Detection of a drug depends largely on its absorption, distribution, and elimination properties. There are various routes of drug administration; oral (e.g., drinking ALCOHOL or swallowing pills), intravenous (e.g., HEROIN injected into a vein) and inhalation (e.g., smoking MARIJUANA; snorting COCAINE; sniffing GLUE). Drugs taken orally are usually the slowest to be absorbed (i.e. the speed at which the drug reaches the brain and other body organs) whereas intravenous and inhalation routes result in the fastest absorption. Once the absorbed drug enters the blood stream it is rapidly distributed to the various tissues in the body. The amount of drug stored depends on the nature of the drug, the quantity, duration of ingestion, the tissue holding the drug and the frequency of use.

Some drugs are fat-soluble and are deposited in fat tissues. For example, δ^9-TETRAHYDROCANNABINOL (THC), the active ingredient in marijuana, is highly fat-soluble, resulting in rapid reductions in blood levels as the drug is being distributed to the various tissues. Blood levels of δ^9-THC peak and start to decline in half the time it takes to smoke a marijuana "joint." Concentrations are known to fall by almost 90 per cent in the first hour. Depending on the amount of drug stored in the fat tissues, detection may be possible in the urine for many days after last use. There are cases where marijuana metabolites have been detected for as long as sixty days after last use, since small amounts from fat go back into blood and appear in the urine. Ethanol or ethyl alcohol (the beverage alcohol) is not fat-soluble but is distributed in the total body water. Since blood is mostly made up of water, the presence of alcohol is easier to detect than fat-soluble drugs like δ^9-THC.

The "absorption" and "distribution" phases are followed by an "elimination" phase. The liver is the major detoxification centre in the body where the drugs are metabolized as blood circulates through this organ. The metabolites are then excreted into the urine through the kidneys. At the same time, drugs deposited in fat tissues are also slowly released into the blood stream and metabolized.

A laboratory technician tests a urine sample for the presence of drugs, 1986. (© Ed Kashi/CORBIS)

Drugs vary by their elimination half-life. An elimination half-life is the amount of time needed for the drug level to fall by 50 percent. Every half-life the drug level falls by 50 percent. Table 1 shows the impact of the half-life on the amount of drug left in the body. At the end of 7 half-lives over 99 percent of the drug will be eliminated from the body. (See Table 2 for drug half-lives). The half-life of a drug is heavily influenced by a variety of factors including the individual's age, sex, physical condition as well as clinical status. A compromised liver and concurrent presence of another disease or drug have the potential of enhancing the toxic effects of the drug by slowing down the elimination process. Under different clinical conditions, however, this process may be speeded up. Therefore, great variation can be found in the half-lives of the same drug.

Approximately six half-lives are required to eliminate 99 per cent of any drug. Because cocaine's half-life is relatively short, averaging one hour, only six hours are needed for elimination of 99 per cent of the drug. On the other hand, cocaine's metabolites have a longer half-life and can be detected for a considerably longer period of time through urine drug assays. Compared to cocaine, PHENOBARBITAL has a much longer half-life of 80-120 hours, so that at least 480 hours (or 20 days) are required to eliminate 99 per cent of the drug. Since there is much variation in the half-life of different drugs and the absolute amount of drug present can be very small, it is crucial that the appropriate body fluid for analysis is selected for testing.

Ethanol is absorbed from the stomach by simple diffusion. Gastric absorption is fastest when strong drinks, distilled spirits containing 40 to 50 percent ethanol by volume are consumed. Dilute beverages, such as beer (4-5% ethanol) or wine (11-12% ethanol) are absorbed slowly. Alcohol is absorbed very rapidly from the small intestines. The essential action of food is to delay gastric emptying and thus slow the absorption process. Typically, studies have shown that peak BAC is reached between 30 minutes and 90 minutes of consumption; earlier on an empty stomach and later on a full stomach. Once absorbed, ethanol rapidly diffuses throughout the aqueous compartments of the body, going wherever water goes.

TABLE 1
Impact of Half-Life

	Amount of drug left in the body	*Amount of drug eliminated*
Start	*100%*	*100%*
End of 1st half-life	50.0%	50.0%
End of 2nd half-life	25.0%	75.0%
End of 3rd half-life	12.5%	87.5%
End of 4th half-life	6.25%	93.75%
End of 5th half-life	3.125%	96.87%
End of 6th half-life	1.56%	98.44%
End of 7th half-life	0.78%	99.22%

TABLE 2
Drug Half-Lives and Approximate Urine Detection Periods*

Drug	*Half-life (t2)*	*Detection period*
Methamphetamine Amphetamine (metabolite of methamphetamine)	12–34 hours 7–34 hours	2–3 days
Heroin Morphine (metabolite of heroin)	60–90 minutes 1.3–6.7 hours	In minutes Opiates positive for 2–4 days (EIA)
6-Mono-acetyl-morphine (MAM)	30 minutes	Few hours
Phencyclidine (PCP)	7–16 hours	2–3 days
Cocaine	0.5–1.5 hours	Few hours
Benzoylecgonine (metabolite of cocaine)	5–7 hours	3–5 days
δ^9-Tetrahydrocannabinol	14–38 hours	90% fall in 1 hour (blood)
δ^9-Tetrahydrocannabinoic acid (marijuana metabolite in urine)		Depending on use, few days to many weeks
Benzodiazepines	Few hours to days	days to weeks, depending on half-life
Diazepam	15–40 hours	2 weeks
Flunitrazepam (rohypnol)	9–25 hours	0.2% excreted unchanged!
Methadone	15–40 hours In chronic patients ~22–24 hours	
Barbiturate (phenobarbital)	35–120 hours	1–2 weeks after last use
Alcohol (ethanol)	Blood levels fall by an average of 4–5 mmol/L/hour (15–18 mg/100 mL)/hour	1.5 > 12 hours depending on the peak blood level. Urine typically positive for an additional 1–2 hour.
Gamma-hydroxybutyrate (GHB)	0.3–1.0 hour	Less than 12 hours

*The detection period is very much dose-dependent. The larger the dose, the longer the period the drug/metabolite can be detected in the urine

Absorption, distribution into different tissues and elimination are dynamic processes and take place simultaneously. The rate of removal of ethanol from the body is the sum of the rates of excretion in urine, breath and sweat, and the rate of the metabolism in the liver and other tissues. In humans, alcohol metabolism follows a "zero" order kinetics, i.e., it is largely independent of alcohol concentration in the blood and its levels decline almost linearly over time. The implication of this is that BAC falls at a constant rate over time. In social drinkers it is from 0.015 to 0.018 percent (15 mg/100mL to 18 mg/100mL) per hour and in heavy drinkers it is typically between 0.018 and 0.025

percent (18mg/100mL to 25mg/100mL) per hour. In the alcoholic patient, the elimination rate is generally higher. In forensic calculations, a rate of 0.015 percent (15mg/100mL) per hour is usually used. In our studies we have found 0.018 percent (18mg/100mL) per hour to be the average rate of metabolism. The larger the dose of alcohol given, the longer the duration of the measurable blood alcohol concentration.

SELECTION OF DRUGS TO BE TESTED

A number of different criteria can be applied to the drug(s) or category of drugs that should be tested or monitored. Drug availability, clinical effects and robustness of the analytical method(s) used for analysis are probably the most important.

Availability. Prescription patterns of psychoactive and other drugs vary from place to place and country to country. Abuse of BENZODIAZEPINE nitrazepam is common in Europe but almost unknown in North America, since it is not sold here. The psychoactive chemical CATHINON (cathine), the active ingredient in the leaves of the KHAT plant, is chewed in northeast Africa, is not a problem in North America. CODEINE, an OPIOID available in Canada as OVER-THE-COUNTER preparations, is sold only by prescription in the United States.

A wide availability of "legal" STIMULANTS poses an interesting problem since they are a common finding in accident victims. A study carried out by the U.S. National Transportation Safety Board from October 1987 to September 1988 showed that over-the-counter stimulants—such as ephedrine, pseudoephedrine and phenylpropanolamine—were commonly found among drivers killed in heavy truck accidents. Amongst the eight States that participated in this safety study almost all AMPHETAMINE use was in the California region. Similar findings are also reported from emergency rooms over the past five years as well as from admissions in a trauma unit due to motor-vehicle accidents. All this suggest that drug use varies not only from place to place but also region to region within a given country.

Thus, the selection of a drug to be tested and monitored, appropriate for one country and place, may not necessarily be appropriate for another country.

Clinical Effects. Drugs that manifest abuse potential and impair behavior such that job performance can be affected are prime candidates for testing or monitoring in the workplace. Alcohol and cocaine are examples of this.

Analytical Methods. A false positive finding can have a serious impact on the livelihood of the person being tested. Therefore, special attention needs to be paid to the testing methods. Ideally the analytical method should be specific for the drug being tested (i.e., no false positive), easy and inexpensive to perform. Confirmation methods should also be readily available. Availability of technical and scientific expertise to perform the tests is also essential.

