assessment.

One important potential role for social capital concerns its ability to ameliorate potential inefficiencies caused by imperfect information. As Hayek (1945) was among the first to point out, information asymmetries are an inescapable feature of human society. As a result, exchange is hindered either because agents who could benefit from trade cannot find each other, or because, having found each other, they do not trust each other enough to trade. In either case, some mutually beneficial exchange does not take place. Similar principles apply to the provision of public goods. Search and trust are thus two fundamental determinants of the efficiency of social exchange. If we can finds ways of facilitating search and of fostering trust, we can improve social exchange.

There are basically two ways of achieving these dual objectives: via formal institutions (e.g., a stock exchange or a trading fair) or via interpersonal relationships (e.g., word-of-mouth communication of opportunities, repeated interactions which benefit both parties). The literature on social capital focuses principally on the latter. In the following discussion, we illustrate how social networks can raise efficiency. We begin by examining the possible effects of social networks on search. In so doing, we focus only on parts (1) and (3) of our definition of social capital since norms and trust are not central to the circulation of information (although they can play a subsidiary role). We then turn to trust, the externalities it generates, and the way to sustain trust through social networks. Public goods are discussed in the following sub-section. The relationship between social capital and economic development is examined next. The last sub-section explores the relationship between social capital and equity.

Social networks and search

The role of social capital in search can be illustrated by comparing US equity and labor markets. Given the existence of a stock market, it is very easy for a seller of stock to find a buyer at the market clearing price. This is not the case in labor markets where no equivalent institution circulates accurate and up-to-date information about jobs and workers. In his path-breaking study of the US labor market, Granovetter (1975) brought to light the role played by interpersonal relationships in channeling information about jobs and job applicants. A large proportion of jobs are allocated on the basis of personal recommendation and word-of-mouth. This can be understood as an endogenous, spontaneous adaptation to the absence of a formal clearing house equivalent to the stock market.[3]

As this comparison demonstrates, observing that social capital plays a role in markets does not, by itself, constitute evidence that social capital is necessary and should

[3] This is not to say that efforts have not been made to emulate the stock market model – from employment offices to internet sites to temporary employment agencies. But to date none of these institutions seems capable of conveying sufficiently precise information about jobs and job applicants, especially regarding worker environment, work ethics, and

be nurtured. Depending on the circumstances, the development of formal institutions may be a superior alternative.

Social capital and trust

As argued in Fafchamps (2004), trust may be understood as an optimistic expectation or belief regarding other agents' behavior. The origin of trust may vary.[4] Sometimes, trust arises from repeated interpersonal interaction. Other times, it arises from general knowledge about the population of agents, the incentives they face, and the upbringing they have received (Platteau (1994a,b)). The former can be called personalized trust and the latter generalized trust. The main difference between the two is that, for each pair of newly matched agents, the former takes time and effort to establish while the latter is instantaneous.

In most situations, trusting others enables economic agents to operate more efficiently – e.g. by invoicing for goods they have delivered or by agreeing to stop hostilities. Whenever this is the case, generalized trust yields more efficient outcomes than personalized trust. The reason is that, for any pair of agents, generalized trust is established faster and more cheaply than personal trust. This observation has long been made in the anthropological literature on generalized morality. Fostering generalized trust can thus potentially generate large efficiency gains. How this can be accomplished, however, is unclear.

Clubs and networks are different concepts having to do with the structure of links among economic agents. Clubs describe finite, closed groupings. Networks describe more complex situations in which individual agents are related only to some other agents, not all. The term 'network' is sometimes used to describe the entire set of links among a finite collection of agents. Other times, it is used to describe the set of links around a specific individual. To avoid confusion, we refer to the second concept as a subjective network.

---

personal motivation. See Fafchamps (2002) and Kranton (1996) for models of spontaneous market emergence organized around interpersonal relationships.

[4] Sometimes trust is misplaced, but for the sake of brevity, we ignore this possibility here. Put differently, we assume rational expectations.

Among other things, clubs and networks can be used to describe the extent to which personalized and generalized trust exist in a population. Perfect generalized trust corresponds to the case where all agents belong to a single club (or complete network) and trust all other members. Situations in which generalized trust exists only among sub-populations (say, Jewish diamond dealers in New York, cf. Bernstein (1992)) could be described as small clubs. Situations in which individual agents only trust a limited number of agents they know individually can be described as a network.

From the above discussion, it is immediately clear that if trust is beneficial for economic efficiency, the loss from imperfect trust can be visualized as the difference between the actual trust network and the minimum network that would support all mutually beneficial trades. Following this reasoning, inefficiency is expected to be highest in societies where the trust network is very sparse (Granovetter (1995)). Inefficiency is also large when sub-groups who could benefit a lot from trading with each other are prevented from doing so by mutual isolation. This is true even if many links exist within each sub-group.

Social capital and public goods

In the preceding sub-section we discussed the role of trust in fostering exchange. Trust is also an essential ingredient in the delivery of public goods. In many cases, the state can organize the provision of public goods by taxing individuals. Whenever this is true, trust is not essential. But there are many forms of public goods that cannot be harnessed through state intervention.

In his work on PTA run schools, for instance, Coleman (1988) shows that parental involvement in school affairs has a beneficial external effect on student achievement, probably because it leads children to believe their parents care about their education. Parental involvement, in turn, requires trust to reduce and solve interpersonal conflicts and to minimize fears of free-riding. In this example, the externality is a public good that cannot be harnessed by state intervention. Voluntary participation by parents is essential.

In poor countries, there are many situations in which the state could, theoretically, intervene to provide a public good, but where it is unable to do so because its tax base

and its capacity to organize are limited. Collective action can serve as a substitute for the state. However, because it cannot rely on the coercive power of the state (e.g. the ability to tax and enforce contracts), collective action is much harder to set in motion. Two essential ingredients are then required: leadership and trust. A leader is required who is capable of convincing community members that they should voluntarily contribute to the public good. Trust is necessary to resolve conflicts among competing interests and to reduce fears of free-riding. Leaders can also help raise the level of trust in the community.

What the above discussion indicates is that delivering public goods via voluntary organizations depends critically on local trust and leadership. If these ingredients are absent, for instance after a civil war, then state intervention is likely to be much easier. Furthermore, good local leaders are rare. Projects that work well in one place because of strong local involvement need not be replicable elsewhere if local leaders are weak. Pilot projects of public good delivery through local communities may provide wrong signals if their placement is correlated with the presence of good local leaders who managed to attract the pilot project to their community.

II.iii Social capital and development

Much of the interest in social capital stems from the view that the absence of social capital represents one of the major impediments to economic development; Woolcock (1998) provides a wide ranging conceptual analysis of the role of social capital for developing societies and economies; a range of applications of social capital to economic development are collected in Dasgupta and Serageldin (2000) and Grootaert and van Bastelear (2002),. In fact, much of the current interest in social capital stems from the now classic book by Putnam, Leonardi and Nanetti (1993) which argues that Northern Italy developed faster than Southern Italy because the former was better endowed in social capital -- measured by membership in groups and clubs. One of the major claims in this literature is that social capital can facilitate the solution of collective action problems.

However, when focusing on advanced societies, the effects of social capital on economic performance are less obvious. For example, Putnam (2000), focusing on the U.S. experience since the 1950's, argues that social capital, defined as membership in formal and informal clubs, has declined monotonically since the 1950's. This is true for all states, all decades, and all measures of social capital. However, he finds no relationship between the speed of the decline of social capital and economic performance across U.S. states or across time periods. Further, the relationship between social capital and socioeconomic outcomes is even harder to characterize when one looks at subperiods. For example, the 1990's were a period of rapid economic growth in the U.S. yet it is also a period of rapid decline in social capital, at least based on the sorts of measures he uses. To be clear, Putnam does attempt to associate higher social capital with better socioeconomic outcomes, our point is that the relationship between the two for the United States is even at first glance relatively complicated.

The differences between the case of Italian regions and that of the United States is suggestive of how one might think about the relationship between development and social capital. One interpretation of these differences is that for the United States, generalized trust has improved over the period studied, so club membership has become less necessary.[5] In contrast, the Italian experience relates to an earlier period in which generalized trust may have been insufficient or incomplete and small clubs helped broaden the range of personalized trust. This raises the general possibility that clubs and networks are important at intermediate levels of development. Their function is to broaden the range and speed of social exchange beyond the confines of inter-personal trust. But once a sufficiently high level of generalized trust has been achieved, clubs and networks are no longer necessary and wither away (North (2001)). A similar kind of reasoning can be followed for public goods. In undeveloped economies, the state is weak

[5] In this discussion, we stipulate that Putnam's claims about declining U.S. social capital are correct. In fact, this claim has been subjected to important criticism. Skocpol (1996), has argued, for example, that while participation in local groups has declined, participations in larger organizations such as the American Association of Retired Persons has increased, and that what really needs be understood is the nature of voluntary group memberships and the like, rather than the number of memberships per se. See Skocpol (2003) for a detailed elaboration of this idea. One important implication of

and under-funded. Consequently it cannot organize the delivery of all needed public goods. This is particularly true for local public goods or for public goods that require a modicum of voluntary involvement to limit free-riding (of which corruption is but one manifestation).

Social capital provides an alternative. Clubs formed for non-economic purposes (e.g., religious worship) have leaders. In the absence of public good provision by the state, these leaders may decide to mobilize club members (e.g., the religious congregation) to provide missing public goods. History is replete with examples of faith-based organizations intervening to build schools and clinics and to provide a variety of public services. Here, sharing a common religious fervor is the basis for trust and the religious hierarchy provides the necessary leaders. Some large secular organizations have adopted similar practices – e.g., political parties yesterday, non-governmental organizations (NGOs) today.[6]

These issues have immediate implications for empirical work on social capital. The difficulty comes from the fact that first-best outcomes can in principle be achieved without paying attention to clubs and networks. Generalized trust in commercial contracts, for instance, can theoretically be achieved via laws and courts. Because of the possibility that revenues may be collectively raised via taxation, public goods can in principle be organized by the state at lower cost in terms of public mobilization and leadership skills. As North (1973,1990) has argued, the rise of the Western world is precisely due to the invention of institutions that protect property rights and make the state more effective at delivering public goods. Clubs, networks, and community-based voluntary organizations can improve efficiency in economic exchange and public good delivery. But these are typically second-best solutions. The first-best approach is generally to develop well-functioning legal institutions and state organizations.[7]

Skocpol's work for economists is that many of the measures that have been proposed to quantify social capital may be fundamentally flawed.

[6]One classic historical example is the role of the Social Democratic Party in organizing a range of social and cultural activities for its members in Imperial Germany, see Blackbourn (1997, chapter 8).

[7]Bowles and Gintis (2002) elaborate this type of reasoning, although in their view social capital plays a role in overcoming limits to government intervention generated by

Whether or not social capital raises efficiency we therefore argue depends on the level of institutional development. Suppose that laws and courts are insufficient to ensure respect of commercial contracts. This situation can arise anywhere (Bernstein (1996)) but it is probably most severe in poor countries where many transactions are small and buyers and sellers are too poor for court action to yield reparation (Bigsten *et al.* (2000), Fafchamps and Minten (2002)).[8] In such an environment, market exchange relies on a combination of personalized trust, legal institutions (e.g., to enforce large contracts and to punish thieves), and informal institutions (e.g., reputation sharing within business networks and communities). Whether or not social capital facilitates exchange can then be seen as a test of the strength and reach of formal institutions.

A similar line of reasoning holds for public goods. Public good delivery is best accomplished when the power of the state to tax and mobilize resources is combined with trust and community involvement. The reason is that, without voluntarily accepted discipline, government action is ineffective: taxes do not get paid, rules are not followed, civil servants become corrupt, and free riding reigns. Discipline in turn depends on the perceived legitimacy of government action and the degree of public involvement in the decision-making process. It also depends on identification with the political elites, sense of national urgency, and many other factors which are still poorly understood. The bottom-line, however, is clear: without some form of voluntary acceptance by the public, government efforts to provide public goods are likely to fail. Social capital is thus probably essential for public good delivery. But the forms it may take are likely to vary depending on local conditions, i.e., from generalized trust in government and formal institutions to interpersonal trust mobilized via clubs and networks.

II. iv. Social capital and equity

We have argued that trust is essential to both economic exchange and public good delivery. We have also argued that clubs and networks can facilitate search and provide

---

information constraints and so acts as a complement to government institutions in producing efficient outcomes.

[8]Except through forced labor, as in 19th century England and France. But this is now outlawed in most countries.

an imperfect substitute to generalized trust: in the absence of generalized trust, it may be necessary to rely on clubs and networks. Unlike generalized trust, however, clubs and networks often have distributional consequences that may be quite inequitable. The reason is that, unlike generalized trust, clubs and networks only offer a partial or uneven coverage of society. If the benefits of social capital principally accrue to network members, those who happen to be included benefit from increased efficiency but those that are excluded are penalized. As Fafchamps (2002) and Taylor (2000) have shown, the creation of clubs or networks can even penalize non-members. This is because members of a club or network find it easier to deal with each other and, as a result, may stop dealing with non-members.[9]

Clubs are least conducive to equity when membership is restricted to a specific group (e.g., men or whites) or when new members are not accepted (e.g., established firms only). Even when new members are accepted without restriction, historical events can shape the composition of clubs for decades whenever entry is slow. In this case, equal opportunity need not be realized because old members have enjoyed the benefits of membership for much longer. By extension, clubs are likely to have undesirable consequences on equity whenever (1) club membership is beneficial to members and (2) entry into the club is not instantaneous. Put differently, clubs raise equity concerns whenever they have real economic benefits.

The creation of clubs may thus reinforce polarization in society between the 'in' group and the 'out' group. Investing in social capital by promoting clubs can thus have serious equity repercussions. This is true even if we ignore the fact that certain clubs may collude to explicitly dominate or exclude others (e.g., the Ku Klux Klan). A similar situation arises with networks because better connected individuals profit from their contacts (Fafchamps and Minten (2002)). Social capital can be used by certain groups to overtake others, generating between-group inequality and political tension. To the extent that between-group inequality itself favors crime and riots and deters investment, promoting social capital by promoting specific groups may, in the long-run, be counterproductive.

[9] Of course, this is not to say that impersonal markets based on generalized trust treat all groups fairly. Statistical discrimination, for instance, naturally arises even in the absence

III. When does social capital matter?

The conceptual discussion has clarified the definition of social capital and its possible role in the development process. This discussion, however, has not precisely identified the conditions under which social capital matters. To achieve this, we need a general conceptual framework in which there is room for social capital to be beneficial.

III.i Sources of inefficiency

For social capital to increase Pareto efficiency, the decentralized equilibrium without social capital must not be Pareto efficient in the first place. Social capital can only have a beneficial effect in a second-best world. Deviations from first-best outcomes arise for a variety of reasons including externalities and free-riding, imperfect information and enforcement, imperfect competition, and the like. For social capital to be beneficial, it must therefore resolve or compensate for one of these sources of inefficiency. Secondly, whatever the source of inefficiency, there are only a limited number of ways by which social capital – or any other mechanism – may improve upon a decentralized equilibrium. First, it may resolve a coordination failure in an economy that has multiple Pareto-ranked equilibria. Second, it may alter individual incentives so as to replace the decentralized equilibrium with a superior one. Third, it may affect the technology of social exchange, for instance by opening new avenues for the circulation of information.

From these two preliminary observations, it is immediately obvious that social capital will never be the only possible solution to inefficiency. There always exist alternative mechanisms to solve coordination failure, improve individual incentives, and upgrade the technology of social exchange – such as contracts, vertical integration, state intervention, or redefinition of property rights. Of course, there are many circumstances in which social capital is a less expensive or simpler institutional solution, but it is important to recognize that it can never be the only one.

---

of clubs and networks (e.g. Fafchamps (2003)).

These observations have immediate implications regarding empirical investigation. Suppose social capital improves efficiency by solving a coordination failure problem. For this to occur, the economy must have multiple Pareto-ranked equilibria. Social capital provides the leadership or coordination device necessary to select a superior equilibrium among the many possible ones. Suppose further that the researchers have multiple observations of such economies, some with social capital and some without. Since nothing precludes these economies from achieving a high equilibrium without social capital, it is inherently difficult to test its effect. Furthermore, social capital may arise endogenously as an institutional response to an inferior equilibrium. To the extent that social capital does not always succeed in moving the economy to the better equilibrium, one could have the paradoxical situation in which economies with social capital are on average at a lower equilibrium than those without. This is a standard difficulty with multiple equilibria but it is not always adequately recognized in empirical work.

Even when there is a single equilibrium, social capital never is the only possible way of improving efficiency by altering incentives or technology. Identifying the effect of social capital requires that the researcher adequately control for other possible institutional solutions. Here too, self-selection is a concern.

III.ii Channels

The literature has identified a number of channels by which social capital improves efficiency. Most of these channels fall under one or a combination of the following three categories: information sharing, group identity, and explicit coordination.

Information sharing

It is a commonplace that human beings derive satisfaction from interacting with others. Socializing often involves the transfer of information, even if the purpose of socialization is not to transfer this information. The sharing of information is then a by-

product of social interaction, a Marshallian externality. To the extent that the shared information is economically useful, socialization generates a positive externality.

Socialization may also be initiated with the intent of acquiring a specific piece of information. In this case, the transfer of information is the purpose of socialization. Because interacting with others is also a consumption good, collecting information through socialization benefits from a kind of 'subsidy' relative to non-social forms of information collection (e.g., going to the library).

The literature on social capital contains many applications of this simple idea. Barr (2000), for instance, argues that social networks among Ghanaian entrepreneurs serve to channel information about new technology. Fafchamps and Minten (1999), Granovetter (1975,1995), Montgomery (1991), Rauch and Casella (2001) and many others have emphasized the role of business networks in conveying information about employment and market opportunities. Fafchamps (2004), Greif (1993), Johnson, McMillan and Woodruff (2000), Kandori (1992) and McMillan and Woodruff (2000) have brought to light the role of social networks in circulating information about breach of contract, thereby enabling business groups to penalize and exclude cheaters. Wade (1987, 1988) discusses the role of social capital in reducing incentive problems in teams by circulating information about effort. This point has also been made in the theoretical literature on industrial organizations, where the possibility for members of a team of workers to monitor and penalize each other has been shown to increase efficiency. Social capital may also circulate information about what tasks need to be done and when. Platteau and Seki (2002) provide an illustration of this idea in the case of Japanese fishermen and the coordination of their fishing efforts to minimize cost (e.g., exchange information about fish location) and maximize revenue (e.g., coordinate the landing of fish to maximize prices).

While the evidence provided is impressive, the literature remains somewhat naïve in its assumption regarding the ease with which accurate information can be exchanged. In practice, three conditions must be satisfied for social capital to raise Pareto efficiency through the sharing of information: (1) imperfect information must be the source of inefficiency; (2) there are disincentives to spread erroneous information; (3) there are no obstacles to Pareto efficiency other than imperfect information. Even if social capital

satisfies the first condition, it may not satisfy the other two. It is also important to recognize that the information sharing benefits generated by social capital can always be obtained in another way. For instance, information sharing can be explicitly organized and budgeted within a large organization, whether public or private (enterprise, NGO). To empirically test the effect of social capital, one should control for the possible presence of such organizations.

It is so customary to blame imperfect information for economic inefficiency that other sources of inefficiency, such as imperfect contract enforcement and insufficient protection of property rights, are sometimes disregarded. Fafchamps (2002), for instance, shows how the decentralized enforcement of contracts naturally takes the form of relational contracting, even without exchange of information. In this example, contract enforcement is the channel through which social capital raises efficiency, not information sharing. In his analysis of market institutions in sub-Saharan Africa, Fafchamps (2004) points out that incentives often exist to distort the conveyed information, either to hurt a competitor or to hide one's own shortcomings. Interviews with entrepreneurs suggest that gossip is never regarded as reliable information. Guaranteeing that accurate information is transferred through social networks requires the existence of punishment mechanisms – such as the loss of reputation – penalizing false reporting. Finally, there often are obstacles to Pareto efficiency other than imperfect information. The most common one is coordination failure. We revisit this issue below.

Group identity and modification of preferences

Under the general heading of group identity and modification of preferences, we put various effects that arise because identification with a group or network affects individual preferences and choices. Economists usually regard individual preferences as exogenously given and relatively stable over time. As psychologists have shown, however, individual preferences can be manipulated through advertising or propaganda. Individual preferences can also fluctuate over time in a systematic, somewhat predictable fashion. Impulses are one particularly relevant example of such phenomenon. Individuals

have been shown to violate their own stated preferences in response to an impulse – to eat, to drink, to buy.

This introduces time inconsistency in preferences. Because agents anticipate they may be subject to impulses, they often resort to various 'tricks' that limit their future choices – such as putting money on a savings account that cannot be accessed easily, or carrying a limited amount of cash when shopping. Agents may also voluntarily enter in restrictive social arrangements in order to protect themselves against their own impulses. Alcoholic Anonymous is a good example of such a process. Participation in Rotating Savings and Credit Associations (ROSCAs) can similarly be understood as a way of forcing oneself to save.

The literature on social capital is replete with descriptions of such virtuous processes. Because these descriptions implicitly assume that social capital alters individual preferences, they often seem alien to economists. One such claim often made in the literature is the idea that social capital favors altruism and raises concerns for the common good – the 'touchy-feely' side of social capital. To see how even a minor increase in altruism can raise efficiency, consider a standard Prisoner's Dilemma (PD) game with standardized payoff matrix:

	Cooperate	Defect
Cooperate	(1,1)	(*-a*,*b*)
Defect	(*b*,*-a*)	(0,0)

with $a > 0$, $b > 1$. It is standard that (Defect,Defect) is the unique Nash equilibrium. Now suppose that players become altruistic, so that their utility is the weighted sum of their individual payoff Π_i and their opponent's individual payoff Π_j, so that $U_i = (1-\alpha)\Pi_i + \alpha\Pi_j$ where $\alpha > 0$. In this case, Defect is no longer necessarily a best response strategy; (Cooperate,Cooperate) is now a Nash equilibrium if $1 > b(1-\alpha) - a\alpha$ or equivalently, $\alpha > \frac{(b-1)}{b+a}$. This condition can be satisfied for values of α well below one half, implying that, depending on the values of a and b, even moderate levels of

altruism can eliminate the Prisoner's Dilemma. Similar reasoning can be applied to games with inferior equilibria, such as the assurance game: in these games some altruism can also eliminate Pareto inferior outcomes. The intuition behind this result is obvious: the more players internalize others' payoffs, the more they care about Pareto efficiency. When both players give equal weight to their payoff and others', they only care about aggregate welfare, what we call the common good. In this case, the equilibrium is always Pareto efficient.[10] Altruism provides an efficient solution to free-riding – a principle that most religions seem to have discovered centuries ago.

The relationship between altruism and social capital probably has to do with group identity (Akerlof and Kranton (2000)). Economic experiments using the dictator game and the trust game indeed suggest that agents exhibit more altruism and play more cooperatively if they have been induced to identify with a group (e.g., Fershtman and Gneezy (2001)).[11] This is true even if members of the group are unknown and even if they are not even seen during the experiment. These results suggest that group identification may trigger agents to adopt more altruistic preferences, thereby yielding more efficient group outcomes. If identification with a group is necessary for preferences to become more altruistic and better aligned with the common good, efforts to foster a sense of community may naturally be seen as an essential component of social capital by many researchers. This probably explains why community building is often construed as a way to foster social capital.

Social capital may also affect preferences in other ways. As argued by Fafchamps (1996) and Platteau (1994a), several mechanisms can be used to enforce contractual obligations: legal and extra-legal penalties, loss of reputation, and guilt. These same mechanisms can enforce contributions to the public good in case individual preferences are not aligned with the common good. By circulating information, social capital can magnify reputational sanctions, a point we have discussed in the previous sub-section. Group identification can also raise guilt for acting against the group's common interest.

---

[10] Note that the common good equilibrium is Pareto efficient in both the original, selfish preferences Π_i and in the altruistic preferences $U_i = (1-\alpha)\Pi_i + \alpha\Pi_j$.

[11] In the trust game players play sequentially. Player 1 gives an amount X to player 2. This amount is multiplied by the researcher, usually by 2 or 3. Player 2 then gives an amount Y to player 1. There is no repetition.

In our PD game, this is formally equivalent to deducting the subjective cost associated with guilt, call it g, from the payoff b associated with defection. If this feeling is strong enough so that $b-g<1$, defection is deterred. Since Max Weber, the literature on market development has emphasized the role played by religion in fostering business honesty (Ensminger (1992), Geertz, Geertz and Rosen (1979), Poewe (1989)). Communist work ethics propaganda can be seen as a similar effort to improve team performance by raising guilt among shirkers.

By favoring identification with a group, social capital may also affect preferences through mimicry. In the literature, this idea appears in many guises, the phrase most commonly used being 'role model'. Coleman's example of PTA-run schools is a good illustration. According to Coleman, children whose parents are involved in running the school adopt a more positive attitude towards study. This change in preferences cannot be understood as altruism: it is in the children's long-term self-interest to study. Nor does it appear to be purely the result of a sharpened sense of guilt for not studying. Rather it is related to a demonstration or role model effect: children change their preferences to mimic that of their parents. By visibly and credibly demonstrating their positive attitude towards school, parents induce a change in attitude among their children.

This kind of phenomenon is related to what economists have called 'herding behavior', that is, the drive to mimic the behavior of others. More research is needed in this area to fully comprehend the phenomenon and its implications for economic efficiency. As has been argued formally in Blume (2002), however, mimicry need not result in superior equilibria: nothing in mimicry itself precludes agents from copying bad behaviors instead of good ones. One famous example is that of a group of high school students who refused to take their graduation exam as a symbol of group identity, even though doing so hurt them all. Other examples of bad mimicry involve hazing, gang rape, crime culture, and the like. Unlike altruism, mimicry is a double-edged sword.

Coordination and leadership

Some of the beneficial effects of social capital on preferences occur by osmosis, without any purposeful action by anyone: people chat around a glass of beer and, quite by

chance, a relevant piece of information is exchanged. In many cases, however, the benefits of social capital are only achieved through purposeful action: someone has to want to improve the group's welfare and must do something about it for benefits to materialize. This is particularly true of any benefit that requires coordination in order to be achieved.

This raises a host of difficult issues having to do with the decision making process within groups. It is well beyond the scope of this Chapter to discuss these issues in detail. A few remarks are nevertheless in order. First, two essential ingredients seem to play fundamental roles in purposeful group action: leadership, and rules regarding group decision making. At this level of generality, their respective role is unclear. What is inescapable, however, is that neither of them constitutes social capital.

In very informal groupings, leadership is likely to be essential to alter individual preferences and elicit voluntary contributions to the common good. While social capital may assist the action of leaders by facilitating the circulation of information and favoring group identification, the respective roles of leadership quality and social capital are likely to be extremely difficult to disentangle. This has important implications for empirical work: if good leadership is required to achieve the coordination required to benefit from social capital, testing the effect of social capital requires controlling for the quality of leadership.

This observation also has implications for policy. Good leaders may improve efficiency by using the levers of social capital – e.g., by fostering altruistic preferences and concern for the common good; favoring group identification; preaching good behavior and making free-riders feel guilty; encouraging mimicry of good behavior through role models and the manipulation of group symbols and representations (e.g., religion, ideology). This is what practitioners in the field call 'building social capital'.[12] Many NGOs, for instance, are engaged in precisely this kind of work. Sometimes they focus on the identification and training of local leaders, something to which many NGOs refer as an example of 'capacity building' (Barr, Fafchamps, and Owens (2004)).

[12]To a number of economists, these forms of policy intervention may seem unusual because they have no effect on material incentives but operate only through mental representations. We revisit these issues in greater detail below.

Purposeful coordination can also be obtained through formal rules by which decisions are made and deviance penalized. A simple majority rule combined with fines and jail sentences for free-riders is in many cases sufficient to reach efficiency. As long as free-riding is not so prevalent as to overwhelm policing, punishments directly alter incentives in ways that align individual behavior with the common good. In this case, social capital plays little role – except perhaps in coordinating not to overwhelm the enforcement apparatus. Leadership also becomes less critical since there is no need for a charismatic leader who can affect individual preferences directly. All that is required is a 'bureaucratic' leader who can apply and enforce the rules decided by the group.

A proper investigation of the importance of social capital in economic life therefore requires a careful analysis of the rules by which decisions are reached. It is important not to credit social capital with outcomes due to formal rules. This means distinguishing between the benefits resulting directly from formal organization and the indirect benefits members derive from contact with each other. For instance, the Rotary Club has a decision making body to coordinate the date and venue of its next dinner. The coordination benefit of meeting on the same day in the same place follows directly from the Club's formal rules. But once at the dinner, there is probably no coordinated mechanism to share information among members.

This same sort of reasoning applies to schools. In addition to the effects of student attitudes discussed by Coleman, PTA-run schools have an organizational structure different from that of other schools. In particular, decisions are taken differently and funding is allocated in a different manner when parents and teachers possess decisionmaking power in schools. As Jimenez and Sawada (1999) have shown in the case of El Salvador, PTA-run schools tend to provide greater remuneration and select better teachers than other schools. These schools also exhibit lower rates of teacher absenteeism. At least part of these differences may plausibly be attributed to differences in funding and internal decision-making rules. Disentangling these effects from those of social capital is likely to be difficult and contentious.

III.iii. Formal theory

While the ideas associated with social capital have been linked to many strands of modern microeconomic theory, there has been relatively little formal modeling of social capital per se. One reason for this, we conjecture, is the absence of a generally accepted and coherent definition of social capital, as discussed.

In terms of the efforts to embody social capital in formal economic models, one approach that has been taken is to incorporate social capital in models in the context of repeated prisoner's dilemma games. In environments in which agents change partners, the sustainability of a cooperative equilibrium depends on either the likelihood with which a match today will be repeated in the future and/or the ability of an agent to access information about the past behavior of a new partner (Kandori (1992)). In this context, social capital is interpreted in terms of the factors that facilitate the existence of a cooperative equilibrium. Routledge and von Amsberg (2003), using a prisoner's dilemma environment of the type we described above, define social capital as present whenever a cooperative equilibrium exists; the key variable that determines whether cooperation can occur is the probability of trade between a pair of agents. Intuitively, if this probability is high, two agents meeting today are likely to meet in the future, so that any loss from cooperation today is compensated by future cooperation in the repeated relationship. Routledge and von Amsberg apply this idea to study how migration across regions or sectors, can, by lowering the likelihood of repeated interactions, lead to a loss of social capital. Annen (2003) defines social capital as an individual's reputation for cooperation in prisoner's dilemma games. In his analysis, this reputation depends on the extent to which information transmission about past behavior is reliable and the complexity of the network in which agents interact. Changes in either reliability or complexity can thus alter levels of social capital. Annen focuses on the question of when increases in network complexity lead to a reduction of network size or an increase in network size accompanied by greater investment in communication capacity.

Other formal theory relevant to social capital includes efforts to model the notions of trust and trustworthiness. Zak and Knack (2001) study a general equilibrium growth model in which agents facing moral hazard problems decide how much to invest in monitoring. The presence and strength of formal and informal sanctions for dishonesty are shown to have powerful implications for growth because of their role in reducing the

need to invest in monitoring. Another approach to modeling trust is due to Somanathan and Rubin (2004), who study the evolutionary stability of honest types in a population.

Perhaps the most important contribution to formal theory is Dasgupta (2002) which provides a wide ranging discussion of the relationship between social capital and formal modeling. Dasgupta argues that social capital should not be defined in terms of the presence of cooperation or some other outcome; rather that it should be regarded directly as social structure.

> "...social capital is most usefully viewed as a system of interpersonal networks...If the externalities network formation gives to are "confined", social capital is an aspect of "human capital", in the sense economists use the latter term. However, if network externalities are more in the nature of public goods, social capital is a component of what economists call "total factor productivity." (pg. 6-7)

Dasgupta's analysis is important as it indicates how the role of social capital in growth cannot be reduced to the addition of a variable to a linear cross-country growth regression. His analysis is also important in its recognition that theoretical claims about the desirability of the sorts of social structures that have been equated to social capital are to some extent artifices of particular modeling assumptions. For example, he argues that the claim that repetition of a one-shot game necessarily benefits the players of the game is not a generic finding and in fact does not generally hold for payoff structures other than the prisoner's dilemma, going on to argue that work such as Fudenburg and Maskin (1996) shows how social capital can lead to exploitive relationships. As such Dasgupta's analysis makes clear how functional notions of social capital are inconsistent with rigorous theorizing. Other conceptual discussions of social capital and social science include Ostrom and Ahn (2002) and Paldam and Svendsen (2000); the former is particularly interesting to contrast with Dasgupta (2002) as it is written from the perspective of non-economists and indicates some of the conceptual gaps between economists and other social scientists on this topic.

IV. From theory to empirics: econometrics and social capital

Having clarified the relationship between social capital and the efficiency of social exchange, we now turn to the statistical analysis of the effects of social capital. We first revisit the points raised in this section, such as the distinction between individual and aggregate efficiency effects. We then ask whether it is possible to uncover social capital effects from the sorts of data available to social scientists. In particular, we discuss the issue of identification, that is, of whether a role for social capital can be uncovered when other types of social effects may be present.

Standard practice in economics and sociology is to run regressions of some outcome of interest against a set of controls and some asserted empirical proxies for social capital. These regressions are often justified by an informal argument that the empirical proxies act as instrumental variables for the unobserved "true" social capital measure. At one extreme, one finds analyses such as Furstenburg and Hughes (1995) in which the probability that an individual drops out of school is related to variables such as the presence of a father in the household or the educational aspirations of the person's friends. In contrast, studies such as Knack and Keefer (1997) attempt to explain growth differences across entire countries using survey measures of trust.

In this section, we discuss some general econometric issues that arise in social capital studies of this type. We first examine difficulties inherent in the estimation of the benefits from social capital on the basis of individual data. These difficulties are not specific to social capital and are shared by other externalities. But they are often ignored in empirical work.

Second, we discuss the question of model specification. In particular, we review some requirements for treating a given social capital regression as causal. Next, we discuss identification. In this case, we assume that a researcher has the "correct" model of some outcome of interest and ask whether observational data on the phenomena will allow for the identification of a causal relationship between social capital and the outcome.

The basic econometric issues associated with identifying a role for social capital may be understood in the context of cross-sections. While panel data have certain advantages, notably that they allow for the researcher to control for fixed effects across units, the conditions under which social capital effects may be identified are not qualitatively different.

IV.i. Externalities and individual vs. aggregate effects

As we have discussed in Section II, the literature on social capital is interested in externalities arising from coordination failure. Much of the empirical work on social capital seeks to identify the effect of social capital on an outcome variable of interest, say, ω_i. This variable of interest can be measured at the aggregate level – e.g., country growth – or at the individual level – e.g., performance of a pupil on an exam. Empirical work on social capital can thus be divided into individual and aggregate level regressions.

The first difficulty many researchers encounter is that individual returns to social capital often are poor predictors of aggregate externalities. There are two main reasons for this: fallacy of composition and free riding. A fallacy of composition arises whenever social capital pegs individuals against each other. In a situation of competition for a finite resource, the gains made by those with more social capital lead to losses for those without, relative to a situation without social capital. Free riding is the opposite situation in which aggregate social gains are larger than those appropriated by the owners of social capital. We discuss them in turn.

Fallacy of composition

To illustrate fallacy of composition, consider a simple job search example inspired by Granovetter's work. Suppose there are M job openings and N job seekers, all identical, with $N>M$. Suppose that employers and workers do not know each other and are matched at random. Since $N>M$, all positions are filled and each worker has an equal probability of getting a job $\frac{M}{N}$. Total surplus is the sum of employer and worker

surplus. Since all workers are equivalent, total surplus is the same irrespective of which workers get the available jobs.

Next suppose that, because of interpersonal connections, a group of workers C hears about the open positions before other workers. Further suppose that $C < M$. Consequently C workers get a job with probability 1. Other workers get the remaining jobs with probability $\frac{M-C}{N-C}$ which is smaller than $\frac{M}{N}$. Total surplus is unchanged since workers are equivalent. Social networks – in this case the existence of a better connected group of workers – have no effect on the efficiency of social exchange. But they have important distributional consequences, which can be measured by regressing the probability of obtaining a job on group membership. Doing so in our example would yield a coefficient of $1-\frac{M-C}{N-C}$ on membership in the group even though the net effect of social networks on aggregate welfare is zero. What this example illustrates is that social networks can have private returns even when they have no effect – other than distributional – on the efficiency of social exchange. Observing private returns to social networks should therefore not be construed as evidence of social capital. In our example, social networks actually generate a discriminatory outcome, which is inconsistent with equality of opportunity as conceptualized by Roemer (1998) for example.[13]

The above reasoning can be extended to situations where groups, not individuals, compete with each other. Consider, for instance, high schools competing to place their graduates at Harvard. We assume that the number of admissions in Harvard is fixed and that the university selects the students with the best grades on a standardized test. Suppose that Coleman is right and that, because of the social capital effects of parental involvement in school affairs, students in PTA-run schools obtain better grades. As a result, they are more likely to go to Harvard than students from non-PTA schools. Whether or not this raises social welfare depends on how critical high school education is to university learning.

[13] A similar example could be constructed in which it is the effect of social capital on trust that matters. For instance, imagine silk produced in China and consumed in Europe. Chinese silk producers do not trust European consumers so that direct sale is not possible.

To illustrate this point, suppose that students learn all they need to know at Harvard. The only purpose of high school education is to screen out less able students. Further assume that the minimum grade required to be admitted at Harvard is higher than the grade necessary to earn one's degree: some applicants do not get in even though, if they did, they would earn their degree. In this case, the role of social capital is again to enable one group – students in PTA schools – preferential access to a rationed resource – admission at Harvard. The effect of social capital is distributional. Regressing the probability of admission in Harvard on social capital would yield a positive coefficient even though, in this example, the effect of social capital on the efficiency of social exchange is zero. Of course, we do not claim that the above example is an accurate depiction of the education system. The only purpose of the example is to illustrate the danger of estimating the beneficial effect of social capital by comparing individual or group outcomes according to whether or not they have social capital. Whenever social capital enables one group to displace another, a statistical comparison of the two groups is bound to overestimate the efficiency gain from social capital.

This example exposes another ambiguity of the concept of social capital. In our review of definitions of social capital, we noted that most authors associate social capital with the idea of beneficial group externalities. In the above – admittedly extreme – example, groups of students in PTA-run schools benefit from the social capital generated by their parents. But society as a whole does not. According to our definition, there is social capital at the level of each group but not at the aggregate level. This contradiction serves to remind us that it is perilous to define a social process as necessarily having beneficial effects.

Free riding

It is also possible that social capital generates beneficial externalities but yields no (or few) individual returns for the holders of social capital. A case in point is when the external effects of social capital are fully captured by outsiders – i.e. individuals or

---

A group of traders who manages to gain the trust of both producers and consumers can then capture the silk trade.

groups who are outside the social networks or do not share the norms and values of the group – who do not incur the cost of generating the externality.

To see this, consider N groups of fishermen tapping the same fishing ground.[14] Without collective action, there is over-fishing. Suppose that fishing groups with better social capital enforce self-restraint – either through shared norms or through relational contracting – while others do not. Gains from self-restraint are shared among all fishermen, irrespective of whether they have social capital or not. Social capital increases aggregate social welfare but fishermen with less social capital have higher profit because they free ride: they benefit from the self-restraint of others without having to incur any cost. Regressing fish catch on social capital would result in a zero or negative coefficient on social capital even though it has a positive social return.

The externality can also be pecuniary. Keeping the fishing example, a similar result obtains if the fishing groups do not share a common fishing ground but sell their fish on the same market: social capital makes collusion to restrict supply possible since all fishermen benefit from higher fish prices.[15] To ascertain the effect of social capital, one needs to compare fishing groups who do not compete with each other by either accessing the same fishing ground or by selling fish on the same market.

What these examples demonstrate is that, in the presence of fallacy of composition or free riding, individual returns from social capital are poor indicators of aggregate returns. If social capital enables certain individuals or groups to capture rents at the expense of others (e.g., jobs in a non-clearing labor market, entry at Harvard when the entry criterion is excessive), individual returns to social capital exceed social returns, and social capital generates unequal outcomes. In contrast, if social capital generates positive externalities not fully appropriated by owners of social capital, individual returns underestimate social returns.

IV.ii. Model specification

---

[14] This example is inspired by the work of Platteau and Seki (2002) on Japanese fishermen.

[15] An example of this situation is OPEC: not all oil producing countries are member, but they all benefit from higher prices even though only members of the cartel restrict their production.

Exchangeability

As we have noted, social capital studies have been applied to a remarkably large number of units of observation, ranging from individual farmers to countries. One natural question is whether these studies in fact use comparable observations. At an abstract level, comparability of observations is a requirement for virtually all causal studies. We raise the question in the context of social capital studies for several reasons.

First, social capital studies, particularly those that employ aggregate data, often use relatively crude sets of control variables. As a result, the residuals in the sample will contain forms of heterogeneity that call into question the placement of the observations in a common regression.

Second, social capital studies often fail to account for the reasons why different agents come to have different levels of social capital. As Durlauf (2002c) states

> ...statistical analyses of social capital typically compare outcomes for individuals or aggregates who have social capital versus those who do not. These studies, in turn, typically do not incorporate a separate theory of the determinants of social capital formation, although they do often employ instrumental variables to account for the endogeneity of social capital. However, without a theory as to why one observes differences in social capital formation, one cannot have much confidence that unobserved heterogeneity is absent in the samples under study. (pg. 464)

Notice that this argument is more general than simply arguing that social capital is an endogenous variable. Since the groups in which individuals are organized often are endogenous, there will be various forms of sample selection that need to be accounted for in empirical work.

To see that these are more than abstract concerns, consider the regressions employed in Helliwell and Putnam (2000) to show the effects of social capital on economic growth. These authors regress regional output growth in Italy against initial output and measures of civic community, institutional performance, and citizen satisfaction. They find that these three measures explain persistent differences in regional growth rates and conclude that this supports social capital explanations of

economic performance. Among the many questionable assumptions that underlie such a conclusion is the assumption that the regression they employ is using comparable objects as observations. In other words, the analysis assumes that each observation is generated by a common growth process. What must be assumed about the growth process in different regions when one includes Northern and Southern Italian regions in a regression? One answer to this question is that one must assume that given the variables included in the regression, the errors for the observations of different regions cannot be distinguished, at least from the perspective of their distributions. Put differently, one must assume that the regression is such that there is no reason to expect that the error from a particular region has a nonzero expected value, for example. But how can a regression of this crudity make such a breathtaking claim? The historical and social science literatures give any number of reasons why this assumption is false in contexts such as Italian regimes. But if the assumption is false then one cannot defend the interpretation provided by Helliwell and Putnam (2000) for their regression results.

Brock and Durlauf (2001b) argue that a way to formalize the notion of comparability is via the mathematical concept of exchangeability. We introduce this formalism as it provides a way of providing a link between the ways one thinks about data as a social scientist and the sorts of statistical assumptions that underlie regression exercises.