Interpretation of the analytical results also needs to be carefully considered as even a normal diet can result in a positive drug identification. For example, poppy seed ingestion can result in a true positive *analytical* result (OPIATES, like heroin, are derived from the poppy plant PAPAVER SONIFERUM) but it is a false positive for drug use. Some ethnic diets may also lead to these confounding problems, as when food containing poppy seeds is eaten during Ramadan.

What should be analyzed? Ideally the analysis should look for the parent drug rather than its metabolite, although this may not always be possible as some drugs are very rapidly metabolized (e.g., heroin metabolism to MORPHINE). Sensitivity of the analytical procedure should be dictated by the drugs' psychoactive pharmacological properties. If the drug is shown to be devoid of abuse potential then its detection beyond the time of pharmacological activity, although important in the clinical management of the patient, does not necessarily serve a useful purpose for a workplace drug screening programme.

The guidelines developed by the NATIONAL INSTITUTE ON DRUG ABUSE in April 1988, address five "illegal" drugs: marijuana, PHENCYCLIDENE, AMPHETAMINE, cocaine and heroin. Rapid screening methods that allowed for "mass screening" were available at that time, as were the confirmation methods for these five drugs. Mood altering substances such as benzodiazepines, BARBITURATES and some stimulants such as antihistamines are at present excluded from these regulations in the United States. This is probably due to the wide availability of these drugs as medications within the general population and the technological re-

quirements for screening and monitoring of these drugs.

TYPES OF TESTING: BLOOD, URINE, AND HAIR SPECIMENS

Blood and urine are the most commonly used biological fluids in the analysis for drugs other than alcohol. Blood, obtained by an invasive procedure, is available only in small quantities and drug concentration levels in blood are typically low. Urine is the preferred sample of choice as it is available in larger volumes, contains the metabolite and requires less invasive procedures in its collection. Both sampling procedures, however, are limited in their ability as they only determine the absolute amount of drug present in the fluid being examined. This quantity is dependent upon the amount of the drug used, when it was last used, as well as the half-life of the drug.

Recently, hair samples have been used to detect drug use. A number of technical problems must be overcome before hair can be used as a definitive proof of drug use. Hair treatment and environmental absorption are but two of the many concerns and problems that have been cited. An advisory committee of the Society of Forensic Toxicology has recently reported that "The committee concluded that, because of these deficiencies, results of HAIR ANALYSIS alone do not constitute sufficient evidence of drug use for application in the workplace."

Various body fluids such as sweat, saliva, blood, urine and breath, have been used for alcohol analysis. Breath, though not a body fluid, is commonly used by law enforcement authorities. Although a number of variables can effect breath/blood ratio, a 2100:1 alveolar breath/blood conversion ratio has been used and accepted for use with BREATHALYZERS. Breath-testing equipment calibrated with a blood:breath conversion factor of 2100 consistently underestimate actual BLOOD ALCOHOL CONCENTRATIONS (BAC). Accuracy of breath analysis results is subject to various instruments and biological factors. Potential errors in breath analysis can also be caused by the presence of residual alcohol in the mouth. Immediately after drinking there is enough alcohol vapour in the mouth to give artificially high concentrations on breath analysis. Generally this effect disappears twenty minutes after drinking but high values for as long as forty-five minutes have been reported.

As of the early 1990s, all existing technologies are limited in terms of determining how much or when the drug was consumed.

Blood and saliva concentrations reflect the current blood alcohol concentration, but generally a blood sample is used in hospitals to access the patient in the casualty wards. In programmes requiring monitoring of alcohol use, urine is probably the sample of choice. Urine alcohol concentration, which represents the average blood alcohol concentration between voiding, has the potential of being "positive" while the blood may be "negative."

MEASURING IMPAIRMENT

Except for alcohol, the degree to which a person is influenced or impaired by a drug at the time of the test cannot be determined from test results alone. Correlations between positive blood levels and degree of impairment are usually stronger than correlations between urine levels and degree of impairment; however, neither blood nor urine tests are sufficiently accurate to indicate impairment even at high levels of concentration. Human studies using marijuana and cocaine have shown that a "perceived high" is reached *after* the drug concentration has peaked in the blood. Generally, blood can only show positive results for a short time after drug consumption, whereas urine can be positive for a few days to weeks after last use. For example, metabolites of δ^9-THC (active ingredient in marijuana) that are lipid-soluble can be detected in the urine from a few days to many weeks, depending on the drug-habit of the user. Excretion of the drug in urine and its concentrations are also affected by several factors, such as dilution and pH (acidity) of the urine. I have seen many cases where a strong, positive urine sample for CANNABINOIDS was found in the morning, a borderline positive in the afternoon, followed by a strong positive the next morning; I have also seen similar cases with respect to phenobarbital.

A positive urine test cannot reveal the form in which the drug was originally taken—or when and how much was taken. For example, CRACK-cocaine, impure cocaine powder or cocaine paste (which can be smoked, inhaled, injected or chewed) all give the same result in the urine test. The consumption of poppy seeds has been reported

to give positive results for opiate use, because some seeds contain traces of opiates and some have been known to be contaminated with OPIUM derivatives. Similarly, consumption of herbal COCA tea has resulted in positive results for cocaine use. These diverse incidences illustrate the difficulties involved in measuring impairment using urine results.

The problem of interpreting urine-test results is one of the major bases of concern for restricting their use in the employment setting. Even the effectiveness of preemployment drug-screening tests, due to the difficulties in interpretation is being questioned. Based on a study of 2,229 pre- employment drug screening tests and follow-up, one group of researchers have come to the following conclusion "our findings raise the possibility that a preemployment drug screening may be decreasingly effective in predicting adverse outcomes associated with marijuana use after the first year of employment". They make a similar comment about cocaine.

There is no threshold for alcohol effects on performance or motor- vehicle-accident risk. Although the effects of alcohol on impairment and crash risk appear more dramatically above 80mg/100mL, a review of literature would suggest that impairment may be observed at levels as low as 15mg/100mL. It is not possible to specify a blood alcohol concentration level above which all drivers are dangerous and below which they are safe or at "normal" risk. An author of a major literature review on the behavioral effects of alcohol concluded that "that alcohol sensitivity can vary from time to time, person to person, and situation to situation, the setting of a "safe" BAC will always be arbitrary, being based on a low, but a non-zero, incidence of effects below that level" and "the most striking feature to emerge from any review of the effects of alcohol on behaviour is the marked lack of agreement between authors, amounting, in many instances, to direct contradiction. This is especially true for the effects of smaller dose."

"Legal" BAC levels differ in different countries. Some even have more than one legal limit over which the driver of a vehicle is considered as "impaired". Some European countries have 50mg/100ml others have 80mg/100ml as their legal limits. In the United States, the legal limits vary from 80mg/100mL to 100mg/100mL in different states, but employees who are regulated by the U. S. Department of Transportation have a BAC legal limit of 40mg/100mL. In Canada there are also two limits: 50mg/100mL and 80mg/100mL. BAC levels between 50mg/100mL and 80mg/100mL call for suspension of driving privileges but above 80mg/100mL are subject to criminal charges.

URINE TESTING METHODS

Urine is the most commonly used fluid for drug screening. The methods most commonly used in toxicology laboratories are: *immunoassay*, *chromatographic* and *chromatography coupled with mass spectrometry*. These methods vary considerably with respect to their sensitivity and reliability. Thin-layer chromatography is least expensive, gas chromatography coupled with mass spectrometry (GC/MS), which is considered as nearly perfect or "gold standard", is the most expensive. Table 2 summarizes the various methods.

Immunoassays (EIA, EMIT, FPIA, CEDIA and KIMS). Immunoassay methods are used for preliminary screening (i.e., initial screening). Since these methods are based on an antibody-antigen reaction, small amounts of the drug or metabolite(s) can be detected. Antibodies specific to a particular drug are produced by injecting laboratory animals with the drug. These antibodies are then tagged with markers such as an enzyme (enzyme immunoassay, EIA), a radio isotope (radioimmunoassay, RIA) or a fluorescence (fluorescence polarization immunoassay, FPIA) label. Reagents containing these labelled antibodies can then be introduced into urine samples, and if the specific drug against which the antibody was made is present, a reaction will occur. RIA is the oldest immunoassay method used to detect drugs. The major drawback of this method is that it requires a separation step and generates radioactive waste. RIA also requires special equipment to measure radioactivity.

Typically, immunoassays are designed for a *class* of drugs. Thus, their specificity (the ability to detect the presence of a *specific* drug) is not very good, since substances that have similar chemical structures will "cross react" and give a false positive reaction. For example, the immunoassay method for cannabinoids was developed to detect the carboxylic acid metabolite of δ^9-THC. Yet, there is a suggestion in the literature that some nonsteroidal anti-inflammatory drugs, such as ibuprofen (a nonprescription drug in the U. S. and

Canada) and naproxyn give random or sporadic false positive results for cannabinoids. Cough-syrup codeine will also give a positive reaction for the morphine (a metabolic product of heroin use) immunoassay and many antihistamines that are available over-the-counter may yield positive reactions for amphetamines. While some reagent manufacturers claim to have overcome many of these cross-reactivity problems, confirmation by a non-immunoassay method is very important.

Urine test kits, designed to detect drugs, have been available in North America for the past few years. More recently, single and multiple test immunoassay kits designed for home and on-site testing have also been introduced. These kits generally carry a cautionary disclaimer that positive test results must be confirmed by the reference GC/MS method. When used in the non-laboratory environment, they are prone to procedural inaccuracies, poor quality control, abuse and misinterpretations. Therefore, these kits should be used with great caution. The risk of labelling a person with a false positive is high without the accompanying confirmatory analysis. Table 3 summarizes the advantages and disadvantages of immunoassay testing.

Chromatographic methods. Separation of a mixture is the main outcome of the chromatographic method. For illustrative purposes, if one were to put a drop of ink on a blotting paper and hold the tip of the paper in water, one would observe the water rise in the paper. After a period of time and under the right conditions, the single ink spot would separate into many different compounds (spots) of different colours (blue ink is a mixture of many dyes). This process, where a mixture of substances is separated in a stationary medium (filter paper), is called chromatography. The types of chromatographic processes used in the analysis of drugs include thin-layer, gas, and liquid chromatography as well as a combination of gas or liquid chromatography with mass spectrometry.

Of the several chromatographic methods, thin layer Chromatography (TLC) is the one most similar to the ink separation example mentioned above. This method requires extensive sample preparation and technical expertise on the part of the analyst, but it is inexpensive and very powerful if used properly. With the exception of *Cannabis*, which requires separate sample preparation, a large number of drugs (e.g., cocaine, amphetamine, codeine and morphine) can be screened at the same time. By combining different TLC systems, a high degree of specificity can be obtained, although the training of the analyst is crucial because of the subjectivity involved in interpreting the results. To identify positive TLC "spots," the technologist looks for the drugs and or its metabolite pattern, often by spraying with reagents that react to form different colors with different drugs. The trained technologist can comfortably identify more than forty different drugs.

TABLE 3
Common Drug-Testing Methods

1.	*Immunoassays*
	Enzyme immunoassay (EIA)
	Enzyme-multiplied immunoassay technique (EMIT)
	Fluorescence polarization immunoassay (FPIA)
	Radio immunoassay (RIA)
	Kinetic interaction of microparticles in solution (KIMS)
	Cloned enzyme donor immunoassay (CEDIA)
	Rapid slide tests (point-of-care testing)
2.	*Chromatographic Methods*
	Thin-layer chromatography (TLC)
	Liquid chromatography (HPLC)
	Gas chromatography (GC)
3.	*Chromatography/Mass Spectrometry*
	Gas chromatography/mass spectrometry (GC/MS)
	Liquid chromatography/mass spectrometry (HPLC/MS)

Similar to TLC, gas chromatography (GC) requires extensive sample preparation. In GC, the sample to be analyzed is introduced via a syringe into a narrow bore (capillary) column which sits in an oven. The column, which typically contains a liquid adsorbed onto an inert surface, is flushed with a carrier gas such as helium or nitrogen. (GC is also sometimes referred to as gas-liquid chromatography (GLC). In a properly set up GC system, a mixture of substances introduced into the carrier gas is volatilized, and the individual components of the mixture migrate through the column at different speeds. Detection takes place at the end of the heated column and is generally a destructive process. Very often the substance to be analyzed is "derivatized" to make it volatile or change its chromatographic characteristics.

In contrast to GC, high pressure liquid chromatography (HPLC) a liquid under high pressure is used to flush the column rather than a gas. Typically, the column operates at room or slightly above room temperature. This method is generally used for substances that are difficult to volatilize (e.g., STEROIDS) or are heat labile (e.g., benzodiazepines).

Gas chromatography/mass spectrometry(GC/MS) is a combination of two sophisticated technologies. GC physically separates (chromatographs or purifies) the compound, and MS fragments it so that a fingerprint of the chemical (drug) can be obtained. Although sample preparation is extensive, when the methods are used together the combination is regarded as the "gold standard" by most authorities. This combination is sensitive i.e., can detect low levels, is specific, and can identify all types of drugs in any body fluid. Furthermore, assay sensitivity can be enhanced by treating the test substance with reagents. When coupled with MS, HPLC/MS is the method of choice for substances that are difficult to volatilize (e.g. steroids).

Given the higher costs associated with CG/MS, urine samples are usually tested in batches for broad classes of drugs by immunoassays and positive screens are later subjected to confirmation by this more expensive technique.

Table 4 gives a summary of the advantages and disadvantages of each method of chromatographic drug testing and Table 5 compares all the methods of testing. The initial minimal immunoassay and GC/MS (cut-off) levels for five drugs or classes of drugs as suggested by the U.S. National Institute of Drug Abuse, are listed in Table 6.

Procedures for alcohol testing. Since the introduction of the micro method for alcohol analysis

TABLE 4
Advantages and Disadvantages of Immunoassays

Advantages

1. Screening tests can be done quickly because automation and batch processing are possible.
2. Technologists doing routine clinical chemistry testing can be easily trained.
3. Detection limits are low and can be tailored to meet the program screening requirements. For example, lower detection thresholds can be raised to eliminate positives due to passive inhalation of marijuana smoke.
4. Immunoassays are relatively inexpensive, although the single-test kits can be very expensive when quality assurance and quality control samples are included.
5. Immunoassays do not require a specialized laboratory. Most clinical laboratories have automated instruments to do the procedures.

Disadvantages

1. Although the tests are useful for detecting classes of drugs, specificity for individual drugs is weak.
2. Since the antibody is generated from laboratory animals, there can be a lot-to-lot or batch-to-batch variation in the antibody reagents.
3. Results must be confirmed by another nonimmunoassay method.
4. A radioactive isotope is used in RIA that requires compliance with special licensing procedures, use of gamma counters to measure radioactivity, and disposal of the radioactive waste.
5. Only a single drug can be tested for at one time.

TABLE 5
Summary of Chromatographic Methods

Advantages

All the chromatographic methods are specific and sensitive and can screen a large number of drugs at the same time.

TLC	Negligible capital outlay is needed.
GC	The procedure can be automated.
HPLC	Of the chromatographic procedures, this has the easiest sample preparation requirements. The procedure can be automated.
GC/MS	This is the "gold standard" test. Computerized identification of fingerprint patterns makes identification easy. The procedure can be automated. This is currently the preferred method for defense in the legal system.

Disadvantages

All chromatographic methods are labor-intensive and require highly trained staff. Although the chromatographic methods are specific, confirmation is still desirable.

TLC	Interpretation is subjective, hence, training and experience in interpretation capabilities of the technologist are crucial.
HPLC or GC	Equipment costs are high, ranging between $25,000 to $60,000, depending on the type of detector and automation selected (1994 $)
GC/MS	Equipment costs are the highest, ranging from $120,000 to $2000,000, depending on the the degree of sophistication required (1994 $). Due to the complexity of the instrument, highly trained operators and technologists are required.

TABLE 6
Cut-off Levels for Initial and Confirmatory Tests[a]

Test	*Initial Test*	*Confirmatory Test*
THC metabolite[b]	100 ng/mL	15 ng/mL
Cocaine metabolites[c]	300 ng/mL	150 ng/mL
Opiate metabolites[d]	2000 ng/mL	
Morphine		300 ng/mL
Codeine		300 ng/mL
Phencyclidine (PCP)	25 ng/mL	25 ng/mL
Amphetamines	1000 ng/mL	
Amphetamine		500 ng/mL
Methamphetamine		500 ng/mL
Alcohol	10 mg/100 mL	10 mg/100 mL

[a]April 1988, National Institute of Drug Abuse (NIDA) Guidelines, SAMHSA 1998.
[b]THC metabolite is 11-nor-delta-9 THC carboxylic acid.
[c]Cocaine metabolite is benzoylecgonine.
[d]25 ng/mL if immunoassay is specific for free morphine.

in blood by Widmark in 1922, many new methods and modifications have been introduced. The distillation/oxidation methods are generally *nonspecific* for alcohol (ethanol), whereas biochemical methods (spectrophotometric) using alcohol dehydrogenase (ADH) obtained from yeast and the gas chromatographic method that are currently used are specific for ethanol. The radiative attenuation energy technique and those using alcohol oxidase method are non-specific and will detect not only ethanol but also other alcohols. The recently introduced alcohol dipstick based on the ADH enzyme system is not only specific for ethanol, but also sensitive and does not require instrumentation. It can be used for the detection of ethanol in all body fluids and can provide semi-quantitative results in ranges of pharmacological-toxicological interest. Alcohol dipsticks are being used in a number of laboratories as a screening device.

Breath can be analyzed by using a variety of instruments. Most of the instruments used today detect ethanol by using thermal conductivity, colorimetry, fuel cell, infrared or gas chromatography. Typically in most countries, local statutes define the instrument and method that can be used for evidenciary purposes. A variety of breathalyser instruments ranging in costs from $100 to $1000 are available to do the test. These instruments are compact and portable. Canadian law enforcement authorities use the breathalyser ''Alert'' which can give a ''pass'' or ''fail'' result as a roadside alcohol-screening device. The ''failed'' person is generally subjected to a ''Borkenstein'' breathalyser to measure the BAC before any charges are brought. Many devices are available to preserve the breath sample for later analysis if a breathalyser is not available immediately. In forensic laboratories, gas chromatography (North America) or biochemical procedures (many European countries) are used to analyze biological samples.