Suppose that for each of I observations, one has associated information F_i. This information may include factors that are quantifiable, such as the savings rate of a country, as well as factors that are not necessarily quantifiable, such as knowledge of a country's culture. Suppose that some outcome ω_i is generated by the linear model

$$\omega_i = \gamma Z_i + \eta_i \tag{1}$$

where Z_i represents that part of F_i that is controlled for in the regression. Typically, models such as (1) are interpreted as meaning that, except for differences in the value of Z_i, ω_i may be thought of as draws from a common distribution, which in turn means that the η_i's are drawn from a common distribution. Notice, however, that this notion of

being drawn from a common distribution should be determined relative to the complete information set available for each observation, i.e. F_i. Hence, interpretation of (1) presupposes that having controlled for the various Z_i's, one has no information that allows one to distinguish the residuals. Formally, the errors η_i are F_i -conditionally exchangeable, which means that

$$\mu\left(\eta_1 = a_1,\ldots,\eta_K = a_K \left| F_1 \ldots F_I \right.\right) = \mu\left(\eta_{\rho(1)} = a_1,\ldots,\eta_{\rho(K)} = a_K \left| F_1 \ldots F_I \right.\right) \qquad (2)$$

where $\rho(\cdot)$ is an operator that permutes the K indices.

Exchangeability is a useful formalization because it creates a benchmark for the assessment of empirical studies. In fact, many of the standard problems that arise in regression analysis amount to exchangeability violations. For example, when a regressor is omitted from a regression, this will mean that the errors in (1) are no longer exchangeable as the distribution of a given error will depend on the distribution of the included and omitted variables. Similarly, if there is parameter heterogeneity between observations, this will imply that the distribution of a given error depends on which country it is associated with. To take a third example, self-selection can induce exchangeability violations as the errors associated with one observation may be differentiated from other differences in the implications of self-selection for the conditional expectations of the residuals. To be clear, as Brock and Durlauf (2001b) observe, exchangeability is not necessary for causally interpreting regressions. For example, heteroskedasticity in errors is an exchangeability violation, but is compatible with a structural regression interpretation. What we argue here is that good empirical practice requires that one assess whether conditional exchangeability of errors holds for the regression under study. To be more precise, we believe that a good empirical practice is to ask, for a given regression specification whether, given the information a researcher possesses about the individual observations, the researcher can justify the assumption of (2) and if not, determine whether the regression retains the interpretation the researcher wishes to place upon it.

Instrumental variables

As observed above, in many contexts social capital is endogenous social capital. The problem of endogeneity is obvious in many contexts; when one talks about membership in organizations, one must account for the fact that membership is a choice variable. In other cases, the endogeneity problem is more subtle. Measures of trust are often used to characterize social capital. Since trust presumably is related to trustworthiness in actual behavior, such measures will exhibit endogeneity problems as well.

Many researchers have recognized that social capital is endogenous and so have employed instrumental variables to allow for consistent estimation of parameters. Leaving aside issues of self-selection that are not often not appropriately addressed by instrumental variables approaches, the use of instrumental variables in social capital studies can be subjected to criticism. Specifically, in many social capital studies the choice of instrumental variables often appears to rely on ad hoc and untenable exogeneity assumptions.

For example, Narayan and Pritchett (1999), using village level data, argue that measures of village level trust can instrument for measures of group memberships. In their analysis social capital effects are argued to occur when one individual's "associational life" affects others in his village; measures of associational life include factors such as the number of group memberships. Since associational life may be a consumption good and thereby an increasing function of individual income, Narayan and Pritchett argue that it must be instrumented if one wants to identify how social capital causally affects income. Yet, there is little reason that such a variable is a valid instrument. As pointed out above, if trust is related to trustworthiness, as presumably is the case, then there is no reason why trustworthy behavior is any different than membership in an organization in terms of whether it is a choice variable. And without a theory of what determines trustworthy behavior, there is little hope of identifying credible instrumental variables for it in these types of regressions.

The choice of instrumental variables is often one of the most difficult problems in empirical work. In social capital contexts, the absence of explicit modeling of the

process by which groups are formed and social capital created means that an empirical researcher is forced to rely on intuition and guesswork. While this does not condemn all studies using instrumental variables, we do believe that inadequate attention has been paid to justifying instrumental variables in social capital contexts.

Group effects versus social capital effects

A final specification issue in social capital studies concerns the question of distinguishing between social capital and other group effects. There is no shortage of reasons why group memberships influence individuals. For example, in recent models of income inequality, primary emphasis has been given to peer group effects and role model effects as influencing educational outcomes for youths. This creates a relationship between the outcomes for a given youth and the outcomes of others in his community of residence.[16] In many modern growth models, a key assumption is the presence of various types of increasing returns to scale that are produced by externalities. These types of models often take the form of positing that the productivity of a given actor depends on the human and physical capital stocks of others. From the perspective of statistical modeling, the description of individual behavior will require the incorporation of various group-level variables.

From the perspective of empirical work, the problem is simple. If one claims that a social capital effect is present for some behavior on the basis of the statistical significance of a group-level variable, this claim will not be credible unless one is able to argue that the group-level variable is capturing social capital versus some alternative group-level effect. This problem is particularly serious when social capital is endogenous, since aggregate levels of social capital are then determined by other group-level variables, which, in absence of strong prior information, presumably include whatever aggregate variables have been omitted from a regression explaining outcomes.

[16]See Durlauf (2001,2002a) for discussion of a range of possible group-level influences on individual behavior.

IV.iii. Identification

The question of social capital and other group effects leads to the question of identification. In this section, we assume that the model under study is correctly specified and evaluate what model parameters can be recovered from observational data. This work is developed in Durlauf (2002c), a paper which builds on early work by Manski (1993) and later work by Brock and Durlauf (2001a,c) on identifying group effects in data. Our basic framework treats the level of social capital in a community as an endogenous variable that represents the aggregation of individual-specific social capital levels (for example, investments in individual-specific social capital as in Glaeser, Laibson, and Sacerdote (2002)). As such, the determination of how social capital effects individuals is an example of the "reflection problem" that Manski's seminal (1993) paper characterizes; identification problems arise when one needs to distinguish the effects of the choices of others versus the characteristics of others on an individual. Identification questions when social capital is exogenous are discussed separately.

IV.iii.a. Individual-level Data

We first consider the case where one wishes to understand the effect of social capital on some individual outcome ω_i. For individual-level data, linear versions of social capital models can be expressed as follows. Suppose that each agent i is a member of some group $g(i)$. Each individual chooses an outcome variable ω_i that is linearly dependent on some control variables. Assume these variables are of four types: an r-dimension vector of variables that are measured at the individual level, X_i; an s-dimension vector of variables (often called contextual effects) that are measured at the group level and are predetermined at the time that choices are made, $Y_{g(i)}$; an individual's expectation of the average choice of others, $\mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right)$ (called an endogenous effect, cf. Manski (1993)), where this expectation is made conditional on some information set $F_{g(i)}$; and expected social capital in the community, $\mathrm{E}\left(SC_{g(i)} \middle| F_{g(i)}\right)$. The assumption that

individual behavior depends on expected rather than actual social capital does not result in any loss of generality. Similarly, our assumption that agents react to the expected behaviors and social capital levels in their group rather than the expected levels among group members other than themselves has no bearing on the analysis, cf. Brock and Durlauf (2001a,c).

We assume that the X_i and $Y_{g(i)}$ vectors are components of the information sets from which expectations are formed; these expectations are further assumed to be rational, so we work with mathematical expectations rather than subjective beliefs. The behavioral outcome is described by

$$\omega_i = k + cX_i + dY_{g(i)} + J_1 \mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right) + J_2 \mathrm{E}\left(SC_{g(i)} \middle| F_{g(i)}\right) + \varepsilon_i \tag{3}$$

In order to close the model, it is necessary to specify how group level social capital is determined. We assume that group level social capital is the average of individual social capital levels, SC_i. These levels are determined by an individual-level behavioral equation that is analogous to (3):

$$SC_i = \bar{k} + \bar{c}X_i + \bar{d}Y_{g(i)} + \bar{J}_1 \mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right) + \bar{J}_2 \mathrm{E}\left(SC_{g(i)} \middle| F_{g(i)}\right) + \eta_i \tag{4}$$

The identification problem amounts to asking whether the parameters in (3) are uniquely determined by the reduced form equations that describe ω_i and SC_i. In order to solve for these reduced form equations, one first applies an expectations operator to both sides of (3) and (4). For the outcome equation,

$$\mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right) = k + cX_{g(i)} + dY_{g(i)} + J_1 \mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right) + J_2 \mathrm{E}\left(SC_{g(i)} \middle| F_{g(i)}\right)$$

or

$$\mathrm{E}\left(\omega_{g(i)}\middle|F_{g(i)}\right)=\frac{k+cX_{g(i)}+dY_{g(i)}+J_2\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)}{1-J_1} \tag{5}$$

and for the social capital equation

$$\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)=\bar{k}+\bar{c}X_{g(i)}+\bar{d}Y_{g(i)}+\bar{J}_1\mathrm{E}\left(\omega_{g(i)}\middle|F_{g(i)}\right)+\bar{J}_2\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)$$

or

$$\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)=\frac{\bar{k}+\bar{c}X_{g(i)}+\bar{d}Y_{g(i)}+\bar{J}_1\mathrm{E}\left(\omega_{g(i)}\middle|F_{g(i)}\right)}{1-\bar{J}_2} \tag{6}$$

In these expressions, $X_{g(i)}$ is the within-group average of X_i and represents the relevant set of variables that relate individual characteristics of group members to the group-level behaviors. Subsituting out $\mathrm{E}\left(\omega_{g(i)}\middle|F_{g(i)}\right)$ and $\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)$ in (3) and (4) using the expressions in (5) and (6) produces reduced form expressions for ω_i and SC_i. Durlauf (2002c) verifies the following proposition, which describes necessary conditions for identification.

Proposition 1. Identification in linear individual-level models with social capital

Identification of the parameters in eq. (3) requires

i. The dimension of the linear space spanned by elements of $\left(1, X_i, Y_{g(i)}\right)$ is $r+s+1$.

ii. The dimension of the linear space spanned by the elements of $\left(1, X_i, X_{g(i)}, Y_{g(i)}\right)$ is at least $r+s+3$.

What this proposition states is that identification depends critically on the relationship between the vector $X_{g(i)}$ that does not appear in the behavioral equations (3) and (4) and the vectors X_i and $Y_{g(i)}$ that do appear in these equations. Intuitively, the key idea is that identification of equation (3) fails if $\mathrm{E}\left(\omega_{g(i)}\middle|F_{g(i)}\right)$ and $\mathrm{E}\left(SC_{g(i)}\middle|F_{g(i)}\right)$ are linearly dependent on the other terms in the regression, i.e. $\left(1, X_i, Y_{g(i)}\right)$. Each of these variables is a linear function of $Y_{g(i)}$ and $X_{g(i)}$. So, if $X_{g(i)}$ is linearly independent of these other regressors, identification may hold.

What does this theorem require in terms of empirical implementation? A key requirement is that there are at least two X_i variables whose within-group averages are not elements of $Y_{g(i)}$. The existence of such variables will of course depend on context. For example, one can imagine situations in which an individual's age affects his behavior, but not the average age of others in his group. The need for such prior information illustrates how field work and qualitative studies can augment formal statistical analyses.

IV.iii.b. Aggregate data

A number of social capital studies employ data that are aggregated. Typically, these studies explore the average behavior of groupings which define the social environment for the individuals that comprise them. From the perspective of estimation, one can think of such models as taking within group averages of (3) and (4), so that

$$\omega_g = k + dY_g + J_1\mathrm{E}\left(\omega_g\middle|F_g\right) + J_2\mathrm{E}\left(SC_g\middle|F_g\right) + \varepsilon_g \tag{7}$$

and

$$SC_g = \overline{k} + \overline{d}Y_g + \overline{J}_1\mathrm{E}\left(\omega_g\middle|F_g\right) + \overline{J}_2\mathrm{E}\left(SC_g\middle|F_g\right) + \eta_g \tag{8}$$

where ω_g and SC_g are group level averages.

Necessary conditions for identification in this case are also developed in Durlauf (2002c). To characterize these conditions, let $H_{\omega,g}$ and $H_{SC,g}$ denote the linear spaces spanned by those regressors Y_g with nonzero coefficients in equations (7) and (8) respectively. Let $H^c_{SC,g}$ denote that part of $H_{SC,g}$ that is orthogonal to $H_{\omega,g}$ (i.e. the linear space formed by the orthogonal complements of any basis of $H_{SC,g}$ after being projected on $H_{\omega,g}$). These spaces are used in the following proposition on identification.

Proposition 2. Identification of social capital effects with aggregate data

i. Identification of the parameters in eq. (7) requires that the dimension of the linear space $H^c_{SC,g}$ is at least 2.

ii. If J_1 is known to equal 0, then identification of the parameters of eq. (7) requires that the dimension of the linear space $H^c_{SC,g}$ is at least 1.

Relative to the identification condition for the individual level model, there are some important differences. Specifically, in the aggregate case, one no longer has access to instrumental variables based on the averaging of individual-level variables. In order to achieve identification, it is necessary to have prior knowledge of aggregate variables that affect social capital but do not affect the aggregate outcome under study. Intuitively, in the aggregate data case, one is in essence working with a standard simultaneous equations system, so cross-equation exclusion restrictions must be employed to achieve identification.

To repeat, the import of these various econometrics issues depends on the context under study, the data available to a researcher, etc. The issues raised in this section should be regarded as providing benchmarks in the assessment of empirical studies; their salience will depend on the context that is under study.

IV.iii.c. Identification with predetermined social capital

When social capital is predetermined, the relevant individual level equation is now

$$\omega_i = k + cX_i + dY_{g(i)} + J_1 \mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right) + J_2 SC_{g(i)} + \varepsilon_i \tag{9}$$

which means that social capital enters the equation in a symmetric way to the contextual effects $Y_{g(i)}$. Identification for models of this type has been initially studied in Manski (1993) and subsequently by Brock and Durlauf (2001a,b); an identification problem still exists because of the potential multicollinearity of $\mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right)$ with the other control variables in (9). Durlauf (2002c) provides the following necessary conditions for identification.

Proposition 3. Identification of individual level behavioral equation with exogenous social capital

Identification of the parameters in eq. (9) requires

i. The dimension of the linear space spanned by elements of $\left(1, X_i, Y_{g(i)}, SC_{g(i)}\right)$ is $r+s+2$.

ii. The dimension of the linear space spanned by the elements of $\left(1, X_i, X_{g(i)}, Y_{g(i)}, SC_{g(i)}\right)$ is at least $r+s+3$.

However, unlike the endogenous social capital case, it may be possible to identify whether the role of social capital is nonzero even if (9) is not identified. Following an argument of Manski (1993), observe that the reduced form for (9) is

$$\omega_i = \frac{k}{1-J_1} + cX_i + \frac{J_1 c}{1-J_1} X_{g(i)} + \frac{d}{1-J_1} Y_{g(i)} + \frac{J_2}{1-J_1} SC_{g(i)} + \varepsilon_i \qquad (10)$$

Identification of the compound parameter $\frac{J_2}{1-J_1}$ is sufficient for determining whether there is some social capital effect. Identification of this parameter requires that the social capital variable is not linearly dependent on the other variables in (10); formally (Durlauf (2002c)) verifies

Proposition 4. Identification of a social capital effect when social capital is exogenous

If the dimension of $\left(1, X_i, X_{g(i)}, Y_{g(i)}, SC_{g(i)}\right)$ exceeds $\left(1, X_i, X_{g(i)}, Y_{g(i)}\right)$ then the presence of a social capital effect may be identified from (10).

Proposition 4 may be readily extended to the case of aggregate data; if aggregate social capital is exogenous then it is simply nothing more than an additional regressor in an aggregate outcome regression. On the other hand, if one is working with aggregate data and social capital is exogenous, then it is impossible to identify any of the model parameters. The reason is simple: there are no longer any instrumental variables available from the social capital equation to instrument $\mathrm{E}\left(\omega_{g(i)} \middle| F_{g(i)}\right)$, so no analog to Proposition 3 exists.

IV.iv. Additional issues

A number of difficulties beyond identification plague empirical work on social capital. As we have emphasized in Section II, reliance on interpersonal relationships and networks can often be seen as a symptom that formal institutions do not work well.[17] To

[17] This does not imply that networks would never be observed in well developed markets. Through interpersonal relationships, economic agents may form coalitions to subvert the market equilibrium to their advantage. Think of cartels, for instance. Clubs and networks can similarly be used to bias market outcomes, e.g., to ban non-whites or women from

illustrate how this might impact statistical analysis, suppose we have data on labor markets in different countries and we seek to estimate whether the density of social networks raises the average quality of the match between workers and employers. Suppose for the sake of argument that we have a convincing measure for the average quality of the match. Regressing this measure against the density of social networks is likely to yield incorrect results if the researcher does not control for differences in formal institutions across the countries.

For instance, employment offices may play an active match-making role in some countries. Failing to control for employment offices would underestimate the effect of social capital. In fact, if employment offices channel information more efficiently than interpersonal networks and if these networks arise in response to the absence of employment offices, countries with more networks will have less efficient labor markets.

Studies of the effects of social capital on the delivery of public goods suffer from other problems as well. Earlier in this section we have argued that social capital is difficult to disentangle from other group effects. One such group effect likely to influence empirical work is the role of leadership. Community leaders often play a crucial role in fostering the creation of social capital – e.g., membership drive – that they can harness for a particular goal. Observing a relationship between social capital and the presence of a public good may be due to the presence of a third, unobserved factor: leadership. The distinction between the two effects is important for policy because good community leaders are rare and leadership is much harder to replicate than groups.

V. Empirical studies of the effects of social capital

Following the econometric discussion, the literature on the effects of social capital may be divided into two types: individual and aggregate studies.

V.i. Individual-level studies

---

certain jobs. Political clientelism is another example (Bayart (1989)). In all these cases, social capital actually reduces aggregate welfare.

Individual-level studies of social capital may be divided into studies that focus on developing societies and studies that focus on OECD societies. This division reflects more than data sets. Studies of social capital in developing societies are associated with somewhat different questions than their OECD (primarily United States-based) counterparts. This division reflects differences in underlying concerns. Development scholars are interested in social capital as a mechanism to ameliorate society-wide problems whereas interest in advanced societies tends to derive from concerns about the persistence of social exclusion and poverty in affluent societies.

A typical social capital study in this literature posits an individual outcome of the form

$$\omega_i = \gamma X_i + \pi Y_{g(i)} + JSC_{g(i)} + \varepsilon_i \tag{11}$$

where, following previous notation, X_i denotes a set of individual controls, $Y_{g(i)}$ denotes a set of group controls and $SC_{g(i)}$ denotes social capital. As such, eq. (11) corresponds to the case of exogenous social capital discussed in Section III. Evidence for the relevance of social capital is equated with the statistical significance of the coefficient *J*. In the various tables we have constructed to summarize various empirical papers, we report dependent variables and social capital measures, as well as findings based on the statistical significance standard.

Social capital and development

Links between social capital and development have been examined in a range of contexts. One reason for this is that the failure of many developing economies to achieve sustained growth has led social scientists to look for previously unexplored factors in the development process. Table 1 lists a number of studies of social capital in developing societies.

As the table indicates, a range of alternative outcomes have been studied. Similarly, a range of social capital measures have been employed. While these studies are quite disparate, there are some commonalities. First, these development studies typically focus on measures describing the social networks in which individuals participate. Fafchamps and Lund (2003), Fafchamps and Minten (2001,2002), Grootaert (2000), Isham (2002) and Narayan and Pritchett (1999) all give primary focus to the role of memberships in various organization and trading networks as determinants of economic outcomes. The quite different social capital measures used by Lee and Brinton (1996) and Palloni *et al* (2001) reflect the different outcomes they are measuring (immigration and placement in elite firms.) Further, the studies in Table 1 give primary focus to participation in organizations that can provide economic benefits in terms of information sharing and the production of collective goods. In this sense, these studies focus on economic benefits to organizations as opposed to more tangible psychological and social benefits.

From the perspective of the discussion of identification in Section III, several questions arise. First, how does one differentiate social capital effects from the presence of other group effects such as information spillovers, or the presence of common factors such as legal or political institutions? In the papers discussed here, relatively little attention has been paid to this question. Notice that the failure to consider this issue is not necessarily a damning criticism, in the sense that one may have reasons to rule out such effects in advance. However, these studies also typically fail to make good arguments that alternative social determinants of outcomes can be ignored. This strikes us as a more serious indictment in that social capital variables can easily proxy for such factors. Put differently, we have argued that social capital represents a new explanation of individual and aggregate outcomes primarily to the extent that it embodies certain types of informal norms. The empirical literature typically does not contrast this view with alternative perspectives on social interactions.

In our judgment, the more successful studies of social capital and development are those that have focused on specific phenomena that have been placed under the social capital rubric. Unsurprisingly, Fafchamps and Minten (2002) is in our view a good example of this approach. As indicated in the paper's title, the focus of the analysis is

less on social capital per se than on the role of social networks in affecting trader profitability. This paper focuses on agricultural traders in Madagascar. These traders are intermediaries between farmers and various markets in the country. Because the goods they sell (staples such as rice, potatoes, and beans) are well defined (the basic goods are homogeneous and are distinguishable by observable features such as whether they have been milled or converted to flour, etc.), it is relatively easy to measure the value added associated with a trader's activity. Fafchamps and Minten (2002) find that measures of the size of an individual trader's business network are positively associated with value added and total sales. The paper argues that a relationship between networks and these economic outcomes may be understood in the context of models of imperfect information and monitoring, which provides a clear theoretical motivation for the empirical framework as well as a plausible theoretical interpretation for the various findings.

Finally, it should be noted that while the different studies in Table 1 consistently support a role for social capital in facilitating various economic outcomes, two of the studies, Krishna (2001) and Varughese and Ostrom (2001), argue that there are important subtleties in this relationship that need to be accounted for. Krishna (2001) finds that for villages in Rajastan India, the relationship between conventional social capital measures and outcomes such as common land development and poverty reduction is sensitive to a notion of effective governance Krishna calls "capable agency." By capable agency, Krishna refers to factors such as strong leadership in organizations, frequent interactions between villagers and clients, etc. His argument is that the density of organizations, a variable often used to measure social capital, will be associated with socially better outcomes only when capable agency is present. Varughese and Ostrom (2001) find, based on a study of groups of forest users in Nepal, that levels of collective action are not well predicted by measures of ethnic, caste, and religious homogeneity within these groups. These sorts of variables are often used to proxy for social capital. Varughese and Ostrom (2001) conclude that institutional design, how decisions are made, etc, can overcome barriers to cooperation that are induced by heterogeneity. Taken together, these studies illustrate that successful group activities depend on more than the presence of social ties per se.

Social capital in OECD societies

Just as social capital has been used to explain a range of outcomes in developing economies, so it has been used to explain a range of US phenomena. Table 2 reports a number of such studies.

In comparing Tables 1 and 2, a number of differences may be identified. First, social capital studies for affluent societies are far more heterogeneous than those which we report for developing economies. One finds studies of social capital for the United States that explore outcomes ranging from mental health (Furstenburg and Hughes (1995)) to dropping out of high school (Teachman, Paasch, and Carver (1997)) to criminal activity (Hagan and McCarthy (1995)). We do not believe this reflects differences in our choices of what studies to report. Rather, interest in social capital in advanced societies has been motivated by different phenomena than in the case of developing economies. In particular, the focus on social capital appears to be motivated by a desire to understand how some individuals avoid self-harming behaviors of various types.

Second, social capital studies for affluent societies focus on somewhat different variables to proxy for social capital than their development counterparts. This may be seen in the frequent examination of parental influences in Table 2. A common assumption in studies for the US is that the parent, child, neighborhood and school relationships are a primary form of social capital. McNeal (1999), for example, explicitly argues that parent/child interactions closely correspond to what Coleman originally meant by social capital.

Another feature that distinguishes the literature on OECD societies is its focus on traditionally sociological concepts in construing social capital. One important notion is intergenerational closure, which holds when parents of a given child know both his friends as well as his friends' parents; both Morgan and Sorenson (1999a) and Sandefur, Meier, and Hernandez (1999) treat closure as an important aspect of social capital. This variable arises because, as argued originally in Coleman (1988), control and monitoring of children is sensitive to the ways that a family is embedded in a community.

While OECD social capital studies typically are based on richer data sets than those available for developing countries, these studies often suffer from serious flaws. One problem is that little discipline has been imposed on the empirical proxies used for social capital, which makes many of the empirical claims in this literature incredible. For example, authors such as Furstenburg and Hughes (1995), McNeal (1999) and Sandefur, Meier, and Hernandez (1999) treat the number of family moves as a measure of social capital for youths. The idea is that the more a family moves, the weaker the social ties between the youth and his community. This is certainly a plausible claim. However, it does not suffice to make family moves a valid social capital measure. Since moves are endogenous, the variable in essence provides an indictor for those characteristics that determine the moves. Such characteristics can be associated with different youth outcomes for reasons that have nothing to do with social capital. For example, families who make more moves plausibly contain parents who are less interested in their children than those who make fewer, since such parents may be putting less weight on the costs to children of changing neighborhoods. Parents with less interest in their children (which can be formalized by using Loury's (1981) model of intergenerational mobility and allowing for heterogeneity in the rates at which parents discount offspring utility) will presumably invest less in their children, altering their outcomes in ways similar to the purported effects of lower social capital. Our point is not that one explanation or the other is correct, but rather that neither is identified from the data. Put differently, there are good reasons to believe that there are systematic differences in the unexplained components of individual behavior that render standard estimation methods inconsistent; specifically, families asserted to posses high levels of social capital, from the perspective of the estimated model, may be expected to be associated with higher levels of parental interest in children, which means the residuals in the associated regressions no longer have conditional expectations of 0. As such, this discussion is an illustration of an exchangeability violation of the type discussed in Section III; Furstenberg and Hughes (1995) are especially susceptible to this criticism due to the lack of attention to control variables.

Similarly, little attention is typically given to the identification problem of distinguishing social capital from endogenous or other group effects. This failure derives

from the flexibility of the social capital definitions that are employed. Is a psychological propensity to behave similarly to one's peers a form of social capital? The answer to this question is unclear from the literature, since such a propensity could easily count as a type of social norm.

While none of the studies in Table 2 can be said to fully address these general statistical questions, some of the studies are nevertheless clearly valuable contributions. One paper we would identify is Morgan and Sorenson (1999a). This paper is noteworthy for its careful attention to different causal mechanisms by which social capital may matter and by the care with which empirical proxies are constructed. We would also note that the paper focuses on a very specific issue, namely why Catholic schools appear to outperform their public counterparts, where there are good prior reasons to believe social factors matter.[18] Palloni *et al* (2001) is in many ways a very different study, yet is also very admirable. This analysis focuses on a very simple notion of social capital, in studying the effect on an individual's migration decision of prior migration by a sibling. What commends this study is the immense care taken to deal with questions of unobserved heterogeneity and common factors between siblings unrelated to social capital.

Before leaving this section, we draw attention to Costa and Kahn (2003b), which provides an historical perspective on social capital. In this paper, the behavior of union soldiers in the Civil War is examined, with particular attention to rates of promotion and desertion across different companies of soldiers. Costa and Kahn find that ethnic and occupational homogeneity of companies was conducive to braver conduct by soldiers. While far removed from the types of behaviors that are usually studied using social capital, the behavior of soldiers is in fact an excellent phenomenon to examine, given the

[18] Morgan and Sorenson (1999a) has in fact engendered some controversy, see Carbonaro (1999) and Hallinan and Kubitschek (1999). The main thrust of these criticisms concerns the extent to which the social closure measures used by Morgan and Sorenson fully capture the relevant social dynamics. We believe that the rejoinder Morgan and Sorenson (1999b) effectively answers these objections; equally important, these objections do not mitigate the reasons we admire the study. The level at which debate on this paper occurred is far deeper than the great majority of efforts to link social capital concepts to data.

well documented role of social factors in battlefield conduct.[19] We believe creative exploration of data sets like this can add a great deal to the understanding of social capital.

V.ii. Aggregate studies

At the beginning of Section III, we outlined the difficulty of estimating the beneficial effects of social capital from individual data. We now turn to empirical studies that rely on aggregate data and examine whether they provide more convincing evidence of social capital. Table 3 reports a number of social capital studies that employ such data. As the Table indicates, a large number of aggregate level social capital studies have focused on the relationship between social capital and per capita output growth at a high level of aggregation, such as a country or region. As such, most of the studies of this type are variants on empirical growth regressions that have become a workhorse of modern growth economics.[20] An assessment of the aggregate studies using social capital is therefore essentially equivalent to an assessment of a set of growth regressions designed to establish that a particular variable is causally related to growth.

Growth regressions of the type found in the studies of Table 3 have been subjected to very serious methodological criticisms; examples include Brock and Durlauf (2001b), Durlauf (2000), Durlauf and Quah (1999), and Temple (2000). As argued in these papers, growth regressions suffer from several fundamental problems that make implausible the types of causal inferences one typically finds in the empirical literature. First, there is the problem of the choice of control variables. Growth theories are open-ended, which means that one growth theory does not have any logical implications for the truth or falsity of another. Hence, there is no natural way, when one wishes to test the importance of a given theory, to identify the appropriate set of theories to incorporate in a correctly specified structural growth model. As Durlauf and Quah (1999) indicate, there

[19]To be clear, social factors can play a negative role in military behavior, such as in violence against civilians. See Aaronson (1999) for discussion of the social dynamics that occurred among US soldiers during the My Lai massacre of Vietnamese civilians.

[20]See Durlauf and Quah (1999) and Temple (1999) for surveys of the methods and findings of the empirical growth literature.

are in fact more extant growth theories than there are countries to which they are supposed to apply. As a result, any given growth regression may be subjected to the criticism that relevant control variables have been omitted. While there are some possible ways to deal with this problem, see Fernandez, Ley, and Steel (2001), this problem has not been addressed in any social capital and growth studies, as far as we know.

Second, growth regressions typically fail to account properly for parameter heterogeneity across countries. Evidence of such heterogeneity may be found in Desdoigts (1999), Durlauf and Johnson (1995), and Durlauf, Kourtellos, and Minkin (2001); theoretical models that imply heterogeneous growth processes for different groups of countries include Azariadis and Drazen (1990) and Howitt and Mayer-Foulkes (2002). Failure to account for parameter heterogeneity calls into question the structural interpretation of a social capital variable as it may be proxying for this form of heterogeneity. One example that is suggestive of this possibility concerns the role of ethnic heterogeneity in growth, a question studied by Easterly and Levine (1997).[21] In this paper, the authors argue that ethnic conflict inhibits public good creation and so acts as an impediment to growth. Ethnic conflict is instrumented with a measure of ethnolinguistic diversity which proves to be strongly negatively associated with growth. Since sub-Saharan Africa has exceptionally high levels of ethnolinguistic diversity, the authors conclude that this is an important mechanism in understanding Africa's growth problems. Brock and Durlauf (2001a) reexamine this study, allowing for various types of exchangeability violations due to parameter heterogeneity, and find that the relationship between ethnolinguistic diversity and growth appears only for sub-Saharan Africa; this variable does not help explain growth patterns in the rest of the world. Brock and Durlauf's finding illustrates how growth explanations may well not be constant across countries. And for the African case, it is unclear whether the growth findings are causal or whether ethnolinguistic diversity simply proxies for some other form of "African exceptionalism."

[21]It should be noted that Easterly and Levine (1997) does not explicitly focus on social capital; however, the mechanisms by which ethnic heterogeneity can affect economic performance are in many cases the same as have been proposed in the social capital literature.

Taken as a whole, these arguments imply that the social capital/growth studies do not meet the exchangeability requirements that we discussed in Section III. While this reflects more general failings of the empirical growth literature (Brock and Durlauf (2001b)), it is also the case that growth studies using social capital have been quite insensitive to efforts in the growth literature to address these problems.

Beyond questions concerning the comparability of observations, there are unresolved issues concerning causal interpretation of growth regressions that apply to the social capital case. This is especially important given the endogeneity of aggregate measures of social capital. We are unaware of any social capital study using aggregate data that addresses causality versus correlation for social capital and growth in a persuasive way. While this is a broad brush with which to tar this empirical literature, we believe it is valid. A related problem is that we are unaware of any compelling instrumental variables for social capital in these regressions. This failure is a corollary of the absence of any strong theories of aggregate social capital determination in the social science literature that would allow one to characterize appropriate instruments.

When one turns from national-level growth studies to other aggregate studies, the plausibility of claims concerning social capital becomes stronger in some cases. A recent study by Goldin and Katz (1999) is particularly interesting in its focus on the sources for the rise of high school attendance in Iowa in the early part of the twentieth century. By focusing on characteristics of Iowa counties, they are able to avoid some of the clear problems of exchangeability that plague studies using coarser levels of aggregation. But even here, other problems arise: more important, the data available are quite weak in the sense that the variables which suggest the presence of social capital effects could equally well suggest alternative explanations. The specific variables that seem most suggestive of social capital effects are the percentage of native born citizens and the population of towns; high percentages of native born and low population sizes are each associated with higher high school attendance. Clearly, linking these correlations to a causal role for social capital or other type of social influence is speculative. To be fair, Goldin and Katz

(1999) point out that there may be alternative explanations, such as the smaller towns having fewer opportunities for those without high school educations.[22]

Overall, we conclude that aggregate social capital studies have not been successful in providing compelling empirical evidence on the effects of social capital. These studies require identifying assumptions that are incredible by conventional social science reasoning. We believe that research efforts should be directed towards micro-level studies as the problems with country-wide studies seem too intractable to overcome. Data at lower levels of aggregation, such as county data for a homogeneous place like 1915 Iowa, are likely to be more amenable to persuasive analysis, provided the issues of exchangeability and identification can be addressed adequately.

VI. Empirical studies of the level and determinants of social capital

Interest in the effects of social capital has spawned a related literature of the level of social capital and how this level is determined. Table 4 lists a range of studies that have explored this issue. It is worth noting that while attention has been given to questions of model specification and identification for models in which social capital is a causal determinant of various outcomes, we are unaware of any formal analyses that have been applied to models of social capital formation. Our conjecture is that the arguments applied to models of social capital effects can be extended in a straightforward fashion to models of social capital determinants, but this remains to be done.

One important question in the literature on the formation of social capital has been whether the extremely prominent claims by Putnam (1995,2000) that social capital in the United States has experienced a major decline are correct, and if so, whether this decline can be attributed to those factors he has described, namely, increased watching of television and the passing of the World War II generation. It appears that many of Putnam's claims have not withstood careful scrutiny. Paxton (1999) shows that there is

[22]At the other extreme, the effort by Robison and Siles (1999) to link aspects of state level income distributions to various social capital proxies fails to make any serious effort to ensure exchangeability; in addition the variables used to measure social capital, such as labor force participation, render the claims made about social capital untenable.

little evidence of secular declines of trust or overall associational activity in the United States. Bianchi and Robinson (1997) find little evidence that patterns of television viewing have much relationship to maternal employment status or other family factors often asserted to lead to lower social capital. Costa and Kahn (2003a), using more disaggregated measures of associational activity, find declines in social capital measures that are qualitatively similar to what Putnam has claimed. However, they find rather different explanations. Their analysis concludes that the decline in social capital produced "outside the home" such as volunteering is explained to a large extent by the rise in female labor force participation in the last 4 decades. This study also finds that declines in social capital produced "inside the home" such as frequency of socializing is strongly related to increases in neighborhood heterogeneity. One important implication of this work is that it places claims about a decline in US social capital in a different normative light. If increasing female labor force participation is due to the breakdown of discriminatory barriers against women in labor markets and if increasing neighborhood heterogeneity reflects a breakdown of the levels of social and ethnic segregation in the United States, then perhaps declines in social capital are best thought of as an unfortunate but necessary side effect of a movement towards a more just society and so should not be mourned.

One important aspect of this research is the move towards a causal understanding of the processes by which social capital is formed. One interesting example of such work is Brehm and Rahn (1997) who employ General Social Survey data to study the reciprocal interaction of community involvement and trust in others. Their analysis finds a stronger causal relationship between community participation to trust than the converse. This finding is indicative of the empirical importance of Dasgupta's (2002) argument that social capital should be modeled as a network.

Other studies have focused on identifying predictors of trust. For the US, Alesina and La Ferrara (2002) find that trust in others is negatively associated with community heterogeneity. Rahn and Rudolph (2002) extend work of this type in an analysis of the determinants of trust in local government. This paper finds that political culture and community heterogeneity play an important role in explaining trust. Interestingly, trust does not appear to be influenced by the form of local government as trust levels are not

predicted by whether a community has a mayor or city manager (the latter implying less popular control of local government). These studies are best regarded as reduced form analyses in that issues of causality are not specifically addressed.

An especially important effort to understand the formation of social capital is the Project on Human Development in Chicago Neighborhoods (PHDCN). This is a remarkably detailed data collection project that covers several hundred neighborhoods in Chicago. These data are proving to be very useful in delineating the detailed social structure of neighborhoods. As described in Sampson, Morenoff, and Earls (1999 pg. 639), the available data include responses to questions such as "About how often do you and people in your neighborhood do favors for each other?" and the likelihood that one's neighbors would intervene if one's child were observed skipping school.

Sampson, Morenoff, and Earls (1999) use the PHDCN to study a range of social aspects of neighborhoods. In particular, they distinguish the social capital of a neighborhood as "the resource potential of personal and organizational networks" (pg. 635) from the collective efficacy of a neighborhood, "a task-specific construct that relates to the shared expectations and mutual engagement by adults in the active support and social control of children." (pg. 635). The purpose of this distinction is to differentiate general notions of neighborhood social resources from the use of these resources. By delineating how neighborhood members help one another, for example through monitoring one another's children, Sampson, Morenoff, and Earls (1999) give a rich portrait of how neighborhoods benefit their members, illustrating how help in childrearing or trust among neighbors are important mediating variables in understanding why poor neighborhoods have adverse effects on their members. By uncovering specific mechanisms by which neighborhoods matter, this study moves beyond the common use of social capital variables in which the link between the variable and a behavioral outcome is metaphorical and all too often a black box.

VII. Suggestions for future research

As our discussion suggests, we believe that social capital studies have very often been unpersuasive. We make the following suggestions as to how one can improve this literature.

First, empirical analyses need to step back from grandiose approaches to social capital and focus on the more mundane but potentially far more fruitful task of analyzing specific social components to individual behavior. This does not require abandonment of social capital as a general organizing idea or metaphor, but rather means that evidence in favor of social capital should be derived from specific claims about social influences on individuals.

A useful contrast may be made between the Helliwell and Putnam (2000) paper, the study of regional differences in growth rates in Italy that we have criticized earlier, and a recent study by Glaeser, Laibson, Scheinkman and Soutter (2000) that explores the determinants of trust. Rather than run regressions that make incredible assumptions about the exchangeability of regional growth rates, Glaeser Laibson, Scheinkman and Soutter employ well crafted experiments to see how attitudes and background characteristics influence the choice of strategies in various economic experiments. In the context of these experiments, notions such as trust are quite well defined since it amounts to expectations about the play of other agents in the game. This well defined environment provides much more compelling evidence of how trust influences behavior than can be obtained from ad hoc regressions. The use of experiments to understand social capital is further developed in Carter and Castillo (2003,2004), who consider how variation in roles by players in economic experiments can allow for differentiation between altruism and trust as determinants of behaviors.

The importance of experimental evidence should not be exaggerated. Economic experiments are not a panacea for the limits of inference with observational data. One problem is generalizability; it is far from clear how behavior in economic experiments maps into behavior in the larger economy and society, although Glaeser Laibson, Scheinkman and Soutter make an important advance in this regard by attempting to correlate behavior in experiments with behavior in the "real world" by participants. Further, as discussed by Manski (2002) in an important recent paper, there are identification problems in experiments as it is often difficult to distinguish behavior that

is driven by altruistic preferences from behavior driven by selfish preferences but with expectations of trustworthy behavior by others. Nevertheless, Glaeser Laibson, Scheinkman and Soutter and Carter and Castillo represent a style of research that is an important advance in the social capital literature.

In addition, moving the discussion of social capital away from generalities to specific mechanisms in the way we suggest will allow one to deal with issues of endogeneity and exchangeability more effectively, since it will facilitate more precise and comprehensive modeling of causal mechanisms than one finds in the social capital literature. While the great majority of social capital studies include numerous control variables, the choice of these variables is rarely determined by careful delineation of the determinants of behavior of the agents under study. In addition, there has been little attention to questions of parameter heterogeneity.

A concrete implication of this discussion is that future research on social capital by the World Bank, for example, should be careful about the use of highly aggregated data. It is difficult to make compelling exchangeability arguments for data sets in which the observations are countries or regions. Ad hoc assumptions concerning the legitimacy of instrumental variables have plagued this literature for good reason: theories of social capital formation are underdeveloped so that it is difficult for researchers to sensibly construct aggregate measures of social capital.

Second, we believe that future data collection exercises must explicitly attempt to gather information on group-level influences, rather than on social capital alone. This should include measures of the quality of leadership. At the core of virtually all microeconomic reasoning is the general idea that decisions are purposeful outcomes based on an individual's preferences over outcomes, constraints on what actions are feasible, and beliefs over the consequences of those actions. The new social economics (cf. Durlauf and Young (2001)), is based upon the recognition that these three components to decisions are deeply influenced by social factors. A data collection exercise designed to explain a given set of outcomes should therefore be based on the

development of a typology of what sorts of social factors affect each of the components and the development of plausible empirical analogs to these social factors.[23]

The sorts of detailed data collection we advocate are in fact underway in some cases. In particular, the Project on Human Development in Chicago Neighborhoods and data collection based on the World Bank Social Capital Assessment Tool are exemplary. In each case, the levels of specificity in terms of uncovering how individuals interact in villages, communities and social networks is a great advance over the crude measures often used in social capital studies. The most obvious suggestion in terms of the design of these studies would be the exploration of the extent to which the existing survey questions are adequate in terms of dealing with the specification and identification problems we discuss in Section III. There is no quick answer to this as it would require integrating some theoretical modeling with the survey design. Nevertheless, the payoffs to such an endeavor could be quite high.

How does our admittedly very general advice differ from the way in which data collection on social capital is typically done? We have already discussed one difference, namely, the effectiveness of data collection is augmented when attention is paid to the uses to which the data will be applied. To repeat, the analysis of potential identification problems should inform data collection and not just define limits to which a data set may be used. Another important difference is that this approach avoids privileging social factors that can be construed as "social capital" over others. As we have argued, the failure to consider alternative social explanations to social capital is an important source of skepticism with respect to existing studies. More importantly, there is no *a priori* reason to assume that social capital is a more likely source of important effects than other social factors. Another difference is that our proposed approach, by separating social factors as concepts from empirical measurement, will avoid conflating the two, as often

[23] Sandefur and Laumann (1998) argue in favor of understanding social capital in terms of its benefits, identifying these as provision of information, influence and control in dealing with others, social solidarity between individuals. These types of benefits represent combinations of the preferences, constraints, and beliefs we advocate employing. An advantage of our approach is that our categories represent empirically meaningful differences in the determinants of individual behavior whereas the Sandefur and Laumann categories are necessarily interdependent and do not correspond to any

occurs. Finally, the exercise of modeling individual choice in order to determine what is meant by social factors should provide some guidance as to the appropriate levels at which these factors should be measured. Does an individual's or a society's level of trust matter for individual conduct? The appropriate answer to a question like this should derive from the decision problem at hand. Empirical studies of social capital have largely not addressed this question.