Blood samples that cannot be analyzed soon after collection should have sodium fluoride (NaF) added as a preservative. Alcohol dehydrogenase (ADH), the enzyme responsible for the oxidation of alcohol, is also present in the red blood cell and will slowly metabolise the alcohol, causing its concentration to drop if the preservative is not added. Large amounts of alcohol can be produced *in-vitro* in the urine samples of diabetic patients if samples are not processed immediately or properly preserved.

INTERPRETATIONS OF TEST RESULTS

False negatives. A positive or negative result is highly dependent on the sensitivity of the drug detection method. A false negative occurs when the drug is present but is not found because the detection limit of the method used is too high or the absolute quantity of the drug in the specimen is too low.

Large amounts of fluids consumed prior to obtaining a sample for analysis can affect detection of drugs in urine samples. Under conditions of dilution, although the absolute amount of drug or metabolite excreted maybe the same over a period of time, the final concentration per millilitre will be reduced and may give a false negative result. Acidity levels in the urine may also affect the excretion of the drug into the urine. In some cases elimination is enhanced, whereas in other cases, the drug is reabsorbed.

Several measures can be used to decrease the likelihood of obtaining a false negative result. First, sensitivity of the method can be enhanced by analyzing for the drugs' metabolites. Heroin use, for example, is determined by the presence of its metabolite, morphine. Increasing the specimen volume used for analysis or treating it with chemicals can also make laboratory methods more sensitive. Studies have shown that a 5mg dose of Valium® is usually detected for three to four days; however, when these improved methods are utilized, sensitivity can be increased, such that, the same dose can be detected for up to 20 days. One important drawback of such high sensitivities is, that estimates of when the drug was taken are far less accurate.

False positives. A false positive occurs when results show that the drug is present, when in fact it is not. False-positive tests are obtained if an interfering drug or substance is present in the biological fluid and it cross-reacts with the reagents. An example of this is Daypro (oxaprozin) will give a false positive for benzodiazepines. Other substances may have a metabolite that will give a positive reaction. An example of this is Selegiline, an antiparkinson drug, which has amphetamine as one of its metabolites. Although this would be analytically a true positive, it is a false positive from a drug abuse perspective. As discussed in the previous section on immunoassay, an initially positive test based on an

immunoassay technique should always be confirmed with an nonimmunoassay method. A confirmed positive finding only implies that the urine sample contains the detected drug and nothing more.

At times false positives are attributable to ingested substances such as allergy medications. Some authors have suggested that employees subject to drug screening refrain from using popular over-the-counter medications, such as Alka-Seltzer Plus and Sudafed, because they have caused false-positives. Some natural substances such as herbal teas and poppy seeds can also give positive responses to screens. These may be analytically true positives but need to be distinguished from those due to illegal drug use. In some instances, false-positives have been due to mistakes or sabotage of the chain of custody for urine samples.

COMMON ADULTERATION METHODS

The method of switching "clean" urine for "dirty" urine; resubmitting one's own or urine that is provided by someone else are the most common ways to fool the drug screening system. A number of entrepreneurs have attempted to bypass urine-specimen inspection by substituting clean urine. For example, a company in Florida sells lyophilized (freeze dried) clean urine samples through newspaper and magazine advertisements. Hiding condoms containing "clean" urine on the body or inside the vagina is another common trick.

Some have substituted apple juice and tea in samples for analysis. Patients are known to add everything from bleach, liquid soap, eye-drops, and many other household products, hoping that their drug use will be masked. Others may hide a masking substance under their fingernails and release it into the urine specimen. Another method is to poke a small hole into the container with a pin so that the sample leaks out by the time it reaches the laboratory.

Since addition of table salt (NaCl) or bleach to the urine is a common practice, many laboratories routinely test for Na and Cl in the urine. Liquid soap and crystalline drain cleaners that are strong alkaline products containing sodium hydroxide (NaOH) are also used to adulterate the urine sample. These contaminators can be detected by checking for high levels of pH in the urine sample. In-vivo alkalizing or acidifying the urine pH can also change the excretion pattern of some drugs

including amphetamines, barbiturates and phencyclidine (PCP).

Water-loading (drinking large amounts of water prior to voiding) poses an interesting challenge to testing laboratories. Specific gravity has been used to detect dilution; however, the measurement range is limited so it is not yet useful. Creatinine levels on random urine samples appear to be a promising method for detection of water-loading. A number of adulteration methods are being advertised on the Internet. Invariably, one of the instructions for adulteration is to drink copious amounts of fluids to bring about *in-vivo* dilution or water loading. Some Internet sites even sell adulterants that can be added to the urine. Typically these products either try to oxidise the drug present or try to change the pH of the urine to interfere with the analytical method. Most of the laboratories involved in drug testing routinely test for the various adulterants. To detect resubmitted samples a "urine fingerprinting" method using dietary components has been described.

Drug users are very resourceful and their ingenuity should not be underestimated. To reduce the opportunities for specimen contamination, some workplaces require that employees provide a urine sample under direct supervision. Another technique used to detect any sample adulteration is to take the temperature of the sample. In a study, we took the temperature of urine samples when taken within one minute of voiding; it falls between 36.5°C and 34 degrees Celsius, reflecting the inner body core temperature. It is very difficult to achieve this narrow temperature range by hiding a condom filled with urine under the armpit or adding water from a tap or toilet bowl to the urine sample. It is important that the temperature of the specimen be measured immediately after the sample is taken, since it can drop rapidly.

LABORATORY PROCEDURAL AND SECURITY STANDARDS

It is important that the laboratory drug testing facility has qualified individuals who follow a specific set of laboratory procedures and meet recommended security standards.

SUMMARY AND CONCLUSION

In this paper, major issues related to drug testing are discussed. For example, drug-testing techniques measure drug presence but are not sophisticated enough to measure impairment from drug use. It is also very difficult to determine the route of drug administration, quantity, frequency, or when the drug was last taken.

Selection of the drug to be tested should depend on the local availability of the drug, its abuse potential, and clinical effects, as well as the available analytical technology and expertise in testing and interpretation of the laboratory results. The most sophisticated drug-testing approach, gas chromatography in combination with mass spectrometry, is considered as a gold standard and thus utilized in confirmatory testing. Typically GC/MS is preceded by a rapid immunoassay method to eliminate the majority of negative samples.

Despite the existence of sophisticated drug-testing methods, incorrect test results can still occur. These can be due to the presence of interfering substances or adulteration of the urine sample. Patients have been known to adulterate urine samples to avoid drug detection. A number of techniques can be employed to reduce the likelihood of obtaining erroneous results, as well as detect adulterated urine samples. [Parana "positive" drug finding can have a serious impact on the livelihood of an individual, therefore the performance of these tests should adhere to the strictest laboratory standards of performance. Only qualified and experienced individuals with proper laboratory equipment should perform these analyses. Standards of laboratory performance must meet local legal and forensic requirements. Access to the patient samples as well as laboratory records must be restricted in order to prevent tampering of samples and results. To maintain confidentiality and assure proper interpretation of results, the results must be communicated only to the physician reviewing the case/patient. Chain of custody and all documents pertaining to the urine sample must be maintained so that they can be examined in case of a legal challenge. Laboratory must have a complete record on quality control. Finally, specific initial and confirmatory testing requirements should be met.

DRUG TRAFFICKING *See* International Drug Supply Systems

DRUG TYPES There are many ways to classify drugs, depending on the purposes for the classification. For example, a classification can be based on the chemical properties of drugs and may actually disregard the effects the drugs have on the body, or it may be based on legal principles, such as legal versus illegal, or prescription versus over-the-counter (prescription not needed). For purposes of discussion and teaching, the various drugs that are used and abused by humans for nonmedical purposes are usually grouped into several major categories, each based on their pharmacological actions and their subjective effects. Although the mechanisms of action may vary among drugs within a single category, the general subjective effects of the drugs are similar.

The major categories include: (1) ethanol (ALCOHOL); (2) NICOTINE and tobacco: (3) central nervous system depressants (BARBITURATES, BENZODIAZEPINES); (4) central nervous system stimulants (AMPHETAMINES, COCAINE); (5) cannabinoids; (6) OPIODS (MORPHINE, HEROIN, METHADONE); (7) psychedelics (LSD, MESCALINE); (8) INHALANTS (glue, nitrous oxide); (9) arylcyclohexylamines (PCP). Some categorizers might put cocaine and the amphetamines into separate categories and group alcohol and the central nervous system depressants together. Some might have a separate category for CAFFEINE; others, one for "DESIGNER DRUGS" (such as MDMA), and refer to them as *entactogens*. There might also be a miscellaneous category, where drugs such as BETEL NUT, KAVA-KAVA, or NUTMEG would be included.

Drugs from the various categories are described below in terms of their pharmacology, abuse, DEPENDENCE, and WITHDRAWAL as well as their toxicity. The legal and readily available drugs (alcohol and tobacco) are described first because the worldwide use and abuse of these drugs is far more widespread than *all* the other categories of abused drugs combined. The ill health associated with the ongoing use of alcohol and tobacco has become a far-reaching problem—not only because of the vast numbers of people who suffer and die each year from the toxic effects of these drugs but also because of the financial drain in terms of employee absenteeism as well as the staggering increases in annual health-care costs. Prescription drugs are covered next, since more prescriptions are written for diazepam (Valium) and the related benzodazepines each year than for any other drug.

The illegal drugs are then discussed. Although the illicit use of heroin, cocaine, and other drugs remains a major social, legal, financial and health problem in the United States today, the proportion of the population physically dependent on these drugs is actually relatively low when compared to the legal drugs listed above. Finally, it is important to take into consideration the fact that individuals often do not restrict their drug use only to drugs within a single category. Alcoholics typically smoke cigarettes and often use benzodiazepines as well. Heroin users also smoke and may consume alcohol and other sedatives, as well as CANNABIS and stimulants in some instances. Multiple-drug use is, therefore, a relatively common occurrence for those using legal and/or illegal drugs.

ETHANOL

Although alcohol (ethyl alcohol, called ethanol) has been in use since prehistory and worldwide throughout recorded history, it is generally accepted that its therapeutic value is extremely limited and that chronic ALCOHOLISM is a major social and medical problem. Perhaps 65 percent of all adults in the United States use alcohol occasionally. Hundreds of thousands of individuals suffer and die each year, however, from complications associated with chronic alcoholism—and tens of thousands of innocent individuals are injured or killed each year in alcohol-related traffic ACCIDENTS. Therefore, alcoholism is a far-reaching problem, affecting the lives of individuals who consume ethanol as well as those who do not. Although alcohol is considered by many people to be a stimulant drug because it typically releases an individual's latent behavioral inhibitions (i.e., through disinhibition), alcohol actually produces a powerful primary and continuous depression of the central nervous system similar to that seen with general anesthetics. In general, the effects of alcohol on the central nervous system are proportional to the

blood concentrations of the drug. Initially, MEMORY and the ability to concentrate decrease, and mood swings become more evident. As the intoxication increases, so does the impairment of nervous function until a condition of general anesthesia is reached ("passing out" or "sleeping it off"). There is little margin of safety, however; between an anesthetic close of ethanol and severe respiratory depression (unconsciousness or coma).

In chronic (long-term) alcoholism, brain damage, memory loss, sleep disturbances, psychoses, and increased seizure susceptibility often occur. Chronic alcoholism is also one of the major causes of cardiomyopathy (heart disease) in the United States due to ethanol-induced, irreversible damage to the heart muscle. Ethanol also stimulates the secretion of gastric acid in the stomach and can contribute to the production of ulcers of the stomach and gastrointestinal system. One of the primary metabolic products of ethanol is acetaldehyde. In chronic alcoholism, acetaldehyde can accumulate in the liver, resulting in hepatitis and cirrhosis of the liver. Finally, the long-term use of alcohol can result in a state of PHYSICAL DEPENDENCE. With relatively low levels of dependence, withdrawal from alcohol may be associated with rather minor problems such as SLEEP disturbances, ANXIETY, weakness, and mild tremors. In more severe dependence, the alcohol withdrawal syndrome includes more pronounced tremors, seizures, and DELIRIUM, as well as a number of other physiological and psychological effects. In some cases, this withdrawal can be life-threatening.

Since alcohol has CROSS-TOLERANCE with other central nervous system (CNS) depressants (i.e., ethanol shares many of the same biological effects as other CNS depressants), benzodiazepines or barbiturates can be substituted for ethanol to successfully decrease the severity of the alcohol withdrawal syndrome. Longer-acting benzodiazepines and related drugs can be used as an ethanol substitute, and the dose of the benzodiazepine can then be gradually reduced over time to attenuate or prevent the occurrence of convulsions and other potentially life-threatening toxic reactions generally associated with alcohol withdrawal.

As outlined above, the chronic use of ethanol can result in a wide range of toxic effects on a variety of organ systems; however, the mechanisms through which ethanol produces its varied effects are not clearly understood. The anesthetic or central nervous system depressant effects may result, in part, from general changes in the function of ion channels that occur when ethanol dissolves in lipid (fat) membranes. Other research suggests that alcohol may interact with specific receptors—binding sites associated with the inhibitory NEUROTRANSMITTER GAMMA-AMINOBUTYRIC ACID (GABA), in a manner somewhat analogous to other central nervous system depressants (e.g., benzodiazepines or barbiturates). Since an ethanol RECEPTOR site has not yet been conclusively identified, specific receptor AGONISTS and ANTAGONISTS are not yet available for the treatment of ethanol intoxication, WITHDRAWAL, and abstinence. The drug DISULFIRAM (Antabuse) is sometimes used in the treatment of chronic ALCOHOLISM, although it does not cure alcoholism. Rather, disulfiram interacts with ethanol to alter the intermediate metabolism of ethanol, resulting in a five- to tenfold increase in plasma acetaldehyde concentrations. Those who drink while on disulfiram experience the acetaldehyde syndrome—vasodilatation, headache, difficulty breathing, nausea, vomiting, sweating, faintness, weakness, anti vertigo. Taking the drug helps persuade alcoholics to remain abstinent, since they realize that they cannot drink ethanol for at least three or four days without provoking ill-effects.

NICOTINE AND TOBACCO

TOBACCO was first introduced to Europe by the crews that accompanied Columbus to the New World, and by the middle of the nineteenth century, tobacco use had become widespread. By the 1990s, almost 30 percent of the adults in the United States were still regular tobacco smokers. This relatively high use of tobacco continues despite the growing warnings that are based on a wealth of scientific evidence linking cigarette smoking to numerous life-threatening health disorders, including lung CANCER and heart disease. The constituents of tobacco smoke that most likely contribute to these health problems include carbon monoxide, NICOTINE, and "tar." However, nicotine also appears to be the primary component of tobacco smoke that promotes smoking. In regular cigarette smokers, nicotine facilitates memory, reduces aggression, and decreases weight gain. Each of these effects could, by itself, provide a rationale for continued tobacco use since most individuals find increased alertness and memory, decreased irritabil-

ity, and decreased weight gain to be somewhat pleasant or desirable; however, these effects may actually be secondary to the primary reinforcing effects of nicotine itself. Nicotine is self-administered by laboratory animals, and in laboratory settings, smokers report that the intravenous injection of nicotine produces a pleasant feeling on its own. It is of interest to note, however, that nicotine is aversive to nonsmokers, often resulting in dizziness, nausea, and vomiting. TOLERANCE rapidly develops to these unpleasant effects in tobacco smokers, however.

Although nicotine obviously binds to nicotinic receptors associated with the neurotransmitter ACETYLCHOLINE, there is evidence that the reinforcing or rewarding properties of nicotine may result from an activation of ascending limbic neurons, which release the neurotransmitter DOPAMINE (i.e., the mesocorticolimbic dopaminergic system). Interestingly, this same system has been implicated in the reinforcing properties of a variety of drugs, including stimulants and opiates. As stated above, tobacco smoking has been associated with a wide variety of serious health effects, including cancer and heart disease; however, the chances of developing them decrease once smoking is terminated. Although some of the smoking-induced damage is irreversible, the incidence rates for cancer and heart disease gradually become more similar between smokers and nonsmokers the longer the smoker refrains from smoking. However, withdrawal from tobacco smoking results in a withdrawal syndrome that varies in intensity from individual to individual and often leads to a relapse of smoking. This syndrome consists of cravings for tobacco, irritability, weight gain, difficulty concentrating, drowsiness, and sleep disturbances. The recent introduction of nicotine-containing chewing gum and transdermal patches have significantly helped to facilitate abstinence from smoking in a number of individuals by delivering nicotine through a relatively less toxic route of administration.

CENTRAL NERVOUS SYSTEM DEPRESSANTS

In general, the incidence and prevalence of the nonmedical use of central nervous system depressants (approximately 6 to 8% of young adults) exceeds that of the opioids. These drugs include the barbiturates, benzodiazepines, and related drugs. The shorter-acting barbiturates, such as pentobarbital (“yellow jackets”) or SECOBARBITAL (“red devils”), are usually preferred to the longer-acting drugs such as phenobarbital. Nonbarbiturates such as MEPROBAMATE, GLUTETHAMIDE, methyprylon, METHAQUALONE (Quaalude) and some of the shorter-acting benzodiazepines are also abused. Presumably, the quicker the onset of action for a particular central nervous system depressant, the better the “high.”

There is no general rule that can be used to predict the pattern of use of a central nervous system depressant for a given individual. Often there is a fine line between appropriate therapy for insomnia or ANXIETY and drug dependence. Some individuals exhibit cyclic patterns of use with gross intoxication for a few days interspersed with periods of abstinence. Other barbiturate or benzodiazepine users maintain a chronic low level of intoxication without observable signs of impairment because of the development of tolerance to many of the actions of these drugs. When higher doses are used, however, the intoxication may resemble alcohol intoxication, with slurred speech, difficulty thinking, memory impairment, sluggish behavior, and emotional instability. Withdrawal from chronic barbiturate or benzodiazepine use can also be manifested to varying degrees. In the mildest form, the individual may only experience mild anxiety or insomnia. With greater degrees of physical dependence, tremors and weakness may also be included. In severe withdrawal, delirium and tonic-clonic (epileptic) seizures may also be present. This severe withdrawal syndrome can be life-threatening. The degree of severity of the withdrawal syndrome appears to be related to the pharmacokinetics of the drug used. Shorter-acting benzodiazepines and barbiturates produce much more severe cases of withdrawal than do the longer-acting drugs. Therefore, in the case of severe withdrawal symptoms associated with the chronic use of a short-acting drug, a longer-acting drug should be substituted. The dose of this drug can be gradually decreased so that the individual experiences a much milder and less threatening withdrawal.