Third, there needs to be greater recognition of the limits to statistical analysis in contexts such as the evaluation of social capital. This is partly a restatement of the first suggestion in that there simply do not exist any available data or methodology that can allow an assessment of the broad claims of the sort one finds in the social capital literature. But beyond this, we believe economists need to be more receptive to the sorts of evidence found in other disciplines beyond the quantitative analyses that are standard in economics. For example, sustained descriptive histories can teach us much about the ways that social structures influence individual conduct even if they are not constructed in the form of claims about *F*-statistics and the like. At the other extreme, there is a wealth of information in the social psychology literature that addresses in precise ways the inchoate ideas about individual behavior that underlie the social capital literature. This suggestion requires greater openmindedness on the part of economists to nonstatistical sources of information. But the payoffs can be high both in terms of substantive understanding as well as in facilitating quantitative analyses. As the discussion of identification argued, social capital effects can only be revealed if one has prior information on what group effects do not directly influence individuals. This is information that nonstatistical studies may be able to provide.[24]

In fact, it is reasonable to argue that some aspects of the question of how social capital has facilitated socioeconomic or political development should be treated in the same spirit as questions such as what led to rise of emergence of democracy in ancient Athens versus a martial culture in ancient Sparta or what were the causes of World War I.

"natural kinds" in terms of either individual activity or collective action, at least as far as we can tell. For example, trust will affect information transmission.

[24] Of course, qualitative studies are not immune to the overinterpretation (due to ignoring identification problems) and overclaiming (due to exaggeration of the import of statistical

These are not meaningless questions; but it is necessary to accept limits as to the quantitative precision with which such questions can be answered and what it means to say the question has been answered. None of this suggests that statistical analysis should play anything other than a primary role in social capital studies; our argument is that the credibility of the social capital literature will be augmented when nonstatistical evidence is better used to motivate assumptions and suggest appropriate ways for formulating hypotheses.

VIII. Conclusions

In this Chapter, we have tried to provide an overview of the state of social capital research by both describing the state of the conceptual, theoretical and econometric literatures on social capital and by surveying a number of empirical studies. Our overall assessment of the social capital research is quite mixed. In terms of conceptual and theoretical studies of social capital, there is a considerable amount of ambiguity and confusion as to what social capital means. One conclusion we draw from our survey is that the most successful theoretical work on social capital is that which, following Dasgupta (2002), models social capital as a form of social network structure and uses the presence of that structure to understand how individual outcomes are affected in equilibrium. From the empirical perspective, the role of networks in facilitating exchange is one of the most compelling empirical findings in the social capital literature (cf. Fafchamps (2004)), so a more narrow focus on this type will likely not diminish the importance of social capital as a concept.

With respect to empirical work in general, social capital research has led to the development of a number of interesting data sets as well as the development of a number of provocative hypotheses, much of the empirical literature is at best suggestive and at worst easy to discount. So while one can point to no end of studies in which a variable that is asserted to proxy for social capital has some effect on individuals or groups, it is

---

findings taken on their own terms) that we have criticized in quantitative studies. See Tarrow (1996) for criticisms along these lines.

usually very difficult to treat the finding as establishing a causal role for social capital. We have highlighted a number of studies that we think are particularly strong, but those studies we find persuasive are relatively exceptional. The defects of the empirical social capital literature are unfortunate, since the work on social capital is an active front in which the "undersocialized conception of man" for which economics has been criticized (Granovetter (1985)) is being addressed.

One recommendation we make in regard to empirical studies is that social capital literature pay far more attention to formal issues of identification, self-selection and unobserved group characteristics. These issues have been extensively studied in the closely related context of social interactions (cf. Brock and Durlauf (2001c)) and many ideas from that literature may be applied to social capital. In addition, we believe that empirical social capital studies must do a much better job of differentiating between social capital effects and alternative types of group effects.

Attempts to provide social richness to economic analysis will only succeed if the theoretical and empirical work that accompanies this effort is subjected to the same rigorous standards that are required of other analyses in economics. In contrast, the extravagant claims so often found in this literature (an outstanding example of which is Putnam (2000) who appears capable of attributing every conceivable societal virtue to social capital)[25] have little prospect of having lasting social science value. Beyond the failure to contribute to the social science enterprise, there is a legitimate concern that studies which make excessive claims and unsupported assertions can discredit social capital as an idea. In conclusion, what the empirical social capital literature ultimately needs is more matter and less art.

---

[25]See Durlauf (2002b) for an extended critique of Putnam (2000) which addresses the problem of overclaiming, faulting Putnam both for not dealing with some of the identification problems we hve described in Section IV as well as for failing to analyze social capital in a fashion conducive to rigorous policy analysis.

TABLE 1: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL IN DEVELOPING COUNTRIES

STUDY	AGENTS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Carter and Maluccio (2003)	Households in KwaZulu-Natal South Africa	Child height for age	Number of associations in community and interaction of family income with community income	Social capital helps ameliorate effects of individual-specific economic shocks
Fafchamps and Minten (2002)	Food traders in Madagascar	Value added and total sales	Number of traders known, number of relatives in agricultural trade, number of potential informal traders	Number of traders known and number of potential informal traders statistically significant.
Grootaert (2000)	Rural households in Indonesia	Per capita household expenditure	Number of memberships in associations, diversity of memberships, number of meetings of associations, index of participation in decisionmaking, measure of cash contribution to associations, measure of time contribution to association, measure of orientation towards community.	Social capital index statistically significant; number of memberships, internal heterogeneity of associations and level of participation in decisionmaking appear most important.

TABLE 1: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL IN DEVELOPING COUNTRIES

STUDY	AGENTS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Isham (2002)	Households in rural Tanzania	Adoption of improved fertilizer	Village level measures of ethnic homogeneity for organizations in which households are members, levels of participation of household in organization decisionmaking, and extent to which leaders of village organization have different livelihoods than village members	Social capital measures are generally statistically significant predictors of adoption, but some regional differences exist
Krishna (2001)	Villages in Rajastan, India	Performance with respect to common land development, poverty reduction, and employment	Survey measures of participation in labor-sharing groups, trust, solidarity, and reciprocity	Efficacy of social capital is related to strength of leaders of associations, patron-client relations, etc.
Krishna and Uphoff (1999)	Villages in Rajastan, India	Collective action to restore degraded or vulnerable common lands	Social capital index based on survey answers to questions on level of collective action in village, village governance, village sense of obligation, etc.	Index is a strong predictor of better development outcomes

TABLE 1: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL IN DEVELOPING COUNTRIES

STUDY	AGENTS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Lee and Brinton (1996)	Graduates of elite colleges in South Korea	Employment opportunities at large firms	Private social capital (family and friendship ties) and institutional social capital (social ties provided by university, eg. introductions to firms)	Institutional rather than private social capital is important in determining employment opportunities
Malucccio, Haddad, and May (2001)	Households in Kwazulu-Natal Province, South Africa	Per capita total expenditure	Index of individual memberships in groups, reflecting number, gender heterogeneity, and performance, based on survey responses. Community social capital levels computed as aggregates of individual indices	Individual and community social capital measures statistically significantly associated with expenditure in 1998 but not 1993
Narayan and Pritchett (1999)	Households in rural Tanzania	Per capita household expenditure	Social capital indices constructed for both households and villages. Indices based on memberships in groups, characteristics of the groups, and household values and attitudes	Village social capital dominates individual social capital
Palloni, Massey, *et al* (2001)	Sibling pairs in Mexico	Migration to the United States	Previous migration of one sibling	Likelihood of migration is increased if a sibling has already migrated

TABLE 1: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL IN DEVELOPING COUNTRIES

STUDY	AGENTS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Pargal, Huq, and Gilligan (1999)	Households in Dhaka, Bangladesh	Establishment of voluntary solid waste management (VWSM) systems for neighborhoods	Indices of trust, reciprocity, and sharing for neighborhoods	Reciprocity index is best predictor of likelihood that a neighborhood has VWSM system
Varughese and Ostrom (2001)	Groups of forest users in Nepal	Level of collective activity, monitoring of forest use, enforcement of harvesting constraints, etc.	Homogeneity within group in wealth, caste, ethnicity	No necessary relationship between homogeneity and level of collective action; institutional design is more important

TABLE 2: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL: OECD COUNTRIES

STUDY	ACTORS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Costa and Kahn (2003b)	Union soldiers in the US Civil War	Performance over course of war in terms of promotions, desertion, etc.	Homogeneity of companies of soldiers with respect to ethnicity, occupation, and age	More homogeneous companies are associated with more promotions and lower rates of desertion
Fernandez, Castilla, and Moore (2000)	Phone center employers	Returns to investments	Use of employees social networks in making new hires	Investment in use of employee referrals is shown to be quite profitable
Frank and Yasumoto (1996)	French financial elite; i.e. prominent individuals associated with financial institutions	Business dealings with one another	Reciprocity, trust. Actors are organized into subgroups based on friendship ties. Trust, equated with absence of hostile business actions, such as a hostile takeover, is expected to be higher between members of common subgroup. Reciprocity, defined as supportive actions such as helping a firm fend off a hostile takeover is expected to be higher between subgroups.	Basic predictions confirmed.

TABLE 2: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL: OECD COUNTRIES

STUDY	ACTORS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Furstenberg and Hughes (1995)	Children of teenage mothers (US)	Graduation from high school, college enrollment, economic status, avoidance of live birth, avoidance of criminal activity, mental health	Within family social capital (presence of father in home, parents' expectations for school performance, etc.), family links to community (religious involvement, help network, neighborhood quality, etc.)	Various outcomes and social capital measures statistically significantly associated, even controlling for some human capital measures
Guiso, Sapienza, and Zingales (2002)	Households in Italy	Financial activities such as use of formal credit, portfolio behavior	Electoral participation and blood donation and province level	Social capital measures for both current location and place of birth predict use of formal credit, and investment in stocks rather than cash. Effects stronger for the poorer and less educated.
Hagan, MacMillan, and Wheaton (1996)	Teenagers in Toronto	Level of educational attainment, occupational status	Parental involvement with children, family moves across neighborhoods	Both types of social capital statistically significant in predicting outcomes
Hagan and McCarthy (1995)	Teenagers (Canada)	Various forms of criminal behavior	Social variables such as criminal mentors and criminal social networks	Social variables predict criminality

TABLE 2: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL: OECD COUNTRIES

STUDY	ACTORS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
McNeal (1999)	Teenagers in US	Academic achievement in science, truancy, staying in school	Parental interactions with child and with school	Favorable social capital effects on child outcomes seem only to apply to white students from middle and upper class backgrounds
Morgan and Sorenson (1999a)	Teenagers in US	Test scores in mathematics	Social closure around school, parental involvement in school, parental knowledge of friends	Social closure is negatively associated with test scores, in contradiction to standard predictions of social capital analyses
Parcel and Menaghan (1993)	Children in US	Index of child behavioral problems	Miscellaneous measures of family structure, parents' working conditions, and parents' personal resources, such as sense of self-estimation	Role of family social capital generally confirmed through statistical significance
Sandefur, Meier, and Hernandez (1999)	Teenagers in US	Intergenerational closure, parent/child interactions, high school graduation, post-secondary enrollment, enrolling in a four-year college	Family structure, number of times child changed schools, Catholic High school attendance	Various social capital measures are associated with outcomes in ways predicted by theory.

TABLE 2: INDIVIDUAL-LEVEL STUDIES OF SOCIAL CAPITAL: OECD COUNTRIES

STUDY	ACTORS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Sun (1999)	Teenagers (US)	Academic performance measured by test scores	Structural measures (number of school changes, family structure) and process variables (parent child interactions, participation in activities, number of parents known),	Various process variables associated with test scores.
Teachman, Paasch, and Carver (1997)	Teenagers (US)	Dropping out of high school	Family social capital (living arrangements with parents, intensity of interactions with parents), community social capital (attendance in Catholic school, number of changes in school, measures of interactions of parents with schools and friends)	Attending a Catholic school and family structure robustly statistically significant across alternative specifications

TABLE 3: AGGREGATE-LEVEL STUDIES OF SOCIAL CAPITAL

STUDY	UNITS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Beugelsdijk and van Schalk (2001)	European Regions	Per capita output growth	Trust, group participation	Group participation helps explain growth, but not trust
Easterly and Levine (1997)	Nations	Per capita output growth	Ethnic heterogeneity measured by ethnolinguistic diversity within a country	Per capita growth negatively associated with ethnolinguistic heterogeneity; important in explaining poor performance of sub-Saharan Africa
Goldin and Katz (1999)	Iowa Counties in 1915	High school attendance	Population size of towns, density of religious organizations, percentage of population that is native born	Small towns led expansion of high school attendance. Positive relationship with other possible social capital variables
Helliwell (1996)	Asian nations	Per capita output growth	Participation in associations, trust	Social capital measures contribute little once other factors such as openness are accounted for

TABLE 3: AGGREGATE-LEVEL STUDIES OF SOCIAL CAPITAL

STUDY	UNITS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Helliwell and Putnam (2000)	Regions in Italy	Per capita output growth	Measure of civic community (index of associations, newspaper readership, and political behavior), institutional performance, citizen satisfaction with government	For the various measures, higher social capital associated with higher growth
Knack and Keefer (1997)	Nations	Per capita output growth	Indices of civic cooperation (measuring questions such as whether it is ever justified to cheat on taxes) and trust (percentage of individuals who say most people can be trusted)	Social capital measures help predict growth
LaPorta *et al* (1997)	Nations	Government efficiency (level of corruption, etc.), participation in politics and associations, social efficiency (infrastructure quality, infant mortality, educational level, etc.)	Trust	Trust generally statistically significant

TABLE 3: AGGREGATE-LEVEL STUDIES OF SOCIAL CAPITAL

STUDY	UNITS	OUTCOMES	SOCIAL CAPITAL MEASURES	FINDINGS
Lochner, Kawachi, Brennan, and Buka (2003)	Chicago neighborhoods	Aggregate and disease-specific mortality rates for neighborhoods and gender and ethnic groups within neighborhoods	Measures of trust, reciprocity, group participation	Social capital measures help to predict white mortality; relationship with mortality of blacks is weaker
Paxton (2002)	Nations	Index of liberal democracy	Number and types of international nongovernment organization in country, trust	Democracy and social capital reciprocally related; number of trade unions, sport associations and religious organizations negatively associated with democracy, number of others positively associated
Robison and Siles (1999)	US states	Means and coefficients of variation for household income	Measures of family structure, educational achievement, crime and labor force participation	Higher social capital proxies generally associated with higher means and lower dispersion in household income
Zak and Knack (2001)	Nations	Per capita output growth	Trust	Trust predicts growth even when factors such as property rights are controlled for.

TABLE 4: STUDIES OF SOCIAL CAPITAL FORMATION AND THE LEVEL OF SOCIAL CAPITAL

STUDY	AGENTS	SOCIAL CAPITAL MEASURES	POTENTIAL DETERMINANTS	FINDINGS
Alesina and La Ferrara (2002)	Adults in US	Trust	Miscellaneous personal and community characteristics	Low social capital measures for individuals are associated with membership in groups that have experienced discrimination (e.g. being African American), lack of economic success, community heterogeneity, experience of personal trauma
Bianchi and Robinson (1997)	Pre-teenagers in California	Time spent on studying and activities other than watching television	Family structure, parental characteristics, mother's labor force status	Study is higher and television watching lower among children of better educated; children of working mothers watch less television than others

TABLE 4: STUDIES OF SOCIAL CAPITAL FORMATION AND THE LEVEL OF SOCIAL CAPITAL

STUDY	AGENTS	SOCIAL CAPITAL MEASURES	POTENTIAL DETERMINANTS	FINDINGS
Brehm and Rahn (1997)	Adults in US	Civic engagement and civic trust	Reciprocal relationship between engagement and trust, confidence in institutions, life satisfaction, ethnicity, socioeconomic status, and many others	Participation strongly affects trust, each positively associated with socioeconomic status, confidence, negatively associated with being black
Charles and Kline (2002)	Adults in US	Carpooling	Ethnicity of neighbors	Ethnic heterogeneity reduces social capital formation for some pairings, notably whites and blacks and whites and Hispanics
Costa and Kahn (2003a)	Adults in US	Volunteering, socializing, non-church memberships,	Gender, community characteristics (race and income heterogeneity)	Declines in social capital produced outside the home such as volunteering are strongly related to higher female labor force participation; declining social capital within home such as frequency of socializing is strongly related to higher community heterogeneity

TABLE 4: STUDIES OF SOCIAL CAPITAL FORMATION AND THE LEVEL OF SOCIAL CAPITAL

STUDY	AGENTS	SOCIAL CAPITAL MEASURES	POTENTIAL DETERMINANTS	FINDINGS
DiPasquale and Glaeser (1999)	Adults in US	Citizenship (voting in local elections, helping solve local problems, knows school head, etc.)	Home ownership	Homeownership helps predict a range of citizenship variables.
Fafchamps (2003)	Traders in Benin, Madagascar, and Malawi	Trust in trading relationships	Ethnicity and religious similarity, gender, network effects	Ethnicity, religion and gender appear to have little effect on trust. Individuals possessing large numbers of business contacts give and receive more trust.
Gugerty and Kremer (2002)	Women's groups and school development projects in western Kenya	For women's groups, group size, attendance, financial status, and level of interactions with other groups and individuals; For schools, participation in school development projects	Funding of groups and funding of school textbooks.	Grants to women's groups appear to have had little effect on the capacities or size of women's groups; grants to governing committees of schools and increases in textbook funding were associated with increased participation of parents in school development; additional effects were found for textbook funding

TABLE 4: STUDIES OF SOCIAL CAPITAL FORMATION AND THE LEVEL OF SOCIAL CAPITAL

STUDY	AGENTS	SOCIAL CAPITAL MEASURES	POTENTIAL DETERMINANTS	FINDINGS
Hofferth, Boisjoly, and Duncan (1999)	Adults in US	Access to time and financial assistance from relatives and friends	Previous provision of time and financial assistance to those same relatives and friends	Time and assistance from friends is predicted by past provision, but not time and assistance by relatives
Miguel, Gertler, and Levine (2001)	Districts in Indonesia	Density of community organizations	Rapid industrialization within district	Industrialization, if anything was associated with rising density of organizations. Districts that neighbored districts experiencing rapid industrialization exhibited some declines, possibly due to out-migration
Oliver (1999)	Adults in US	Local civic participation	Community affluence and associated levels of social needs, competition for resources induced by population heterogeneity	Heterogeneous, middle income cities exhibit higher levels of civic participation than heterogeneous, affluent cities
Paxton (1999)	Adults in US	Trust, participation in various associations	Time	No strong evidence of declines in social capital in the US since the 1970's

TABLE 4: STUDIES OF SOCIAL CAPITAL FORMATION AND THE LEVEL OF SOCIAL CAPITAL

STUDY	AGENTS	SOCIAL CAPITAL MEASURES	POTENTIAL DETERMINANTS	FINDINGS
Rahn and Rudolph (2002)	Adults in US	Trust in local government	Measures of political institutions, political culture, income inequality, ethnic fractionalization, ideological polarization, controls for individual characteristics	Ideological polarization, income inequality, and political culture are more important and political institutions in explaining variation in trust
Sampson, Morenoff, and Earls (1999)	Adults in Chicago	Intergenerational closure, reciprocal social exchange, and shared expectations for informal social control	Miscellaneous neighborhood characteristics	Residential stability and relative affluence predict intergenerational social closure and reciprocal exchange, whereas neighborhood disadvantage predicts low expectations of shared child control

THE EFFECT OF ECONOMIC GROWTH ON SOCIAL STRUCTURES [1]

François Bourguignon
The World Bank

October 23, 2004

[1] Prepared for the Handbook of Economic Growth edited by Philippe Aghion and Steve Durlauf. This paper was finished, with great difficulty, after I joined the World Bank as Chief Economist in the summer 2003. I am grateful to Philippe Aghion for useful comments. I thank for their patient and efficient help Jean-Jacques Dethier and Victoria Levin. Views expressed here are essentially personal and do not engage the World Bank in any manner.

INTRODUCTION

If economic growth actually resembled the 'extended reproduction' coined by Marx and implicit in the steady state regimes of many contemporary growth models, one would not expect growth to have major social consequences. All economic magnitudes, including the standards of living of individuals or social groups, would be kept in the same proportion to each other so that only the scale of the economy would be changing over time.

Of course, economic growth is something more than a mere uniform change of scale of economic magnitudes. For a host of reasons, it is in the very nature of growth to modify economic structures and, because of this, to affect social structures and social relations. For instance, growth may modify the sectoral structure of an economy leading firms in one sector to close down and firms in other sectors to be created or expand. Growth modifies the structure of prices, thus affecting the standard of living of households in a way that depends on their consumption preferences. In other cases, growth will call on some particular skills, increasing the remuneration of those endowed with those skills and also, possibly, their decision-making power within society. Finally, growth may reduce the availability of public goods like clean air or water, requiring public intervention in order to maintain the adequate supply of environmental goods. In all these cases, it is not only the economic structure – i.e., the relative importance of sectors, labor skills, remuneration of factors, and size of the public sector – that may be modified by growth. It is also the whole social structure, that is the relative weight of socio-economic groups or the way in which individuals define themselves with respect to the rest of the society, that is affected. As a consequence, social relations that govern how individuals in a society interact with each other through explicit or implicit rules may also be modified by economic growth and may in turn affect the growth process itself.

Rough evidence of such changes is provided by simple comparisons of economic and social structures and institutions across countries which have reached different levels of development. At the risk of caricaturing, it is sufficient to compare poor sub-Saharan

African countries today with some highly developed countries in Europe, North America or in the South Pacific. At one end of the spectrum, one observes largely rural societies dominated by household farms, few wage workers except in the limited urban sector, social protection ensured by an extended family system and a relatively small public sector often controlled by an unstable oligarchy. At the other end, one finds almost exclusively democratic urban societies with salaried employment and private ownership of capital as the main economic organization, with sophisticated redistribution system run by governments the size of which is 3 to 4 times that observed in poorer countries.

It is tempting to attribute all of these differences to economic growth and to expect that growth in the poorest countries will progressively make them comparable to developed countries today. Unfortunately, things are not so simple. In particular, it is clear that differences in economic and social structures and institutions cause differences in the pace and structure of economic growth as much as they are caused by it. But, it is also the case that some other factors may be influencing simultaneously both the process of economic growth and social structures and institutions. To take an example, a longer life expectancy due to technical advances in the field of health is likely to modify social structures through the aging of the population but it is also likely to modify economic behavior and the growth process, for instance because higher saving rates are rendered necessary by the prospect of longer periods of inactivity. In turn, this effect on economic growth rates and on the level of development may affect social structures and institutions by changing the weight of particular sectors in the economy.

The effects of economic growth on social structures are more complex than what the reduced form regressions found in recent literature may suggest. The relationships are likely to be non-linear (as hypothesized, for instance, by Kuznets for income inequality) and to depend on several country characteristics, including policy and institutional variables. This chapter argues that simple statistical methods are unable to identify these forces and these interactions, and that the limited number of observations available is a serious hindrance for this identification. Under these conditions, the only methodological approach able to identify the social consequences of economic growth is of a structural

nature. It first requires establishing hypotheses about the channels through which economic growth may affect the social structures under analysis. These hypotheses should then be empirically tested, provided of course that the data necessary to do so are available.

The purpose of this chapter is to examine, among the changes in social structures that may be observed along the growth path of a country or when comparing countries at different levels of development, what may be considered to be the *direct* consequences of economic growth. Other changes, thus, have to be considered as autonomous or possibly caused by factors or initial conditions that may have also affected growth but that have only an *indirect* relation to growth. An important example of such autonomous changes would be technological progress.

As noted above, some of these direct social consequences of growth may affect the pace and the structure of future growth and thus feed back into themselves through various channels. For instance, growth may under some circumstances generate more inequality in the distribution of economic resources, this increased inequality in turn affecting the dynamics of the economy. This chapter focuses on that part of the circular argument that goes from growth to social structures and ignores the other side of the circle. Such a choice is made for reasons of analytical expediency. It turns out that the economic mechanisms that lie behind the two parts of the circle are quite different; it would be too ambitious a task to deal with them simultaneously. Readers interested in the effect of social structures and institutions on growth should refer to other chapters in this Handbook.

The social consequences of growth may be of diverse nature. A natural distinction to be made is between the consequences of growth for ‘social structures’ and the consequences for ‘social relations' and 'social institutions'. As suggested by Kuznets (1966, p. 157-8), c*hanges in social structures* have to be understood essentially as the differential effects of economic growth on predetermined social groups. For example, urban skilled workers may benefit more from economic growth at some stage than unskilled workers, rentiers

more than farmers, men than women, or young people than older people. Growth may also affect the size of those various groups. Some substantial proportion of people migrate from the countryside to the cities under the pressure of urban growth, or more people may be willing to acquire a secondary or tertiary educational level. In both cases, social distances between individuals are modified. Changes in *social institutions* may result from changes in these social structures or from autonomous forces. For instance, changing the weight of specific socio-economic groups within society modifies the dominant mode of social relations, and changing the economic distance between individuals may modify the way they interact.

This chapter concentrates on the consequences of growth for social structures rather than on social institutions or relations. Its ambition is to identify the role played by economic growth in observed changes in social structures and to disentangle it from other factors. Casual comparison of social structures in developed and developing countries shows obvious and enormous differences. However, just because these two country groups differ by their mean income level does not imply that observed social differences must be exclusively attributed to economic growth per se. There may be many other reasons for these differences. In particular, it is possible that initial or historical conditions are responsible for some specific social evolution and for a particular growth path in a given country. It is also possible that exogenous forces, such as technical progress, have a direct specific impact on social structures, on the one hand, and on the pace and structure of economic growth, on the other. Analyzing the social consequences of growth consists of trying to isolate somehow the pure 'income effect' in the evolution of social structures.

This chapter is organized in three parts. The first part introduces the topic by examining the nature of the statistical relationships existing between social indicators and development across countries and/or across periods. It illustrates the differences in social structures associated with differences in income, but it also shows the difficulty of obtaining precise estimates of the size of the 'income effect' from this kind of evidence and the need to rely on more structural analyses. The second part reviews theoretical models of the effect of economic growth on social structures, with an emphasis on

several dimensions of social differentiation and on economic inequality. Finally, the third part focuses on the empirical evidence in support of this structural view of the consequences of growth for social structures.

1. Statistical Relationships between Growth and Social Structures

One may think of literally thousands of aggregate characteristics of societies showing extremely high degrees of correlation with indicators of economic development, either when comparing different countries at different levels of development or when analyzing the evolution of a single country over time. Collecting all existing results of this nature in the economic and non-economic literature is beyond the scope of this chapter.[2] Moreover, it is not clear how informative these correlations are from the point of view of causality. This section aims at showing that even the most sophisticated statistical techniques for the analysis of the relationship between socio-economic indicators and the level of development are unlikely to permit identifying the desired causality link between them. Given the available evidence, identifying that link requires dealing implicitly or explicitly with structural models, rather than with the reduced form models behind correlation analysis, whatever the degree of technical sophistication of that analysis.

As an example of the correlation approach to the consequences of growth, Table 1 shows the relationship between the level of economic development and a few indicators that very roughly describe changes in societies' economic and social structure generally associated with economic growth. As it will be seen later in this chapter, these indicators describe important channels through which growth and development may modify social structures. They include the size of the government, the level of urbanization, education, health, demographic patterns, labor force participation, gender differences and income inequality. The first three columns of the table report the results of a simple regression of

[2] For an early comprehensive attempt of this type, see Adelman and Morris (1967) who argue that development is a complex multi-causal process explained by many interactions between social, economic, political and institutional variables and use factor analysis to reduce the large number of explanatory variables into a small number of key categories. Zhang, Johnson, Resnick and Robinson (2004) present a typology of development strategies applying the same technique to Sub-Saharan Africa.

these indicators on GDP per capita expressed in 2000 US dollars after correction for purchasing power parity. The first two columns are based on pure cross-country observations – observed country means for the 1970s and the 1990s - whereas the third one is based on a pooling of all data available across countries and years during the period 1960-2002.[3]

It can be checked there that, with two exceptions, all indicators appear to be significantly and strongly correlated with economic growth. For instance, focusing on the pooled regression, the GDP share of public expenditures is shown to increase by 0.5 percentage point when GDP increases by $ 1,000 (thus confirming 'Wagner's law') although this coefficient is not statistically significant for the 1970 cross-section. Likewise, the urbanization rate is shown to increase by 0.3 per cent and the literacy rates by 3 to 4 percentage points in presence of the same increase in income per capita, whereas fertility decreases by 0.15 children; the 1970 cross-section shows slightly different results in all of these cases. As a final example, income inequality and female gender bias appear to be significantly and negatively correlated with growth. In the case of the former, a parabolic regression exhibits the familiar inverted U-shape introduced by Kuznets some 50 years ago [4]– with a non-significant result occurring with the 1990 cross-section.

<Table 1 around here>

All these results are interesting. Yet, there are various reasons to think that simple regression on a cross-section of countries or even on a pool of cross-section time-series observations is a very crude approach to identifying the consequences of growth. On the one hand, the existence of a correlation does not say much about the causality link between two variables. Causality may be direct in either one direction, or possibly in both. It may also be indirect and simply reflect the fact that the two variables under scrutiny are both related to a common set of other variables. On the other hand, GDP per

[3] All data are from World Bank's SIMA database (World Bank 2003).

[4] On the basis of historical data, Kuznets (1955) proposed the hypothesis that income inequality tended to increase in a first stage of economic development and to fall in a second one. See the discussion in section 2 below.

capita tends to increase more or less regularly over time so that there may be a confusion between its effect on socio-economic indicators and that of other variables with a comparable time trend.

Alternative econometric specifications permit taking into account some of the preceding points. At the same time, however, they often modify the order of magnitude and the significance of the preceding relationships. In a few instances, they even modify their direction.

The next four columns of table1 show estimates of the growth sensitivity of socio-economic indicators obtained with alternative econometric specifications. In all cases, the sample is obtained by pooling country data over various years in the periods 1960-2002. In column 4, a set of year dummy variables is added to the regression. This accounts for the fact that socio-economic indicators might evolve over time under the influence of some common factors independent of national economic growth. In column 5, it is a set of country dummy variables that is introduced so as to control for 'fixed effects' or, in other words, the effect of largely unobserved fixed country characteristics that might affect both the original level of GDP per capita and that of the indicator under scrutiny. The corresponding estimate of growth sensitivities thus abstracts from differences in country means and takes into account only differences in the average time behavior of GDP per capita and socio-economic indicators across countries. Column 6 combines both approaches by abstracting from differences in country means as well as from an exogenous non-linear time trend common to all countries. Finally the estimates in column 7 are obtained by running the simple regressions of socio-economic indicators on GDP per capita in decadal differences.

Adding a common non-linear time trend to the original simple model does not modify the growth sensitivity of the socio-economic indicators in a significant way. More substantial changes are obtained when fixed country effects are introduced. As could be expected, growth sensitivity generally falls when cross-country differences are ignored, or more exactly when cross-country differences are attributed to fixed characteristics that include,

inter alia, initial development levels. The effect of growth on the urbanization rate, the literacy rate or life expectancy is divided by about 2 The growth sensitivity of the GDP share of public expenditures becomes non-significant, the same being true of income inequality, both with the linear and with the parabolic model. The only exception is labor force participation of women, the effect of growth on which tends to increase when controlling for fixed effects. Changes with respect to simple estimates are still bigger when fixed effects are introduced both for countries and years. In some cases – as for instance with fertility and gender life expectancy differential- the sign of growth sensitivity is even reversed.

Of course, such a correction of the original estimates may well be excessive. Adding a time trend is certainly bound to reduce growth sensitivity estimates, especially when estimation abstracts from cross-country differences. The time trend is likely to pick up those changes in the indicators which are independent from country specific economic growth. Yet, results obtained with that method are not always very convincing. In particular, that fertility would significantly increase as a response to growth once independent forces are taken into account, as shown in the last two columns of table 1, seems to be in contradiction with the intuition of most demographers.[5] The results shown in table 1 are likely to mask some heterogeneity among countries with respect to the drop in fertility that is not dependent on economic growth.

The estimates reported in the last column of table 1 confirm the preceding results. Restricting the analysis to correlation in decadal differences overall shows the same order of magnitude for the growth sensitivity of socio-economic indicators, but also makes those sensitivities often non-significant.[6] In comparison with simple regressions and correlations, estimates based on differences or on fixed effects thus suggest that the evolution of the few general socio-economic indicators considered in table 1 probably obeys other forces in addition to economic growth, or that the effect of growth is less

[5] See for instance Easterlin (1996) chapter 8, and Lee (2003).
[6] The difference in T-statistics between columns (6) and (7) is mostly due to the fact that the regression in column (7) relies on fewer observations. Note, however, that ignoring possible correlation in the residuals of the regressions behind column (6) for contiguous years may tend to a gross underestimation of the variance of the estimates.

simple than implicitly assumed in these statistical models. In particular, it is quite possible that the effects of growth on socio-economic indicators are strongly heterogeneous across countries. Identifying that heterogeneity or the forces other than economic growth that affect the evolution of socio-economic indicators is thus necessary in order to identify the true social consequences of economic growth. But the econometric approach illustrated in this section is unlikely to meet that objective.

Taking into account this heterogeneity across countries and going beyond the simple statistical techniques used to produce the results of table 1 meets a fundamental constraint: the limited number of observations. Estimating the preceding model country by country on a time series basis would certainly permit to fully account for country specificity. But it would only inform on the consequences of growth at a particular stage of the development process of a given country. On the other hand, taking into account observed heterogeneity by interacting growth rates or development levels with a host of country characteristics and policy variables and by introducing non-linearity is also bound to run into too few degrees of freedom. Social consequences of growth take time to show up, so that the informational content of annual time series is not proportional to the length of these series. In table 1, one can see that there is little difference between the last two columns even though column (6) relies on full annual series whereas column (7) uses only decadal differences. This means that the information that matters is not year-to-year fluctuation but 'episodes' of growth characterized by uniformly high, moderate or low growth rates. If this is the case, then available data may make it difficult to estimate with satisfactory precision the observed heterogeneity in the consequences of growth.[7]

In summary, the analysis in this section suggests that other forces than economic growth are behind the time evolution of most socio-economic indicators, even though the absolute value of simple correlation coefficients is often very high. It is also possible that

[7] Another approach to estimating the growth sensitivity of social indicators would be to estimate jointly the difference equation in column (7) and the level equations in columns (1) and (2). Resulting estimates would simply be midway. Working with annual series, it would also be possible to explicitly introduce some lag in the effect of growth on social indicators and to use GMM-based Arellano-Bond or Blundell-Bond 'system' estimates (Arellano and Bond 1991, Blundell and Bond 1998) instead of the fixed effect model (6). Given the proximity of the estimates in columns (6) and (7), the lag is likely to be quite long and the overall sensitivity not very different from the estimates shown in these columns.

the effect of economic growth on these indicators and the social features they describe is too complex to be described by simple regression analysis. In particular, the relationship may be non-linear – as hypothesized for instance by Kuznets for income inequality – or it may depend on specific country characteristics, including policy and institutional variables. There is no simple statistical method to identify *a priori* these other forces or these interactions, and limited observations may also be a serious hindrance for this identification.

Under these conditions, it is likely that the only methodological approach able to help identify and understand the consequences of economic growth is of a 'structural' nature. In other words, what is required is to establish hypotheses on the phenomena that guide the overall evolution of the socio-economic indicators under analysis and to test the corresponding model. This is in stark contrast with the reduced form approach so often found in the literature and illustrated by table 1. Within a structural approach, a theoretical model of the behavior of the socio-economic indicator being studied must first be established on the basis of economic theory. This is what the next section attempts to do for some possible social consequences of growth.

2. THE EFFECT OF ECONOMIC GROWTH ON SOCIAL STRUCTURES : THEORETICAL CONSIDERATIONS

Does economic growth tend to affect people's income and welfare in the same way? Alternatively, does economic growth tend to favor the expansion of some particular socio-economic groups with respect to others? Of course, these two types of changes in social structures are related to each other. It is because economic growth favors urban workers over rural workers that the latter tend to migrate to the cities and the size of the agricultural population declines. Likewise, it may be because, in some circumstances, growth favors skilled work that parents have an incentive to send their kids to school for longer periods and the literacy rate in the labor force tends to rise. In line with the plea for a 'structural approach' to these questions in the preceding section, this section reviews various theoretical models meant to describe the 'distributional' consequences of growth.

It is well-known, since the pioneering work by Chenery and Syrquin (1975) on the structural aspects of growth, that growth favors some specific sectors and therefore specific social groups, mostly those who work in them or consume their products. Thus, when growth occurs, changes take place in the weight of these sectors in the economy and in the weight of these groups in the population. However, it is not necessarily the case that those changes also produce permanent modifications in relative incomes. Indirect mechanisms might partially or completely compensate for these direct effects by spreading them to the rest of the society. Competition on the labor market may spread sectoral effects to the whole economy, for instance, or migration may be a natural response to urban-oriented growth leaving urban-rural income differentials unchanged. Evaluating this chain of effects may need fairly elaborate models, however. Evaluating the effect of growth on social structures thus is more or less straightforward depending on what aspect of social structures is being studied. Given the considerable interest it arose in the literature over the past 30 years or so, this review concentrates on the issue of income inequality, while considering at the same time related dimensions of social differentiation.

The relationship between economic growth and the inequality of the distribution of income and economic resources in general has attracted the interest of economists ever since the classical age of the discipline. More recently, very much interest arose with Kuznets' (1955) observation that, historically, inequality tended to increase in a first stage and then to decrease at a later stage of development. Cross-country analysis undertaken in the early 1970s by Paukert (1973) and Ahluwalia (1976) seemed to confirm that there was indeed an inverted U-shape relationship between inequality and the level of development, as measured by the GDP per capita.

As can be seen in at the bottom of table 1, the cross-country data available circa 1970 seemed indeed in full agreement with Kuznets' hypothesis. Data that became available later did not confirm that feature of the 1970 sample, however, whereas estimations based

on panel data suggested that, in many countries, the evolution of inequality did not fit Kuznets' patterns. In table 1, the coefficient of GDP per capita (y) and its square (y^2) show an inverted U-curve in 1970s, a significant U-shaped curve when these data are pooled together with more recent data, and a non-significant relationship when controlling for fixed effects.

Interestingly enough, the debate about the Kuznets hypothesis gave rise to a renewal of the theoretical literature on the general effects of growth on inequality. That literature also provides a representation of the channels through which economic growth may affect social structures in general. This literature is briefly reviewed in what follows.

The literature on the effect of growth on inequality emphasizes two fundamental channels: sectoral shifts, on the one hand, and factor markets on the other. Both channels have been represented with different types of modeling and have been subject to continuous scrutiny and analytical elaboration. They remain the cornerstones of any analytical approach to the social consequences of growth.

(a) The Sectoral Shift View

The explanation that Kuznets himself gave to the inverted U-curve hypothesis was based on the sectoral shifts away from traditional agriculture that characterizes long-run economic growth. In effect, the model he had in mind was very much along the lines of the classical surplus labor model as formulated in the modern literature by Lewis (1954) and later by Fei and Ranis (1965). There are two sectors in the economy with fixed relative prices and fixed relative incomes. The development process consists of shifting some proportion of the population from one sector to the other. An obvious formalization of this model is as follows. Let y_i be the fixed income level in sector i, and n_i the share of the population in that sector. Let sector *2* be traditional agriculture and suppose that income in that sector is smaller than in the 'modern' sector, labeled *1* – i.e. $y_1 > y_2$. Long-run growth in that model is then essentially described by the increase in the proportion of the population employed in the modern sector, n_1, for fixed income levels y_1 and y_2. Such

a process may for instance be explained by some capital accumulation taking place in sector *1* and some labor-market imperfection preventing labor remuneration to equalize in the two sectors.

This simple representation of the process of economic growth has obvious implications for social structures in general. Everything depends on the interpretation given to the two sectors *1* and *2*. If sector *2* is indeed assimilated with traditional agriculture, then the drop in n_2, and the consequent increase in n_1, implies altogether an increase in urbanization and all social transformations that may possibly accompany it, like lower fertility, higher school enrolment, higher crime rate, etc… But the dichotomy between sectors *1* and *2* may also represent manufacturing versus services, formal versus informal or high versus low technology. In each case, growth comes with a more or less rapid modification in the structure of society in a particular dimension.

This framework may be easily extended so as to represent the evolution of income inequality within society. Following Robinson (1976), let income inequality be measured by the variance of the logarithm of income.[8] Thus, denote V_i the variance in sector *i* and assume that this variance is constant. Total income inequality in the economy is then given by:

$$V = n_1.V_1 + (1-n_1).V_2 + n_1.Log^2 y_1 + (1-n_1).Log^2 y_2 - \left[n_1.Log\ y_1 + (1-n_1).Log\ y_2\right]^2 \quad (1)$$

where use is made of the fact that $n_1 + n_2 = 1$. As before, the development level of the economy is fully described by the proportion of people in sector *1*, n_1. If it is assumed that $V_1 > V_2$, then total inequality in (1) is a parabolic function of n_1. Under some plausible conditions on the values of V_1 , V_2, y_1 and y_2, total inequality may thus go up and then down as observed by Kuznets on some historical data.

8 Knight (1976) and Fields (1979) use the same framework but different income inequality measures. Anand and Kanbur (1993) present a more general version of this model where the analysis is conducted in terms of the full distribution of income in both sectors and in the whole economy rather than on a specific summary inequality measure.

Yet, this result on inequality, and more generally the fact that this model represents the social consequences of growth through a single parameter, n_1, must be taken with very much care. First, as n_1 is bounded, it may well be the case that inequality will be increasing or decreasing monotonically throughout the development process. Depending on the various parameters of the model, the time profile of inequality may be extremely flat or, on the contrary, have a sizable slope. Second, representing growth through a mere sectoral shift of the population may seem overly simplistic and restrictive. Assuming that income in the two sectors of the economy does not change along with growth is equivalent to assuming that markets are imperfectly competitive or that compensating phenomena are at work. Practically, more people in sector *1* could lower the relative price of that sector's output. This might reduce the initial level of inequality between the two groups of workers and may be enough to prevent inequality among individuals to go up in the first stage of the process just described. Likewise, it is restrictive to assume that migration from one sector to the other is distribution neutral. A change in n_1 is likely to modify both V_1 and V_2. The direction of that change will depend on whether migration concerns the least well off people in sector *2* or people in the middle of the income scale.

In short, representing economic growth trough a simple sectoral shift parameter appears unsatisfactory to account for the effect of growth on social structures, except maybe in very particular cases where inequality across socio-economic groups may indeed be considered as constant. In general, however, the implicit fixed price assumption in the sectoral shift model seems unduly restrictive.

Several authors have proposed extensions of the preceding model for the analysis of the evolution of inequality among individual incomes. In some cases, the conclusion of an inverted U-shape relationship between growth and inequality was reinforced, as in Rauch (1993), for instance, while in other cases, the inverted U-shape conclusion was undermined – see for instance the demand-based models by Taylor and Bacha (1979), de Janvry and Sadoulet (1983) or Bourguignon (1990).

It is not clear that the inverted-U shaped relationship between inequality and the level of development is an important issue by itself. It may have been important in the debate of the early 1970s on whether development efforts had to concentrate solely on growth as opposed to growth and distribution.[9] What seems more important today is the recognition that at all stages of the development process economic growth has indeed the capacity of modifying social structures, and in particular the hierarchy of relative incomes among individuals or socio-economic groups, through its natural sectoral bias. The way in which this bias is actually translated into more or less inequality is likely to be country-specific, but this strand of the literature suggests that it is not justified a priori to start from the postulate that economic growth is neutral in the sense that it affects everybody's living standard in the same proportion.

It is interesting that this emphasis on the sectoral bias of growth as the source of social changes is still present in the recent literature on inequality. Indeed, several authors see the appearance of a new branch in the Kuznets curve in the surge of wage and income inequality observed in the US economy in the late 1970s and in the 1980s – see for instance List and Gallet (1999). This evolution is often interpreted as the consequence of technical progress and/or international trade. A new sectoral specialization is appearing and social structures are affected by a progressive transition of the whole labor force towards the most modern sectors of the economy, in a process reminiscent of the industrialization process behind Kuznets' original argument.[10]

(b) General Equilibrium Models of the Distributional Effects of Growth

The sectoral shift view at the distributional consequences of growth refers to a 'fix-price' view of economic development where population movements across sectors or socioeconomic groups respond to some disequilibrium. This disequilibrium may itself be caused by economic growth, but that relationship and the growth process itself are not explicitly considered. An alternative approach to the distributional effects of economic

9 Chenery et al. (1974) provides a good summary of the various elements of this debate. A detailed account of the recent history of economic thought in this area is offered by Arndt (1987).
10 For empirical evidence from the US, see Katz and Autor (1999) and Baumol, Blinder and Wolff (2003).

growth consists of considering changes in factor prices that may take place along the growth path, together with the factor accumulation behavior that is causing growth. Such an analysis is equivalent to linking the micro-economic analysis of distribution with standard macro-economic theories of growth and the functional distribution of national income. Sectoral differences and disequilibria which were prominent in the preceding approach are now ignored because it is now implicitly assumed that factor and good markets are permanently in equilibrium. The theoretical framework thus is that of dynamic general equilibrium rather than that of temporary fix-price partial equilibrium.

Numerous dynamic general equilibrium models have been proposed to analyze the relationship between economic growth and inequality, many of them inspired by the recent revival of the growth literature. No attempt will be made here to give an exhaustive summary of that literature, which in effect tends to concentrate on the way inequality affects economic growth rather than the opposite.[11] Instead, this section looks at the other face of the coin, namely what is to be learnt from this literature about the distributional consequences of growth.

Following the pioneering paper by Stiglitz (1969), assume that the income, y_i, of agent i comes on the one hand from labor and on the other hand from the return on his/her wealth, k_i. To simplify, assume that all agents have the same labor productivity and supply one unit of labor. Thus their labor income is uniform and equal to the wage rate, w. These assumptions are more general than they look at first sight if k_i incorporates both physical (or financial) and human capital. The uniformity of labor income thus is an assumption that tries to represent the fact that (raw) labor income is in general more equally distributed than physical or human capital. Generalizing the following argument to the case of some exogenous distribution of labor productivities does not raise major difficulty. Denoting the rate of return to capital by r leads to the following definition of individual income:

[11] For a survey of this literature, see Aghion et al (1999), Benabou (1996) or Bertola (2001), as well other chapters in this volume.

$$y_i = w + r.k_i \qquad (2)$$

Expression (2) shows a first way through which growth may affect the distribution of income among individuals. By modifying the relative rewards of labor and capital, growth modifies relative individual incomes. For a given distribution of wealth, the distribution becomes more equal when the relative reward of labor rises.

As growth proceeds through the accumulation of individual wealth, there is a second way by which it may modify the distribution of income and wealth. A simple general assumption is that saving or investment by agent *i*, S_i, is a linear function of the various sources of income :

$$S_i = \alpha.r.k_i + \beta.w - \gamma \qquad (3)$$

where α is the marginal propensity to save out of capital income, β out of labor income and γ stands for the effect on savings of the existence of some minimum consumption level. Assuming in addition a depreciation of capital at rate δ, for all agents i, leads to the following accumulation behavior :

$$\dot{k}_i = (\alpha r - \delta).k_i + \beta w - \gamma \qquad (4)$$

or in growth rates :

$$\dot{k}_i / k_i = (\alpha r - \delta) + (\beta w - \gamma) / k_i \qquad (5)$$

where the notation $\dot{}$ refers to infinitesimal time change.

It may appear that the preceding specification only allows for the representation of the evolution of the distribution of income and assets among individuals and does not permit analyzing social structures as described by the composition and relative income of socio-economic groups. This is not the case, however. It is sufficient to define socio-economic

groups by some particular endowments of assets for (1) to describe the evolution of the relative incomes between, for instance, unskilled workers and skilled workers, or between workers and 'capitalists'. In effect, what matters here is the return to the various types of assets that are used to define socio-economic groups. The evolution of these rates of return defines the evolution of between group inequality. Likewise, equations (4)-(5) implicitly define the dynamics of group composition. For instance, some unskilled workers—with k initially equal to zero—acquire some positive human capital (k) and become skilled workers, whereas some skilled workers may become 'capitalists'. Thus, it should be clear that all that follows applies as well to a description of the effects of growth on inequality among individuals as well among socio-economic groups on social structures.

An obvious implication of the linearity of (4) is that the distribution of wealth and income *does not affect* the aggregate growth path of the economy and therefore the evolution of the factor prices, w and r, that comes with it. Yet, it can be seen in (5) that another implication of that saving function is that *growth generally induces a change in* wealth or income inequality. In the general case, inequality decreases or increases with growth depending on whether savings out of wages, βw, cover the dissaving due to minimum consumption, γ, or not.[12] Since the wage rate is expected to increase with growth, inequality may increase with growth in a poor economy but this evolution may revert itself when the economy has reached a certain level of affluence, in a process that is consistent with the Kuznets hypothesis.

This is an extremely simplified model. At the same time, it incorporates enough flexibility to analyze several interesting issues. To do so, it is helpful to derive from the preceding equation the time behavior of relative incomes. It is easily shown that the evolution of the relative income of two agents i and j is given by :

[12] Results would not be qualitatively different if it were assumed that savings cannot be negative but are nil if income is below minimum consumption – see Stiglitz (1969) and Bourguignon (1981).

$$\frac{\dot{y}_i}{y_i} - \frac{\dot{y}_j}{y_j} = \left(\frac{1}{y_j} - \frac{1}{y_i} \right).\{w.(\dot{r}/r - \dot{w}/w) + w.(\alpha r - \delta) - r.(\beta w - \gamma)\} \qquad (6)$$

This expression shows that distributional changes along a growth path have various sources. The first term in the curly bracket on the RHS corresponds to the changes in factor prices resulting from growth, whereas the last two terms correspond to capital and non-capital sources of savings, respectively. Sources for distributional changes are thus richer than with the sectoral shift approach. As mentioned above, the accumulation component may be compared, to some extent, to population shifts in the sectoral model. Differential accumulation behavior in the present representation of growth is equivalent to individuals moving from one socio-economic group to another. But, of course, it also corresponds to possible changes in 'within-sector' inequality parameters (V_i). The factor price effect corresponds to a change in the income differential across groups, that is the ratio y_1/y_2 in the sectoral shift model.

Expression (6) readily shows what evolution in factor prices and what kind of saving behavior may be responsible for increasing or decreasing income disparities among individuals or socio-economic groups along the growth path. According to the factor price effect, any increase in the reward to capital, relative to labor, increases inequality by lowering the relative income of 'pure' workers. The same is true of a high propensity to save out of capital income. On the contrary, a high propensity to save out of labor incomes contributes to more equality in the economy, at least after a wage threshold has been passed.

Of course, accumulation behavior and factor price changes cannot be considered as independent of each other. In this respect, it is interesting to consider some particular cases of the preceding general model. A first simple case is when agents save only out of their capital income ($\beta = 0$) and there is no minimum consumption requirement ($\gamma = 0$). It is well known that such a saving behavior can be obtained as the implication of a simple

life cycle consumption allocation model.[13] As can be seen in (5), the rate of growth of individual wealth is then the same for all agents with positive initial wealth, which implies that the distribution of wealth remains constant over time, maintaining the features inherited from history. Note that this does not necessarily mean that the distribution of income will remain constant since relative factor prices and factor shares in individual incomes may change along the growth path. Yet, in the standard neo-classical framework with unit elasticity of substitution between capital and labor, it is easily shown that the distribution of relative incomes remains constant over time, precisely because the factor shares of total and individual incomes are constant. [14]

A related particular case, very much emphasized in the recent literature, arises when $\beta = \gamma = 0$, the rate of return to capital is constant and the wage rate grows at the same rate as individual and aggregate wealth. This would correspond to an economy where output is proportional to capital and is divided in constant proportion between labor and capital. The implicit growth model behind this description could be a version of the Harrod model or the 'aK' endogenous growth model proposed by Frankel (1962), extended later by Romer (1986) and others. The implications of these two particular cases are worth to be stressed. They indeed provide an interesting benchmark where *economic growth is essentially distribution neutral*, even after taking into account both the process of wealth accumulation and its effects on good and factor markets. However, it can be seen that this result is not so much due to the assumptions made on the production side of the economy - i.e. constant or declining returns to scale – as to the assumption that savings arise only out of capital income.

Another interesting particular case is the one originally explored by Stiglitz (1969). Assume $\alpha=\beta$ and that factor prices are determined by the marginal products of an

[13] In an infinite horizon model it is necessary to assume first that the inter-temporal elasticity of substitution (σ) is constant. If r is the rate of interest and ρ the utility discount rate, this leads to a constant rate of optimal consumption $g = \sigma.(r-\rho)$. It is sufficient to assume that non-capital income grows at the same rate g, as will be the case at the steady state in an economy with constant returns to scale, to obtain that savings are proportional to existing wealth – see Bertola (1993).

[14] The unit elasticity of substitution ensures that aggregate shares of capital and labor in total income are constant. As all individuals accumulate capital at the same rate, individual shares of total capital remain constant. Together, this implies that both individual capital and labor incomes grow at the same rate as the whole economy.

increasing and concave aggregate production function. Then, the aggregate economy behaves as in the well-known Solow model (1956) with the distribution of income following a Kuznets curve if the wage rate is initially low enough. More interestingly, and somewhat paradoxically, it can be shown that the distribution of income and wealth tends asymptotically towards full equality if the steady-state wage/profit rate ratio is large enough.[15] This result is considerably weakened if labor productivity and labor incomes are assumed to be heterogeneous across individuals. The distribution of both wealth and total income may then be shown to converge asymptotically to the distribution of labor productivities.

(c) Non-linear Savings Behavior

The preceding results are all based on the assumption that the wealth accumulation process underlying growth is linear with respect to individual wealth. This assumption is debatable. There are various reasons why savings may be thought to be a non-linear function of income or wealth, even when saving behavior is strictly assumed to result from inter-temporal optimization. Liquidity constraints and/or credit market imperfections are the most obvious factors that may explain such non-linearities. For instance, credit rationing may imply that zero is a lower bound for the savings of somebody with zero wealth. Combining this feature and the preceding linear model leads to savings being defined by :

$$S_i = Inf\{0, \alpha.r.k_i + \beta.w - \gamma\}$$

[15] Namely, w/r>γ/δ at the steady state. The proof of the convergence towards equality is simple. (5) may be rewritten as $\dot{k}_i = \left[\alpha(r\bar{k} + w) - \delta.\bar{k} - \gamma\right] + \left[(\alpha r - \delta)(k_i - \bar{k})\right]$ where $\bar{k}$ is the mean wealth in the economy. At the steady state of the economy, the first square bracket on the RHS is nil and the first term in the second square bracket is negative. It follows that individual wealth necessarily converges towards the mean wealth, $\bar{k}$. In comparison with the general model, this proof shows that the equal distribution asymptotic result in this particular case is due to : a) the equal marginal propensity to save out of capital and labor income; b) decreasing marginal returns to production factors.

In effect, this apparently small modification is sufficient to drastically alter the conclusions obtained previously. First, aggregating individual accumulation behavior leads to a change in aggregate wealth that depends on the distribution of wealth. Thus, the distribution of wealth affects the aggregate growth path of the economy, which was not the case before. Second, some of the conclusions obtained previously on the evolution of the distribution of income and wealth do not hold anymore. In particular, the result that the distribution of income tends towards equality in the Solow-Stiglitz model is not anymore granted. Depending on the initial distribution of wealth, inequality may well be non-decreasing throughout the whole growth path of the economy. Analogous conclusions may be obtained with more general non-linear specifications of the saving function.[16]

A way of justifying non-linear saving functions is to account for the fact that the rate of return to capital in the original (linear) model above may be heterogeneous across agents with different levels of wealth or income. Credit market imperfections associated with the existence of some indivisible investment project with an exogenous rate of return are sufficient to generate such a result. For moral hazard or adverse selection reasons those individuals who have to borrow to undertake this project face a borrowing rate of interest above rates served on conventional savings – and possibly decreasing with the amount borrowed, or equivalently their wealth.

Under the preceding assumptions, the original individual accumulation equation writes then :

$$\dot{k}_i = \alpha[r(k, k_i).k - \delta.]k_i + \beta w - \gamma \qquad (7)$$

[16] Of course, the inegalitarian steady state result may be obtained for any saving function that is convex with respect to income or wealth. Schlicht (1975) and Bourguignon (1981) offer a general treatment of convex saving functions within a Solow-Stiglitz framework, without analyzing the reasons for convexity. Moav (2002) reaches the same conclusions assuming intertemporally maximizing agents with convex bequest functions.

where r( ) is a function of k_i that has the shape of an inverted U – poor people are credit rationed and only people in some intermediate wealth range are borrowers facing an implicitly higher rate of return on their wealth.

A significant proportion of the recent literature on the effects of the wealth distribution on economic growth is implicitly based on credit market imperfections and an accumulation equation of type (7). This is true in particular of the seminal papers by Galor and Zeira (1993), Banerjee and Newman (1993), Aghion and Bolton (1996) and Piketty (1997). These models also have implications for the distributional consequences of growth. As the rest of the literature, however, they suggest that all types of evolution are possible, from continuously increasing or decreasing inequality to Kuznets-curve-like movements.

d) The role of technical progress

The preceding is based on a view of economic growth being essentially driven by factor accumulation. Growth modifies the distribution of income and wealth among individuals or across socio-economic groups essentially because individuals or groups do not accumulate at the same rate and because factor accumulation may cause changes in the remuneration of the productive factors owned by individuals. But, of course, another engine of growth is technical progress, which may itself modify both the relative remunerations of productive factors and factor accumulation behavior.

If technical progress was neutral, affecting the remuneration of all factors in the same way, then nothing would have to be changed in the preceding argument. An issue arises when technical progress is 'biased' in the sense that it favors one factor more than others. A case that has received very much attention in the recent literature is that of the 'skill-biased' technical change, which is a shift in technology that increases the demand for skilled labor.[17]

[17] See Acemoglu (2002), Katz and Autor (1999)

From a theoretical point of view, one may analyze the effect of skill-biased technical change on social structures as resulting simply from a change in the return to the human capital component of individual wealth in the preceding framework. The increased demand for skilled labor increases the return to skill and, other things being equal, increases the income differential between skilled and unskilled workers. Of course, an increase in the return to skill is likely to cause an acceleration in the human capital accumulation, reducing progressively the differential between skilled and unskilled workers and, at the same time, shifting workers towards high skill socio-economic groups. The effect of this 'race' between technical change and education or training was first analyzed by Tinbergen (1975). Since then, it received very much attention.[18] In effect, the implications of this race for inequality are a priori ambiguous since it depends on the speed at which the demand for skill labor increases following some technological innovation and the speed at which skill accumulation responds on the supply side of the labor market. If growth is seen as successive waves of skill-biased technical innovations, it may thus be accompanied by long-run fluctuations in earning differentials across skill groups of workers. These fluctuations may also be influenced by the fact that the bias of technical change may itself be affected by the skill differential and the relative availability of skilled workers, as in Acemoglu (2002).

The dynamics of the earning differential is not necessarily as simple as the preceding supply-demand argument would imply. For instance, Aghion et al. (1999) and Aghion (2002) develop an original model of the diffusion of an innovation in General Purpose Technology where skill-biased technical change contributes to a continuous increase in the skill wage differential, after a preliminary period where the differential remains constant. The skill gap starts increasing when all skilled workers have been absorbed by firms which have adopted the new technology and the gap keeps increasing as long as other firms seek to adopt the new technology too. All firms eventually adopt the new technology and all workers acquire the new skill. In effect, this process combines both a sectoral shift of the type analyzed above and a general equilibrium price effect.

[18] For recent formalizations of this argument see Eicher (1996), Galor and Tsiddon (1997). See also the survey by Aghion et al. (1999).

Although most of the effect of skill-biased technical change is expected to take place between skill groups, some authors insist that it may also affect inequality within groups. Any innovation requires adaptation of the first workers who are confronting it, and this adaptation is easier for workers with some specific ability on top of the skill required to perform the new task. The increased remuneration of that specific ability contributes to increasing the degree of inequality among workers, an inequality that may persist over time if the adaptation to the new technology has created a new type of human capital among the workers who were first exposed to the technical innovation (see Violante, 1996, Rubinstein and Tsiddon, 1998, Aghion, Howitt and Violante, 2002).

<Leave some space>

To conclude this section on the theoretical mechanisms through which growth affects social structures, it must be emphasized that, as mentioned in the case of technical progress, sectoral shift and general equilibrium mechanisms are not necessarily mutually exclusive. It was already seen above how the individual asset accumulation equations (4)-(5) could actually represent the shift of individuals across socio-economic groups defined by their factor endowments. More explicitly, however, recent theoretical models built on the imperfect credit market mechanism actually combine the factor market and the sectoral shift approach. An interesting aspect of the model proposed by Banerjee and Newman (1993), for instance, is that the distribution of wealth in the economy practically determines economic agents' kind of occupation and the sector where they operate. People with little wealth are pure wage workers, employed either in the formal or the informal sectors. People with a higher initial level of wealth engage in small businesses and determine the size of the 'informal' sector, whereas richer people are the owners, managers and top employees in the formal sector. The change in the wealth distribution that takes place, together with growth, along time has thus the effect of changing the distribution of occupations in the economy and the relative size of the formal and informal sectors. To some extent, this particular dynamic general equilibrium model

provides a kind of formalization of the intersectoral shifts emphasized in the Kuznets tradition of the analysis of the effects of growth on inequality.

Overall, the short preceding review shows that considerable efforts have been devoted to identifying and understanding the mechanisms through which growth affects social structures and inequality. As far as social structures are concerned, the analysis points to the evolution of the employment structure of the population away from lowest productivity sectors and occupations. An obvious social consequence of growth thus is to reduce the share of the population living in traditional agriculture in a first stage, in informal non-agricultural activities in a second stage, in 'low-tech' manufacturing activities in a third stage, etc. At the same time, the accumulation of human capital implies that growth comes with a continuous reduction in the share of the population with no or low education.[19] On the other hand, the economic analysis of growth is largely inconclusive concerning other aspects of social structures and the distribution of wealth or income.

In this respect, three sources of ambiguity must be stressed. First, theory is necessarily silent on aspects of social structures that do not appear as central in economic growth mechanisms. That the population shifts sector and occupation in a well defined direction is one thing. Whether this movement is uniform across population subgroups defined by gender or ethnicity is another thing—about which economic growth theory has little to say . This is essentially because factor endowments put forward by growth theory do not incorporate this dimension of social differentiation. Second, whether the shift of the population from one sector or socio-economic group to another is accompanied by an increase in income differentials among those sectors or groups is unclear. For instance, the share of educated people in the population is increasing with growth, but that evolution is in theory consistent with constant, increasing or decreasing income differentials between educational levels. Third, if economic theory permits to identify the

[19] The preceding argument is straight economics. But the increase in schooling has also a demographic explanation. The demand for children—and thus family size and human capital levels—changes with economic growth. One tends to observe less children of better 'quality' at higher levels of income per capita. For surveys of this literature, see the two volumes of Rosenzweig and Stark (1997) and Rosenzweig (1990).

various channels through which growth may affect inequality among individuals, the sum total of these effects is ambiguous: no change, equalizing or unequalizing evolution throughout the whole growth process, or the inverted U-shape put forward by Kuznets. This conclusion holds whatever the analytical framework being used, whether theoretical models belong to the sectoral shift fix-price or to dynamic general equilibrium modeling tradition.

3. THE EFFECT OF ECONOMIC GROWTH ON SOCIAL STRUCTURES : EMPIRICAL EVIDENCE

The preceding analysis suggested various channels through which growth is affecting social structures: a) by shifting individuals from one sector or socio-economic group to another; b) by modifying income differentials across sectors and socio-economic groups; c) by modifying income and welfare disparities across individuals. Of course, these three channels are not independent. In particular, it must be clear that sectoral shifts and inequality changes between socio-economic groups have a direct impact on inequality among individuals.

This section briefly reviews the empirical evidence available on these three channels. Both on a cross-country and case study basis, the sectoral shift effect of growth turns out to be the fundamental way through which economic growth affects social structures. Cross-country analysis is relatively less conclusive both for differential effects of growth across socio-economic groups or among individuals. However, this certainly does not mean that growth has no impact on social structures outside the sectoral shift component. Rather, case studies suggest that this effect is relatively more complex and most likely strongly country-specific.

(a) The Sectoral Shift Effect of Growth on Social Structures

Two rows in table 1 illustrate the power of growth related sectoral shift to influence on social structures. Urbanization and all the phenomena that it entails is a the first example. The structural explanation behind it is clear. It has to do with the falling share of agriculture – or, better said, of low-productivity traditional agriculture - throughout the growth process. Although only a reduced form model appears in table 1, coefficients shown there are strongly significant and it would be relatively easy to devise a structural model focusing more on the mechanisms behind the urbanization process with equally strong statistical significance.

A second sectoral shift effect of growth shown in table 1 concerns education. Here again, the positive correlation with development levels is very strong. It is true that the coefficient obtained with decadal differences is not statistically significant, but this might have to do with the extremely long lags with which changes in schooling behavior, possibly generated by economic growth, spread to the whole population. [20] It is also true that focusing on literacy rates yields a perspective on education and skills that may seem too narrow. However, it is unlikely that considering the proportion of 'skilled workers' in the labor force - assuming that some uniform definition of skills is available across countries- or the proportion of people with secondary education would yield very different qualitative results.[21] In effect, regressing the average number of years of schooling of individuals in the labor force on GDP per capita in table 1 yields results qualitatively similar to the regression on literacy rate.

One could undoubtedly multiply regressions showing strong structural effects of economic growth through which changes in social structures are likely to occur. For instance, one could focus on the weight of the manufacturing or the service sector instead of focusing on agriculture, or one could focus on the relative weights of low- and high-tech industries or enterprises. Interestingly, this kind of approach to growth which has

[20] From this point of view, empirical evidence may seem more pertinent . See Clemens (2004), Lindert (2003) and Krueger and Lindahl (2001).

[21] For a more detailed analysis of the way in which the structure of the population by educational level changes with the level of development, see Thomas, Wang and Fan (2000).

been prominent in the 1970s, as a continuation of Kuznets research program on 'modern economic growth' and under the impulsion of Chenery and associates [22] is presently weakening. There are various reasons for this neglect, in particular for developed countries as will be seen below. Yet, it would be wrong to conclude from this relative lack of interest that sectoral shift phenomena have disappeared from the research agenda when analyzing the social effects of growth. Indeed, the whole recent literature on the skill bias in the sources of growth and, in particular, technical progress or international trade (see, for instance, the survey by Katz and Autor, 1999, and Baldwin and Cain, 2000) may be considered as an updated sectoral shift argument in the analysis of growth and its effects.[23]

Changes in female labor force participation may also be considered as a sectoral shift phenomenon. But it may also be considered as deriving from a change in behavior itself caused by economic growth. According to the sectoral shift logic, women would be moving from being 'inactive' or more exactly specialized in low-productivity domestic production to market employment at a higher level of productivity. According to the behavioral interpretation, the role of women would have been changing in a way concomitant with growth but under forces of a different nature. For instance, some authors see an explanation of the increased female labor force participation in most developed countries after WWII as resulting from the excess demand in the labor-market that developed during the war and that had to be filled, a phenomenon that produced a durable change in behavior. Others would insist that the drop of fertility partly due to the diffusion of contraceptive means in the last three decades or so was the reason behind women's increased labor force participation.[24]

---

[22] See Chenery et al. (1974) and Chenery and Syrquin (1975). For a more recent statement and a comparison with the contemporaneous growth literature, see also Syrquin (1994).

[23] It is true that much of that literature is concerned with changes in skilled/unskilled wage differential, an issue which we take up in the next subsection, but the basic argument—which goes back to Tinbergen (1975)—is that the evolution of technology which is behind economic growth requires more educated labor.

[24] The first hypothesis is critically reviewed by Goldin (1991). For the second, see for example Birdsall and Chester (1987), Asbell (1995), Goldin and Katz (2002).

The preceding phenomena may well provide a partial explanation for the fast increase in female labor force participation in the developed world over the last 60 years or so. However, regressions in table 1 reveal a rather strong association between participation and economic growth that is not due to cross-country differences, whereas both the fertility and the WWII argument would suggest that those cross-country differences should dominate. Pure cross-country regressions in the first columns of table 1 yield unsignificant results or wrongly signed coefficients when participation is specified as a linear function of GDP per capita. On the contrary, strongly significant results are obtained when within country time behavior of participation and GDP per capita is taken into account. The simple structural argument that increased female labor force participation may correspond to a shift from low to higher productivity occupations is not undermined by the data. Interestingly enough, the same difference between cross-country and within country estimates appears when participation is regressed on a quadratic form of GDP per capita. A U-shape relationship is obtained when not controlling for country fixed effects, whereas a monotonic relationship holds in the opposite case. [25]

For the sectoral shift effect of growth on social structures to be of relevance, it is necessary that it takes place between sectors or socio-economic groups with sufficient initial important differences in terms of welfare level. This is certainly the case for the shift across skill (or education) levels, between traditional agriculture and the modern sector of the economy in developing countries or between inactivity and market work for women. Things are less clear in the case of sectoral shifts in developed countries when markets function smoothly and tend to equalize returns of human capital across occupations or sectors. Most likely, this is the reason why this dimension is somewhat neglected in the recent growth literature in developed and emerging countries. The attention there tends to concentrate on differences in the evolution of returns to assets and in their accumulation rather than their sectoral allocation.

[25] On the U-shaped female labor force participation function see Durand (1975) or Goldin (1995). The decreasing part of the curve is explained by the decline in female unskilled employment opportunities due to the contraction of the agricultural sector, whereas the increasing part would be due to rising education. See, for instance, Clark, York and Anker (2003). In table 1, an inverted U-shape is obtained when controlling for fixed effects, but the top of the curve occurs at income levels much above what is observed in the sample.

The previous remark illustrates possible differences across countries that are hidden by the cross-country work that has been referred to. That differences do exist between developed and developing countries in terms of the social consequences of sectoral shifts of population due to growth is obvious. In table 1, these differences often are accounted for through the Cox transformation on the dependent variable. But other country differences might exist so that one would ideally like to estimate sectoral shift equations using national time series rather than a cross-section of countries. To some extent, this country specificity is what Chenery and his associates were after when they tried to identify 'patterns of development' among developing countries. Unfortunately, due to lack of adequate data, they most often had to rely on calibrated structural models rather than time series structural econometrics. The situation has changed little since then.

(b) Effect of Growth on Inequality between Socio-economic Groups

As mentioned above, the sectoral shift effect of economic growth is important to explain social structures inasmuch as it is accompanied by a persistent differential between socio-economic groups or sectors, in terms of current of permanent income or welfare level. At the same time, it may be envisaged that economic growth contributes to a deepening, or on the contrary, to a weakening of this social differentiation. In effect, those two evolutions are certainly not independent. Sectoral shifts need income differentials to develop and, in turn, they produce changes in these differentials. This subsection focuses on the potential effects of growth on earnings or income differentials across socio-economic groups. Given the dualism with the sectoral shift argument, we adopt the same presentation as in the previous subsection and consider in turn income differentials between sectors - essentially agriculture and the rest of the economy, between skills or educational levels, and between genders.

Sectoral Income Differentials

The regressions in table 1 illustrate the fact that sectoral productivity - and presumably income - differentials tend to diminish with economic growth. Thus, growth contributes to harmonize social structures across sectors. The process behind this is clear and has indeed very much to do with the sectoral shift process. As growth proceeds and high productivity activities arise, people tend to leave low-productivity occupations predominantly located in traditional agriculture. But, this migration process contributes to increasing productivity and income in the sector of origin - and possibly to lower income growth in the sector of destination. The 'dualism' of the economy, emphasized by early development economists, tends to diminish with growth. It eventually vanishes when the economy is more mature and market mechanisms ensure the equalization of productivity and earning rates across sectors.

At early stages of development, the preceding process is undoubtedly a powerful source of changes in social structures. At later stages, the emphasis on the agricultural sector is probably ill-placed. A comparison between informal and formal (non-agricultural) sectors would be more appropriate. If comparable data were available across countries on this formal/informal distinction, they would probably show a similar phenomenon, that is a narrowing of productivities and incomes across sectors as the informal sector loses weight. At some point, however, the issue becomes essentially that of the functioning of the labor market. The difficulty then is to identify whether earning differentials are due to some segmentation of the labor market or correspond to the self-selection of individuals across jobs with different characteristics and productivity levels.[26] Undoubtedly, these differences raise important social issues regarding the social status differential of workers linked to workers' social status. But they are of a nature different from the social transformations taking place at earlier stages of development, and it is not clear whether they may be unambiguously associated with growth.

Effect of Education on Earnings

[26] For references, see Ashenfelter and Card (1999). See also Card (1999) which reviews the methodological problems involved in estimating the causal effect of education on earnings.

In a competitive factor market environment, it was argued above that differences in productive asset bundles owned by individuals would be a better indicator of social differentiation than the sector of occupation. Education was thus seen as an important dimension of social differentiation. In this context, the sectoral shift analysis coincides with the change in the distribution of the population, or possibly the labor force, in terms of educational levels. It is now time to examine whether earning differentials across educational groups - often assimilated to skill groups - tend to change in a systematic fashion with economic growth.

There is a huge literature on earning differentials by educational or skill levels and their evolution over time. This is not the place to summarize it.[27] There is considerably less literature on comparing differentials across countries. To our knowledge, the main contributor in this area is Psacharopoulos who devoted very much effort to the collection of rates of return to education derived from the estimation of Mincerian earning equations based on labor force or household surveys around the world - see in particular Psacharopoulos (1994) and Psacharopoulos and Patrinos (2002). Putting together Psacharopoulos' findings and the lessons from country studies on the evolution of earning differentials leads to some interesting and somewhat paradoxical conclusion. Namely, cross-country comparisons suggest that there is a strong long-run tendency for earning differentials across educational levels to fall, whereas country studies show a very high level of medium-run variability without clear trend.

<Table 2 around here>

Table 2 shows mean earning differentials across schooling levels for country groups defined by GDP per capita. These groups cover a total of 98 developed and developing countries for which Mincerian earning equations were available during the period extending from 1970 to 1996, the most recent estimate being used (usually from the late 1980s or early 1990s). All individual earners are supposed to be covered by the data, whether they are wage earners or self-employed. The striking fact is that earning differentials tend to decline with the level of average income above primary, whether the differential is taken between secondary and primary, or between tertiary and secondary.

[27] See Katz and Autor (1999)

The last column of the table shows the average rate of return by year of schooling for the same data sets. They, also, fall with the level of GDP per capita.

This empirical regularity—which nevertheless hides very much variability across countries—is consistent with a simple competitive story of the labor market. As the accumulation of human capital proceeds, the return to skill tends to fall. If cross-country differences are taken to represent the effect of long-run growth, then the idea behind this story is essentially that the demand for skilled labor tends to grow at a slower pace than supply, thus reducing gaps between educational groups. Interestingly enough, however, time series analyses for countries where successive estimates of the Mincerian equation are available tell a different story. Restricting now the analysis to the average rate of return by year of schooling, it can be seen in figure 1 that practically all evolutions are possible over period extending from 8 to 23 years. Near constancy as in the case of Brazil to steady increase as in the US between 1976 and 1990, a phenomenon extensively studied in the literature, to steady decline as in the case of Netherlands, to erratic behavior as in Sweden.

<Figure 1 around here>

There are various reasons behind this paradoxical difference between cross-sectional and time series evidence. First, time variations in returns per year of schooling may have different origins depending on the level of development. They may originate more across primary and secondary in developing countries and more between secondary and tertiary or even within tertiary in developed countries.[28] This is because practically everyone has 8 years of schooling or more in developed countries, whereas most low-income and middle-income countries are far from that goal. Second, there may be problems of comparability of samples across countries at different levels of development. In particular, most earning equations are estimated on samples of urban workers. This group of workers represents a high percentage of the labor force in high-income countries, much less in others. Third, the period on which time series are observed may not be long enough to be fully consistent with cross-country differences in development levels.

[28] This is a natural consequence of the fact that schooling until middle secondary has been compulsory in developed countries for quite a long time.

Finally, there are reasons to expect some time specificity in the evolution of the rate of return to schooling and skill differentials in general. As alluded to before, they are related to Tinbergen's (1975) idea of the race between technology and education driving the evolution of skill differentials in earnings. For more or less continuous progress achieved on the educational side, it is sufficient to imagine fluctuations or trends in a definite direction in skill-biased technical progress - or possibly in trade policies - to generate time series behavior of the type shown in figure 1. Alternatively, one may also think of technical progress and its diffusion in the economy following a continuous – not necessarily linear – trend and the educational response intervening with a different time profile to generate various patterns in the evolution of the rate of return to schooling.[29]

For all preceding reasons, it is not contradictory to infer from existing evidence that, indeed, a narrowing of skill differentials and a fall in the rate of return to education is accompanying growth in the long-run, at least in the early stages of development. At the same time, however, this trend may be hidden for long or short periods by accelerations of skill-biased technical progress, major changes in the international trade environment of a country, and velocity of the supply response to changes in skill differentials.

Gender Earnings Differentials

The examination of evidence on gender gaps in individual earnings leads to conclusions opposite to the preceding ones. There, one observes a rather clear downward trend in most countries, although information is scarce for developing countries. By contrast, cross-country comparison points to no systematic differences between countries ranked by development level.

There are relatively few cross-country comparisons of male-female earnings differentials in the literature except for developed countries. Terell (1992) collected estimates on

[29] See for instance Aghion (2002). See also the chapter by Jorgenson in this volume.

male-female earning differentials from the ILO Yearbook of Labour Statistics. She found very much cross-country variability, and more importantly as much variability within low and middle-income countries as within high-income countries. For instance the female-male earnings ratio varied from .60 to .85 in developed countries, and from .50 to .90 in developing countries. Of course, the problem is that the samples on which these ratios are evaluated, typically salaried urban workers, differ quite substantially across countries. Thus, the comparison may be of little relevance between a country where 80% of both men and women are in that group and countries where only 20% of men and still a lower proportion of women qualify. This is what explains the paucity of cross-country comparisons encompassing the whole world. Better comparisons can be performed using indirect indicators of earnings. For instance, the regression on male-female difference in literacy rates in table 1 shows a steady decline with the development level both across-countries and across 10-year periods. However, literacy or schooling differences is only one among many determinants of earnings differences. Not much is known about gender differences in these other dimensions, nor about their impact on earnings differentials. [30]

In contrast to cross-country, time series of female-male earning ratios available in developed countries show an unambiguous increase over the last few decades. In the US, for instance, this ratio increased from .56 to .72 between the late 1960s and the late 1990s - see Welch (2000). Comparable increases are observed in European countries .[31] Only a few data points are available for middle-income countries but they reflect a parallel evolution. Between the early 1980s and the mid 1990s, the female-male ratio among wage earners increased from .74 to .80 in Taiwan, from .62 to .72 in Colombia, and from .52 to .61 in Brazil.[32]

[30] The life expectancy regression in table 1 also shows an evolution that seems relatively more favorable to women along the growth process in pure cross-section. Yet, the sign of the coefficient is reversed when fixed effects are taken into account and the coefficient is unsignificant in decadal differences.. More detailed characteristics are analyzed in the World Bank (2001).
[31] For a thorough and exhaustive discussion of these issues, see for instance Gunderson (1989).
[32] The latter figures are taken from Bourguignon, Ferreira and Lustig (2004)

The problem is to know whether such an evolution should be related to economic growth or not. This requires distinguishing between two sources of change in female-male earnings ratios, one associated with the differential evolution of the characteristics of female and male workers, and the other with changes in the remuneration of these characteristics - i.e. the well-known Oaxaca-Blinder decomposition. In effect, it so happened that the increase in female wage employment concomitant with the previous evolution contributed overall to a lowering of the average skill of employed women in many instances, an effect contributing to a widening rather than a narrowing of the gap. Thus, the observed narrowing must prominently be due to changes in remunerations rather than in the differential characteristics of male and female workers.

The issue then arises of the source of changes in remunerations. Are they related to specific observed characteristics or more diffuse in the whole labor force? In the latter case, it would then be tempting to associate the decline in the female-male ratio to non-economic phenomena like the evolution of social norms about gender differences, to regulation in the labor markets - minimum wage for instance - or, in some countries, to some kind of affirmative action policies. All these phenomena probably bear some responsibility for the narrowing of the male-female gap, but there also is indirect evidence that it may be due to a change in the remuneration rate of some specific characteristics that distinguishes male and female work. This indirect evidence is the positive correlation that has been noted between the female-male earnings ratio and the degree of inequality of male earnings, both in time series -see Blau and Kahn (1997) and Welch (2000) - and in a cross-section of developed countries - see Blau and Kahn (2003). A possible interpretation of that correlation is that changes in male earnings inequality reflect changes in the remuneration rate of earnings determinant, the relative intensity of which happens to differ much between male and female labor. As observed worker characteristics like education or experience do not appear to have played this role, this explanation must rely on unobserved earnings determinants. For instance, Welch (2000) refers to "brains relative to brawn", with the idea that the relative remuneration of brains in the labor market increases with technical progress, and in effect with economic growth, whereas woman labor is typically more intensive in that factor.

Such an interpretation of the narrowing female-male earnings gap in high-income - and possibly some middle-income countries - is attractive. Yet, it remains to be tested more carefully, an uneasy task given that this hypothesis is essentially based on unobserved labor characteristics. At this stage, it is thus difficult to conclude whether it is indeed economic growth that so strongly influences this fundamental dimension of social differentiation. At the same time, it is worth stressing that the preceding issues probably arise only beyond some development level where the labor market is sufficiently unified and competitive. The thinness of the modern labor market and the low weight of women in that market may explain why low income countries are not really comparable to others in terms of gender earnings differentials.

(c) Effects of Growth on Inequality among Individuals

The preceding subsections looked into the effect of growth on the structure of the population by sector of activity and by socio-economic groups defined by some observed characteristics, and on income differentials between them. It is now time to consider the possible effect of growth on the overall distribution of income among all individuals in the population. Such a perspective goes beyond the preceding points of view in that it adds to the analysis the possible effect of growth on unobserved individual characteristics through changes in disparities within socio-economic groups. The analysis will proceed in three steps. First, the observed statistical relationship between development levels and income inequality is briefly discussed for a sample of countries and periods where comparable data are available. Second, a more structural approach is discussed where additional variables representing in some way the socio-economic group structure of the population are introduced. Finally, semi-structural studies of the evolution of the distribution in selected countries are discussed. Interestingly enough, the conclusions obtained about the effect of growth on inequality varies rather radically from one approach to another.

Correlation between Growth and Inequality: Rise and Fall of the Kuznets Curve

As illustrated in the bottom table 1 above, the cross-country evidence on the distributional effects of growth is essentially inconclusive. It is true that a cross-section of countries taken in the 1970s suggests a parabolic relationship that seems in agreement with Kuznets' hypothesis. But cross-sections taken at a later date, and presumably with better data, fail to yield statistically significant results. More importantly, when controlling for country fixed effects so as to isolate the average consequences of within country growth on distribution, no statistically significant effect can be identified either.

The preceding results fit well the existing literature on the distributional consequences of growth and the Kuznets curve. Back in the 1970s and in the early 1980s, several papers provided pure cross-sectional estimates of the distributional consequences of growth that seemed in agreement with Kuznets' hypothesis, with very much emphasis on the estimation of the turning point at which further growth would cause inequality to go down rather than up – see in particular Paukert (1971), Ahluwalia (1974, 1976a and b), Lecaillon et al. (1979). This early literature was very much criticized for its lack of econometric rigor and the quality of the data being used - see in particular Anand and Kanbur (1991). When better and more complete data became available, it indeed turned out that the parabolic shape of the relationship between income and inequality was a feature of the 1970s. This feature vanished with the data available in subsequent periods, whereas the first attempts at controlling for country fixed effects confirmed that the findings based on the observations of the 1970s were not robust – see Anand and Kanbur (1993), Fields and Jakubson (1993) and Deiniger and Squire (1998), probably the most data-comprehensive analysis available although it relies on secondary data sources.

The interest in the Kuznets hypothesis has not completely vanished today and this hypothesis is frequently revisited in the light of new data and estimation techniques. But the cottage industry that developed around trying to confirm or reject this hypothesis is in

decline.[33] At this stage, it seems fair to say that a consensus has emerged according to which available data *do not suggest any strong and systematic relationship* between inequality and the level of development of an economy. Even those authors who identified a significant relationship agree that it is weak and explains little of the observed differences in inequality.[34]

As in the preceding sections, it may be worth exploring how time series compare to cross-country differences in terms of the correlation between income inequality and development levels. Indeed, considerable attention has been given lately to the evolution of inequality and to the question of whether there was a systematic tendency for modern growth to generate more inequality, as observed in a few countries during the 1980s. This literature is mostly concerned with developed countries because of data availability, even though time series of distribution data in those countries are not always consistent - see Atkinson and Brandolini (2001). The common conclusion of most existing analyses is that inequality has substantially increased in a number of countries between the mid 1980s and the mid 1990s - 12 out of the 17 countries analyzed by Gottschalk and Smeeding (2000). Yet, this evolution must be contrasted with the fact that inequality had been declining in almost all developed countries throughout the 1960s and the 1970s, so that inequality in many countries today is comparable to what it was 30 years ago. It is also worth stressing that inequality failed to increase in a few countries, most likely thanks to very efficient -and possibly increasingly so - redistribution. Time series in developed countries thus seem to confirm the evidence based on cross-country analysis,

[33] No reference has been made here to the historical literature on the Kuznets curve. It generally points to sizable changes in some particular inequality measures over long periods of time, which sometimes conform with Kuznets' own finding. Yet, the problem is that it relies on very rough measures of inequality – see below p. 46.