Receptor-binding sites for benzodiazepines and barbiturates are part of a macromolecular complex associated with chloride ion channels and the inhibitory neurotransmitter GABA. The interaction of these drugs with their distinct binding sites re-

sults in a facilitation of GABAergic neurotransmission, producing an inhibitory effect on neuronal impulse flow in the central nervous system.

CENTRAL NERVOUS SYSTEM STIMULANTS

Central nervous system stimulants include caffeine, cocaine, and amphetamine, although the use and abuse of amphetamines and cocaine represent a much greater health risk, with deviation from social norms.

Caffeine. Perhaps 80 percent of the world's population ingests caffeine in the form of TEA, COFFEE, COLA-flavored drinks, and CHOCOLATE. In the central nervous system, caffeine decreases drowsiness and fatigue and produces a more rapid and clearer flow of thought. With higher doses, however, nervousness, restlessness, insomnia, and tremors may result. Cardiac and gastrointestinal disturbances may also be observed. Tolerance typically develops to the anxiety and dysphoria experienced by some individuals. Some degree of PHYSICAL DEPENDENCE has, however, been associated with the chronic consumption of caffeine. The most characteristic symptom of caffeine withdrawal is a long throbbing headache, although fatigue, lethargy, and some degree of anxiety are also common. In general, the long-term consequences of chronic caffeine consumption are relatively minor.

COCAINE AND AMPHETAMINE

The problems associated with chronic cocaine and amphetamine use and withdrawal are much more serious than those associated with caffeine. By the mid-1980s, more than 20 million people had used cocaine in the United States. With the recent introduction of cocaine in the free alkaloid base ("FREEBASE" or "CRACK") form, there has been a significant increase in cocaine-related medical, economic, social, and legal problems. In the free-base form, cocaine can be smoked, resulting in blood levels and brain concentrations of the drug that compare to those observed when the drug is injected intravenously. In non-user subjects in a laboratory setting, the administration of cocaine or amphetamine produces an elevation of mood, an increase in energy and alertness, and a decrease in fatigue and boredom. In some individuals, however, anxiety, irritability, and insomnia may be observed.

In nonlaboratory settings, heavy users of cocaine often take the drug in bouts or binges, only stopping when their supply runs out or they collapse from exhaustion. Immediately following the intravenous administration or inhalation of cocaine, the individual experiences an intense pleasurable sensation known as a "rush" or "flash," followed by euphoria. Cocaine rapidly penetrates into the brain to produce these effects, but then is rapidly redistributed to other tissues. In many cases, the intense pleasure followed by the rapid decline in the cocaine-induced elevation of mood is sufficient for the individual to begin to immediately seek out and use more of the drug to prolong these pleasurable effects. Following the intranasal administration of cocaine, the pleasure is less intense and the decline in brain concentrations of the drug progresses much more slowly, so that the craving for more of the drug is less pronounced. Cocaine and amphetamine appear to produce their reinforcing or pleasurable effects through interactions with the neurotransmitter dopamine, especially in limbic and cortical regions of the brain (i.e., within the mesocorticolimbic dopaminergic system). Both cocaine and amphetamine block the reabsorption of dopamine into the NEURONS, where it was released, thereby prolonging the action of dopamine in the synapse—the space between nerve cells. Amphetamine can also cause the direct release of dopamine from nerve cells and can inhibit the metabolism of the neurotransmitter. It is important to note, however, that every drug that augments the action of dopamine does not produce pleasurable or rewarding subjective effects.

The toxicity associated with cocaine or amphetamine use can be quite severe; it is often unrelated to the duration of use or to preexisting medical conditions in the individual. This potential for serious toxic side effects is amplified by the fact that tolerance usually develops to the subjective feelings of the cocaine-induced rush and euphoria, but not to some of the other central nervous system effects of the drug (especially seizure susceptibility). Some of the more minor toxic reactions include dizziness, confusion, nausea, headache, sweating, and mild tremors. These symptoms are experienced by virtually all cocaine and amphetamine users to some degree, as a result of stimulation of the sympathetic nervous system. More serious reactions are also fre-

quently observed. These serious toxic effects can include irregular heartbeats, convulsions and seizures, heart attacks, liver failure, kidney failure, heart failure, respiratory depression, stroke, coma, and death. The effects on the heart and cardiovascular system can sometimes be treated with alpha and beta noradrenergic-receptor antagonists or calcium channel blockers, although even prompt medical attention is not always successful. The convulsions can sometimes be controlled with diazepam (Valium); ventilation (oxygen) may be required for the respiratory depression. In addition to the effects described above for cocaine, amphetamine has been reported to produce direct and irreversible neuronal damage to dopaminergic neurons. A similar effect for cocaine has not yet been identified.

Psychiatric abnormalities resulting from chronic central nervous system stimulant abuse can include anxiety, DEPRESSION, HALLUCINATIONS, and, in some cases, a paranoid psychosis that is virtually indistinguishable from a paranoid SCHIZOPHRENIC psychosis. A withdrawal syndrome is also observed following the abrupt cessation of chronic cocaine or amphetamine use. This syndrome begins with exhaustion during the "crash" phase and is followed by prolonged periods of anxiety, depression, anhedonia (loss of pleasure), hyperphagia (gluttony), and high craving for the drug. This craving may persist for several weeks, depending on the individual. The administration of dopaminergic agonists or tricyclic ANTIDEPRESSANTS may have some utility in decreasing the severity of the withdrawal symptoms.

CANNABINOIDS

Marijuana is probably still the most commonly used illicit drug in the United States, with about 55 percent of young adults reporting some experience with the drug during their lifetimes. The active ingredient in MARIJUANA is delta^9-TETRAHYDROCANNABINOL (Δ^9-THC), which exerts its most prominent effects on the central nervous system and the cardiovascular system. A marijuana cigarette that contains approximately 2 percent of the active ingredient can produce an increase in feelings of well-being, euphoria, and relaxation when smoked; however, short-term memory can be impaired as is the ability to carry out goal-directed behavior. The ability to drive or operate machinery is similarly impaired, often much longer than the persistence of subjective effects. With higher doses, paranoia, hallucinations, and anxiety or panic may be manifested.

Chronic marijuana users sometimes exhibit what is called the AMOTIVATIONAL SYNDROME—which consists of apathy, impairment of judgment, and a loss of interest in personal appearance and the pursuit of conventional goals. However, it is not clear whether this syndrome results from the use of marijuana alone or from other factors. Although this is seldom severe, Δ^9-THC also produces a dose-related increase in heart rate. Tolerance does develop to the effects of marijuana, and in some countries, regular users of HASHISH (a concentrated resin containing increased amounts of Δ^9-THC) consume quantities of the drug that would be toxic to most marijuana users in the United States. The withdrawal associated with the cessation of marijuana smoking is relatively mild—consisting of irritability, restlessness, nervousness, insomnia, weight loss, chills, and increased body temperature.

OPIOIDS

The use of opioids in the United States is much less prevalent than reported for the other drugs discussed above. For example, as of the 1990s, less than 0.5 percent of young adults have reported trying heroin at some time during their lives. There are three basic patterns of opioid use and dependence in the United States. The first group constitutes the smallest percentage of opioid users—those who initially began using morphinelike drugs medically, for the relief of PAIN. The second group began using illegal drugs through experimentation and then progressed to chronic use and dependence. The third group represents physically addicted individuals who eventually switched to oral METHADONE, obtained through organized treatment centers. Interestingly, the incidence of opioid addiction is greater among physicians, nurses, and related health-care professionals (who have access to these drugs) than in any group with a comparable educational background. In many instances (but not all), those addicted either to heroin (usually purchased illegally on the street) or to methadone (usually from treatment centers) are able to hold jobs and raise a family. Opioids reduce pain, aggression, and sexual drives, so the use of these drugs is unlikely to induce crime. Those who can-

not afford opioids, those who like the "drug life," and those who are unable or unwilling to hold a job, resort to crime to support their drug habits.

Opioid drugs produce their pharmacological effects by binding to opiate RECEPTORS. The euphoria associated with the use of opioids results from interactions of these drugs with the mu-opiate receptor, possibly resulting in the stimulation of mesocorticolimbic dopaminergic neuronal activity. The rapid intravenous injection of morphine (or heroin, which is converted to morphine once it enters the brain) results in a warm flushing of the skin and sensations in the lower abdomen that are often described as being similar in intensity and quality to sexual orgasm. This initial rush ("kick" or "thrill") lasts for about 45 seconds and is followed by a high—described as a state of dreamy indifference. Depending on the individual and the social circumstances, good health and productive work are not incompatible with the regular use of opioids. Tolerance can develop to the ANALGESIC, respiratory depressant, sedative, and reinforcing properties of opioids, but the degree and extent of tolerance depends largely on the pattern of use. Desired analgesia can often be maintained through the intermittent use of morphine. Tolerance develops more rapidly with more continuous opioid administration.