[34] See for instance the conclusion reached by Barro (2000) and his reference to Papanek and Kyn (1986) for a similar statement. No mention has been made here of the few studies focusing on the effect of the rate of growth, rather than the level of economic development on inequality. Lundberg and Squire (2003) and Banerjee and Duflo (2003) find that faster economic growth tends to be associated with increasing inequality, but here again the effect is extremely small. Note finally that, after raising the same hopes as the Kuznets hypothesis in the 1970s and 1980s, the recent literature on the reverse causation, seems also to converge to the conclusion of no 'systematic' effect of inequality on growth. This was pointed out by Benabou (1996) and has been confirmed since then by contradictory results obtained with different specifications and samples - see Banerjee and Duflo (2003) .

namely that there is no significant long-run trend, related to the growth process or not, affecting the degree of within-country inequality.

Although data are still more shaky, the same conclusion seems to hold for middle- and low-income countries. Cornia (2001) and Cornia, Addison and Kiiski (2004) find that, out of 34 developing countries for which they have several observations between the 1950s and the mid 1990s, inequality is higher in the terminal period for 15 of them, equal for 14 and lower for 5. Yet, little is said about the intermediate years. When data are available, a U-shape evolution is observed in a number of cases where inequality is found to be increasing when comparing the terminal and the initial years. Overall, clear ascending or descending trends over long periods of time thus are infrequently observed.

Dealing with the effect of growth on social structures, one might prefer to use the concept of poverty, which may have a firmer social connotation than inequality. With this concept, a dimension of social structures is simply the poor-non-poor difference, that is the proportion of people living in poverty and the distance at which those people find themselves from the poverty line and from the average income of the non-poor. Of course, if income is taken as the only dimension of welfare, poverty and inequality are rather equivalent concepts when poverty is defined in relative terms, as for instance the proportion of people living with less than 50% of the median income. Poverty, then, becomes a particular inequality measure and much of the preceding argument presumably applies to poverty as well as inequality. Things are different when poverty is defined in absolute terms, as with the widely used international poverty line of $1 a day or any national poverty line representing the minimum budget deemed necessary for survival. Growth then plays a direct role to explain the evolution of poverty. In particular, if the distribution of relative incomes remains constant over time, then changes in poverty essentially reflect uniform income growth in the population. On the contrary, when distribution changes over time, economic growth may play a more complex role depending on its actual effects on distribution.[35] That cross-country analysis fails to find

[35] On the identity that relates income distribution, poverty and growth see Fields (2001), Ravallion and Datt (2002) or Bourguignon (2003).

any systematic relationship between distribution and growth suggests indeed that growth has the simpler and more direct impact on poverty that was just mentioned. This is essentially the argument that led Dollar and Kraay (2002) to conclude that 'growth is good for the poor'. However, it will be seen below that this conclusion may hide considerable disparities across countries.

Towards structural estimates of the effects of growth on distribution ?

By focusing on the correlation between inequality and development levels, both in cross-section and time series, the preceding section does not do justice to existing work. Most empirical models that may be found in the literature actually comprise additional variables that may explain the evolution of inequality alongside with, or independently from growth. For instance, the regressions in the pioneer paper by Alhuwalia (1976b) had the income share of various quantiles on the left-hand side and a host of variables on the right-hand side, together with GDP per capita and its square. These variables included the GDP share of agriculture, some educational indicators and some fertility indicators. Thus, the effect of the development level of inequality was supposed to come on top of the effects of sectoral shifts, and associated changes in relative factor rewards. In terms of the analysis in this chapter, the implicit objective of such a specification is somewhat unclear. The distribution between socio-economic groups implicitly defined by variables like the GDP share of agriculture or the degree of urbanization and its impact on overall inequality is taken care of precisely by the presence of these variables in the regression. Under these conditions, the purpose of keeping GDP per capita among the regressors could only have been to identify the effect of economic growth on the distribution of income *within* those groups, a rather restrictive objective. Retrospectively, the economic framework behind those regressions thus appears as essentially ad hoc, between the reduced form model implicit in the regressions in table 1 and a true structural model identifying the channels through which growth may indeed affect the distribution. Unfortunately, this imprecision of the economic framework behind the regressions being estimated is rather frequent in the empirical literature on inequality and development.

Using structural forms in cross-country regressions is possible, but probably requires gathering the appropriate data. In Bourguignon and Morrisson (1990, 1998), for instance, the objective is to explain cross-country differences in distribution explicitly through a model resembling (2) above but with a larger number of assets. Agent ”'s income is thus taken to be given by :

$$y_i = \sum_j a_{ij} w_j F_j$$

where a_{ij} is the share of factor j owned by agent i, the total endowment of factor j is given by F_j, and w_j is its remuneration rate. Endogenizing the latter within the framework of a small open economy, it is then possible to write the overall distribution of income $\{y\}$ as:

$$\{y\} = H\left[\{a_{.j}\}, F_{.}, p, t\right] \qquad (8)$$

where the arguments of the function $H(\,)$ are the distribution of resources in the population, $\{a_{.j}\}$, the vector of total endowments, $F_{.}$, the vector of international prices faced by the economy, p, and the tax rates and tariffs that it imposes, t. Then, one may try to proxy for these various arguments by aggregate data available on a comparable basis across countries and use the resulting empirical model to analyze the effects of economic growth on the distribution.

The two papers referenced above stop short of the latter objective, mostly because of the difficulty of identifying all the variables necessary for the analysis and the necessity of using very imperfect proxies, which prevent proceeding with a truly structural analysis. For instance, physical capital per worker is approximated by GDP per capita. This is not unjustified for a given value of other aggregate endowments of productive factors, but this makes it impossible to distinguish the distributional effects of capital accumulation and of total factor productivity. Even so, however, the analysis shed light on the effects of the ownership distribution variables - land, human capital - on the distribution of income at one point of time, as well as on the impact of relative aggregate endowments (land,

physical and human capital and raw labor) and policy variables like trade protection. In line with the argument in the previous sections, it also showed the importance of labor market competitive imperfection, and in particular the 'dualism' of the economy as represented by the relative productivities of the agricultural and non-agricultural sectors.

Going beyond these partial results and analyzing the potential effects of growth in the distribution of income within the framework of (8) is still on the agenda. Better data are necessary. As rough as existing empirical applications may be, however, this analysis suggests that the distributional effects of growth are complex and most likely to be strongly differentiated across countries. With the preceding specification and in view of the results obtained, it appears clearly that growth affects the distribution through various channels - changes in relative factor endowments, changes in the distribution of these factors, changes in policies, changes in the functioning of factor markets – and in a way that may depend on the initial value of these various macro-economic characteristics.

Case Study Analysis

Should one then conclude with Dollar and Kraay (2002) that growth is distributionally neutral and therefore that 'growth is good for the poor', whatever the engine behind it? The preceding argument suggests that it would be going too far. What the important literature on the effect of growth on inequality shows is essentially that there is apparently no significant relationship that would be valid across countries and time periods. It certainly does not say that this is true for specific countries during a particular period. In effect, sizable changes have been observed in several countries in the recent past, the causes of which are not always readily apparent but which are not necessarily independent from economic growth and some of its features.[36] In effect, most case studies on the evolution of inequality over time single out characteristics of the growth process or of policies behind it that are responsible for specific distributional changes.

[36] See for instance Atkinson and Brandolini (2002) for developed countries and Ravallion and Chen (1997) for developing countries.

The debate that took place recently on whether recent increases in earnings inequality in various developed countries were due to technical progress and the consequent shift of developed economies towards high-tech is a good example of such an approach.

An important stream of case studies on the distributional consequences of growth is found in the historical literature. Following the example of Kuznets himself, numerous economic historians tried to identify the trend in some inequality measure over long periods of time. Findings often conform with the Kuznets curve hypothesis. Yet, a common problem is that very much of that literature relies on very rough measures of inequality often based on a few macro-economic characteristics and ignores important sources of micro-economic heterogeneity. Because of this, it tends to over-emphasize the role of phenomena like urbanization or the shift away from self-employment, that is sectoral shift phenomena. A survey of findings is offered by Lindert (2000) and Morrisson (2000).

Identifying empirically the forces through which economic growth may shape the distribution of income in actual growth experiences is a difficult task because it requires correcting the observed evolution of the distribution for sources of change unrelated or very loosely related to growth. An exercise of this type was undertaken in a series of case studies that explore the microeconomics of income distribution dynamics (MIDD) in a small number of middle-income countries.[37] The following example illustrates the difficulty of empirically isolating the distributional effects of growth and shows at the same time the major potential role that growth plays in distributional issues.

The methodology used in the MIDD study consists in decomposing the observed change in the distribution of earnings or per capita income into three types of effects, which parallel the general argument in this chapter. The first type corresponds to changes in the structure of earnings for given socio-demographic characteristics of individuals, and possibly by labor market segment if the labor market is imperfectly competitive. The second set of effects corresponds to a change in the labor supply of individuals or

[37] Bourguignon, Ferreira and Lustig (2004)

household members, and possibly their allocation across labor market segments. The final set of effects includes those occurring due to a change in the distribution of socio-demographic characteristics of individuals and households. In terms of the analysis in this chapter, the second and third type of effects would, in some sense, correspond to the shift of people across socio-demographic groups, whereas the first one would correspond to changes in income differentials across these groups, a residual term actually included in the third effect, accounting for changes in the distribution within groups. Each effect is estimated by simply importing in the initial year the features of the final year in one of the various dimensions just indicated, or vice-versa. Thus, the effect of the structure of earnings is obtained by simulating what would be the distribution of income in year *1* if the structure of earnings by socio-demographic characteristics (gender, education, region, etc) had been the one observed in year *2*. The 'fertility effect' is obtained by importing in the initial year the same relationship between family size and parents' characteristics (education, age, race, region, etc) as the one observed in the terminal year, etc… [38]

This methodology has been applied, among other countries, to Brazil during the period 1976-1996.[39] What is remarkable during that period in Brazil is that neither the mean income – or GDP per capita – of the Brazilian population nor inequality changed much, even though most usual aggregate inequality measures show a moderate decline. From this direct observation, one might then conclude that very slow growth was associated in Brazil with virtually no change in the distribution of earnings or income. This would be erroneous, however. What happened is that other phenomena compensated for the distributional effects of slow growth. The decomposition methodology presented above led to 3 points. a) Over the period under analysis, family size went down significantly and more so among people with low education and income. Because of this factor, inequality in Brazil should have substantially declined. b) The structure of earnings changed moderately against least-skilled and self-employed workers. c) It also turned out that the occupational structure of the population was modified. Employment in general, and employment in the formal sector in particular, had gone down, hitting more severely

[38] This methodology is explained in detail in chapter 2 of Bourguignon Ferreira and Lustig (2004). See also Bourguignon, Fournier and Gurgand (2001).
[39] See Ferreira and Paes de Barros (1999, 2004).

the segments of the population with the lowest education levels and at ages where access to the labor market is the least easy – young and old people. Overall, however, these various changes tended to compensate each other.

Although the methodology described above does not include any formal representation of the labor market and the way it may be affected by growth, it is difficult not to relate points b) and c) to the sluggish growth performance of Brazil during the two decades under analysis. Within a dual economy framework, which seems to fit well the Brazilian economy, the general story would thus be as follows. Slow growth was responsible for a weak labor market, which may have caused an increasing skill differential in the earnings of wage workers and self-employed, as well as job losses or worker discouragement among the least skilled. Both phenomena, but mostly the latter, actually contributed to an increase in inequality. The reason why this inequality increase did not actually show up is that it was compensated by falling family sizes which were more pronounced at the bottom of the distribution - and to a lesser extent progress in the education level of the poorest. Slow growth in Brazil might thus have been responsible for increased inequality after all.

This example shows that identifying the actual effects of economic growth on the social structure of a population may require more than simply observing the changes in that structure and the rate of growth during a given time period. Some of the observed change in social structures may indeed be directly imputed to what is happening on the economic growth front, but may also be due to other concomitant phenomena which are independent of growth or very indirectly related to it. With this example in mind, one may then understand perfectly that the phenomena put forward by economic theory to explain how economic growth is likely to affect social structures may be difficult to observe in actual growth episodes. This is because parallel phenomena, not directly related to growth - but not necessarily independent from it either - affect the distribution and introduce some noise in the observation, this being true both in cross-sectional and time series analyses.

The important point here is that the channels identified by theory may well prove empirically relevant when the necessary correction of available data for other non-neutral distributional phenomena has been made. Of course, the difficulty is to know whether these phenomena are themselves growth dependent or not. In the preceding case, did the change in fertility take place in an autonomous way, or was it the result of economic growth per se, or possibly the result of an educational improvement which itself could have been autonomous or the result from growth? It is this kind of structural model that must be confronted with the data, rather than the very reduced form models behind cross-sectional work or simple comparisons of changes in inequality and income per capita measures. This is a much more difficult exercise, which has barely begun.[40]

4. CONCLUSIONS

Some strong conclusions emerge from our review of the literature on the consequences of economic growth for social structures. They may be summarized as follows.

(a) The Foremost Importance of Sectoral Shift Phenomena

If we take a historical or a cross-country perspective, it is clear that the major consequences of economic growth for social structures go through sectoral shifts of the population, and possibly, at a later stage, through shifts across more narrowly defined socio-economic groups. The shift from traditional agriculture to modern agriculture or non-agricultural activities in the urban sector is at the heart of the social and cultural history of most industrialized countries. It is still today at the heart of the social evolution in countries that are 'emerging' as well as in those at a much earlier stage of development. The sectoral shift is also present in so-called advanced countries that have started their journey towards the 'post-industrialization' stage where most activity will increasingly be directly or indirectly linked to services of various types rather than manufacturing.

[40] Steps in that direction have been taken in the recent 'micro-macro' literature. See in particular Browning, Hansen and Heckman (1999), Bourguignon and Pereira da Silva (2003, introduction), Heckman, Lochner and Taber (1998), Townsend and Uema (2001)

Transforming factory workers into administrative employees involves major changes in social structure, just like transforming small farmers into industrial workers.

Other important shifts take place throughout the growth process, the most powerful ones from a social point of view being the drive towards education and a skilled labor force and a fuller integration of women into market activities.

(b) The Role of Market Integration

It was observed historically that economic development proceeds together with a 'marketisation' of societies. Markets develop by covering an increasing share of all transactions. The most significant difference between sectoral shifts observed in industrialized countries on the one hand and in low- or lower-middle income countries on the other is not only the nature of the sectors involved but also the degree of market integration of society. Sectoral shifts at early stages of economic growth take place within markets that are functioning very imperfectly. Because of this, they have a strong impact on society, radically changing relative income levels and income-related behaviors. At later stages of development, markets function better and sectoral shifts take place in a smoother manner. At the limit, some sectors may lose weight in favor of others with only small changes taking place in the structure of earnings and in the social features associated with it. With such a market integration, the real issue is the speed of adjustment to growth, i.e., whether the structure of the demand for productive factors changes faster than the supply of these factors, modifying in one direction or another the structure of remunerations of these factors. Thus, economic growth in a market integrated economy has social consequences different from less integrated economies. In the former case, economic growth may take place in a somewhat 'balanced' way without any marked impact upon social structures and, in particular, on the distribution of well-being within the population. This is what is implicitly assumed in many contemporaneous models.

(c) Social Costs of Transitory Adjustment

In reality, such balanced growth paths are unlikely to be observed. In presence of any permanent shock in technology or in policy, adjustment lags in either the demand or the supply side of factor markets produce tensions with possibly durable social effects. Case studies of both developing and developed countries reveal the presence of such tensions. Unemployment problems in some European countries or the rise in earnings inequality in the US during the 1980s and 1990s are sometimes seen as symptoms of such tensions. Even though these disequilibria may be expected to be transitory, they may have powerful and long-lived social consequences, potentially able to affect future economic growth. A fortiori, this conclusion holds true when markets mechanisms are working imperfectly.

Some other dimensions of social structures have been examined in this chapter that fit these conclusions or may be direct consequences of them. This is the case in particular of the economic role of women and male-female economic and social differences. Sectoral shifts explain the changing roles of men and women, whereas the move towards market integrated economies may be the cause of increased female labor force participation, as well as of decreasing male-female differences both in the economic and the social spheres.

These are important conclusions. Yet, as indicated at the beginning of this chapter, this is only part of the whole story. Two other parts are missing. The first is the second half the circle that links economic growth and social structures. By choice, this chapter has focused on the social consequences of growth, but the effect of changes in social structures on the pace and structure of economic growth is equally important—as shown in various chapters of this Handbook. The second missing part has to do with the effect of changes in social structures on social institutions themselves, and on social relations. This is briefly discussed in closing this chapter.

(d) Effect of Growth on Social Structures through Social Institutions

In addition to the changes in social structures resulting directly from economic growth, the general way in which individuals relate with each other is also likely to be modified under the effect of growth. For instance, a more affluent population may have more time and interest for collective tasks and for political participation, thus modifying the nature of the public decision-making process. As another example, a higher standard of living may induce a higher risk aversion and therefore a demand for more social insurance. We conclude this chapter by focusing on two examples of how social relations are likely to be modified under the effect of economic growth, with the social structure effect analyzed above often playing an intermediate role in that evolution.

The first example has to do with the size of the public sector. It is the well-known "law of expanding state activities" formulated in 1883, in the midst of a period of rapid industrialization and social change, by Adolf Wagner (Wagner 1883, Cameron 1978). Several explanations have been proposed to explain this law, some of them directly linked to growth and some others indirectly, through the channels of increasing education and political participation.[41] Theories of the direct link between economic growth and government size emphasize the income elasticity of the demand for certain types of public goods, such as roads or education, or for the correction of negative public externalities due to growth, such as pollution or congestion. Theories of the indirect link insist on the redistribution role of government and the way in which growth may affect the factors that determine that role. For instance, in the classic Meltzer and Richard (1981) paper, the growth of government is explained by the combination of the expansion of universal suffrage and initial inequality in the distribution of income. Then the drive towards democracy is explained by the effect of economic growth on political participation either through a direct income effect [42], or through an indirect one as in the political economy models proposed for instance by Justman and Gradstein (1999) or

[41] These different theories regarding the size of government are reviewed by Lybeck and Henrekson (1988), who focus on empirical tests of these theories, and Mueller (2003).

[42] See for instance Frey (1971, 1972), Huntington and Nelson (1976), Gradstein and Justman (1995).

Acemoglu and Robinson (2000). A second channel is education brought about by, or coming together with growth.[43]

It is difficult to test for the relationship between economic growth and government size while taking into account the various channels mentioned above. In a cross-country reduced form framework, however, it is interesting that the relationship is a rather weak one, especially when one controls for fixed county effects – see table 1.[44]

As a second, and not unrelated example, consider the demand for social insurance. As for Wagner's law, there are direct and indirect effects of growth on social insurance and family structures. Direct effects may go through risk aversion or idiosyncratic risks themselves increasing with the income level, or through richer societies being able to afford the fixed costs of social insurance "technology" (related to monitoring of income, contribution collection, management and information systems and other organisational costs of social insurance).[45] An indirect effect of growth on social insurance is via urbanization and the consequent phasing out of high fertility and extended household arrangements throughout societies. This creates a demand for a substitute to the insurance provided by the extended family system in poorer societies.

These two examples about the way social institutions may be affected directly or indirectly by economic growth show the power of economic growth and its determinants to transform the social functioning of societies and not only their economic characteristics. Of course, these changes in the way individuals relate to each other, the way they make public decisions and the nature of these decisions come on top of all other effects of growth. These include changes in consumption behavior caused by increasing income and technical progress as well as the changes in social structures analyzed throughout this chapter. More than in the latter cases, however, changes in social

[43] See the sociological literature on political participation, for instance Brady, Verba and Shlozman (1995). See also the formal analysis of the link between democracy, education and growth in Bourguignon and Verdier (1999).

[44] Some authors also postulate an inverted U-curve relationship between government size and income level. See Grossman (1987, 1988) and Peden (1991).

[45] As in the modeling of financial development in Saint-Paul (1992) or Tressel (2003).

institutions are affected by a host of non-economic phenomena that make it difficult to identify and isolate the role of economic growth. Economic determinism might be dangerous here. In-depth case studies combining the whole range of social sciences would seem the appropriate way of approaching this issue.

1 Introduction

The relationship between economic growth and the environment is, and may always remain, controversial. Some see the emergence of new pollution problems, the lack of success in dealing with global warming and the still rising population in the Third World as proof positive that humans are a short-sighted and rapacious species. Others however see the glass as half full. They note the tremendous progress made in providing urban sanitation, improvements in air quality in major cities and marvel at the continuing improvements in the human condition made possible by technological advance. The first group focuses on the remaining and often serious environmental problems of the day; the second on the long, but sometimes erratic, history of improvement in living standards.

These views are not necessarily inconsistent and growth theory offers us the tools needed to explore the link between environmental problems of today and the likelihood of their improvement tomorrow. It allows us to clarify these conflicting views by use of theory, and when differences still remain, to create useful empirical tests that quantify relative magnitudes.

For many years, the limited natural resource base of the planet was viewed as *the* source of limits to growth. This was, for example the focus of the original and subsequent "Limits to Growth" monograph and the efforts by economists refuting its conclusions.[1] Recently however it has become clear that limits to growth may not only arise from nature's finite source of raw materials, but instead from nature's limited ability to act as a sink for human wastes. It is perhaps natural to think first of the environment as a source of raw materials, oil and valuable minerals. This interpretation of nature's service to mankind led to a large and still growing theoretical literature on the limits to growth created by natural resource scarcity. Empirically it led to studies of the drag limited natural resources may have on growth, and a related examination of long run trends in resource prices.[2]

Nature's other role - its role as a sink for unwanted by-products of economic activity - has typically been given less attention. As a sink, nature dissipates harmful air, water and solid pollutants, is the final resting

[1] See Nordhaus (1992) for the latest refutation.
[2] For work on resource price trends see most importantly Barnett and Morse (1963) and Slade (1982).

place for millions of tons of garbage, and is the unfortunate repository for many toxic chemicals. When the environment's ability to dissipate or absorb wastes is exceeded, environmental quality falls and the policy response to this reduction in quality may in turn limit growth. Growth may be limited because reductions in environmental quality call forth more intensive clean up or abatement efforts that lower the return to investment, or more apocalyptically, growth may be limited when humans do such damage to the ecosystem that it deteriorates beyond repair and settles on a new lower, less productive steady state.[3]

This link between growth and the environment has of course received much more attention recently because of the rapidly expanding empirical literature on the relationship between per capita income and pollution. This literature, known as the Environmental Kuznets Curve (EKC) literature, has been enormously influential. So to a certain extent, the tables have now turned: there is far less concern over the ultimate exhaustion of oil or magnesium, and far more concern over air quality, global warming, and the emissions of industrial production.

The economics literature examining the link between growth and the environment is huge; it covers, in principle, much of the theory of natural resource extraction, a significant body of theory in the 1960s and 1970s on resource depletion and growth; a large literature in the 1990s investigating the implications of endogenous growth theories; and a new and still growing literature created in the last decade examining the relationship between pollution and national income levels. Every review has to make difficult choices about exclusion and we make ours on the basis of novelty. There are excellent book length treatments on the depletion of renewable and non-renewable resources, and several reviews of endogenous growth theory's contributions already exist.[4] This leaves us to focus on the relatively new theoretical literature linking environmental quality to income levels. For the most part, we discuss the link between industrial pollution and growth, but also show how this most recent work is related to earlier contributions on exhaustible resources and growth.

While no review can settle the perennial debate over the limits to growth, this review hopes to play a positive role in moving the literature forward by identifying important unresolved theoretical questions, reporting on the results of recent empirical work, and providing an integrative assessment of where we stand today.[5] To do so, we focus on three questions. These are: (1) what is the relationship between economic growth and the environment?; (2) how can we escape the limits to growth imposed by environmental constraints?; and (3), where should future research focus its efforts?

To answer these questions we start by introducing definitions and providing a preliminary result linking the environment and growth. We define the scale, composition and technique effects of growth on the environment, and then use these definitions to prove a useful but negative result on the limits to growth. We show that changes in the composition of national output – as occur when the economy specializes in relatively less pollution intensive services or relatively less natural intensive industries- can at best delay the impact of binding environmental constraints. In the long run, emission intensities must fall towards zero if growth is to be sustainable.

In many models this constraint is met through the substitution of clean inputs for dirty ones, in others via increased abatement, and in still others through some combination of technological progress and the other channels. This result is helpful to us because it allows us to distinguish between empirical regularities that are consistent with a short run growth and environment relationship (along a transition path) from those consistent with the long run relationship (along a balanced growth path). It also helps us sort through the literature by focusing on how a given model can generate what we take as our definition of sustainable

[3] This branch of the literature relies on case study evidence of irreversible damage created in the past and argues that our now greater technological capabilities may portend even worse outcomes in the future. For a primarily theoretical discussion of irreversibilities and hysteresis caused by nonlinearities see the symposium edited by Dasgupta and Maler (2003). For related nonlinear theory see Dechert (2001). For case study evidence from prehistory see Brander et al. (1998).

[4] See the classic book length treatments of renewable and nonrenewable resources by Clark (1990), and Dasgupta and Heal (1979). A good introduction to the relationship between endogenous growth theory and the environment is contained in the review by Smulders (1999).

[5] Whether there are serious limits to growth is an unending controversy that reached its peak with the publication of the Limits to Growth by Meadows et al. in 1972. See the subsequent contributions by Solow (1973) followed by Meadows et al. (1991) and then Nordhaus (1992).

growth: a balanced growth path with increasing environmental quality and ongoing growth in income per capita.[6]

With our definitions and result in hand we then turn to present some stylized facts on the environment and growth. These facts concern the trend and level of various pollutants, and measures of the cost of pollution control. In many cases, the data underlying the construction of these facts is of limited quality; the time periods are sometimes insufficiently long to draw strong conclusions and the relevant magnitudes imprecise relative to their constructs in theory. Nonetheless, they are the best data we have.

Overall these data tell three stories. The first is that by many measures the environment is improving at least in developed countries. The level of emissions for regulated pollutants is falling, and the quality of air in cities is rising. The U.S. and other advanced industrial countries have seen secular improvements in the quality of their environments over the last 30 years. To a large extent cities are cleaner than in the past, emissions of health-threatening toxics are reduced, and in some cases the changes in environmental quality are quite dramatic.

The second feature of the data is that pollution control measures have been both relatively successful and relatively cheap. While there are severe difficulties in measuring the full cost of environmental compliance most methods find costs of at most 1-2% of GDP for the U.S. Comparable figures from OECD countries support this finding.[7]

The last feature of the data is that there is a tendency for the environment to at first worsen at low levels of income but then improve at higher incomes. This is the so-called Environmental Kuznets Curve. We first present raw emission data drawn from the U.S. and then briefly review the empirical literature on the Environmental Kuznets's Curve that relies on cross-country comparisons. The raw data from the US are unequivocal, while the cross-country empirical results are far less clear but generally supportive of the finding.

Having reviewed the relevant data and set out definitions we turn to a review of the theory. To do so, we develop a series of 4 simple growth and environment models. The models serve as a vehicle to introduce related theoretical work. For the most part we focus on balanced growth path predictions and eschew formal optimization taking as exogenous savings or depletion rates and sometimes investments in abatement. We do so because in many cases, these rates must be constant along any balanced growth path and hence we identify a set of feasible conditions for sustainable growth. Moreover the resulting simplicity of the models allows us to identify key features of fully developed research contributions already present in the literature. In some cases, the choice of abatement or savings matters critically to the point we are making and hence in those cases we provide optimal rules.

The 4 models were developed to highlight the different ways we can meet environmental constraints in the face of ongoing growth in per capita incomes. In the first, which we dub the Green Solow Model, emission reductions arise from exogenous technological progress in the abatement process. Although this model is very simple it provides three useful results. First, we show that even with the economy's abatement intensity fixed, the dynamics of the Solow model together with those of a standard regeneration function are sufficient to produce the Environmental Kuznet's Curve. The transition towards any sustainable growth path has environmental quality at first worsening with economic growth and then improving as we approach the balanced growth path. This is a surprising result. While numerous explanations for the EKC relationship have been put forward, this explanation is simple, novel, and quite general as it relies only on basic properties of growth functions.

Second, the Green Solow model provides a useful benchmark since this model predicts that a more strict pollution policy has no long run effect on growth. In true Solow tradition, different abatement intensities

[6] This is different from other definitions. We wanted to avoid stagnation as a sustainable growth path and hence require positive growth; but with positive income growth giving more marketable goods along the balanced growth path it seems only appropriate to require an improving environment as well since this gives us more non market goods.

[7] Aggregate compliance costs were reported in a 1990 EPA study that has apparently never been updated. (See EPA (1990) Environmental Investments: The cost of a clean environment) The earlier study predicted year 2000 compliance costs of approximately 200 billion dollars (1990 dollars), but recent EPA publications (EPA's 2004 Strategic Plan) distances themselves from this estimate and reiterates just how difficult it is to estimate compliance costs. OECD evidence can be found in the publication Pollution Abatement & Control Expenditures in OECD countries, Paris: OECD Secretariat.

create level differences in income but have no effect on the economy's growth rate along the balanced growth path. This result provides partial justification for the current practice of measuring the costs of pollution control as the sum of current private and public expenditures with no correction for the reduction in growth created. It also points out the stringent conditions needed for a stricter policy policy to cause no drag whatsoever on economic growth.

Third, the model clearly shows how technological progress in goods production has a very different environmental impact than does technological progress in abatement. Technological progress in goods production creates a scale effect that raises emissions, technological progress in abatement creates a pure technique effect driving emissions downwards. In the Green Solow model both rates are exogenous, and as such they provide especially clean examples of scale and technique effects for us to refer to later. And as we show throughout the review, the presence or absence of technological progress in abatement is key to whether we can lower emissions, support ongoing growth, and provide reasonable predictions for the costs of pollution control.

The second model, which we dub the Stokey Alternative, was inspired by Nancy Stokey's (1998) influential paper on the limits to growth. Here we present a simplified version to highlight the role abatement can play in improving the environment over time. The model we present focuses on balanced growth paths and not the transition paths as emphasized by Stokey, but nevertheless it contains two results worthy of note. The first is simply the observation that once we model abatement as an economic activity that uses scarce resources, increases in the intensity of abatement that are needed to keep pollution in check will have a drag on economic growth. Rising abatement creates a technique effect by lowering emissions per unit output, but also lowers pollution by lowering the growth rate of output.

By rewriting the model along the lines of Copeland and Taylor (1994) so that pollution emissions appear as if they are a factor of production, it is now relatively simple to conduct growth drag exercises for the cost of pollution control in much the same way that others have examined the growth drag of natural resource depletion.[8] By doing so, the model makes clear the limits to growth brought about by environmental policy.

The second feature we focus on is the model's prediction concerning the intensity of abatement. In models with falling pollution levels, neoclassical assumptions on abatement, and no abatement specific technological progress, the intensity of abatement must rise continuously through time. For example, in Stokey's analysis the share of "potential output" allocated to abatement approaches one in the limit. Since this share represents pollution abatement costs relative to the value of aggregate economic activity, models that rely on abatement alone tend to generate counterfactual predictions for abatement costs. This is true even though ongoing economic growth is fueled by technological progress, and hence this result reinforces our earlier remarks about the importance of technological progress in abatement.

Our third model links the source and sink roles of nature by assuming energy use both draws down exhaustible resource stocks and creates pollution emissions that lower environmental quality. This "source and sink" formulation allows us to examine how changes in the energy intensity of production help meet environmental constraints. In this model, the intensity of abatement is taken as constant and there is no technological progress in abatement. Instead the economy lowers its emissions to output ratio over time by adopting an ever cleaner mix of production methods. As such the model focuses on the role of composition effects in meeting environmental constraints. We show that the economy is able to grow while reducing pollution because of continuous changes in the composition of its inputs, but this form of "abatement" has costs. Growth is slowed as less and less of the natural resource can be used in production.

This "source and sink" formulation is important in linking the earlier 1970s and 1980s literature focusing on growth and resource exhaustion with the newer 1990s literature focusing on the link between economic growth and environmental quality. We show that the finiteness of natural resources implies a constraint on per capita income growth that is worsened with higher population growth rates. This constraint is relaxed if the rate of natural resource use is slower as this implies reproducible factors have less of a burden in keeping growth positive. But sustainability also requires falling emissions, and this constraint is most easily met if the economy makes a rapid transition away from natural resource inputs as this reduces the energy and pollution intensity of output.

[8] See for example Nordhaus (1992).

Putting the constraints from the source and sink side together, we show there exist parameter values for which the twin goals of positive ongoing growth and falling emission levels are no longer compatible. This is not a doomsday prediction. Together with our previous analysis it suggests that abatement or composition shifts alone are unlikely to be responsible for the stylized facts. Technological progress directly targeted to lowering abatement costs (i.e. induced innovation) must be playing a key role in determining growth and environment outcomes. Therefore, in the remainder of the paper we turn to a model where technological progress in abatement is set in motion by the onset of active regulation and works to generate sustainable growth paths.

To highlight the importance of technological progress in abatement our final model draws on the analysis of Brock and Taylor (2003) by adopting their Kindergarten Rule model. While the previous models were useful vehicles to discuss the literature and describe possibilities, they were necessarily incomplete because they eschew formal optimization. Optimizing behavior is however important in discussions of the magnitude of drag created by pollution policy, and also important in discussions concerning the timing or onset of active regulation. The Kindergarten model provides two contributions to our discussion.

First, it shows how technological progress in abatement can hold compliance costs down in the face of ongoing growth. In contrast to the Green Solow model, there are ongoing growth drag costs from regulation, but as long as abatement is productive it is possible to generate sustainable growth without skyrocketing compliance costs. By highlighting the important role for progress in abatement, the model points out the need to make endogenous the direction of technological progress as well as its rate.

Second, the model generates a first worsening and then improving environment much like that in Stokey (1998). In contrast however to the methods employed in the empirical EKC literature, we show that the path for income and pollution will differ systematically across countries. This systematic difference leads to the model's Environmental Catch-up Hypothesis relating income and pollution paths to countries initial income levels. Poor countries experience the greatest environmental degradation at their peak, but once regulation begins environmental quality across both Rich and Poor converges. Despite this, at any given income level an initially Poor country has worse environmental quality than an initially Rich country. Moreover, since both Rich and Poor economies start with pristine environments, the qualities of their environments at first diverge and then converge over time. In addition to this cross-country prediction, the model also links specific features of the income and pollution profile to characteristics of individual pollutants such as their permanence in the environment, their toxicity, and their instantaneous disutility. Together these predictions suggest a different empirical methodology than that currently employed, and expand the scope for empirical work in this area considerably.

The final section of our review is a summary of the main lessons we have drawn from the literature, offers suggestions for future research and briefly discusses some of the most important topics that we did not discuss elsewhere in the review.

2 Preliminaries

2.1 Scale, Composition and Technique

We start with some algebra linking emissions of a given pollutant to a measure of economic activity, its composition and the cleanliness of production techniques. By doing so we illustrate that any growth model that predicts both rising incomes and falling pollution levels has to work on lowering pollution emissions via one of three channels. Consider a given pollutant and let E denote the sum total of this pollutant's emissions arising from production across the economy's n industries.[9] Let a_i denote the pounds of emissions per dollar of output produced in industry i, s_i denote the value share of industry i in national output, and

[9] The pollutant could instead be produced via consumption. In that case we adopt weights reflecting industry i's share in final demand. This has little impact on our results here, but would have some relevance in an open economy setting.

Y national output. Then by definition total emissions E are given by:

$$E = \sum_{i=1}^{n} a_i s_i Y \text{ where } \sum_{i=1}^{n} s_i = 1 \tag{1}$$

Since this is a definition we can differentiate both sides with respect to time to find:

$$\hat{E} = \sum_{i=1}^{n} \pi_i \left[\hat{a}_i + \hat{s}_i\right] + \hat{Y} \text{ where } \pi_i = \frac{E_i}{E} \tag{2}$$

where a $\hat{}$ over x indicates $[dx/dt]/x$. Changes in aggregate emissions can arise from three sources that we define to be the Scale, Composition and Technique effects.[10]

To start, note that holding constant the cleanliness of production techniques and the composition of final output (i.e. holding both $\hat{a}_i = 0$ and $\hat{s}_i = 0$ for all i) emissions rise or fall in proportion to the scale of economic activity as measured by real GDP or Y. This is the scale effect of growth and unless it is offset by other changes, emissions rise lock step with increases in real output.

Alternatively, we can hold both the scale of real output and the techniques of production constant to examine the impact of changes in the composition of output. To do so, in (2) we set $\hat{Y} = 0$ and $\hat{a}_i = 0$ for all i as this isolates the pure composition effect on pollution emissions.

$$\hat{E} = \sum_{i=1}^{n} \pi_i \hat{s}_i \tag{3}$$

Emissions fall via the pure composition effect if an economy moves towards producing a set of goods that are cleaner on average than the set they produced before. To see why this is true, note that the change in value shares across all n industries must sum to zero; i.e. $\sum_{i=1}^{n} ds_i = 0$. Now using this result in (3) we obtain the change in emissions arising from a pure composition effect as:

$$\hat{E} = \sum_{i=1}^{n} \hat{s}_i \left[\pi_i - s_i\right] \tag{4}$$

Given our definitions $\pi_i - s_i > 0$ if and only if $E_i/p_i y_i > E/Y$. In words, the element $\pi_i - s_i$ is positive if and only if industry i's emissions per dollar of output is greater than the national average. Define a dirty industry as one whose emissions per dollar of output exceed the economy wide average E/Y; define a clean industry as one where emissions per dollar of output are less than the economy average. Then equation (4) holds that aggregate emissions fall from the pure composition effect whenever the composition of output changes toward a more heavy reliance on clean industries and rises otherwise.

Finally, emissions can fall when the techniques of production become cleaner even though output and its composition remain constant. To isolate this technique effect, we set $\hat{Y} = 0$ and $\hat{s}_i = 0$ for all i to find that emissions fall if emissions per unit output fall for all activities. In this case we find:

$$\hat{E} = \sum_{i=1}^{n} \pi_i \hat{a}_i \tag{5}$$

and hence if techniques are getting cleaner, emissions per unit of output fall, and overall emissions fall from this pure technique effect.

When the environment is modeled as a sink for human wastes it is often assumed that emissions together with natural regeneration determine environmental quality. When the environment adjusts relatively slowly to changes in the pollution level, natural regeneration can play an important role in determining environmental quality. A typical and very useful specification assumes the environment dissipates pollutants at an

[10] See Copeland and Taylor (1994) for model based definitions of these effects in a static setting. This terminology was popularized by Grossman and Krueger's (1993) NAFTA study.

exponential rate. Let X denote the pollution stock (an inverse measure of environmental quality) and let the pristine level be given by $X = 0$. Then since the flow of emissions per unit time is E, the evolution of the pollution stock is given by:

$$\dot{X} = E - \eta X \text{ where } \eta > 0 \tag{6}$$

This formulation is convenient because it is generally assumed that X must be bounded for human life to exist and hence (6) yields a simple negative linear relationship between the steady state flow of pollution E, and the pollution stock X. A bound on X then implies a similar bound on steady state emissions, E.[11] Moreover, given the linear relationship any scale, composition or technique effect on emissions is translated directly into impacts on X.

One cost of (6) is that the percentage rate of natural regeneration is independent of the state of the environment. A common modification is to assume the rate of natural regeneration rises as X gets further and further from its pristine level. Letting $\eta = \eta(X)$, we can introduce this possibility by writing the evolution of X as:

$$\dot{X} = E - \eta(X) X \text{ where } \eta'(x) > 0 \tag{7}$$

$\eta(X)$ is often assumed to be linear.

An alternative and equally valid interpretation of (2) is that E is the instantaneous flow of natural resources used in production. Under this interpretation, equation (1) gives us an economy wide factor demand for this natural resource evaluated at the equilibrium level of use given by E. For example, the demand for oil equals the sum of demand arising from all sectors of the economy. In this interpretation a_i are barrels of oil used per unit of output in industry i, s_i is the value share of industry i in national output, and Y is again national output.

For example, if the flow of resources extracted is falling at some constant rate over time while real output is rising, then we know that some combination of changes in energy efficiency per unit of output (a technique effect) and changes in the output mix to less energy intensive goods (a composition effect) must be carrying the burden of adjustment. Changes in resource use over time can then be linked to the relative strength of scale, composition and technique effects. To complete the translation let the current stock of natural resources S be given by our initial endowment K less the sum over time of extraction by humans, E. If this resource has a zero regeneration rate we obtain the standard equation governing stock depletion in exhaustible resources:

$$\dot{S} = -E \tag{8}$$

Alternatively, we can leave open the possibility of regeneration. Making the needed changes to (8) gives us the standard accumulation equation for a renewable resource such as a forest or fishery when growth is stock dependent.

$$\dot{S} = \eta(S) S - E \tag{9}$$

And again if $\eta(S)$ is linear we obtain the familiar logistic growth for a naturally regenerating resource.[12]

Although (1) is a definition it implicitly contains an assumption on how economic growth and the environment interact. Note that the value shares sum to 1 and $a_i(t) \geq 0$ for all i and t. Assume that $a_i(t) > 0$ for all i and t. This assumption turns out to be an important, because if some activities are perfectly clean, or approach perfectly clean activities in the limit, then it is possible for composition effects alone to hold pollution in check despite ongoing growth. Conversely, if all economic activities must pollute even a small

[11] Along a balanced growth path the time rate of change of X must equal that of E. To see this divide both sides of (6) by X and note that a constant rate of change in X requires the ratio E/X to be constant.

[12] It should be noted however that different assumptions on $\eta(S)$ can lead to drastically different conclusions when they lead to growth functions with what biologists call critical depensation [See Clark (1990) for a formal definition and discussion]. Critical depensation refers to a property of the natural growth function such that at some minimum S, natural growth becomes negative. Natural growth can turn negative because of predator prey interactions across species, or because the species has a minimum viable population. Introducing thresholds and critical depensation into either (9) or (7) can alter results considerably. Unfortunately little is known about the extent of non-convexities of this type empirically. For theoretical work examining their impact see the symposium edited by Dasgupta and Maler (2003). Scheffer and Carpenter (2003) document some examples of catastrophic regime shifts in ecosystems.

amount, then environmental quality can only rise in the long run via continuous changes in the techniques of production and these may run into diminishing returns.

It is not helpful here to enter into philosophical discussions over the definition of pollution or the likelihood of today's unwanted outputs becoming tomorrow's valuable inputs. Instead we just note that all production involves the *transformation* of one set of materials into another and that this transformation requires work. All work requires energy and energy is always wasted in work effort. Therefore some unintentional by products of production are always produced and we most often call these by products pollution. Since this is a statement of belief and not a rigorous proof, we note this as an assumption.

Assumption 1. Pollution is a by-product of all production:

$$for\ all\ i,\ t \geq 0,\ lim\ inf\ \{a_i(t)\} > 0 \tag{10}$$

this implies that there exists for each i, a strictly positive $\varepsilon > 0$ such that $a_i(t) > \varepsilon$. With Assumption 1 in hand, it is now possible to show that composition effects are at best a transitory method to lower pollution emissions. Let us explain in detail why this conclusion holds. Suppose there is a bound, $B > 0$ such that if $E(t)$ exceeds B, human life cannot exist. Then if $Y(t)$ goes to infinity as t goes to infinity, (10) implies:

$$E(t) \leq B \Rightarrow \sum_{i=1}^{n} a_i(t)\, s_i(t) \leq \frac{B}{Y(t)}\ for\ all\ t \geq 0 \tag{11}$$

Thus we must have

$$\overset{*}{a}_i(t) := \min\{a_i(t)\} \leq \frac{B}{Y(t)} \to 0\ as\ t \to \infty \tag{12}$$

But (12) contradicts Assumption 1. Hence if we are to have bounded emissions with growing $Y(t)$, we must have the cleanest industry emission rate $\overset{*}{a}_i(t)$ going to zero. Therefore, falling pollution levels and rising incomes are only possible if there are continual reductions in emissions per unit output and zero emission technologies are possible, at least in the limit.

3 Stylized Facts on Sources and Sinks

We present three stylized facts drawn from post WW II historical record. We present data on pollution emissions and environmental control costs and leave the discussion of energy prices to later sections. Since data is typically only available for pollutants that are presently under active regulation we discuss the US record with regard to its six so-called criteria air pollutants, but amend these with international sources where possible. These are: sulfur dioxide, nitrogen oxides, carbon monoxide, lead, large particulates and volatile organic compounds.[13] With the exception of lead, these air pollutants all typically classified as irritants and so we also briefly discuss the US history of regulation of long-lived and potentially harmful chemical products. For the most part we present data on emissions rather than concentrations because data on emissions covers a much longer time period and is unaffected by industry location and zoning regulation. On the other hand, the longest time spans of data (from 1940 onwards) reflect some changes in collection and estimation methods.[14] Nevertheless, this data is the best we have available and where possible we direct the reader to concentration data and related empirical work. In addition we present data on industry pollution abatement costs from Vogan (1996), although these are only available for the 1972-1994 period.

[13] The long series of historical data presented in the figures is taken from the EPA's 1998 report National Pollution Emission Trends, available at http://www.epa.gov/ttn/chief/trends/trends98.

[14] As methods of estimation improve new categories of emissions are included and some revision occurs as well. For example, prior to 1985 the PM10 data excluded fugitive dust sources and other miscellaneous emissions, so these are eliminated from the time series graphed in Figure 7. As well revision occurs. A close look at the 2001 Trends report shows that emissions reported for our pollutants during the 1970s and 1980s does not exactly match the figures given in the 1998 report. We use the 1998 figures rather than those from 2001 since the 2001 report only contains estimates to 1970, and we import the EPA's graphics directly into our figures because we cannot match them precisely from the raw data.

We start by presenting in Figure 1 emissions per dollar of GDP for all pollutants except lead. Lead is excluded since data is only available over a much shorter period. As shown, emissions per unit of output for sulfur, nitrogen oxides, particulates, volatile organic compounds, and carbon monoxide all fall over the 1940-1998 period. For ease of comparison emission intensities were normalized to 100 in 1940 and the figure adopts a log scale. PM10 fell by approximately 98%, sulfur, volatile organic compounds and carbon monoxide fell by perhaps 88%, and nitrogen oxides fell by perhaps 60%. Somewhat surprisingly, it is also apparent that if we exclude the years of WWII at the start of the data, the rate of reduction for each pollutant appears to be roughly constant over time.

Although there is a tendency to see good news in falling emission intensities, there are good reasons for not doing so. One reason is simply that real economic activity increased by a factor of 8.6 over this period and this masks the fact that emissions of many of these pollutants rose during this period. The second is that this measure – like that for aggregate emissions – has very little if any welfare significance. Since our measure is physical tons of emissions added up over all sources, it necessarily ignores the fact that some tons of emissions create greater marginal damage than others.[15]

Our second stylized fact is presented in Figure 2. In it we plot business expenditures on pollution abatement costs per dollar of GDP over the period 1972-1994. These twenty-two years are the only significant time period where data is available.[16] As shown, pollution abatement costs as a fraction of GDP rise quite rapidly until 1980 and then remain relatively constant. As a fraction of overall output, these costs are relatively small. Alternatively, if we consider pollution abatement costs specifically directed to the six criteria air pollutants and scale this by real US output, the ratio is then incredibly small – approximately one half of one percent of GDP - and has remained so for over twenty years (See Vogan (1996)).[17]

Data from other countries supports the general conclusion that pollution abatement costs are a small fraction of GDP and show perhaps a slight upward trend. For example, total expenditures by both government and business in France rose from 1.2% of GDP in 1990 to 1.6% in 2000. Over the 1991-1999 period, these same expenditures in Germany rose from 1.4% of GDP to 1.6%. Austria and the Netherlands show somewhat higher expenditures on the order of 2.1% and 1.6% in 1990 rising to 2.6% and 2.0% in 1998. While this data is clearly fragmentary, expenditures in the order of 1-2% of GDP seem to be the norm in OECD countries, with perhaps half of this being spent by private establishments and the remainder by governments.[18]

These figures however reflect to a certain degree the changing composition of output over time and therefore understate the impact higher pollution abatement costs have had on some industries. Levinson and Taylor (2003) for example argue that since the composition of U.S. manufacturing has been shifting towards less pollution intensive industries, aggregate measures understate the true costs of pollution regulations. They construct estimates of pollution abatement costs holding the composition of industry output fixed at the 2 and 3 digit industry levels and then compare these estimates with estimates allowing the composition of output to change. In all cases, holding the composition of US output fixed in earlier periods leads to a higher estimate of industry wide abatement cost increases. As a result, the small increases in pollution abatement costs shown in the aggregate data are at least partially due to the U.S. shedding some of its dirtiest industries over time.

Our third and final fact is presented in Figures 3 to 8. These figures show a general tendency for emissions to at first rise and then fall over time. Note that the falling emissions/intensities reported in Figure 1 are necessary but not sufficient for this result. This pattern in the data is visible for all pollutants except nitrogen

[15] In contrast, a quality-adjusted measure of emissions would add up the various components weighing them by their marginal damage; or a quality-adjusted measure of aggregate concentrations in a metropolitan area would weigh concentrations in each location by the marginal damage of concentrations at point (urban, industrial, suburban, etc.).

[16] In 1999 the PACE survey was run again this time as a pilot project. Using the 1999 survey we find the ratio of PACE to GDP of approximately 1.9% which is very much in line with Figure 2. This 1999 survey is different in some respects from earlier ones. For details see the Survey of Pollution Abatement Costs and Expenditures, U.S. Census Bureau 1999 available at www.census.gov/econ/overview/mu1100.html

[17] These figures are also similar to those presented in the review of pollution abatement costs in Jaffe et al. (1995).

[18] These data are drawn from the Organization for Economic Cooperation and Development 2003, "Pollution Abatement and Control Expenditures in OECD Countries", Paris: OECD Secretariat.

oxides that may at present be approaching a peak in emissions. Conversely, particulate pollution peaked much earlier than the other pollutants, while lead has a dramatic drop in the mid-1970s. These raw U.S. data support the contention that environmental quality at first deteriorates and then improves with increases in income per capita.

Another interesting aspect of these figures is the breakdown of emissions by end-use category. Apart from some exceptions arising from the miscellaneous category the within-pollutant source of the emissions remains roughly constant in many of the figures. For example, consider SO2. Aggregate emissions follow an EKC pattern, but the components of fuel combustion and industrial processes do as well. A similar pattern is found in volatile organic compounds, but less so in the case of carbon monoxide which presumably is due to the change in automobile use over the period. In total the rough constancy in the within-pollutant sources of emissions suggests that the overall EKC pattern is not driven by strong compositional shifts.

Our finding of an EKC in the raw emission data is consistent with the recent flurry of formal empirical work linking per capita income and pollution levels. This empirical literature was fueled primarily by the work of Grossman and Krueger (1993, 1995) who found that, after controlling for other non-economic determinants of pollution, measures of some (but not all) pollution concentrations at first rose and then fell with increases in per capita income.[19] Their work is important in several respects: it brought the empirical study of aggregate pollution levels into the realm of economic analysis; it debunked the commonly held view that environmental quality must necessarily decrease with economic growth; and it provided highly suggestive evidence of a strong policy response to pollution at higher income levels.

Unfortunately, empirical research has progressed very little from this promising start. Subsequent empirical research has focused on either confirming or denying existence of similar relationships across different pollutants.[20] Subsequent research has shown that the inverse-U relationship does not hold for all pollution, and there are indications the relation may not be stable for any one type of pollution.[21] Since the empirical work on the EKC typically employs cross-country variation in income and pollution to identify parameters, it is perhaps not surprising that there are signs of parameter instability. This instability could arise from country specific differences in the mechanism driving the two processes, but very little, if any, work has gone into evaluating the various hypotheses offered for the EKC. This interpretation of the econometric problems is of course consistent with our finding that the raw US data offers a dramatic confirmation of Grossman and Krueger's cross-country results. Cross-country differences leading to parameter instability are of course irrelevant in a one-country context.

In its original application, the EKC was interpreted as reflecting the relative strength of scale versus technique effects. However, it is difficult to support this interpretation. To isolate either the scale or technique effect we need to hold constant the composition of output, but this is not typically done in this literature. Therefore, the shape of the EKC may reflect some mixture of scale, composition and technique effects.

Despite these criticisms, the major and lasting contribution of this literature is to suggest a strong environmental policy response to income growth. The EKC studies are generally supportive of the hypothesis that income gains created by ongoing growth lead to policy changes that in turn drive pollution downwards. However, as our discussion in later sections will show, an EKC is compatible with many different underlying mechanisms and is entirely compatible with pollution policy remaining unchanged in the face of ongoing growth.

While most studies do not present evidence that allows us to distinguish between the underlying mechanisms responsible for the EKC, two recent studies offer additional insights. Hilton and Levinson (1998) examine the link between lead emissions and income per capita using a panel of 48 countries over the twenty-year period 1972-1992. This study is important because it finds strong evidence of an inverted U-shaped relationship between lead emissions and per capita income, and then factors the changes in pollution into

[19] In addition to Grossman and Krueger (1993,1995), other early contributions are Shafik and Bandyopadhyay (1994), Selden and Song (1994), Hilton and Levinson (1998), Gale and Mendez (1996).

[20] See, for example, Selden and Song (1994), El-Ashry (1993), Harbaugh et al (forthcoming), Stern and Common (2001) and the surveys mentioned previously.

[21] Hilton and Levinson (1998) contains some of the most convincing evidence of an EKC. Harbaugh, et al. (forthcoming) examines the sensitivity of the original Grossman and Krueger finding to new data and alternative functional forms.

two different components. The first is a technique effect that produces an almost monotonic relationship between lead content per gallon of gasoline and income per capita. The second is a scale effect linking greater gasoline use to greater income.[22] This study is the first to provide direct evidence on two distinct processes (scale and technique effects) that together result in an EKC.

To interpret the empirical evidence as reflecting scale and technique effects one needs to rule out other possibilities. Although the authors do not couch their analysis in this context, their analysis implicitly presents the necessary evidence. First, they document a significant negative relationship between the lead content of gasoline and income per capita (post 1983). This relationship shows up quite strongly in just a simple cross-country scatter plot of lead content against income per capita. Since lead content is arguably pollution per unit output, it is difficult to attribute the negative relationship to much other than income driven policy differences.[23]

Second, the authors find a hump-shaped EKC using data from the post-1983 period, but in earlier periods they find a monotonically rising relationship between lead emissions and income. The declining portion of the EKC only appears in the data once the negative health effects of lead had become well known. The emergence of the declining portion in the income pollution relationship is very suggestive of a strong policy response to the new information about lead. The fact this only appears late in the sample makes it difficult to attribute the decline in lead to other factors that could be shifting the demand for pollution. For example if the declining portion of the EKC was due to increasing returns to scale in abatement, then it should appear in both the pre and post-1983 data and vary across countries being correlated with an appropriate measure of economic scale. If it was due to shifts in the composition of output arising naturally along the development path, why would it only appear in the post-1983 data? While it is possible to think of examples where these other factors are at play, the scope for mistaking a strong policy response for something else is drastically reduced in this study. The natural inference to draw is that the decline only occurs late in the sample because with greater information about lead's health effects, policy tightened and emissions fell.

A second important study is Gale and Mendez (1998). They re-examine one year of sulfur dioxide data drawn from Grossman and Krueger's (1993) study. The study does not offer a theory of pollution determination, but is original in investigating the role factor endowments may play in predicting cross-country differences in pollution levels. They regress pollution concentrations on factor endowment data from a cross-section of countries together with income-based measures designed to capture scale and technique effects. Their results suggest a strong link between capital abundance and pollution concentrations even after controlling for incomes per capita. Their purely cross-sectional analysis cannot, however, differentiate between location-specific attributes and scale effects. Nevertheless, their work is important because the strong link they find between factor endowments and pollution suggests a role for factor composition in determining pollution levels. That is, even after accounting for cross-country differences in income per capita, other national characteristics matter to pollution outcomes.

Combining our three stylized facts on pollution emissions presents us with an important question. How did aggregate emissions and emissions per unit output fall so dramatically in the U.S. without raising pollution abatement costs precipitously?

There are several possible explanations. One possibility is that ongoing changes in the composition of US output have led to a cleaner mix of production that has lowered both aggregate measures of costs and emissions. The downward trend in emissions per unit output shown in Figure 1 prior to the advent of the Clean Air Act suggests some role for composition effects. While changes in the composition of US output are surely part of the story, there are reasons to believe that they cannot be the most important part. Over the 1971-2001 period of active regulation by the EPA, total emissions of the 6 criteria air pollutants (Nitrogen Dioxide, Ozone, Sulfur Dioxide, Particulate matter, Carbon Monoxide, and Lead) decreased on average by

[22] Lurking in the background of this study is a composition effect operating through changes in the fleet of cars. This composition effect is not investigated in the paper, although it may be responsible for the jump in lead per gallon of gasoline use at low income levels shown in Figure 4 of the paper.

[23] To be precise we should note that since lead content per gallon is an average, and cars differ in their use of leaded versus unleaded gas, the composition of the car fleet is likely to be changing as well. Therefore, the fall in average lead content may reflect an income-induced change in the average age of the fleet (which would lower average lead content) plus a pure technique effect.

25%. Over this same period, gross domestic product rose 161% and pollution abatement costs have risen only slightly.[24] The magnitude of these emission reductions is too large for it to reflect composition changes alone.

To get a feel for the magnitudes involved note that if changes in the composition of output over the 1971-2001 period are to carry all the burden of adjustment, then we would set the changes in a_i to zero in (2). Then using the EPA's estimate of an average 25% reduction for E and the 161% increase for Y, we find that the weighted average of industry level changes must add up to - 186% change. This is just too large a realignment in the composition of industry to be credible.

It is also apparent from the figures that emissions for most pollutants have been falling since the early 1970s and as we saw earlier there are limits to how far aggregate emissions can fall via composition effects. Our earlier discussion of the static nature of the within-pollutant sources of emissions also argues against strong composition effects. Finally, there is little evidence that international trade is playing a major role in shifting dirty goods industries to other countries but stronger composition effects after the advent of federal policy in early 1970s would be necessary to explain the fall in emissions seen in the figures.[25] For this set of reasons it seems clear that composition effects alone cannot be responsible for the result.

Another possible explanation is that ongoing growth in incomes has generated a strong demand for environmental improvement. In this account, income gains over the post WWII period produce a change in policy in the early 1970s and usher in the EPA and the start of emission reductions. While this explanation fits with the decline in emission to output ratios and the lowered emissions since the early 1970s, it too cannot be the entire story. As we discuss in Section 4, if rising incomes are to be wholly responsible for the change in pollution policy, agents must being willing to make larger and larger sacrifices in consumption for improving environmental quality. For example, the theory models of Stokey (1998), Aghion and Howitt (1998), Smulders (2001), Lopez (1994), etc. all require a rapidly declining marginal utility of consumption to generate rising environmental quality and ongoing growth. But as Aghion and Howitt note:

> "Thus it appears that unlimited growth can indeed be sustained, but it is not guaranteed by the usual sorts of assumptions that are made in endogenous growth theory. The assumption that the elasticity of marginal utility of consumption be greater than unity seems particularly strong, in as much as it is known to imply odd behavior in the context of various macroeconomics models..." (p. 162.)

A rapidly declining marginal utility of consumption is required in earlier work because increasingly large investments in abatement are required to hold pollution in check.[26] This implies the share of pollution abatement costs in the value of output approaches one in the limit, which is inconsistent with available evidence.[27]

A final possibility is technological advance. Ongoing technological progress in production *and* abatement could simultaneous drive long run growth and hold pollution abatement costs in check. Technological progress in goods production could be the driving force for growth in final output, while technological progress in abatement allows emissions per unit of output to fall precipitously without raising environmental control costs skyward. In this explanation, income gains from ongoing growth are responsible for the onset of serious regulation in the 1970s, but the advent of regulation then brought forth improvements in abatement methods. As a consequence agents have not been required to make increasingly large sacrifices in consumption for improving environmental quality. As we show in section 4, this explanation is consistent with the predictions of both our Green Solow and Kindergarten models.

[24] These figures are from the EPA's Latest Findings on National Air Quality, 2001 Status and Trends, available at http://www.epa.gov/air/aqtrnd01/ published September 2002.

[25] See for example Antweiler et al. (2001) and Grossman and Krueger (1993).

[26] This restriction also implies a large income elasticity of marginal damage and many question whether the demand for a clean environment can be so income elastic. For example, McConnell (1997) argues that current empirical estimates from contingent valuation and hedonic studies do not support the very strong income effects needed.

[27] See the discussion in Aghion and Howitt (1998, page 160-161) and our discussion of abatement in Section 5 of Brock and Taylor (2003).

Before we proceed we should note that the stylized facts given thus far exclude a discussion of many other pollutants. By selecting only pollutants for which data is available we may have erred on the side of optimism since the measurement of pollutants is often a precursor to their active regulation. One important omission from the above is any discussion of air toxics such as benzene (in gasoline), perchloroethylene (used by dry cleaners), and methyl chloride (a common solvent). These are chemicals are believed to cause severe health effects such as cancer, damage to the immune system, etc. At present the EPA does not maintain an extensive national monitoring system for air toxics, and only limited information is available.[28]

Another omission is any discussion of the set of long-lived chemicals and chemical by-products that have found their way into waterways, soils and the air. These products have very long half-lives and produce serious health and environmental effects. Prominent among these in US history are DDT, PCBs, Lead, and most recently CFCs. Official estimates on emissions of these pollutants is difficult to find, but historical accounts and partial data indicate their emissions follow a pattern roughly similar to that of lead shown in Figure 8. As shown by the figure the history of lead is one of strong initial growth in emissions, followed by a rapid phase-out and virtual elimination. In fact, lead continues to be emitted in small amounts, whereas PCB emissions rose from very low production levels in the 1930s to millions of pounds per year of production in the 1970s, to end with a complete ban in 1979. Similarly, DDT was used extensively after WWII but banned in 1972. CFC production in the US rose quickly with the advent of refrigeration and air conditioning, but this set of chemicals now faces a detailed phase-out with CFC-11 and CFC-12 already facing a complete production ban. The salient feature of these accounts is strong early growth followed by quite rapid elimination.

A final failing of these data is that they are on emissions and not concentrations.[29] Concentration data is available for most of these data at least over the last 20 to 30 years, but the data is well known to be noisy and suffers from other problems related to comparability over time. Nevertheless most aggregate measures of air quality in cities have been improving over time. For example, data on the number of US residents living in counties that were designated non-attainment because of their failure to achieve federal air quality standards shows that over the 1986 to 1998 period these numbers have been falling quite dramatically for sulfur dioxide, nitrogen oxide, carbon monoxide, lead and PM10. The number of people living in counties who failed the federally mandated ozone air quality has however risen from 75 million in 1986 to 131 million in 1998.[30]

4 Some Illustrative Theory

4.1 The Green Solow Benchmark[31]

Every model relating economic growth to emissions or environmental quality has by construction made implicit assumptions regarding the strength of scale, composition and technique effects. These assumptions are often hidden in choices made over functional form, over the number of goods, the inclusion of finite resources, or in assumptions concerning abatement. Since we have data on the composition of output, its scale, and emissions per unit of output, it is often useful to divide models into categories according to their reliance on scale, technique and composition effects rather than model specifics like the number of goods, types of factors or assumptions over abatement. By dividing up the literature along these lines, we can weigh the relative merits of model's that rely exclusively on composition effects by looking at their strength in the data rather than by asking ourselves far less obvious questions such as are capital and resources good or poor substitutes or does abatement exhibit increasing returns.

The literature linking growth and pollution levels is immense starting with very early work in the 1970s by Forster (1973), Solow (1973), Stiglitz (1974), Brock (1977) and others, and culminating in the more recent

[28] See U.S. EPA, Toxic Air Pollutants, at www.epa.gov/airtrends/toxic.html.

[29] Note however that much of the empirical EKC work employs pollution concentration data as does Antweiler et al. (2001).

[30] For these data see U.S. Environmental Protection Agency, Office of Air Quality Planning and Standards, National Air Quality and Emissions Trend Report, 1998 (EPA, Research Triangle Park, NC 2000) and earlier trend reports.

[31] For a detailed exposition see Brock and Taylor (2004).

work investigating the Environmental Kuznet's curve such as Stokey (1998), Aghion and Howitt (1998), or Jones and Manuelli (2001). Although the earlier and late literatures differ greatly in their assumptions regarding the driving force behind growth, all models of economic growth must produce changes in scale, composition, or techniques that satisfy (1). Models that produce similar aggregate relationships between income and pollution often rely on different mechanisms to drive pollution downward. Because of these differences, they have other observable implications that we can use for evaluation.

To start our enquiry into the various mechanisms authors have employed to generate sustainable growth or an EKC prediction, we develop an augmented Solow model where exogenous technological progress in both goods production and abatement leads to continual growth with rising environmental quality. This is the simplest model to explore the importance of technological progress in driving down emissions per unit of output.[32]

Consider the standard one sector Solow model with a fixed savings rate s. Output is produced via a CRS and strictly concave production function taking effective labor and capital to produce output, Y. Capital accumulates via savings and depreciates at rate δ. We assume the rate of labor augmenting technological progress is given by g. All this implies:

$$\begin{aligned} Y &= F(K, BL) \\ \dot{K} &= sY - \delta K \\ \dot{L} &= nL \\ \dot{B} &= gB \end{aligned} \tag{13}$$

To model the impact of pollution we follow Copeland and Taylor (1994) by assuming every unit of economic activity, F, generates Ω units of pollution as a joint product of output. The amount of pollution released into the atmosphere may differ from the amount produced if there is abatement. We assume abatement is a CRS activity and write the amount of pollution abated as an increasing function of the total scale of economic activity, F, and the economy's efforts at abatement, F^A. If abatement at level A, removes the ΩA units of pollution from the total created, we have:

$$\begin{aligned} E &= \textit{pollution created} - \textit{pollution abated} \\ &= \Omega F - \Omega A\left(F, F^A\right) \\ &= \Omega F\left[1 - A\left(1, \frac{F^A}{F}\right)\right] \\ &= Fe(\theta) \text{ where } e(\theta) \equiv \Omega\left[1 - A(1, \theta)\right] \text{ and } \theta \equiv \frac{F^A}{F} \end{aligned} \tag{14}$$

where the third line follows from the linear homogeneity of A, and the fourth by the definition of θ as the fraction of economic activity dedicated to abatement.

The relationship in (14) requires several comments. The first is simply that (14) is a single output analog of (1) showing that emissions are determined by the scale of economic activity F, and the techniques of production as captured by $e(\theta)$. The second is that the production of output per se and not input use is the determinant of pollution. Since there is only one output, this means the composition effect must be zero. In a subsequent section we alter our formulation to consider pollution created by input use, but note in passing here that making pollution proportional to the employment of capital has no effect on our results. Finally, since F^A is included in F, even the activity of abatement pollutes.

To combine the assumptions on pollution in (14) with our Solow model, it is useful to assume the economy employs a fixed fraction of its inputs – both capital and effective labor – in abatement. This means the fraction of total output allocated to abatement θ is a fixed much like the familiar fixed saving rate

[32] A full description of the model together with supporting empirical work can be found in Brock and Taylor (2004), NBER working paper No. 10557.

assumption.[33] As a result, output available for consumption or investment Y, becomes $[1-\theta]F$. In addition we must adopt some assumption concerning natural regeneration. To do so we assume the quality of the environment evolves over time according to (6). Therefore, the evolution of the pollution stock is given by:

$$\dot{X} = Fe(\theta) - \eta X \tag{15}$$

Finally, since the Solow model assumes exogenous technological progress, we assume emissions per unit of output fall at the exogenous rate g^A. Putting these assumptions together and transforming our measures of output and capital into intensive units, our Green Solow model becomes:

$$\begin{aligned} y &= f(k)[1-\theta], \\ \dot{k} &= sf(k)[1-\theta] - [\delta + n + g]k \\ E &= BLf(k)e(\theta), \\ \dot{X} &= E - \eta X, \\ \dot{\Omega} &= -g^A \Omega \end{aligned} \tag{16}$$

where k is K/BL and y is Y/BL; i.e. capital and output measured in intensive units. The top line of (16) repeats the basic Solow model where net output is a fraction of total output. Taking θ as given, and assuming the Inada conditions, there is a k^* such that output, capital, and consumption per person all grow at rate g.

Using standard notation, direct calculation reveals that along the balanced growth path we must have $g_y = g_k = g_c = g > 0$. A potentially worsening environment however threatens this happy existence. From (16) it is easy to see that constant growth in environmental quality requires $g_x = g_E$. Since k^* is constant along the balanced growth path, the growth rate of emissions is simply:

$$g_E = g + n - g^A \tag{17}$$

which may be positive, negative, or zero. The first two terms in (17) represent the scale effect on pollution since output grows at rate $g + n$. The second term is a technique effect created not by greater abatement efforts, but because emissions per unit output fall via exogenous technological progress at rate g^A.

Therefore our requirements for sustainable growth are very simple in this model.

$$\begin{aligned} g &> 0 \\ g^A &> g + n \end{aligned} \tag{18}$$

Technological progress in abatement must exceed that in goods production because of population growth; and some technological progress in goods production is necessary to generate per capita income growth.

The Green Solow model, although very simple, demonstrates several important points. The first is that investments to improve the environment may cause only level and not growth effects. This is obviously true here since the growth rate of per capita magnitudes is explicitly linked to the rate of technological progress, but not to θ. By setting the time derivative of capital per effective worker to zero in (16) it is straightforward to show that a tighter environmental policy (higher θ) lowers output, capital and consumption per worker, but has no effect on their long run growth rates.

The implied income and consumption loss from a tighter policy is however quite small. Adopting a Cobb-Douglas formulation for final output with the share of capital equal to α shows that the ratio of consumption per person along the balanced growth paths of the economy adopting weak versus strong abatement is just:

$$\frac{c_w}{c_s} = \left[\frac{1-\theta_W}{1-\theta_s}\right]^{\frac{1}{1-\alpha}} \tag{19}$$

[33] We treat θ as endogenous when examining transition paths in section 5. It is possible that no abatement is optimal in some limited circumstances, but in models generating balanced growth this would imply every increasing pollution levels. In models without growth, such as Keeler et al. (1972), a Murky Age or Polluted Age equilibrium result is possible with θ set to zero.

since both economies grow at rate $g+n$. If weak abatement means adopting a share of pollution abatement costs in national output of .5%, and strong abatement means 10%, then consumption per person will differ by 16% along the balanced growth path (assuming capital's share in output is 0.35). Therefore, a twenty-fold difference in the intensity of abatement creates only a 16% difference in consumption per person!

The calculation however seems to imply that environmental policy cannot be much of a limit on economic growth. Recall though that for any given choice of abatement intensity, if we are to have ongoing growth, an improving environment, and a constant (relative) cost of environmental policy, then technological progress in abatement must be sufficiently strong. If technological progress is slower than that given in (18) then one of two things must happen. Either additional investments in abatement must be undertaken to maintain environmental quality, or environmental quality must decline. At this point however we should note that the strict concavity of A implies there are diminishing returns to greater and greater abatement efforts. From (14) we find that $e'(\theta) = -A_2 < 0$, but $e''(\theta) = -A_{22} > 0$. Therefore, in the absence of strong technological progress in abatement, growth in income per capita is only consistent with lower pollution levels if abatement grows over time.[34]

One final observation concerns the transition path of the model. Despite the fact that the intensity of abatement is fixed and there are no composition effects in our one good framework, simulations of the Green Solow model produce a path for income and environmental quality tracing out an Environmental Kuznets Curve. This surprising result is shown graphically in Figure 9 below. In Figure 9 we present the trajectories for two economies that are identical in all respects except for their abatement intensity. Each starts from an initially pristine environment and a small initial capital level. Strong abatement refers to a 10% share of output spent on abatement; weak abatement to a 0.5% share. The other parameters were chosen for the purposes of illustration. Per capita income grows at 1% along the balanced growth path, the population grows at 2% and the abatement technology improves at 5%. Note that these parameters ensure that growth is sustainable according to (18). Capital's share is set at 0.35, the savings rate is 10% and depreciation is 2%. Regeneration is set with $\eta = 0.1$ implying a 10% rate for any $X > 0$.

As shown, the environment at first worsens and then improves as the economy converges on its balanced growth path. Note that along the balanced growth path emissions fall and the environment improves at 2% per unit time, which is close to what the simulation delivers in its last periods.

This result follows for three reasons. First, the convergence properties of the Solow model imply that output growth is at first rapid but then slows as k approaches k^*. With a fixed intensity of abatement, pollution emissions grow quickly at first but slower later. Therefore, part of the dynamics is governed by the convergence properties of the neoclassical model.

Second, when we start at a pristine environment the effective rate of natural regeneration is zero. This is true because "nature" is at a biological equilibrium with $X = 0$. When production begins the environment deteriorates. At $X = 0$, the introduction of any emissions overwhelms the rate of regeneration and lowers environmental quality. As X rises, natural regeneration rises. This must be a feature of the regeneration function in order for $X = 0$ to be a stable biological equilibrium.

Third, we have assumed emissions fall along the balanced growth path.

Together the first two facts imply that at the outset of economic growth the rapid pace of growth swamps nature's slow or zero regeneration; but the economic growth rate slows and regeneration rebounds. As we approach the balanced growth path natural regeneration must overwhelm the now less rapid inflows of pollution. The environment improves.

It is important to recognize that this result is more general than our Cobb-Douglas technology and instead relies on quite general properties of production and growth functions. To verify write the dynamic system governing k and X as:

$$\begin{aligned} \dot{k} &= sf(k)[1-\theta] - [\delta + n + g]k \\ \dot{X} &= c_o \exp[-c_1 t] f(k) - \eta X \end{aligned} \tag{20}$$

[34] A rising intensity of abatement will lower growth rates introducing other problems in meeting the sustainability criteria. We leave this issue for the next section.

where $c_0 > 0$ and $c_1 = g^A - (g+n) > 0$ are positive constants. To show the environment must at first worsen evaluate the accumulation equation for X at $t = 0$. Since the environment is initially pristine, $X(0) = 0$, and the initial capital stock cannot be zero so $k(0) > 0$. Substituting these values into (20) and evaluating shows the environment must at first worsen. X has to be growing at least initially. To examine the rest of the transition path recall that $k(t)$ is increasing in time until it reaches k^* because this is, after all, a Solow model. Using this fact, we can bound the path for X by noting:

$$\dot{X} = c_o \exp[-c_1 t] f(k) - \eta X < c_o \exp[-c_1 t] f(k^*) - \eta X \tag{21}$$

Therefore for any $t > 0$, $X(t)$ must be below the solution to the ordinary differential equation: $\dot{X} = c_o \exp[c_1 t] f(k^*) - \eta X$, $X(0) = 0$. This ordinary differential equation has a closed form solution showing $X(t)$ tends to zero as t goes to infinity. Using the inequality in (21) we can conclude that pollution must fall along its trajectory.[35]

This explanation for the EKC is entirely distinct from those offered in the literature. There are no composition effects, no increasing intensity of pollution abatement, no increasing returns to abatement, no evolution of the political process, and no international trade. The result follows primarily from the mechanics of convergence coupled with the dynamics predicted by a standard natural regeneration function. Moreover from (14) it is easy to see that emissions per unit of GDP falls *both* during the transition and along the balanced growth path at the constant rate g_A (recall Figure 1 at this point). This is quite surprising because both output and emissions growth varies over time, with the level of emissions tracing out an EKC. Since θ is fixed throughout, the share of pollution abatement costs in value-added is constant. Therefore, although very simple, the Green Solow model matches three important features of the data: declining emissions to GDP ratios, the EKC, and pollution abatement costs that are roughly constant over time.

The Green Solow Model bears a family resemblance to several papers examining the growth and pollution link within a neoclassical framework. Forster (1973) examines a neoclassical model with zero population growth and no technological progress in either abatement or production. His main result is that steady state consumption per person and capital per person are lower when society invests in pollution control since these controls lower the net return to capital.

Although Forster's assumptions on abatement and pollution creation are different from ours, we can reproduce his main results in our fixed savings rate setting by adopting his assumptions of $g_A = g = n = 0$. When we do so we find steady state capital per person and consumption per person both fall with increases in θ while pollution is lowered. Forster's work is important because it was perhaps the first examination of optimal pollution control in a neoclassical setting.

The Green Solow model is also similar to the neoclassical model adopted in Stokey (1998), but differs in that Stokey gives no role to technological progress in abatement. As a result increasing abatement intensity must carry the day in reducing pollution. Stokey also generates the EKC prediction but her result follows from a change in pollution policy along the transition path. Her simulations of the model must however to some extent reflect the same dynamic forces we have identified since the model is neoclassical and the evolution equation for the environment is identical.

More closely related work is Bovenberg and Smulders (1995). In their endogenous growth formulation "pollution augmenting technological progress" holds pollution in check *and* drives long run growth. In their two-sector model, ongoing investments in the knowledge sector raise the productivity of pollution leading to a balanced growth path with a constant level of environmental quality. Again our Green Solow model reproduces the flavor of their results. Setting $n = 0$ to mimic their zero population growth assumption, and assuming $g = g_A$ to mimic the identical rates of technological progress found in both sectors, we find from (22) that emissions are constant along the balanced growth path and output per person grows at rate g.

This similarity should not be all that surprising because Bovenberg and Smulders' "pollution augmenting technological progress" is very similar to our technological progress in abatement. To see why divide both sides of our emissions function in (14) by Ω, and then employ the monotonicity of A in θ to invert the

[35] With a further assumption on technology we can ensure the EKC must be single humped. Our Cobb-Douglas formulation adopted in the figure is covered by our assumption.

intensive abatement function and solve for $[1-\theta]$. Use this to write net output $Y = F[1-\theta]$ available for consumption or investment as:

$$Y = G\left(F\left(K, BL\right), AE\right) \tag{22}$$

where $A = 1/\Omega$, and G is both CRS and concave. Hence "pollution augmenting technological progress" is equivalent to our technological progress in abatement.

4.2 Intensifying Abatement: The Stokey Alternative

We now amend our Green Solow model to incorporate a role for intensified abatement to lower pollution levels. In the model above reductions in pollution came about solely because of changes in the emission technology and not because society allocated a greater share of its resources to pollution prevention. In an important paper Nancy Stokey [Stokey (1998)] presented a series of simple growth and pollution models to investigate the links between the limits to growth and industrial pollution. She examined the ability of these models to reproduce the results of empirical work finding an Environmental Kuznets Curve and investigated how an active environmental policy may place limits on growth. An important feature of Stokey's analysis was its dependence on increased abatement and tightening regulations to drive pollution downward.

Her analysis contains two contributions. The first is a simple explanation for the empirical finding of an Environmental Kuznets curve. Like Lopez (1994) before her, and Copeland and Taylor (2003) after, Stokey shows how an income elastic demand for environmental protection can usher in tighter regulations and eventually falling pollution levels. This assumption on tastes, together with certain assumptions on abatement, succeeds in generating a first worsening and then improving environment as growth proceeds.

Stokey's second contribution was to investigate whether there are limits to growth imposed by regulating industrial pollution. In section 5 we discuss her analysis within an AK framework; here we focus on her work within the neoclassical model that formed the bulk of her paper. To do so we make the smallest departures possible from the Green Solow model. We again take the savings rate as fixed, but allow the intensity of abatement to vary over time. Since we are primarily interested in feasibility rather than optimality, our fixed savings rate assumption will simplify the analysis at little or no cost. Stokey assumed zero population growth, exogenous technological progress in goods production, a Cobb-Douglas aggregator over capital and labor in final goods production, and adopted an abatement function drawn from Copeland and Taylor (1994). In Stokey's analysis an optimizing representative agent determine savings and abatement decisions.

Although it is not obvious from Stokey (1998), a process of pollution abatement is implicit in her analysis. In Stokey's formulation the planner chooses a consumption path and the techniques of production as indexed by "z". The choice of techniques determines the link between potential output, F, and final output Y available for consumption or investment. The two are related by $Y = Fz$; while aggregate emissions are given by $E = Fz^{\beta}$ for some $\beta > 1$. To see how this choice of "techniques" is really one over abatement intensity make the change of variables $(1-\theta) = z$, and then let $\mathrm{e}(\theta) = (1-\theta)^{\beta}$ for $\beta > 1$. It is now easy to see that the "techniques" chosen by the planner correspond to choices over the abatement intensity θ. The resulting $e(\theta)$ is just a specific form of an emissions function coming from the assumptions of constant returns to abatement and pollution being a joint product of output. Since θ is in principle observable, we conduct our analysis in this unit.

Our amended model assumes zero technological progress in abatement, and to follow Stokey adopts the specific emissions function given above and a Cobb-Douglas aggregator over factors. The model is described by:

$$\begin{aligned} Y &= F[1-\theta] \\ F &\equiv K^{\alpha}(BL)^{1-\alpha} \\ \dot{K} &= sY - \delta K \\ \dot{L} &= nL \\ \dot{B} &= gB \\ E &= Fe(\theta) \equiv F[1-\theta]^{\beta} \end{aligned} \tag{23}$$

To examine the feasibility of balanced growth with a non-deteriorating environment we start with the last equation in (23) giving emissions and log differentiate to find:

$$G_E = \alpha G_k + (1-\alpha)(g+n) + G_{e(\theta)} \tag{24}$$

recall G_E must be zero or negative or else the environment deteriorates. In the absence of technological progress in the emissions function, this implies the growth rate of emissions per unit of output $G_{e(\theta)}$ must be negative. To identify what this may imply for growth, we eliminate G_K. To do so, note balanced growth requires Y/K constant. Divide both sides of the final goods production function by Y^{α}. Rearrange and log differentiate with respect to time to find:

$$G_Y = G_K = g + n + \frac{G_{e(\theta)}}{(1-\alpha)\beta} \tag{25}$$

where G_Y is the growth rate of final output. At this point it is worthwhile to note that final output growth is reduced by active abatement since $G_{e(\theta)}$ must be negative.

To determine the evolution of emissions along the balanced growth path substitute (25) into (24) and rearrange slightly to obtain:

$$G_E = g + n + \frac{G_{e(\theta)}}{(1-\alpha)\beta} + \frac{(\beta-1)G_{e(\theta)}}{\beta} \tag{26}$$

The first two terms of this expression, $(n+g)$, represent the scale effect of growth. They represent the growth rate of emissions that would arise along the balanced growth path if θ was held constant. This is clear from (23) since if θ is constant $G_{e(\theta)} = 0$.

The final two terms in (26) represent the technique effect created by lowering emissions per unit output along the balanced growth path. This technique effect is itself composed of two parts. The first component is the reduction in the growth rate of final output caused by the diversion of resources to abatement. Since θ is increasing along the balanced growth path, the growth rate of F exceeds that of final output by this amount.[36] Therefore, this component of the technique effect lowers pollution by slowing down the growth rate of final output (recall (25)).

The second component of the technique effect is the reduction in emissions per unit of final output created by abating more intensively. This is the standard component identified in static models. This component of the technique effect need not be as large as previously to lower pollution. To see this solve (26) for the rate at which emissions per unit of output must fall to drive emissions downward. Algebra yields:

$$-G_{e(\theta)} > \left[\frac{g+n}{1+[\alpha/[(1-\alpha)\beta]]}\right] \tag{27}$$

which is smaller than the minimum rate of $(g+n)$ needed in (17). Not surprisingly because abatement has a negative effect on growth rates, it has less of a role to play in lowering emissions per unit of output. Therefore in set-ups where abatement is responsible for pollution reduction, the burden is shared across two margins: abatement lowers growth rates and abatement also lowers emissions per unit output.

These two roles for abatement now introduce the possibility that a sustainable growth path may not exist. To see why, note that the reduction in growth created by an ever tightening environmental policy is very similar to the growth drag found in models with either fixed land or exhaustible natural resources.[37] In the case with fixed or declining resources the ratio of resource use to effective labor falls along the balanced growth path and this lowers growth rates. The same is true here once we make the right translations. To see this parallel, use the final goods production function and the emissions function to write net output as if pollution were an input into production. Doing so we find:

$$Y = F^{1-\frac{1}{\beta}} E^{\frac{1}{\beta}} \tag{28}$$

[36] The growth rate of θ and $e(\theta)$ are related by $G_{e(\theta)} = -\beta[\theta/(1-\theta)]G_{\theta}$.

[37] An excellent review of growth drag is contained in Jones (2002; chapter 9).

Along the balanced growth path E must fall while F grows; therefore the reduction in E works very much like the exhaustion of a resource that lowers growth. It is now apparent that while (27) tells us that the decline in emission intensity must be sufficiently fast to lower emissions; equation (25) tells us this same magnitude cannot be too large if we are to have positive growth in income per capita. Solving (25) for the implied restriction and combining with (27) yields, after some manipulation:

$$g > -G_{e(\theta)} > \frac{g+n}{\alpha + (1-\alpha)\,\beta} \tag{29}$$

The range given by this inequality defines the set of emission intensity reductions that are consistent with declining emissions and positive per capita output growth: i.e. sustainable growth. If we recall that $\beta > 1$, then it is straightforward to see that the feasible region is not empty when there is zero population growth. When $n > 0$ the region may not exist. By equating the two sides of (29) we can solve for the relationship between population growth and parameters that must be true for a sustainable growth path to exist. Algebra gives us:

$$g\left[(1-\alpha)\,(1-1/\beta)\right] > n\left[\frac{1}{\beta}\right] \tag{30}$$

The left hand side of (30) is exactly labor's share in final goods production (use (28)and the definition of F) times the rate of labor augmenting technological progress, g. The right hand side is exactly emissions share in final output, $1/\beta$, times the rate of population growth, n. The intuition for this condition is straightforward, and is identical to that we give later in a model where exhaustible energy resources create drag.

The left hand side of the expression represents the Solow forces of technological progress raising growth to the extent determined by labor's share and the rate of progress. The right hand side could be called the Malthusian forces since they capture the impact of diminishing returns caused by a falling ratio of emissions to effective labor along the balanced growth path. These forces are stronger the more important are emissions in the production of final output, and stronger the faster is population growth.

If the inequality in (30) goes the other way then we have two choices. Either per capita income growth is negative, or per capita income growth is positive but emissions rise. In either case we do not have sustainable growth according to our definition.