The abrupt discontinuation of opioid use can lead to a withdrawal syndrome that varies in degree and severity depending on the individual as well as the particular opioid used. Watery eyes (lacrimation), a runny nose (rhinorrhea), yawning and sweating occur within twelve hours from the last dose of the opioid. As the syndrome progresses, dilated pupils, anorexia, gooseflesh ("cold turkey"), restlessness, irritability, and tremor can develop. As the syndrome intensifies, weakness and depression are pronounced, and nausea, vomiting, diarrhea, and intestinal spasms are common. Muscle cramps and spasms, including involuntary kicking movements ("kicking the habit"), are also characteristic of opioid withdrawal; however, seizures do not occur and the withdrawal syndrome is rarely life-threatening. Without treatment, the morphine-induced withdrawal syndrome usually runs its course within seven to ten days. Opiate-receptor antagonists (e.g., NALOXONE) are contraindicated in opioid withdrawal, since these drugs can precipitate a more severe withdrawal on their own. Rather, longer-acting, less potent, opiate-receptor agonists such as methadone are more commonly prescribed. The symptoms associated with methadone withdrawal are milder, although more protracted, than those observed with morphine or heroin. Therefore, methadone therapy can be gradually discontinued in some heroin-dependent individuals. If the patient is unwilling or unable to withdraw from methadone, the individual can be maintained on methadone indefinitely.

PSYCHEDELICS

Psychedelics include drugs related to the indolealkylamines, such as lysergic acid diethylamide (LSD), PSILOCYBIN, psilocin, DIMETHYLTRYPTAMINE (DMT) and diethyltryptamine (DET), to the phenylethylamines, such as mescaline, or to the phenylisopropylamines, such as 2,5-dimethoxy-4-methylamphetamine (DOM or "STP") as well as 3,4-methylene-dioxyamphetamine (MDA) and 3,4-methylene-dioxymethamphetamine (MDMA or "ecstasy"). The feature that distinguishes these psychedelic agents from other classes of drugs is their capacity to reliably induce states of altered perception, thought, and feeling. There is a heightened awareness of sensory input accompanied by an enhanced sense of clarity, but a diminished control over what is experienced. The effects of LSD and related psychedelic drugs appear to be mediated through a subclass of receptors associated with the inhibitory neurotransmitter serotonin (i.e., serotonin $5HT_2$ receptors). Immediately after the administration of LSD, somatic symptoms such as dizziness, weakness and nausea are present, although euphoric effects usually predominate. Within two to three hours, visual perceptions become distorted; colors are heard and sounds may be seen. Vivid visual hallucinations are also often present. Many times this loss of control is disconcerting to the individual, resulting in the need for structure—in the form of experienced companions during the "trip." The entire syndrome begins to clear after about twelve hours.

Little evidence exists for long-term changes in personality, beliefs, values, or behavior produced by the drug. Tolerance rapidly develops to the behavioral effects of LSD after three or four daily doses of the drug. In general, however, the psychedelic drugs do not give rise to patterns of continued use over extended periods. The use of these drugs is generally restricted to the occasional trip. With-

drawal phenomena are not observed after the abrupt discontinuation of LSD-like drugs, and deaths directly related to the pharmacological effects of LSD are unreported in humans—however, fatal ACCIDENTS and SUICIDES have occurred during periods of LSD intoxication.

INHALANTS

The intoxicating and euphorigenic properties of nitrous oxide and ethyl ether were well known even before their potential as anesthetics was recognized. Physicians, nurses and other health-care professionals have been known to inhale anesthetic gases even though they have access to a wide variety of other drugs. Adolescents with restricted access to alcohol often resort to "glue sniffing" or the inhalation of vapors from substances with marked toxicity, such as gasoline, paint thinners, or other industrial solvents. The alkyl nitrites (butyl, isobutyl, and amyl) have been used as aphrodisiacs, since the inhalation of these agents is suggested to intensify and prolong orgasm. At least 12 percent of young adults have reported some experience with inhalants—however, fatal toxic reactions (usually due to cardiac arrhythmias) are often associated with the inhalation of many of these drugs. Inhalation from a plastic bag can result in hypoxia (too little oxygen) as well as an extremely high concentration of vapor. Fluorinated hydrocarbons can produce cardiac arrhythmias and ischemia (localized anemia). Chlorinated solvents depress heart muscle (myocardial) contractility. Ketones can produce pulmonary (lung) hypertension. Neurological impairment can also occur with a variety of solvents.

ARYLCYCLOHEXYLAMINES

Arylcyclohexylamines include phencyclidine (PCP or "angel dust") and related drugs that possess central nervous system stimulant, central nervous system depressant, hallucinogenic, and analgesic properties. These drugs (also known as dissociative anesthetics) are well absorbed following all routes of administration. With even small doses, intoxication is produced, with associated staggering gait, slurred speech, and numbness in the extremities. PCP users may also exhibit sweating, catatonia, and a blank stare as well as hostile and bizarre behavior. Amnesia during the intoxication may also occur. In higher doses, anesthesia, stupor, convulsions, and coma may appear. The typical high from a single dose can last four to six hours and is followed by a prolonged period of "coming down."

PCP and related compounds bind with high affinity to a number of distinct sites in the central nervous system, although it is not certain which site(s) is responsible for the primary pharmacological effects of these drugs. PCP binds to the sigma site, which also has a high affinity for some selected opioids, although the function of the sigma site is unknown. PCP blocks the cation channel (e.g., Ca^{2+}) that is regulated by N-methyl-D-aspartate (NMDA), one type of receptor for excitatory amino acid neurotransmitters such as glutamate or aspartate. PCP also blocks the reabsorption of the neurotransmitter dopamine into the neurons, where it was released, resulting in a prolonged action of the neurotransmitter, especially within the mesocorticolimbic dopaminergic neuronal system.

There appears to be some degree of tolerance to the effects of PCP, and some chronic users of PCP complain of cravings and difficulties with recent memory, thinking, and speech after discontinuing the use of the drug. Personality changes can range from social withdrawal and isolation to severe anxiety, nervousness, and depression. Although the frequency is uncertain, deaths due to direct toxicity, violent behavior, and accidents have been reported following the use of PCP. PCP can also produce acute behavioral toxicity—consisting of intoxication, aggression, and confusion, as well as coma, convulsions, and psychoses. A PCP-induced psychosis can persist for several weeks following a single dose of the drug.

NICK E. GOEDERS

DRUNK DRIVING Drunk driving results in one of the most costly social consequences of ALCOHOL abuse. The toll on human life and health exacted by drunk drivers can, on its own, make alcohol abuse one of the most serious U.S. social problems. The extent and consequences of drunk driving demonstrate the challenges of harmonizing a drinking culture with a modern industrial society.

The combination of drinking and driving has been recognized as a serious problem since the invention of the automobile in the 1880s. In 1904, the *Quarterly Journal on Inebriety* editorialized that "the precaution of railroad companies to have only total abstainers guide their engines will soon extend to the owners of these new motor wagons . . . with the increased popularity of these wagons, accidents of this kind will multiply rapidly." By 1910, drunk driving had already been codified as a misdemeanor offense. Moreover, the dangerous mixture of alcohol and driving was a key point in the Prohibitionists' argument in favor of the Eighteenth Amendment.

During the 1950s and 1960s, with postwar prosperity and a developing highway network, both alcohol abuse and traffic safety became serious national widespread issues. The Highway Safety Act of 1966 was crucial to mobilizing attention and resources in an attack against drunk driving. In effect, it established a federal (not just a state and local) jurisdiction by creating the National Highway Safety Bureau, the precursor of the National Highway Safety Administration (NHTSA), and it authorized the U.S. Department of Education's 1968 Report, *Alcohol and Highway Safety*. This report found that "the use of alcohol by drivers and pedestrians leads to some 25,000 deaths and a total of at least 800,000 crashes in the United States each year." The report warned that "this major source of human morbidity will continue to plague our mechanically powered society until its ramifications and many present questions have been exhaustively explored and the precise possibilities for truly effective countermeasures determined."

NHTSA became the main sponsor of research and action projects aimed at reducing drunk driving. In 1970, NHTSA launched the Alcohol Safety Action Project (ASAP), the first major U.S. initiative against drunk driving. The ASAP, established in thirty-five communities, sought to achieve a significant reduction in drunk driving through a mixture of intensive countermeasures—including law enforcement, rehabilitation, and education. These programs were rigorously monitored. Unfortunately, despite huge increases in arrests and tens of thousands of referrals to drunk-driver schools and rehabilitation programs, a significant decrease in drunk driving could not be confirmed, and the ASAP was terminated in 1977.