This observation of course suggests we follow the path of earlier authors and calculate the growth drag due to pollution policy. For example, Nordhaus (1992) adopts a model similar to (28) with emissions E replaced by either land or an exhaustible natural resource and then generates estimates for the drag caused by finite land and natural resources. But without a formal framework in which to estimate the long run growth impact of tighter environmental policy, Nordhaus resorts to estimates of contemporaneous expenditures on abatement to calculate future costs of pollution control.

We can go further here, although our methods are far from ideal. To generate an estimate for the growth drag caused by environmental policy we need estimates of β, α and $G_{e(\theta)}$. We note using (23) that $G_{e(\theta)} = G_{E/Y}\beta/[\beta-1]$ where $G_{E/Y}$ is the observable growth rate of emissions per unit of final output. For various measures of E it is shown in Figure 1. We take capital's share of production, α to be 0.35. To eliminate the parameter β write emissions per unit of output, using (23) as $E/Y = (1-\theta)^{\beta-1}$. Since we have data on emissions, final output and pollution abatement costs we could in theory estimate β. Using this estimate we could then calculate the growth drag due to pollution policy. Since our purpose is not to provide definitive answers but rather suggest a methodology, take the log of E/Y and differentiate with respect to time to find:

$$\beta = 1 - \frac{G_{E/Y}}{G_\theta}\left[\frac{1-\theta}{\theta}\right] \tag{31}$$

where G_θ is the growth rate of the pollution abatement cost share, and θ the average pollution abatement cost share over the period in consideration. Now use (31) to eliminate β and rewrite (25) as:

$$G_Y = g + n - \frac{G_\theta}{(1-\alpha)}\frac{\theta}{(1-\theta)} \tag{32}$$

PAC share percentage increase per year	2.5	5.0	7.5
Pollution abatement costs share 1970	1.0	1.0	1.0
Pollution abatement cost share 2000	2.1	4.3	8.8
Average $\theta/[1-\theta]$ across period	1.57	2.72	5.15
Growth drag percentage	0.06	0.2	0.5

Table 1: The drag pollution policy on growth (percentages)

The drag due to environmental policy is now directly linked to observable measures: the share of pollution abatement costs in the value of overall economic activity, and the percentage growth rate of this measure. To investigate what a reasonable magnitude of growth drag maybe, we report in the table below a series of illustrative calculations. Recall that the share of pollution abatement costs in either manufacturing value-added or GDP is small – on the order of 1 or 2%. In certain industries it can of course be much higher. Take 1970 as the base year and set the pollution abatement costs share in that year at 1%. Then applying growth rates of 2.5 to 7.5% per year in this cost share, we obtain with the help of (32), the following results.

The first column assumes the share of pollution abatement costs in the value of output rises from 1% to a little over 2% in thirty years. The other columns report larger increases for illustrative purposes, although they are far in excess of the historic increases as shown by our data in Figure 2. A striking feature of the table is that the drag due to environmental policy is very small except in extreme cases. When pollution abatement costs rise from 1% to a little over 2% in 30 years, the drag on growth is only 6 hundredths of 1% point. When pollution abatement costs grow by 5% per year, the policy reduces growth by 0.2%. If costs grow by the extremely large 7.5% per year, drag is now $\frac{1}{2}$ of 1% point which is significant. Note that growth in per capita income, $G_Y - n$, over the last 50 years is approximately 2% per year; therefore the last column would predict an ever strengthening environmental policy that raises the share of pollution abatement costs in value-added by 7.5% year would reduce per capita income growth by 25%.

To a certain extent the relatively small effects in Table 1 are not that surprising. If pollution abatement costs as a fraction of value-added are in the order of 1%, it is difficult to see how even relatively large percentage increases in their level would lower growth tremendously. To go slightly further, note from (31) that if $G_{E/Y}$ and G_θ are of the same magnitude, then it is easy to see that β is approximately $1/\theta$.[38] This implies the share of emissions in final production in (28), $1/\beta$ is on the order of 0.01 or 0.02.And if pollution emissions are such an unimportant input into the production of final output, then drag from any reduction in emissions over time must also be small.

Despite the optimistic results in Table 1 concerning growth rates, models that rely on active abatement often contain the prediction that abatement becomes a larger and larger component of economic activity. This is a direct consequence of two facts. The first is that for emissions to fall, emissions per unit of output must shrink continuously with ongoing growth. The second is that with constant returns to abatement, lowering emissions per unit output comes at increasing cost. As a consequence, an implication of an exclusive reliance on abatement is that abatement costs rise along the growth path to eventually take up most of national product. To verify this, return to our simple example and note $G_{e(\theta)}$ is constant along the balanced growth path. Using our specific emission function in (23), we know:

$$G_{e(\theta)} = -\beta \left[\frac{\dot{\theta}}{1-\theta} \right] \tag{33}$$

Solving this differential equation for θ yields:

$$\theta(t) = 1 - (1 - (1 - \theta(0)))\, e^{\left(G_{e(\theta)}/\beta\right)t} \tag{34}$$

[38] This may not be such a bad assumption. In Figure 1 it appears that the growth rate of emissions per unit output for each pollutant may be roughly constant over the last 50 years. The important point is that the two growth rates are of a similar magnitude and not necessarily equal.

starting from some $\theta(0)$ near the balanced growth path we see that as time goes to infinity θ goes to one because $G_{e(\theta)} < 0$. Abatement must take up a larger and larger share of national product as time progresses. This is an uncomfortable conclusion in light of the data we have already presented showing a relatively weak increase in abatement over time. In addition the reader may wonder why it is that agents would willingly make such sacrifices in final consumption necessary for such a large abatement program.

At this point it is useful to refer to Stokey (1998) explicitly for an answer since Stokey's analysis shows that consumer's are indeed willing to make the sacrifice needed in net output to lower pollution albeit under certain conditions. Specifically, by adopting a CRRA utility function Stokey shows emissions fall along the balanced growth path if and only if the elasticity of marginal utility with respect to consumption exceeds one. Only if consumers valuation of consumption falls quickly are they willing to take a smaller and smaller slice of (an ever expanding) national income as growth proceeds.

Stokey's analysis also allows for a more theoretically based growth drag calculation. By adopting specific functional forms, Stokey solves for the growth rate of final output and emissions in terms of primitives. By rearranging slightly and recasting these results in terms of our notation we find the growth rate of output per person and overall emissions are just:

$$\begin{aligned} G_y &= g - g\left[\frac{\sigma+\gamma-1}{\sigma+\gamma-1+(1-\alpha)(\beta-1)\gamma}\right] \\ G_E &= \frac{1-\sigma}{\gamma}G_y \end{aligned} \tag{35}$$

where σ is the elasticity of marginal utility in the CRRA utility function, $\gamma \geq 1$ is a measure of the convexity of damages from pollution, α is capital's share, g is the exogenous rate of labor augmenting technological progress. There is zero population growth so $n = 0$.[39]

In comparison to our simple example the drag of environmental policy is now directly linked to the primitives of tastes and technology although it reflects similar forces at work. For example, by rearranging we can isolate the percentage reduction in growth caused by active pollution policy:

$$G_y = g\left[1 - \frac{1-G_{E/Y}}{1-G_{E/Y}+(1-\alpha)(\beta-1)}\right] \tag{36}$$

the greater is the rate of reduction in emissions per unit output, GE/Y, and the larger is emissions share in final output $1/\beta$, the greater will be the drag. This is the same set of forces we found using our simpler framework.

We can of course estimate growth drag in this optimizing framework as well. In order to replicate the Environmental Kuznet's curve Stokey adopts a set of parameters for all the primitives we need. In doing so, the model predicts the EKC found in empirical work, but using these same values for capital's share, the abatement technology, etc. we find that growth drag is an unbelievable 60% of potential growth. Using the parameter specification chosen to mimic the EKC, growth in income per capita in the absence of pollution policy is 4% per year.[40] But using (35) growth is actually approximately 1.6% per year with active pollution policy; therefore, growth in income per person is slowed by 60% from what it would be in the absence of environmental concerns. This is clearly far too high.

If we lower the elasticity of marginal utility to approach the lowest limit consistent with falling pollution (σ approaching 1), and set $\gamma = 1$, then drag hits its minimum. But even in this case, drag is almost 55% of potential growth. The problem with these calculations is our assumption of $\beta = 3$, which implies a share of pollution emissions in final output of 1/3 which is clearly far too high. Altering β to values similar to those used in our growth drag calculations suggests a much smaller drag.

For example, from Figure 1 it is apparent that 3 of the US criteria pollutants had an emissions per unit of output in 1998 that were just 1/10 of their value in 1940. This implies a growth rate of approximately

[39] This is found by rearranging (3) page 14 of Stokey (1998). To rewrite the equation in our set up we need to note the rate of labor augmenting technological progress would be $g/(1-\alpha)$ which we write as g in the above.

[40] This is just the effective rate of labor augmenting technical change which is $g/(1-\alpha) = 0.024/0.6$ in Stokey's notation.

-4% per year from these pollutants. Assuming the share of emissions in final output is 0.02, β is 50, and with a capital share of 0.35 we find the percentage reduction predicted by (36) to be just 0.03. Therefore a 2% growth rate would be reduced to just 1.94% because of the drag of environmental policy.[41]

We would hasten to add however that these calculations are purely for illustration. They demonstrate how the growth drag due to environmental policy may be calculated from primitives on technologies, abatement costs, knowledge of historic growth, and emission levels. We leave it to future research to develop and refine these methods to generate estimates of the growth drag due to environmental policy.[42]

Many other papers rely on an active role for abatement in lowering pollution levels, and therefore must contain predictions for both the drag of environmental policy and the evolution of pollution abatement costs over time. In some work, abatement is specified differently so that it escapes diminishing returns by assumption. For example, early work by Keeler et al. (1972) examines no growth steady states and assumes foregone output is the *only input* into abatement. As a result of this assumption, marginal abatement costs are constant in their formulation. Even with constant marginal abatement costs they find that when abatement is not very productive a "Murky Age" equilibrium arises: abatement is not undertaken and emissions are high in the steady state. Alternatively, when abatement is very productive in reducing emissions, the steady state is given by a Golden Age equilibrium with active abatement and lower emissions.

Other related work appears in Lopez (1994) and Copeland and Taylor (2003). In these contributions an optimizing social planner chooses the optimal level of abatement but factor supplies and technology are taken as parametric in their exclusively static analyses. Both adopt formulations where abatement is a constant returns activity using conventional inputs and examine how once for all growth in either technology or factor endowments affect pollution levels.[43] When growth is fueled by neutral technological progress, Copeland and Taylor show that emissions fall with this source of growth if the elasticity of marginal damage from pollution exceeds one. In a CRRA framework this corresponds to the condition Stokey derived of $\sigma > 1$.

In contrast when growth occurs by primary factor accumulation alone, then Lopez (1994) shows that whether pollution rises or falls now depends on both the elasticity of substitution between factor inputs and the income elasticity of marginal damage. If the elasticity of substitution between primary factors and emissions is large, then emissions fall quite easily. When production is Cobb-Douglas, Lopez's condition is identical to that of Stokey and $\sigma > 1$ generates the result that emissions fall with growth.

Together these contributions demonstrate that an improving environment and rising incomes are surely feasible in a standard neoclassical model where abatement is a constant returns activity. This path is also optimal under certain conditions. But by relying exclusively on changes in the intensity of abatement to lower pollution levels consumers must be willing to make rather large sacrifices for a cleaner environment over time. It is in fact this rather large willingness to sacrifice for a cleaner environment that leads to regulation in the first place.

In Stokey (1998), regulation is at first not present as the shadow value of capital is too high and the shadow value of pollution too low when growth begins for the planner to allocate any output to abatement. An important input into this decision is that the marginal product of the first unit of abatement is bounded above even at zero abatement.[44] As a result, no abatement is undertaken $\theta = 0$ and pollution rises lockstep with output. Once the environment has deteriorated sufficiently and the now larger capital stock has depressed its shadow value, active abatement begins. There is then a transition period and the economy approaches the balanced growth path described previously.

[41] The problem with this set of parameters is that the output elasticity of emissions in production is far too high at 1/3. If the regulator used pollution taxes to implement the social optimum, this implies that at all periods of time the share of pollution taxes in value-added would be 1/3. Setting β much higher generates numbers closer to those we reported in Table 1.

[42] Other methods used to estimate the impact of tighter pollution policy on growth include the use of quite detailed computable general equilibrium models of the U.S. economy, econometric studies, and more aggregative data exercises like the one we just conducted. The results from these studies are quite different. For example, Jorgenson and Wilcoxen (1990) build a 35 industry model of the U.S. economy to estimate the impact of pollution abatement costs and motor vehicle emission standards on overall output and growth. They find that output growth in the U.S. was reduced by almost 0.2% over the 1973-1985 period by these environmental policies, and in level terms U.S. real GDP is lower by a quite significant 2.6%.

[43] Lopez (1994) does not present an abatement function per se but it is implicit in his use of the revenue function listing primary factors and emissions as productive factors.

[44] We will show this in section 5.

This explanation for the EKC is quite persuasive. It links rising income levels with a lower shadow cost of abatement and a higher opportunity cost of doing nothing. It captures the idea that policy responds positively to real income growth and generates an EKC is a straightforward way. We have already seen however that a further implication of the model is an ever-rising pollution abatement cost share that may be inconsistent with the data. In addition we should note that this explanation predicts a constant emissions to output ratio prior to the regulation phase when emissions are rising. After regulation begins, the emissions to output ratio falls and does so at a constant rate along the balanced growth path (see (35)). Figure 1 however shows the emission to output ratio was falling long before emissions peaked in Figures 3 through 8. Therefore, using this data as our guide the model misses the long reduction in emissions per unit output that occurred in the US prior to peak pollution levels being achieved.

These observations suggest, at the very least, that other forces are simultaneously at work and partially responsible for the falling emissions to output ratio and roughly constant control costs in the U.S. historical record. One natural candidate is of course changes in the composition of output towards less energy intensive, and hence less pollution intensive, goods. Much has been made recently about the dematerialization of production and its environmental consequences, and hence we now turn to examine a model relying on just these effects.

4.3 Composition shifts: The Source and Sink Model

There are several ways to escape a worsening environment as economic growth proceeds. One possibility is for technological progress in abatement to lower pollution levels as shown in the Green Solow model; another is intensified abatement as shown by the Stokey Alternative. A third method is to alter the composition of output or inputs towards less pollution intensive activities. In this section we investigate the implication of changing energy use in production. Much of current concern over pollution arises from energy use and hence if the economy as a whole could conserve on energy this would have important implications for environmental quality. But raising energy efficiency per unit of output comes at some cost because energy is a valuable input and constraining its use will lower overall productivity. These losses must be compensated for by increases in capital, effective labor or new technology if growth is not to be slowed. Therefore, solving our pollution problems by altering an economy's input mix may introduce significant drag. These growth concerns are of course one of the major reasons why many countries have delayed ratification of the Kyoto protocol; and why many developing countries refuse to sign the agreement.

While many models investigating the growth and pollution relationship rely on compositional changes to lower pollution levels, few make the role of energy explicit in their analyses. For example, Copeland and Taylor (2003) present a "Sources of Growth" explanation for the Environmental Kuznets curve arguing that if the development process relies heavily on capital accumulation in the earliest stages and human capital formation in later stages, these changes will alter the pollution intensity of production so that the environment should at first worsen and then improve over time. Related empirical work in Antweiler et al. (2001) finds growth fueled by capital accumulation is necessarily pollution increasing, while growth fueled by neutral technological progress lowers pollution levels. Behind these results is presumably a link between the different types of growth, energy use, and emissions.

Similarly, in Aghion and Howitt (1998)'s analysis of long run growth and environmental outcomes, their clean capital - knowledge - takes on a larger and larger role in growth in the long run and this too creates an eventually improving economy. But since they adopt the same assumptions on abatement as Stokey (1998), even with a changing composition of output large increases in abatement must made to hold pollution down to acceptable levels.

In most of these formulations the link to energy use is at best implicit with the reader having to interpret capital or other productive factors in a broad way to include energy or other natural resources. One of the major accomplishments of the early resource literature was to identify how and when finite resources impinge on the growth process. By ignoring the role of exhaustible resources in generating pollution, we run the risk of making pollution reductions look relatively painless because these analyses will miss the induced drag on economic growth created by lower energy use. In this section we make the connection between energy use,

growth and environmental outcomes precise by combining earlier models of growth and exhaustible resources with newer models examining the pollution and growth link. By doing so we demonstrate how some of the results of the earlier 1960s and 1970s literature on natural resources and growth have relevance today.

One of the major research questions of the earlier 'limits to growth" literature was the extent to which exhaustible natural resources impinged on growth. Seminal contributions by Solow (1974) and Stiglitz (1974) showed that growth with exhaustible resources was indeed possible, although it required a joint restriction on the rate of population growth, technological progress and the share of natural resources in output. There are two well-known results from this literature.

The first, due to Solow (1974), is that a program of constant consumption is feasible even with limited exhaustible resources and a constant population if the share of capital in output exceeds the share of resources in final output. This observation led to a consideration of the optimal rate of savings to maximize the constant consumption profile. The answer was provided by John Hartwick (1977) and embodied in the now-famous Hartwick's rule: invest all the rents from the exhaustible resource in capital and future generations will be as well off as the currently living despite the asymptotic elimination of natural resources.[45]

The second result, due to Stiglitz (1974), is that growth in per capita consumption is possible with positive population growth if the rate of resource augmenting technological progress exceeds the population growth rate. Our formulation will also yield a similar restriction on technological progress to generate positive per capita output growth, but in addition we add the further restriction that environmental quality improves. Therefore, even when growth with exhaustible resources is feasible in terms of generating positive output growth (as required by Stiglitz (1974)), it may be unsustainable because this same plan implies rising pollution levels.

We remain as close as possible to our earlier formulation while introducing a role for natural resources. We make two important changes. First, we introduce energy as an intermediate good. The intermediate good "energy" is produced from an exhaustible natural resource, R, capital, and labor via a CRS and strictly concave production technology. Final output (used for investment or consumption) is then produced via capital, labor and the energy intermediate. To keep things simple we assume both production functions are Cobb-Douglas, and to remain consistent with our earlier formulations we assume technological progress is labor augmenting.[46]

Our second change is to assume pollution is produced via energy use, and not the overall scale of final goods production. In doing we sever the strong link we had thus far between pollution and final output by making pollution the product of input use. We retain our earlier assumption that pollution can be abated, but take the fraction of resources devoted to abatement as constant. We have already shown in the Stokey Alternative that increasing abatement creates drag on economic growth; here we show that even with the abatement intensity fixed, a move towards less energy intensive production lowers growth while it reduces the growth rate of emissions.

With these assumptions in hand, the production side of the economy becomes:

$$\begin{aligned} Y &= K_y^{b_1} \left(BL_y\right)^{n_1} I^{b_2} \\ I &= K_I^{b_3} \left(BL_1\right)^{n_2} R^{b_4} \left[1-\theta\right] \end{aligned} \tag{37}$$

where I is the energy intermediate, θ is the fraction of the energy industry's activities devoted to abating pollution, R denotes the flow of resources used per unit time, and subscripts denote quantities of capital and labor used in final good production, Y, and the intermediate good energy, I.

Capital and labor has to be allocated efficiently across the two activities – intermediate and final good production. It is straightforward to show that this implies a constant fraction of the capital stock is employed in intermediate good production and the remainder in final goods. The same is true for labor. This allows

[45] Adopting Hartwick's rule in our source-and-sink model leads to increasing utility over time as the environment improves with resource exhaustion. Proof available upon request.

[46] This implicitly assumes that energy is not an essential input into production; i.e. energy per unit of output is not bounded below.

us to aggregate and rewrite the production function for final good output as follows:

$$Y = K^{a_1} (LB)^{a_2} R^{a_3} [1-\theta]^{b_2} \tag{38}$$

which is necessarily CRS with $a_1 + a_2 + a_3 = 1$.[47]

To complete the model we add equations governing the labor force and technology growth, the relationship between extraction and the resource stock, S, plus our abatement assumptions linking emissions to energy use, I. These conditions are:

$$\begin{aligned} \dot{K} &= sY - \delta K \\ \dot{L} &= nL \\ \dot{B} &= gB \\ E &= I\Omega e(\theta) = I\Omega [1-\theta]^{\beta} \\ \dot{S} &= -R \end{aligned} \tag{39}$$

where $e(\theta)$ measures the flow of emissions released per unit of energy used. It is instructive at this point to rewrite the emissions equation to focus on the role of a changing composition of inputs in determining pollution levels. To do so define the variable $\chi = I/Y$ which is the ratio of energy use to final good production, or what is commonly called the energy intensity of GDP. Then rewriting the emissions function we find:

$$E = \chi Y \Omega e(\theta) \tag{40}$$

A change in emissions can now come from any one of three sources: scale effects via changes in final good output Y; composition effects coming from changes in the energy intensity of final good production χ; and technique effects that lower $\Omega e(\theta)$ directly.

We examine balanced growth paths and impose two requirements on the set of paths we investigate. First, as usual we require non-deteriorating environmental quality. Second, we require positive growth in per capita income.[48]

To solve for a balanced growth path note Y/K must be constant along any such path. Using this requirement we can log differentiate (38) with respect to time, impose the requirement that Y/K be constant, and find the growth rate of final output:[49]

$$G_Y = (g+n) - \left[\frac{a_3}{1-a_1}\right][(g+n) - g_R] \tag{41}$$

The first term is the usual growth rate of output in the Solow model; the second is a negative element capturing the growth drag caused by natural resources. To see why this term appears suppose resources were in unlimited supply; then their services could grow over time at the same rate as effective labor and we would have $g_R = g + n$. In this case, capital, output, resources and effective labor would grow at the rate g+n and there would be no resource drag. In fact, however, the resource base $S(0) > 0$ is finite and exhaustible, and this implies that $g_R < 0$.[50] Any non-positive g_R is feasible because we can always choose the

[47] Algebra shows $a_1 = b_1 + b_2 b_3$, $a_2 = n_1 + b_2 n_2$, and $a_3 = b_2 b_4$.

[48] To this the reader may choose to add various efficiency conditions. For example, Stiglitz (1974) imposes the arbitrage condition requiring the return on capital equal that of the resource. This additional constraint is the well-known Hotelling (1931) result that the rate of capital gain on the resource in situ must equal the return on capital. This efficiency condition fails here because energy use creates the disutility pollution. We could impose a similar efficiency condition but its form would depend on how pollution entered utility. Alternatively, or in addition, the reader may add a condition requiring the marginal rate of substitution between consumption and pollution equal its marginal product. We leave a discussion of optimality until section 5.

[49] It is helpful to recall θ is constant and (38) is CRS.

[50] >From our stock equation we have $S(t) = S(0) - \int_o^t R(\tau)\, d\tau$ where $S(t)$ must be non-negative. This implies that $R(\tau)$ cannot rise over time along a balanced growth path.

level of resource use such that the finite stock is eliminated asymptotically. Therefore, the ratio of resources to effective labor in production falls over time and this reduces growth below the Solow level. Indeed as (41) shows, growth in final output could be negative if resource constraints loom too large.[51]

>From our earlier equations it is straightforward to show that $a_3 = b_2 b_4$ and hence the existence of finite resources lowers growth by an extent determined by the resource share in final output. To see this note that if the share of final output going to resources approached zero, then a_3 approaches zero, and G_Y in (41) approaches $g + n$ the Solow growth rate.

It is now straightforward to write growth in per capita output as just:

$$g_y = g - \left[\frac{a_3}{1 - a_1}\right][g + n - g_R] \tag{42}$$

which shows technological progress has to offset both population growth and the reduction in resources over time in order for per capita income to rise. To make this clear and relate our model here to the Stokey Alternative, suppose the resource in question offered an indestructible flow of services per unit time; i.e. suppose it was Ricardian land. Then $g_R = 0$ and growth in per capita income is positive if and only if:

$$a_2 g > a_3 n \tag{43}$$

The left hand side of (43) represents the Solow forces of technological progress the strength of which depends on the share of labor in overall production and the rate of labor augmenting technological progress. Aligned against these are the Malthusian forces lowering output per person by applying more and more labor to the fixed stock of land. The rate of population growth and the share of land in production determine the strength of the Malthusian forces. Note the similarity between (43) and our earlier (30). The condition in (43) arises when $g_R = 0$ and $g_y > 0$; the condition in (30) has $g_E = 0$, and $g_y > 0$. Note the parallel between emissions and resources.

To generate falling pollution we will need a strong compositional shift and hence $g_R < 0$ is our standard case. Our first condition for sustainability is that (42) is positive. Our second condition is that pollution must fall over time. Log differentiating our emissions function in (40) yields:

$$g_E = -g_A + g_\chi + g_Y + g_{e(\theta)} \tag{44}$$

to eliminate the possibility of emissions falling because of technological progress in abatement as in the Green Solow model, we set g_A to zero. To eliminate the possibility of greater abatement efforts holding pollution in check as in the Stokey Alternative, we set $g_{e(\theta)} = 0$. This leaves only changes in the composition of inputs to offset the rising scale effect of ongoing growth.

Straightforward calculations then show that the growth rate of energy per unit of final output is simply given by:

$$g_\chi = -[1 - b_3]\left[\left[\frac{b_4}{1 - b_3}\right] - \left[\frac{a_3}{1 - a_1}\right]\right][g + n - g_R] < 0 \tag{45}$$

The sign of (45) is negative (see footnote 47). Not surprisingly, the energy intensity of final output must fall over time.

Putting the growth rate of output and energy intensity together we find emissions will fall if and only if:

$$g_E = (g + n) - \left[b_3\left[\frac{a_3}{1 - a_3}\right] + b_4\right][(g + n) - g_R] < 0 \tag{46}$$

Note the first element in (46), $(g + n)$, is exactly the scale effect of output growth in the Green Solow model. And instead of technological progress in abatement appearing to offset the scale effect of growth, we

[51] Recall however the Solow result [See Solow (1974)] that with zero technological progress and zero population growth, a program of constant consumption can be maintained as long as the share of resources in final output is less than the share of capital. We cannot derive this condition from (41) directly because we have already imposed a constant Y/K, which is inconsistent with this program.

now have emissions per unit of final output falling from the composition effect given by the second negative term. The growth rate of output is lowered by the drag of natural resources and hence as the economy "abates" by altering its input mix this creates drag much as in Stokey (1998).

There is a tension therefore between the desirability of moving away from natural resource use in order to lower pollution emissions and the cost of doing so in terms of growth. This of course is a primary concern of many developing countries and has limited their participation in the Kyoto Protocol to limit global warming. Because of our addition of a fixed natural resource, in some cases, composition effects alone cannot generate positive balanced growth with a non-deteriorating environment.

To investigate we graph Gy from (42) and G_E from (46) in Figure 11 below. We have graphed these growth rates against the rate of change in effective labor per unit resource; that is against, $[(g+n)-g_R]$ since this term plays a key role in both emissions growth and per capita growth. There are several things to note about it. First, suppose resources were in unlimited supply; then their services could "grow" over time at the same rate as effective labor: $g+n$ and we would have $g_R = g+n$. Such a wonderful existence corresponds to points along the vertical axis in the figure. In particular we see that with no resource drag, per capita output growth equals g. With a finite resource base the growth rate of resource use must be negative and this means that per capita income growth must be lower as shown by the negatively sloped line labeled G_y starting at g and intersecting the horizontal axis at point B. Movements along this line correspond to changes in the growth rate of resource use g_R.

Similarly, if there were unlimited resources the energy intensity of GDP would remain constant and emissions would rise lock step with output. This unlimited resources scenario corresponds to a point along the vertical axis with the rate of aggregate output growth and emissions of $(n+g)$. Again, since resource use must decline over time the true growth rate of emissions must be lower as shown by the line labeled G_E that intersects the horizontal axis at A. The growth rate of emissions falls as we move to the right along this line because final output grows more slowly, and final output uses less energy per unit output.

>From these observations it is clear that at all points to the left of A, growth in emissions is positive; points to the right of A, growth in emissions is negative. Similarly, all points to the left of B have positive per capita output growth; points to the right have negative growth. Putting these results together we see that ongoing growth in per capita incomes and an improving environment may not be feasible in some cases. In particular, the bold line segment AB represents the feasible region. Taking g and n as exogenous, this region gives us a range of resource exploitation rates, g_R, that are consistent with our twin goals.[52]

To understand the determinants of the feasible region it proves useful to consider the zero population growth case. If population growth is zero, then the two lines have the same vertical intercept as shown by the dotted $n=0$ line that is parallel to G_E. Whether positive growth and falling emissions is possible only depends on the relative slopes of G_E versus G_y. Algebra tells us a region such as AB will always exist with zero population growth. The logic is simply that emissions growth falls with both reduced output growth *and* a changing energy intensity of production. Both occur as we increase drag by moving right in the figure. Therefore, once resource drag has lowered per capita output growth to zero at a point like B the scale effect is zero, but emissions growth must be strictly negative because the composition effect is still driving energy intensity downwards. Consequently, a feasible region like AB exists.

When population growth is positive, this logic fails. As we raise the population growth rate the G_E curve shifts to the right and eventually intersects the horizontal axis at B. This in effect raises the scale effect. At this point, positive growth with declining emissions is not possible. The reason is simply that emissions growth is rising in n (a scale effect), whereas growth in output per capita falls with n because of resource drag. Once we choose n large enough – as shown by the dashed line labeled $n_1 > n$ – the feasible region disappears.[53]

These results have a decidedly negative flavor to them. An environmental policy that lowers the growth rate of emissions and lowers the energy intensity of final output, also lowers per capita growth to such an

[52] You can derive the exact extraction level associated with any rate of exploitation by employing the materials balance constraint for resources.

[53] The issue of feasibility also arises in the Stokey Alternative although we didn't focus on it there. Recall Stokey (1998) assumed $n=0$. Our analysis here suggests that this is not an innocuous assumption.

extent that an improving environment and real income gains may be unattainable. There are several reasons why we should be cautious in interpreting these negative results. The first is simply that we have ruled out a role for active abatement as in the Stokey Alternative. And we have ruled out technological progress as in the Green Solow model. While adding more avenues of adjustment is always good, active abatement lowers pollution emissions but creates drag just as reducing energy use does. Routine calculations show that if we let all three avenues of adjustment operate, we can write our two balanced growth path requirements as:

$$G_y = \underbrace{g}_{\text{Green Solow}} - \underbrace{RD\left[(g+n)-g_R\right]}_{\text{natural resource drag}} + \underbrace{PPD\left[g_{e(\theta)}\right]}_{\text{pollution policy drag}} > 0 \tag{47}$$

$$G_E = \underbrace{g+n-g_A}_{\text{Green Solow}} - \underbrace{EI\left[(g+n)-g_R\right]}_{\text{composition effect}} + \underbrace{TE\left[g_{e(\theta)}\right]}_{\text{technique effect}} < 0$$

where RD is a positive constant representing resource drag, and PPD a positive constant representing pollution policy drag. Note that in general with both resource exhaustion and abatement rising, there are two sources of drag on per capita income growth. Corresponding to each source of drag is of course a component of emission reduction. In the second equation EI is a positive coefficient representing energy intensity changes. This corresponds to a composition effect. In addition TE is a positive coefficient representing changes coming from increased abatement; this represents a technique effect.

Putting all this together in terms of our figure, we find that allowing for technological progress in abatement ($g_A > 0$) shifts the growth of emissions line G_E inward expanding the feasible region. This should come as no surprise. Adding active abatement shifts both lines down (the economy grows slower as do emissions), having an ambiguous effect on the feasible region. Raising population growth from zero however shrinks the region making it more likely that both requirements cannot be met.

What then are we to make of our stylized facts from the introduction? Emission levels have been falling in many countries while growth in per capita income remained positive. Pollution abatement costs have trended upwards but only slowly, and energy prices – while rising – have not been rising at fast rates.[54] We have already seen that these features are roughly consistent with the Green Solow model and less so with the Stokey Alternative. Here we find that relying on changes in energy intensity alone can work in lowering emissions but it does so only with strong compositional shifts towards less energy intensive goods. In our formulation these shifts are only consistent with a rising real price of energy over time. To see this note that energy's share in final output is fixed; take final output as the numeraire, and conclude that the real price of energy must rise along the balanced growth path at the rate $-\chi > 0$.

In Figure 10 we plot the real price of three energy sources: oil, natural gas, and coal. For ease of reading all prices are set to 100 in 1957. It is very risky to draw any strong conclusions from this data. The real price of oil has almost doubled since 1957; the price of natural gas is rising quite quickly, while the price of coal has increased the least over the period. Naturally these price increases have created some composition effects as predicted by our source and sink model, but only over certain periods of time. For example, Wing and Ekhaus (2003) examine the history of energy intensity in US production and divide its changes into those accruing from a changing mix of US industries and those accruing from within industry improvements in energy efficiency (which would correspond to a fall in Ω). Their findings suggest that from the late 1950s until the mid 1970s changes in the composition of US industries played a major role in reducing overall energy intensity. But during the 1980s and 1990s the reduction in US aggregate energy intensity has come from improvements in energy efficiency at the industry level. Therefore changes in the composition of output cannot carry the burden of explanation of our data.

Instead these compositional changes must have been helped along by significant technological progress in abatement or energy efficiency (Ω). The evidence for these changes is very strong. For example in a detailed study of the energy efficiency of consumer durables Newell et al. (1999) find strong support for a significant role for autonomous technological progress (over 60% of the change in energy efficiency), and supporting

[54] Note from (37) that the relative price of energy to final good output must rise along the model's balanced growth path because we have already shown that the energy intensity of production, χ, falls over time (see (45)).

roles for induced innovation created by higher energy prices. Similar evidence is presented by Popp (2002) who examines the impact of higher energy prices on the rate of innovation in key energy technologies. Using a database of US patenting activity over the 1970-1993 period, Popp explains variation in the intensity of energy patenting across technology groups as a function of energy prices, the existing "knowledge stock" in a technology area and other covariates such as federal funding for R&D. There are two main results from the study. The first is that a rise in energy prices shown in Figure 10 created induced innovation and a burst in patenting activity after the oil price shocks.

The second major result is that while prices are a significant determinant of patenting activity, other factors are also very important. For example, the existing stock of knowledge (as measured by an index of previous patenting weighted for impact) in a technology area has a large impact on subsequent patenting. For example, Popp reports that the average change in knowledge stocks over the period raise patenting activity on average by 24%; while the average change in energy prices over the period raise patenting on average by only 2%. Knowledge accumulation and spillovers are very important in determining the pace of future innovation.[55]

Taking these considerations into account would likely expand our feasible region AB. For example, if the emission intensity Ω fell when either energy prices rose (as in the source-and-sink model) or abatement intensified (as in the Stokey Alternative), then composition changes and active abatement could play a smaller role in checking the growth of pollution. This would of course make feasibility more likely.

Adding complications to our existing models would however take us too far afield, and as yet we know of no research that explicitly links energy prices, induced innovation and pollution emissions within a growth framework. Instead we take a small step towards a theory of induced innovation in the next section when we introduce a model with learning by doing in abatement and reconsider our stylized facts. But before doing so, we should note that we have, to a certain extent, stacked the decks against sustainable growth by assuming environmental quality has no effect on production possibilities. We have assumed that reducing the flow of emissions has only a cost in terms of drag and no benefit in terms of heightened productivity in goods production due to higher environmental quality. Several authors have however postulated a direct and positive link between the productivity of final goods output and environmental quality. This link casts doubt on the validity of growth drag exercises like ours. A typical formulation would add to our models a shift term on the final goods production function that is increasing in environmental quality. For example, Bovenberg et al. (1995) and Tahovnen (1991) both postulate this type of additional interaction. Once we allow for a direct productivity response to an improved environment it is not clear that emission reductions lower growth. Bovenberg et al. and Tahovenen et al. both give sufficient conditions under which this additional channel dominates.

In general the less important are emissions in the direct production function, the more responsive is natural growth to a reduction in emissions, and the greater is the marginal productivity boost from a cleaner environment, the more likely it is that emission reduction could, in theory, boost growth. While it is certainly plausible that a deteriorating environment will lower productivity, it is however unclear how important these impacts are empirically. We suspect that for most of industrial production these environmental impacts are small. Certain industries such as farming or fishing are certain to have larger productivity effects from an improved environment, but these industries are small contributors to GDP in developed countries. It is likely that these induced productivity effects are greatest in poor developing economies and as yet have escaped the notice of serious empirical researchers.

While it is certainly possible for these direct productivity effects to exist, we feel the biggest restriction imposed by our analysis thus far is its failure to link the rising costs of pollution control to innovation targeted at raising the productivity of abatement. Induced changes in technology of this sort are likely to lower energy intensity over time given the price paths shown in Figure 10 and innovation in abatement

[55] Related empirical work by Kaufmann (2004) however is less sanguine about the ability of technical change to lower energy intensity in the long run. Kaufman examines the 1929-1999 period and argues that estimates of autonomous energy efficiency increases have been drastically overstated because changes in the composition of inputs and outputs have had led to a significant lowering of energy intensity. Instead he argues that inter fuel substitutions and reductions in household energy purchases are largely responsible for the declining trend in the energy intensity of GDP.

technologies is likely to be forthcoming as abatement costs rise. Both of these induced effects would lower emissions per unit final output by altering Ω. There is of course a large body of empirical research finding just such effects. But clearly these links are important although difficult to model in a growth framework, for as Popp notes

> "The most significant result [sic of the study] is the strong, positive impact energy prices have on new innovations. This finding suggests that environmental taxes and regulations not only reduce pollution by shifting behavior away from polluting activities but also encourage the development of new technologies that make pollution control less costly in the long run. . . ..simply relying on technological change is not enough. There must be some mechanism in place that encourages new innovation", p178.

With this quote in mind we now turn to consider the role of innovation induced by regulation.

5 Induced Innovation and Learning by Doing

The series of models we have examined thus far explain the growth and environment data by focusing on technological progress in goods production, increased abatement efforts or changes in the composition of output over time.[56] Missing from this list is a consideration of induced innovation lowering abatement costs. Induced innovation or learning by doing is prominent in both growth theory (since the writings of Arrow (1962)), and in environmental economics more generally. For example, Jaffe, et al (1995) stresses the role of induced technological advance in solving pollution problems and holding down abatement costs. New growth theory often adopts formulations that are in essence learning by doing models. In models where knowledge accumulates over time, innovators learn from this stock of knowledge. In models of human capital acquisition the evolution of human capital reflects the learning of past generations. And the simplest AK specification can be thought of a model where learning by doing in capital accumulation generates constant returns to capital accumulation at the economy wide level.

The introduction of learning by doing offers several new features to the growth and environment relationship. First, if abatement efforts are subject to learning by doing then this feature alone may generate the prediction of a first worsening and then improving environment. In a static setting, learning by doing is identical to increasing returns, and Andreoni and Levinson (2001) show how increasing returns to abatement can generate an EKC in a partial equilibrium endowment economy.[57]

Secondly, learning by doing alters the costs of pollution control. If learning by doing effects are unbounded, then growth with falling pollution levels could conceivably come at decreasing cost to society. In a world with bounded learning by doing the implications are less clear, but it seems likely that the drag of pollution policy would be smaller if learning by doing effects are present. An important feature of the static analysis mentioned above is that the authors generate falling pollution levels under quite weak assumptions on preferences. Specifically they do not need to adopt formulations where the demand for environmental protection is very income elastic. This suggests that a parallel dynamic analysis may escape these restrictions as well, because the cost of environmental control is now lower.

Third, if learning by doing arises from economy wide growth in the knowledge stock then learning by doing models offer the possibility of linking technological progress in abatement with that in goods production. Learning by doing models give us one way to make our assumptions about knowledge spillovers and technological progress consistent across sectors. And as our previous analysis makes clear, the relative rates of technological progress in goods production and abatement are key to determining the sustainability of a balanced growth path.

[56] To this we could add the set of papers invoking political economy arguments. See for example Jones and Manuelli (2001) and the related empirical work by Barrett (1998).

[57] Copeland and Taylor (2003) extend their analysis to a two-sector general equilibrium model with industry wide external economies in abatement and replicate their finding for a production economy.

Finally, although learning by doing is often modeled as a passive activity and not purposeful investment, learning by doing can be a form of induced innovation. If a worsening environment necessitates the imposition of pollution controls, and abatement is subject to learning by doing, we have effectively followed the advice of Popp in identifying a causal factor behind subsequent improvements in abatement technology.

5.1 Induced Innovation and the Kindergarten Rule Model

To discuss these issues, we now introduce the Kindergarten Rule model of Brock and Taylor (2003). This model, like those in the static literature, relies on learning by doing in the abatement process to hold pollution in check. Importantly, though since learning by doing is really an assumption about knowledge spillovers, the Kindergarten model adopts a consistent set of assumptions regarding the beneficial impact of knowledge spillovers. It assumes, similar to contributions in the AK growth literature, that knowledge spillovers in capital accumulation lead to constant returns at the aggregate level. Similarly, knowledge spillovers in abatement eliminate diminishing returns to abatement. As a consequence, we obtain a relatively simple model of growth with pollution controls where learning by doing reduces abatement costs but does not eliminate the drag of environmental policy entirely.

In order to focus on the *implications* of ongoing technological progress for the environment and growth, Brock and Taylor (2003) adopt the very direct link between factor accumulation and technological progress employed by Romer (1986), Lucas (1988) and others. By doing so they generate a simple one-sector model of endogenous growth and environmental quality.[58]

For simplicity they adopt a conventional infinitely lived representative agent, and assume all pollution is local. There is one aggregate good, labeled Y, which is either consumed or used for investment or abatement. There are two factors of production: labor and capital. There is zero population growth and hence $L(t) = L$; recall it is the rate of population growth relative to the rate of technological progress that is key, so here one of these rates is set to zero. In contrast to labor, the capital stock accumulates via investment and depreciates at the constant rate δ.

5.1.1 Tastes

A representative consumer maximizes lifetime utility given by:

$$W = \int_0^\infty U(C, X)\, e^{-\rho t} dt \tag{48}$$

where C indicates consumption, and X is the pollution stock. Utility is increasing and quasi-concave in C and $-X$ and hence $X = 0$ corresponds to a pristine environment. When we treat X as flow, $X = 0$ occurs with zero flow of pollution. When we allow pollution to accumulate in the biosphere we assume the (damaging) service flow is proportional to the level of the stock. Taking this factor of proportionality to be one, then X is the damaging service flow from the stock of pollution given by X.

A useful special case of $U(C, X)$ is the constant elasticity formulation:

$$\begin{aligned} U(C, X) &= \frac{C^{1-\varepsilon}}{1-\varepsilon} - \frac{BX^\gamma}{\gamma} \text{ for } \varepsilon \neq 1 \\ U(C, X) &= \ln C - \frac{BX^\gamma}{\gamma} \text{ for } \varepsilon = 1 \end{aligned} \tag{49}$$

where $\gamma \geq 0$, $\varepsilon \geq 0$ and B measures the impact of local pollution on a representative individual.

[58] Extensions of their framework to allow for purposeful innovation and a distinction between these two forms of capital, along the lines of Grossman and Helpman (1991) or Aghion and Howitt (1998), seem both feasible and worthwhile.

5.1.2 Technologies

The assumptions on production are standard. Each firm has access to a strictly concave and CRS production function linking labor and capital to output Y. The productivity of labor is augmented by a technology parameter T taken as given by individual agents. Following Romer (1986) and Lucas (1998) we assume the state of technology is proportional to an economy wide measure of activity. In Romer (1986) this aggregate measure is aggregate R&D, in Lucas (1988) it is average human capital levels; in AK specifications it is linked to either the aggregate capital stock or (to eliminate scale effects) average capital per worker. We assume T is proportional to the aggregate capital to labor ratio in the economy, K/L, and by choice of units take the proportionality constant to be one.[59]

5.1.3 From Individual to Aggregate Production

Although we adopt a social planning perspective, it is instructive to review how firm level magnitudes aggregate to economy wide measures since this makes clear the assumptions made regarding the role of knowledge spillovers. We aggregate across firms to obtain the AK aggregate production function as follows:[60]

$$\begin{aligned} Y_i &= F(K_i, TL_i) \\ Y &= \sum_i F(K_i, TL_i) \\ Y &= TLF(K/TL, 1) \\ Y &= KF(1,1) = AK \end{aligned} \tag{50}$$

where the first line gives firm level production; the second line sums across firms; the third uses linear homogeneity and exploits the fact that efficiency requires all firms adopt the same capital intensity. The last line follows from the definition of T.

Summarizing: diminishing returns at the firm level are undone by technological progress linked to aggregate capital intensity leaving the social marginal product of capital constant.

We now employ similar methods to generate the aggregate abatement technology. To start we note pollution is a joint product of output and we take this relationship to be proportional.[61] By choice of units we take the factor of proportionality to be one. Pollution emitted is equal to pollution created minus pollution abated. Abatement of pollution takes as inputs the flow of pollution, which is proportional to the gross flow of output Y^G, and abatement inputs denoted by Y^A. The abatement production function is standard: it is strictly concave and CRS. Therefore denoting pollution emitted by P, we can write pollution emitted by the ith firm as:

$$P_i = Y_i^G - a\left(Y_i^G, Y_i^A\right) \tag{51}$$

Now consider a Romeresque approach where individual abatement efforts provide knowledge spillovers useful to others abating in the economy. To do so we again introduce a technology shift parameter Γ, and assume it raises the marginal product of abatement. To be consistent with our earlier treatment of technological progress in production we assume Γ is proportional to the average abatement intensity in the economy, Y^A/Y^G. Then much as before we have the individual to aggregate abatement technology

[59] As is well known, one-sector models of endogenous growth blur the important distinction between physical capital and knowledge capital and force us to think of "capital" in very broad terms. Extensions of our framework along the lines of Grossman and Helpman (1991) or Aghion and Howitt (1998) seem both possible and worthwhile. These extensions would however add additional state variables making our examination of transition paths difficult.

[60] Implementing our planning solution by way of pollution taxes and subsidies to investment and abatement should be straightforward.

[61] Nothing is lost if we assume pollution is produced in proportion to the services of capital inputs. The service flow of capital is proportional to the stock of capital, and the stock of capital is proportional to output.

transformation as:

$$\begin{aligned} P_i &= Y_i^G - a\left(Y_i^G\Gamma, Y_i^A\right) \\ P_i &= Y_i^G\left[1 - \Gamma a\left(1, Y_i^A/Y_i^G\Gamma\right)\right] \\ \sum_i P_i &= \sum_I Y_i^G\left[1 - \Gamma a\left(1, Y_i^A/Y_i^G\Gamma\right)\right] \\ P &= Y^G\left[1 - \Gamma a\left(1,1\right)\right],\ a\left(1,1\right) > 1 \\ P &= Y^G\left[1 - \theta a\left(1,1\right)\right],\ \theta \equiv Y^A/Y^G \end{aligned} \tag{52}$$

where the first line introduces the technology parameter Γ; the second exploits linear homogeneity of the abatement production function; the third aggregates across firms; the fourth recognizes that efficiency requires all firms choose identical abatement intensities, uses the definition of Γ and notes that for abatement to be productive it must be able to clean up after itself. The fifth line defines the intensity of abatement, $\theta \equiv Y^A/Y^G$. Since abatement can only reduce the pollution flow we must have $\theta \leq 1/a\left(1,1\right)$.[62]

It is important to note that the aggregate relationship between pollution and abatement given by the last line in (52) is consistent with empirical estimates finding rising marginal abatement costs at the firm level. Each individual firm has abatement costs given by foregone output used in abatement, and hence partially differentiating the first line of (52) and rearranging we find:

$$\frac{\partial Y_i^A}{\partial P_i} = -1/\left[\frac{\partial a}{\partial Y_i^A}\right] < 0,\ \frac{\partial Y_i^{A2}}{\partial P_i^2} > 0 \tag{53}$$

Marginal abatement costs are rising at the firm level.

Marginal abatement costs at the society level, are however, constant. To see why totally differentiate (52) allowing Γ and individual abatement to both vary. We find:

$$\frac{dY_i^A}{dP_i} = -1/\left[\partial a/\partial Y_i^A\right] - \frac{\left[\partial a/\partial Y_i^G\right]}{\left[\partial a/\partial Y_i^A\right]}\frac{d\Gamma}{dP_i} \tag{54}$$

Γ is the average abatement intensity in the economy, which given identical firms, is just the abatement intensity for the typical ith firm. Using $\frac{d\Gamma}{dP_i} = \left[\frac{1}{Y_i^G}\right]\left[\frac{dY_i^A}{dP_i}\right]$ and rearranging we obtain:

$$\begin{aligned} \frac{dY_i^A}{dP_i} &= -\frac{Y_i^A}{\left[\left[\frac{\partial a}{\partial Y_i^A}\right]Y_i^A + \left[\frac{\partial a}{\partial Y_i^G}\right]\Gamma Y_i^G\right]} \\ &= -\frac{Y_i^A}{a\left(Y_i^A, \Gamma Y_i^G\right)} = -\frac{1}{a\left(1,1\right)} < 0 \end{aligned} \tag{55}$$

where the first line follows from rearrangement and the second by CRS in abatement. The result given in (55) is identical to what we find by differentiating the aggregate relationship between pollution and abatement given in the last line of (52).

Summarizing: diminishing returns at the firm level, that lead to rising marginal abatement costs, are undone by technological progress linked to aggregate abatement intensity leaving the social marginal cost of abatement constant.

The formulations of learning by doing that we have adopted are extreme. In general we would expect the productivity in abatement (or production) to adjust gradually in response to a slow moving measure of knowledge capital. In the cases developed here however the productivity boost from an increased knowledge

[62] Adding the possibility of investments in restoration would probably strengthen the case for sustainable growth. Abatement of pollution and restoration are however distinct activities. We imagine that a restoration production function would take as an input the current damage to the environment – our stock variable X – and then apply inputs to restore it. This is quite different from abatement which operates to lower the current flow of pollution by use of variable inputs.

capital occurs instantaneously. So instead of Γ being a complicated function of the abatement intensities adopted in the infinite past history of the economy weighed by their relevance to productivity today, it is simply proportional to the current intensity. This is of course an abstraction, but a useful one since it frees us from keeping track of the evolution of two additional state variables (knowledge capital in abatement and knowledge capital in production), and allow us to capture the main feature of learning by doing models by linking the productivity of abatement to the intensity of this activity at the economy wide level. It also yields simple linear forms for production and abatement that add greatly to the model's tractability. This last feature is especially important in a model where the stock of environmental quality has already raised the number of state variables to two.

Putting these pieces together our planner faces the aggregate production relations for output and abatement given by the last lines of (50) and (52) together with the atemporal resource constraint linking gross output, abatement and net production:

$$Y = Y^G - Y^A \tag{56}$$

The Kindergarten model is only one approach to modeling endogenous growth and environment interactions. Closely related approaches in an AK framework are those of Stokey (1998), Smulders (1993) and Smulders and Gradus (1996). These papers all adopt AK models, but end up with different conclusions. Early work in a one-sector framework by Smulders (1993) and Smulders and Gradus (1996) demonstrated how continuing economic growth and constant environmental quality are compatible in an AK model. In constrast, Stokey (1998) demonstrated how continuing growth and constant environmental quality are not compatible within a AK set up. The difference in their results comes from their different assumptions on abatement. To see why this is true, start with (51), ignore knowledge spillovers, and work forward using now familiar steps to find:

$$P_i = Y_i^G \phi\left(1-\theta\right), \ \phi\left(\theta\right) \equiv \left[1 - a\left(1, 1-\theta\right)\right] \tag{57}$$

Stokey employs the specific functional form for ϕ given by $\left(1-\theta\right)^{\beta}$ for $\beta > 1$, and this implies the CRS abatement production function given by:

$$a\left(Y_i^G, Y_i^A\right) = Y_i^G \left[1 - \left(1 - \frac{Y_i^A}{Y_i^G}\right)^{\beta}\right] \tag{58}$$

Using (57) it is now easy to show abatement is subject to diminishing returns:

$$\frac{\partial P_i}{\partial Y_i^A} = -\beta\left(1-\theta\right)^{\beta-1} < 0, \ \frac{\partial P_i^2}{\partial Y_i^{A2}} > 0$$

which implies marginal abatement costs are rising at the aggregate level. Setting $Y^A = 0$ we find the first unit of abatement lowers pollution by the amount $\beta > 1$, somewhat similar to our formulation where $a(1,1) > 1$.[63] If we now combine (57) with (50), recall net output is $(1-\theta)$ times gross output, and introduce the variable $z = 1-\theta$, we find the exact specification employed in Stokey (1998).

$$Y = AKz, \ P = AKz^{\beta} \tag{59}$$

Stokey's (1998) result that growth is not possible follows from matching an AK aggregate production function with strictly neoclassical assumptions on abatement adopted from Copeland and Taylor (1994). That is, if we think of the AK model as one of knowledge spillovers then Stokey has assumed these spillovers occur in production but not abatement. By doing so, she eliminates "technological progress" in abatement and this eliminates the possibility of sustainable growth.

Comparing our approach to the work of Smulders is more difficult because abatement is not specifically modeled and he considers a variety of formulations. By specializing his framework to the AK paradigm we find:

$$Y = \alpha K, \ P = \left[\frac{K}{A}\right]^{\gamma} \tag{60}$$

[63] Since the marginal product of abatement is bounded when abatement is zero, Stokey (1998) is able to show that no regulation is undertaken initially and pollution rises lock-step with output.

The first element is just a standard AK production function. The second relates what Smulders refers to as net or emitted pollution to the capital stock, K, and abatement, A. If we employ (60) and solve for emissions per unit of gross output we find:

$$\frac{P}{Y} = \left[\frac{K}{A}\right]^{\gamma} / \alpha K \tag{61}$$

If the economy allocates a fixed fraction of its output to abatement, K/A is constant, and emissions per unit of gross output fall with the size of the economy. This reflects a strong degree of increasing returns. Moreover, the reader may note from (60) that pollution emitted goes to infinity as abatement goes to zero, which is inconsistent with pollution being a joint product of output. Therefore, Smulders and Gradus (1993, 1996) match AK aggregate production with assumptions on abatement ensuring increasing returns; and, in contrast with the Kindergarten specification, assume pollution is not a joint product of output.

5.1.4 Endowments

We treat pollution as a flow that either dissipates instantaneously – such as noise pollution – or a stock that is only eliminated over time by natural regeneration – such as lead emissions or radioactive waste. When X is a stock we have:

$$\dot{X} = AK\left[1 - \theta a\right] - \eta X \tag{62}$$

where η represents the speed of natural regeneration, and where for economy of notation we have denoted $a(1,1)$ by a. When X is a flow we have:

$$X = AK\left[1 - \theta a\right]$$

5.1.5 The Kindergarten Rule

We focus first on the possibility of balanced and continual growth, leaving to the next section a discussion of transition paths. Before we proceed with the formal analysis it proves instructive to step back slightly to consider the feasibility and optimality of sustainable growth. From our assumptions on abatement it is clear that if θ is set high enough all pollution emissions will be eliminated and we will enter a zero emission world. Therefore as long as $a > 1$ there will exist a $\theta < 1$ that generates zero emission technologies. And if $\theta < 1$ then some output will be left over for consumption and investment which can in turn drive growth in output. It appears then that feasibility is guaranteed by knowledge spillovers in abatement generating a constant marginal product.

The assumption of $a > 1$ is innocuous. Recall that abatement, like all other economic activities, pollutes. One unit of abatement creates one unit of pollution, but cleans up $a > 1$ units of pollution. It is only this surplus between costs and benefits, $1 - 1/a > 0$ that makes abatement useful at all. But even if growth is feasible, abatement is costly and this will cause drag as in our earlier formulations. The remaining questions for sustainability are how large is this drag, how much will it lower the return to capital, and what restrictions on preferences will be needed to generate sustainable growth.

To answer these questions consider the following problem:

$$\begin{aligned} & Maximize \int_0^{\infty} U\left(C, X\right) e^{-\rho t} dt \\ \text{s.t.} \quad & K\left(0\right) = K_0, \; X\left(0\right) = X_0, \text{ and } \theta \leq 1/a \\ & \dot{K} = AK\left[1 - \theta\right] - \delta K - C \\ & \dot{X} = AK\left[1 - \theta a\right] - \eta X \end{aligned} \tag{63}$$

where we adopt $U(C, X)$ from (49). Recall the fraction of gross output allocated to abatement is θ and since the flow of pollution into the environment cannot be negative this will never exceed $1/a$. We can write the

Hamilton-Jacobi-Bellman equation as:

$$\rho W(K,X) = Max \left\{ \begin{array}{c} H = \frac{C^{1-\varepsilon}}{1-\varepsilon} - \frac{BX^{\gamma}}{\gamma} + \\ \\ \lambda_1 \left[AK\left[1-\theta\right] - \delta K - C \right] + \lambda_2 \left[AK\left[1-\theta a\right] - \eta X \right] \end{array} \right\} \tag{64}$$

where $\rho W(K,X)$ is the maximized value of the program for the given initial conditions $\{K_0, X_0\}$, and H is the current value Hamiltonian for our problem. The controls for this problem are consumption, C, and abatement intensity, θ.

Observe the term involving our control variable, θ,

$$Max\left\{AK\theta\left[-\lambda_1 - a\lambda_2\right]\right\} \text{ s.t. } 0 \leq \theta \leq 1/a$$

where λ_1 is the positive shadow value of capital and λ_2 is the negative shadow cost of pollution. Since the Hamiltonian is linear in θ, the value of the term $S = [-\lambda_1 - a\lambda_2]$ will largely determine the optimal level of abatement. When $S > 0$, the shadow cost of pollution is high relative to that of capital. In this case abatement is relatively cheap and maximal abatement will be undertaken. Conversely when $S < 0$ the shadow value of capital is high relative to that of pollution. In this case abatement is relatively expensive and zero abatement will occur. Finally, when $S = 0$, the shadow values are equated and active, but not necessarily maximal, abatement will occur. Therefore, the value of S determines when and if the economy switches from a zero-to-active-to-maximal abatement regime. We deal with these possibilities in turn.

Regardless of the value of S, the optimal level of consumption will always satisfy

$$\frac{\partial H}{\partial C} = C^{-\varepsilon} - \lambda_1 = 0 \tag{65}$$

although the shadow value of capital and its dynamic path may differ across regimes.

When $S > 0$, maximal abatement occurs and the dynamics are given by:

$$\begin{array}{rcl} S & > & 0 \\ \theta & = & \theta^K,\ \theta^K \equiv 1/a \\ \dot{\lambda}_1 & = & -g\lambda_1,\ g \equiv A\left[1-\theta^K\right] - \delta - \rho \\ \dot{K} & = & \left[g+\rho\right]K - C\left(\lambda_1\right),\ K\left(0\right) = K_0,\ C\left(\lambda_1\right) \equiv \lambda_1^{-1/\varepsilon} \\ \dot{\lambda}_2 & = & \lambda_2\left[\rho+\eta\right] + BX^{\gamma-1} \\ \dot{X} & = & -\eta X,\ X\left(0\right) = X_0 \end{array} \tag{66}$$

By choosing the intensity of abatement $\theta = \theta_K$ there are no net emissions of pollution and the environment improves at a rate given by natural regeneration. We dub θ_K "the Kindergarten rule" because when economies adopt the Kindergarten rule pollution is cleaned up when it is created.[64]

Alternatively, S may be exactly zero. In this case we have an interior solution for abatement, with the following dynamics:

$$\begin{array}{rcl} S & = & 0 \\ \theta & \in & \left[0, \theta^K\right] \\ \dot{\lambda}_1 & = & -g\lambda_1 \\ \dot{K} & = & \left[A\left[1-\theta\right] - \delta\right]K - C\left(\lambda_1\right),\ K\left(0\right) = K_0,\ C\left(\lambda_1\right) \equiv \lambda_1^{-1/\varepsilon} \\ \dot{\lambda}_2 & = & \lambda_2\left[\rho+\eta\right] + BX^{\gamma-1} \\ \dot{X} & = & AK\left[1-a\theta\right] - \eta X,\ X\left(0\right) = X_0 \end{array} \tag{67}$$

[64] This is one of the most common rules taught in Kindergarten. For a list of common Kindergarten rules see All I Really Need to Know I Learned in Kindergarten: Uncommon Thoughts on Common Things by Robert Fulgham. Fulgham argues that the basic values we learned in grade school such as "clean up your own mess" (in effect our Kindergarten rule) and "play fair" are the bedrock of a meaningful life.

In this situation pollution is not completely abated, and hence the evolution of environmental quality reflects both the level of active abatement and natural regeneration. And finally, with no abatement at all we must have $S < 0$. Both pollution and output rise over time yielding:

$$\begin{aligned} S &< 0 \\ \theta &\in 0 \\ \dot{\lambda}_1 &= -\lambda_1 \left[A - \delta - \rho\right] - \lambda_2 A \\ \dot{K} &= \left[A - \delta\right] K - C\left(\lambda_1\right),\ K\left(0\right) = K_0,\ C\left(\lambda_1\right) \equiv \lambda_1^{-1/\varepsilon} \\ \dot{\lambda}_2 &= \lambda_2 \left[\rho + \eta\right] + BX^{\gamma - 1} \\ \dot{X} &= AK - \eta X,\ X\left(0\right) = X_0 \end{aligned} \tag{68}$$

Consider growth paths with active abatement. Then from (67) and (66) we find the shadow value of capital falls over time at a constant exponential rate:

$$-g \equiv \frac{\dot{\lambda}_1}{\lambda_1} = -\left[A\left[1 - \theta^K\right] - \rho - \delta\right] < 0 \tag{69}$$

provided the net marginal product of capital, at the Kindergarten rule level of abatement, A[1-θ^K], can cover both depreciation and impatience. We leave for now a detailed discussion of what this requires and assume it is true: $g > 0$. Then it is immediate that consumption rises at the constant rate $g_C = g/\varepsilon > 0$.

>From the capital accumulation equations in both (66) and (67) we can now deduce that capital and output must grow at the same rate as consumption if θ is constant over time. To determine whether the intensity of abatement is constant over time, consider the accumulation equation for pollution:

$$\dot{X} = AK\left[1 - \theta a\right] - \eta X \tag{70}$$

There are two ways (70) can be consistent with balanced growth. The first possibility is that we have a maximal abatement regime where $S > 0$ holds everywhere along the balanced growth path. In this situation, K grows exponentially over time and θ is set to the Kindergarten rule level. Using (66), this balanced growth path must have:

$$\dot{X} = -\eta X \text{ and } \theta = \theta^K \tag{71}$$

In this scenario, the environment improves at the rate η over time and abatement is a constant fraction of output $1 > \theta^K > 0$. As time goes to infinity the economy approaches a pristine level of environmental quality. Therefore the balanced growth path exhibits constant growth in consumption, output, capital and environmental quality. Consumption is a constant fraction of output and we have:

$$g_c = g_k = g_y = g/\varepsilon > 0,\ g_x = -\eta < 0 \tag{72}$$

A second possibility is that abatement is active but not maximal. Define the deviation of abatement from the Kindergarten rule as $D(\theta) = (\theta^K - \theta)/\theta^K$. Using this definition rewrite (70) to find:

$$\frac{\dot{X}}{X} = \frac{AK\left[D\left(\theta\right)\right]}{X} - \eta \tag{73}$$

It is apparent that if the deviation of abatement from the Kindergarten rule fell exponentially, then it may be possible for X to fall exponentially while K rises. That is, in obvious notation, a possible balanced growth path would have:

$$g_k + g_D = g_x < 0 \tag{74}$$

In this situation abatement is at an interior solution at all times and becomes progressively tighter over time approaching the Kindergarten rule asymptotically. The inflow of pollution from production into the environment is always positive but environmental quality improves nevertheless. This intuitive description

suggests that the possibility of this outcome must rely on both the pace of economic growth and the ability of the environment to regenerate. This is indeed the case as Brock and Taylor (2003) show that a necessary condition for us to remain in a $S = 0$ regime with active abatement is simply:

$$\eta\left(\gamma - 1\right) > g \tag{75}$$

This condition reflects two different requirements. The first is simply that γ cannot equal one. If it did then the (instantaneous) marginal disutility of pollution is a constant and λ_2 is a constant as well. This would also imply that consumption be fixed as well. This is inconsistent with growth of any sort.

Assuming γ not equal to one is necessary for balanced growth with an interior solution for abatement. But a second condition must also hold. Natural regeneration, η, must be sufficiently large relative to the growth rate g. If the rate of regeneration is high and growth rates quite low, then the optimal plan is to use nature's regenerative abilities to partially offset the costs of abating because the shadow value of foregone output is high in slow growth situations. Conversely, if regeneration is low and the growth rate g relatively high, then no amount of abatement short of the Kindergarten rule will hold pollution to acceptable levels.

This intuition suggests a natural corollary for the case of flow pollutants. If pollution has only a flow cost it is "as if" the environment is regenerating itself infinitely fast. This intuition suggests that as we let η get large, the results in the stock pollutant case should replicate those for a flow. This intuition is, in fact, correct. Brock and Taylor prove that when $g > 0$ and X is a flow pollutant, then sustainable economic growth with an ever improving environment is possible and optimal. With a flow pollutant, if $\gamma > 1$, then the intensity of abatement approaches the Kindergarten rule level of abatement, θ^K, asymptotically. Alternatively, if $\gamma = 1$, then $\theta = \theta^K$ everywhere along the balanced growth path.

These results are important in showing how the Kindergarten rule generates sustainable growth. Sustainable growth requires two conditions. The first is that g given in (69) is positive. The assumption $g > 0$ requires the marginal product of capital, adjusted for the ongoing costs of abatement, be sufficiently high. A necessary condition is that $A[1 - \theta^K]$ be positive, but this is guaranteed as long as abatement is a productive activity. Given abatement is productive, we still require the adjusted marginal product of capital, $A[1 - \theta^K]$, to offset both impatience and depreciation. If abatement is not very productive, then $\theta^K = 1/a$ will be close to one and growth cannot occur. If capital is not very productive or if the level of impatience and depreciation are high then ongoing economic growth cannot occur. These are however very standard requirements for growth under any circumstances.[65]

The second is that $h = g(1 - 1/\varepsilon) + \rho > 0$. This condition is the standard sufficiency condition for the existence of an optimum path in an AK model with power utility.[66] This condition is of course weaker than that needed in earlier models generating declining pollution levels. For example, ε is just σ in the CRRA specification we used earlier and we have already seen that Stokey (1998), Lopez (1998) and others require $\sigma > 1$ to generate declining emissions. Here the requirement is far weaker and this follows from the fact that consumer's are not required to make larger and larger sacrifices in consumption to fund an every growing abatement program.

5.2 Empirical Implications

The Kindergarten model relies heavily on the assumed role of technological progress in staving off diminishing returns to both capital formation and abatement. It is impossible to know apriori whether technological progress can indeed be so successful and hence it is important to distinguish between two types of predictions before proceeding. The first class of predictions are those regarding behavior at or near the balanced growth

[65] In Keeler, Spence and Zeckhauser (1972) a similar condition describes their Golden Age capital stock. In their model with no endogenous growth the Golden Age capital stock is defined by (in our notation) the equality $f'(K)[1 - 1/a] - \delta = \rho$ simulations of the model assume a to be 12 (see p.22). Chimeli and Braden (2002) assume a similar condition. Both studies assume abatement or clean up is a linear function of effort thereby ignoring the reality of diminishing returns and the necessity of ongoing technological progress.

[66] Denote the growth rate in an AK model with power utility by g^*, then in terms of our parameters we have $g^* = g/\varepsilon$ and the standard condition is $\rho + (\varepsilon - 1)\, g^*$. This is equivalent to $h > 0$. See Aghion and Howitt (1998, Equation (5.3)).

path. This set has received little attention in the empirical literature on the environment and growth, although balanced growth path predictions and their testing are at the core of empirical research in growth theory proper (see the review by Durlauf and Quah (1999)). The second set of predictions concern the transition from inactive to active abatement and these are related to the empirical work on the Environmental Kuznets Curve (See Grossman and Krueger (1993,1995) and the review by Barbier (2000)).

5.3 Balanced Growth Path Predictions

Using our previous results it is straightforward to show that near the balanced growth path we must have: convergence in the quality of the environment across all countries sharing parameter values but differing in initial conditions; the share of pollution abatement costs in output approaching a positive constant less than one; overall emissions rates falling and environmental quality rising; and emissions per unit output falling as production processes adopt methods that approach zero emission technologies. The model also presents predictions for the intensity of abatement that we discuss subsequently.

Whether the cross-country predictions will be borne out by empirical work is as yet unknown but an examination of US data shows the model's strongest predictions – those regarding falling emissions and improving environmental quality - are not grossly at odds with available U.S. data. The most favorable evidence for the model is the slow movement in pollution abatement costs in the face of dramatically declining pollution levels. The model explains this feature of the data by recourse to specifics of the abatement function that hold abatement costs down much as exogenous technological progress does in the Green Solow model.

The prediction of declining emission intensities along the balanced growth path is also consistent with the data shown in Figure 1, but as in Stokey (1998) the model only predicts declining emissions to output ratios after regulation begins.

5.4 The Environmental Catch-up Hypothesis

We have so far focused on balanced growth paths but the large EKC literature concerns itself with what must be transition paths towards some BGP. To examine these predictions we present several transition paths in Figure 5. One of these paths is that of a Poor country having small initial capital K^P but a pristine environment. The other is the path of a Rich country starting again with a pristine environment but with a much larger initial capital K^R. These differences in initial conditions could reflect variance across countries in geography, resource endowments or institutions that impact on initial productivity levels. Each economy starts with a pristine environment in stage I and grows. During this stage there is no pollution regulation: the environment deteriorates, X rises, and the capital stock grows until the trajectory hits the Switching Locus labeled SL. Once the economy hits the Switching Locus active regulation begins and the economy enters stage II.[67]

It is apparent from the figure that the Poor country experiences the greatest environmental degradation at its peak, and at any given capital stock, (i.e. income level) the initially Poor country has worse environmental quality than the Rich. Moreover, since both Rich and Poor economies start with pristine environments, the qualities of their environments at first diverge and then converge. This is the Environmental Catch-up Hypothesis.

Divergence occurs because the opportunity cost of abatement (and consumption) is much higher in capital poor countries. A high shadow price of capital leads to less consumption, more investment and rapid industrialization in the Poor country. Nature's ability to regenerate is overwhelmed. The quality of the environment falls precipitously. In capital rich countries the opportunity cost of capital is lower: consumption is greater and investment less. Industrialization is less rapid and natural regeneration has time to work. The peak level of environmental degradation in the Rich country is therefore much smaller. But

[67] Brock and Taylor (2003) show the exact position and shape of the locus depend on whether parameters satisfy the fast growth or slow growth scenario. For the most part we will proceed under the assumption that economic growth is fast relative to environmental regeneration; that is (75) fails strongly and we have $\eta(\gamma - 1) < g$. This implies $\theta(t) = \theta^K$ everywhere along the balanced growth path (Figure 12 implicitly assumes this result). For illustrative purposes we will sometimes discuss the parallel flow case (where we can think of η approaching infinity but (75) failing because $\gamma = 1$).

once we enter Stage II abatement is undertaken and since abatement is an investment in improving the environment, it is only undertaken when the rate of return on this investment equals (or exceeds) the rate of return on capital. Since economies are identical, except for initial conditions, rates of return are the same across all countries in Stage II. Equalized rates of return require equal percentage reductions in the pollution stock. Therefore absolute differences in environmental quality present at the beginning of Stage II disappear over time.

Note how similar this intuition for the ECH is to that given for the EKC prediction in the Green Solow model. In the Green Solow model initial rapid growth overwhelms nature's ability to dissipate pollution starting from its initial position at a biological equilibrium. Eventually growth slows and the environment's regenerative powers restore its quality slowly over time. Growth is initially rapid in the Solow model because of diminishing returns. In the Kindergarten model, growth is initially rapid because there is no regulation and no drag from pollution policy to lower the marginal product of capital. And once regulation is active, growth slows because regulation lowers the net marginal product of capital. The environment's regenerative powers then restore its quality slowly over time. Both explanations have nature overwhelmed early on and both give prominent roles to a declining marginal product of capital.

The discussions above, and Figure 5, assume the fast-growth-slow-regeneration assumptions hold. We chose this case to discuss and illustrate because it illustrates the forces at work very clearly. Since many of the same conclusions hold when growth is relatively slow we only provide a sketch here of some differences. There is again a Switching Locus which divides Stage I from Stage II. The Switching Locus again defines a unique X^* that is declining in K^*. The most important difference is that once a trajectory of the system hits this new Switching Locus it remains within it forever. If the economy is below the locus then abatement is inactive and K rises at a rapid rate: X increases rapidly until the Switching Locus is reached in finite time. If the initial (K, X) is above the locus, maximal abatement is undertaken but this drives down the shadow cost of pollution very quickly and we again hit the locus, this time, from above.

Once on the locus, countries remain trapped within it thereafter and this implies the economy's choice of abatement remains interior; i.e. the trajectory follows along the Switching Locus maintaining $MAC = MD(K, X)$ throughout. Over time abatement rises and the intensity of abatement approaches the Kindergarten rule in the limit. Therefore, the slow growth case is very similar except that the model now predicts an even stronger form of convergence. All transition paths remain on the Switching Locus once active abatement begins; therefore policy active countries share the *same* path for environmental quality and income levels in Stage II.

5.5 The ECH and the EKC

Brock and Taylor prove that all economies capable of sustained growth must follow the stage I – stage II life cycle producing an EKC like relationship between income and environmental quality.[68] Their income and growth prediction is however somewhat different from a standard EKC result. They predict that countries differentiated only by initial conditions exhibit initial divergence in environmental quality followed by eventual convergence.[69] Moreover, as Figure 5 makes clear countries make the transition to active abatement at different income and peak pollution levels. This of course throws into question empirical methods seeking to estimate a unique income-pollution path. More constructively it suggests that an important feature of the data may well be a large variance in environmental quality at relatively low-income levels with little variance at high incomes. Empirical work by Carson et al. (1997) relating air toxics to U.S. state income levels is supportive of this conjecture:

[68] The addition of perfect capital markets can affect the pollution and income path greatly. To a certain extent a country is running down its environment initially to accumulate capital. With *perfect* capital markets it is possible to eliminate stage I entirely in some cases. Given many less developed countries have very limited and imperfect access to capital markets it is difficult to know the empirical importance of this result. It suggests however that access to capital markets may be an excluded country characteristic in EKC style regressions.

[69] It is possible to show X is rising throughout Stage I and this ensures points along the Switching Locus do indeed represent peaks in pollution levels.

> "Without exception, the high-income states have low per-capita emissions while emissions in the lower-income states are highly variable. We believe that this may be the most interesting feature of the data to explore in future work. It suggests that it may be difficult to predict emission levels for countries just starting to enter the phase, where per capita emissions are decreasing with income", p. 447-8.

In some cases however, (initially) Rich and Poor will make the transition at the same income level but still exhibit our Catch-up Hypothesis. To investigate, we report the switching locus in the fast growth case. It takes on an especially simple form given by:

$$MAC = \frac{1}{a} = \frac{B}{[\rho + \gamma\eta]} X^{*\gamma-1} [hK^*]^{\varepsilon} = MD(K^*, X^*) \tag{76}$$

which is the downward sloping and convex relationship between pollution and capital depicted in Figure 5. The left hand side of (76) represents marginal abatement costs. The right hand side is marginal damage evaluated at $\{K^*, X^*\}$. Marginal damage is increasing in the pollution stock provided γ exceeds one, and since the flow of national (and per-capita) income Y is always proportional to K, it is apparent that the income elasticity of marginal damage with respect to flow income is given by ε. Large values of ε correspond to the strong income effects referred to earlier

Let γ approach one. Then the slope of the Switching Locus approaches infinity and all countries attain their peak pollution levels at the same K^*. But even with a common turning point differences in environmental quality remain. Moreover, these are not simple level differences because countries initially diverge and then converge after crossing K^*. To eliminate our catch-up hypothesis we must assume regeneration is infinitely fast: X is a flow. In this case Brock and Taylor show the Switching Locus is again vertical at a given K^*. More importantly, since pollution is proportional to production before K^*, and policies are identical after K^*: initial conditions no longer matter.

These results tell us that when pollution is strictly a flow, all countries share the same income pollution path. But when pollution does not dissipate instantaneously, initial conditions matter. We have the Environmental Catch-up Hypothesis, and empirical methods must now account for the persistent role of initial conditions.[70]

5.6 Pollution Characteristics

The ECH focuses on cross-country comparisons in pollution levels, but says little about how predictions vary with pollutant characteristics. And while most authors have focused on generating an EKC relationship there has been very little work examining how these predictions vary with pollutant characteristics. This is unfortunate since there is good data in the U.S. and elsewhere that could be fruitfully employed to test within country but across pollutant predictions. This is especially important since many models can generate the EKC result.

To demonstrate the Kindergarten model's across pollutant predictions consider regeneration first and start from a position where $\eta = 0$ (radioactive waste). Brock and Taylor (2003) show that the Switching Locus in Figure 5 shifts outwards as we raise η. The response is to delay action and allow the environment to deteriorate further. Once we raise η sufficiently the economy eventually enters the fast regeneration regime and here we find abatement delayed in another manner – it is introduced slowly by the now gradual implementation of the Kindergarten rule. Faster regeneration then implies that countries either begin abatement at higher income levels or allow their environments to deteriorate more before taking action. Surprisingly, fast regeneration will be associated with lower and not higher environmental quality - at least over some periods of time or ranges of income.[71]

[70] This result may explain why empirical research investigating the EKC has been far more successful with air pollutants like SO2, than with water pollutants or other long lasting stocks (see the review by Barbier (2000)).

[71] An especially colorful example of delay in abatement caused by rapid natural regeneration is that of the City of Victoria in British Columbia. Every day, the Victoria Capital Regional District (CRD) dumps approximately 100,000 cubic meters

A change in regeneration rates also affects the pace of abatement. If a pollutant has a long life in the environment, then once abatement begins it is clear that natural regeneration can play only a small role. Consequently the optimal plan calls for an initial period of inaction before starting a very aggressive abatement regime: the immediate adoption of the Kindergarten rule. When η is relatively large we are in the fast regeneration regime and abatement is intensified gradually and only approaches the Kindergarten rule level in the limit.

Putting the predictions for the timing and intensity of abatement together, Brock and Taylor find that very long-lived pollutants should be addressed early with their complete elimination compressed in time. It is optimal to delay action on short-lived pollutants and adopt only a gradual program of abatement. This description of optimal behavior is of course consonant with the historical record in several instances where long-lived chemical discharges and gas emissions were eliminated very quickly by legislation, whereas short-lived criteria pollutants have seen active regulation but not elimination over the last 30 years.

Pollutants also differ in their toxicity. The marginal disutility of toxics could exceed those classified as irritants, and damages from toxics may rise more steeply with exposure. The first feature of toxics implies their abatement should come early. This is clear from (76) where increases in B shift the Switching locus inwards and hasten abatement. Surprisingly very convex marginal damages (a high γ) call for the gradual and not aggressive elimination of pollution. The logic is that any reduction in the concentration of toxics has a large impact on marginal damage. Therefore, only by lowering emissions slowly can we match a steeply declining value of marginal reductions with a falling opportunity cost of abatement. Therefore, although toxics may have large absolute negative impacts on welfare, this argues for their early, but not necessarily aggressive, abatement.

And finally how does the income elasticity of the demand for environmental quality (ε) affects the onset and pace of regulation? We have already shown that the restriction of $\varepsilon > 1$ is not needed to generate sustainable growth. This parameter does however have a role to play in determining the timing of regulation. To illustrate its role consider the fast growth regime and let the gross marginal product of capital, A, rise. This necessarily raises g and if $\varepsilon > 1$, the Switching Locus shifts in. Abatement is hastened. When $\varepsilon < 1$, abatement is delayed and peak pollution levels shift right.[72] A similar set of results holds for increases in the productivity of abatement although there is an additional conflicting force. Therefore, in contrast to earlier work Brock and Taylor (2003) finds that the income elasticity of marginal damage has an important role to play in determining the income level at which abatement occurs and the resulting pollution level, but virtually no role in determining if the environment will improve nor its rate of improvement.

6 Conclusion and Suggestions for Future Research

The relationship between economic growth and the environment is not well understood: we have only limited understanding of the basic science involved – be it physical or economic – and we have very limited data. In this review we have tried to evaluate ongoing efforts, both theoretical and empirical, to understand this relationship. We started by introducing definitions for the scale, composition and technique effects of growth on pollution, and then constructed three simple theoretical models to highlight the role each can play in generating sustainable growth. Throughout we have tried to link these models to the existing literature and in a very rudimentary way evaluated their predictions using data on pollution emissions, abatement costs and resource prices.

This is a research topic on the periphery of growth theory proper. It placement reflects the lack of a core model to work with and the paucity of data for empirical analyses. This is unfortunate because an

of sewage into the Juan de Fuca Strait. Scientific studies have long argued that since the sewage is pumped through long outfalls into cold, deep, fast moving water there is no need for treatment. The CRD has always used these studies to delay building a treatment facility. Current plans are for secondary treatment to begin in 2020, but until then over 40 square kilometers of shoreline remains closed to shell fishing. Background information can be found at the Sierra Legal Defense fund site http://www.sierralegal.org/m_archive/1998-9/bk99_02_04.htm

[72] Our use of the terms delayed or hastened does not refer to calendar time, but rather to whether actions occur at a higher or lower income level.

understanding of the relationship between economic growth and the environment may be key to long run prosperity; it is certainly of interest to developing country governments searching for a balance between material growth and environmental protection, and it is also of great interest in the developed world given current debates over global warming, its costs, and the costs of its amelioration.

Our review has revealed much heterogeneity in terms of approach and methods used in theoretical work. Some heterogeneity is to be expected, but too much dissipates effort. By examining the pollution creation and abatement process in some detail we hoped to direct future efforts more productively. We showed that standard assumptions such as CRS and concavity of the abatement production function lead to tractable formulations where pollution emissions appear in much the same way as other factors. By doing so we were able to show how we can evaluate the costs of environmental policy in a manner similar to that used to evaluate the drag of natural resources on growth. By making this connection precise we provided a bridge between the early resources and growth literature of the 1970s with the recent literature on pollution and income. We also hope to instill in others the need to provide micro foundations for assumptions over the amount of pollution emitted or abated in production, since we have repeatedly shown the importance of these assumptions for a model's ability to generate sustainable growth.

Our theoretical review contains three main messages. The first comes directly from our Green Solow model where we showed how the typical convergence properties of the neoclassical model together with a standard natural regeneration function yield an Environmental Kuznets Curve. This suggests that efforts to explain the EKC via complicated processes of political economy, IRS, freer trade, and differential factor growth, etc. may be unnecessary. At the very least it points out that the interplay of natural and Solow growth dynamics certainly work towards this finding.

Our second message concerns drag. We have shown throughout that efforts to limit pollution and raise environmental quality create a drag on growth rates. This finding was stronger in some cases since rapid population growth could eliminate the possibility of sustainable growth entirely. The drag calculations we provided are for illustration and not meant to substitute for more serious enquiry that must include empirical estimation of key parameters. Nevertheless these calculations are helpful in focusing our efforts on key parameters (the share of emissions in final good production or the rate of change in pollution abatement costs), and demonstrate how difficult it is to generate sustainable growth in a country with significant population growth. The calculations also offer a quick litmus test; if a specification suggests environmental policy reduces growth by 40%, something is surely amiss. It is hoped that drag calculations of the type we have conducted become a more standard feature in the literature.

Finally, we have shown how different assumptions on abatement can produce very different results for sustainability (recall the contradictory results of Smulders and Stokey in the AK model). To a certain extent progress in this literature has been slowed because researchers have too many degrees of freedom in choosing their specification. Some restrictions are imposed by the requirement of a balanced growth path, but this still leaves much leeway to the researcher. We have adopted a consistent specification of pollution creation and abatement based on the common, if not innocuous, assumptions of constant returns, concavity and pollution being a joint product of output. Within these confines we have then argued that technological progress in abatement, distinct from that in final goods, is key to generating sustainable growth at reasonable costs. By identifying this as a key requirement we hope to direct future research efforts towards a theory of induced innovation where both relative prices and pollution regulations determine the pace and direction of improvements in abatement technology.

Our review of empirical work shows that the existing literature has made relatively few contributions to our understanding. The Environmental Kuznet's curve stands out as a key empirical regularity, but continued progress in this area can only come with a more serious consideration of other related data. One contribution of this review has been to show that many of the theoretical models capable of generating an EKC also contain predictions in other directions that are worthy of examination. The simple Green Solow model had strong predictions for the emission intensity of GDP; the Stokey Alternative contained sharp predictions about the time profile of abatement costs; the Source-and-Sink model contained links between energy prices, energy use, and pollution levels; and finally, the Kindergarten model produced a cross-country catch-up hypothesis as well as yielding several within-country but across-pollutant predictions. Further

progress in our understanding can only come from a tighter connection between theory and data.

This review has been limited by its focus. It has been a review of work linking industrial pollution and growth with only small asides to consider natural resource use. In many cases the formal structure of the models resembled those in the renewable resource literature, but we did not provide a review of findings there. As such we have sidestepped the rather thorny issues of property rights protection and the efficiency of environmental policies. We have done so not because we believe that these issues do not merit attention, but rather because adding a useful discussion of these topics would make this review unwieldy. It should be emphasized however that a common feature of the resources we examined was their well-defined property rights. This is true for air quality when the quality is determined by local pollution; and it is true of oil and other energy resources.

There are however an important class of resources where property rights enforcement is lax or where no property rights exist at all. Property rights problems arise in three main areas. These are: local and transnational fisheries; the global atmospheric commons; and lastly, the forest stocks in many developing countries. It is somewhat ironic that these renewable resources are under far more threat than the so-called exhaustible resources such as oil, gas or minerals. The reason for this is inescapable: the diffuse nature of many of these resources has led to a lack of property rights and very little management. Therefore, while our focus on industrial pollution is perhaps defensible in that it determines the air quality and health prospects for hundreds of millions of people across the globe, we should not forget other vexing problems arising from the lack of property rights. And while our data and the existing empirical results suggest that many local pollution problems are well in hand or respond well to increases in incomes brought about by growth, global pollution problems, such as global warming, appear to be far more difficult to solve.[73] Therefore, it may be that the real threat to continued growth arises not from the relatively small drag introduced by existing environmental policies, but from the absence of new policies to stem more serious global problems.