The attack on drunk driving did not subside. In the late 1970s, there emerged a remarkable grassroots anti-drunk driving movement comprised of

victims, their families, and many other concerned citizens. MOTHERS AGAINST DRUNK DRIVING (MADD), Students Against Driving Drunk (SADD), and REMOVE INTOXICATED DRIVERS (RID) opened local chapters throughout the United States and vigorously campaigned for new and tougher drunk-driving countermeasures. The crusade launched by these groups attracted a great deal of media attention, vaulting drunk driving to the top of the nation's social problems agenda. In 1982, President Ronald W. Reagan appointed a Presidential Commission on Drunk Driving. Congress linked state highway funds to the states' passage of specified anti-drunk driving measures, including a minimum drinking age of twenty-one. Ultimately, every state raised its drinking age accordingly. The states passed a deluge of legislation, providing for more and better law enforcement and more severe criminal penalties of a greater range—including mandatory jail terms, automatic license forfeiture, public education, drunk-driver schools, and rehabilitation.

MAGNITUDE OF THE PROBLEM

More than 2 million people are arrested each year for drunk driving. The actual number of offenses, while unknown and unknowable, must be far greater, since only a fraction of all violators are apprehended. A few researchers have mounted roadside surveys in which drivers are stopped and asked to voluntarily provide a breath sample from which the amount of alcohol in the blood can be calculated. While this is the best strategy for determining the actual amount of drunk driving, there are many problems with this methodology (which roads? what times? how many refusals?). A 1985 Minnesota roadside survey found that of 838 drivers on the road between 8:00 P.M. and 3:00 A.M. (prime time for drunk driving), 82.3 percent tested negative for any alcohol, 6 percent tested at BLOOD ALCOHOL CONCENTRATION (BAC) 0.05–0.09 percent (included as a lesser Driving While Intoxicated [DWI] offense in some states), and 2.4 percent tested above the drunk-driving threshold of BAC 0.1 percent.

Drunk drivers do not pose a uniform risk to themselves, their passengers, other motorists, and pedestrians. The most dangerous of the drunk drivers are the vehicular equivalent of the "fighting drunk"; they drive far in excess of the speed limit, weave in and out of traffic, and cross into lanes of traffic going in the opposite direction. At the low end of the continuum are drunk drivers who make an impaired effort to drive safely; although operating with diminished skill and judgment, they pose less of a risk than the agressive drunk drivers.

The most impressive experimental study of the causal role of alcohol in traffic crashes was carried out during the 1960s by Professor Robert Borkenstein (inventor of the BREATHALYZER) and his University of Indiana colleagues. The researchers obtained breath samples from 6,000 accident-involved drivers and, as controls, from 7,500 non-accident-involved drivers. They found that 6.3 percent of the accident-involved drivers, but fewer than 1 percent of the control drivers, had BACs equal to or greater than 0.1 percent (the prevailing definition of drunk driving in the 1980s). Moreover, each higher BAC level included a disproportionate number from the accident-involved group. Thus Borkenstein and his colleagues concluded that "BACs above .04% are definitely associated with an increased accident rate. The probability of accident-involvement increases rapidly at BACs above .15%. When drivers with BACs over 0.08% have accidents, they disproportionately involve only the driver's vehicle, and are more costly in terms of personal injury and property damage."

While most drunk-driving episodes do not result in a crash or injuries, the aggregate personal and property damage perpetrated by drunk drivers is staggering. A good deal of methodological controversy exists about the percentage of the approximately 45,000 annual traffic fatalities in the United States that can be attributed to drunk drivers. NHTSA's Fatal Accident Reporting System, which has been operating since the mid-1970s, presents important information about alcohol and traffic fatalities but does not attempt to estimate what proportion of all traffic deaths were *caused by* drunken driving. James Fell and Terry Klein, using statistical modeling techniques, have estimated that approximately 30 percent of all traffic fatalities can be attributed to drunk driving; other analyses have put this estimate at 50 percent.

Drunk drivers themselves, often in single-car collisions, comprise a large proportion of those who are killed, giving fatal drunk-driving episodes as much resemblance to suicide as to homicide. Nevertheless, each year thousands of innocent pedestrians and motorists are killed by drunk drivers,

and tens of thousands are badly injured. There is also a huge amount of property damage.

THE OFFENDER

It is difficult to find reliable data on which to base a profile of the drunk driver. Using arrest data, we find that the vast majority, 90 percent, of drunk drivers are male and white. Despite the common belief that teenage drivers are most likely to be drunk, it is the mid-twenties age group that deserves this notoriety. Since it takes heavy drinking (from four to six drinks in two hours, depending on the drinker's weight) to reach the prohibited level, it is unlikely that light drinkers very often commit drunk-driving offenses. Thus, people who drive drunk are likely to be heavy drinkers and alcohol abusers. Nevertheless, light and moderate drinkers may on occasion drive drunk, perhaps due to a binge. Since light and moderate drinkers greatly outnumber heavy and abusive drinkers, they may in fact comprise a substantial proportion of arrested drunk drivers.

The consensus of studies based on screening tests of drunk drivers is that about 50 percent arrested for this offense are alcohol abusers, about 35 percent are social drinkers, and the remainder fall in between. While the categories *alcohol abuser* and *social drinker* are amorphous, a disproportionately high percentage of those arrested for drunk driving are actually heavy drinkers.

The large majority of drunk drivers arrested in any given year have not been arrested before. A well-executed Minnesota study found that only 7 percent of drivers involved in fatal accidents had been convicted of drunk driving in the preceding three years; of drunk drivers involved in fatal accidents, 13 percent had a DWI conviction in the previous 3 years, and 25 percent had a license revocation during the preceding 8 years. The low official rate of recidivism probably means that the chance of a drunk driver's being caught is extremely small.

THE CRIME OF DRUNK DRIVING

The first drunk-driving laws made it an offense to drive while intoxicated or to drive under the influence (DUI) of alcohol. Starting in the 1950s, states began to pass *per se* laws, which made it an offense to operate a motor vehicle with a BAC that exceeds certain levels. When a suspect is arrested for drunk driving, he or she is asked to take a deep breath and blow into a machine (the Breathalyzer is one model) that measures the amount of alcohol in the breath and converts it into a measure of the amount of alcohol in the blood. Pursuant to *implied consent* laws, suspects who refuse to provide a deep-lung breath sample are penalized by loss of their driver's license and sometimes by other sanctions as well. The evolution of breath-testing equipment, including hand-held devices (like the Intoxilyzer), has greatly eased the identification and conviction of drunk drivers. Despite folklore to the contrary, it is extremely rare that suspects who "fail" the breath test obtain acquittals. Indeed, the conviction rate for drunk driving is well over 90 percent.

In most states, a first drunk-driving offense is a misdemeanor, and a second offense within a specified time period (up to ten years in some states) is a felony. In a few states, a first offense is treated as a traffic violation, a second offense a misdemeanor, and a third offense a felony. Punishments vary from state to state; however, the usual range of punishments includes forfeiture of a driver's license for up to 1 year, fines of 500 to 1,000 dollars, and incarceration up to 30 days. In the late 1980s, spurred by the anti-drunk driving citizens' groups and federal financial incentives, several states passed laws mandating at least forty-eight hours of incarceration for a first DWI offense and a longer time for a second or subsequent offense. Another penalty that has been gaining popularity is the automatic and immediate forfeiture of the driver's license at the police station when the suspect fails or refuses to take the breath test (*administrative per se* law). In the early 1990s, and once again in response to federal pressure, states began lowering the prohibited BAC from 0.1 percent to 0.08 percent.

At least since the early 1970s, the criminal justice system's processing of drunk drivers has been linked to alcohol-treatment programs. In many jurisdictions, all drunk-driving offenders are routinely screened for ALCOHOLISM and alcohol abuse. Alcoholics and abusers may be diverted from prosecution to TREATMENT. More likely, however, the judge will require the offender to participate in treatment as a condition of probation or in order to obtain a provisional or regular driver's license. In some jurisdictions, the criminal-justice system is the largest source of clients flowing into alcohol-

treatment programs. Thus, enforcement of the drunk-driving laws is one of the major ways that alcohol abusers are brought into the alcohol-treatment matrix.

In addition to the standard alcohol treatments, the attack on drunk driving has produced one unique kind of treatment—the drinking-driver school, which several million people have passed through since the mid-1970s. States and localities that have such schools often require all drunk drivers to attend. New York's school consists of five two-hour sessions and two three-hour sessions. The classes provide information about such matters as the deterioration of driving skills at different BAC levels, the inability to counteract intoxication with coffee or cold showers, and criminal penalties for drunk driving. People taking these classes are also required to fill out the Michigan Alcohol Screening Test (MAST) to determine whether they are alcohol abusers.

ENFORCEMENT

Enforcement of drunk-driving laws is the responsibility of local police, county sheriffs, and the state police or highway patrol. The Fourth Amendment to the U.S. Constitution prevents police from stopping cars at random and requiring drivers to take breath tests. Police must have probable cause to believe that drunk driving or some other offense (including traffic offenses) has been, is, or is about to be committed. Once a driver has been legitimately stopped, the police officer can order the driver to submit to a *field sobriety test*, which may consist of walking heel-to-toe, counting backwards, or performing other tasks that reveal intoxication. If the driver's performance on the test gives the officer probable cause to believe that the driver is intoxicated, the officer will arrest the driver. At the station, drivers will be told that they are required by the implied-consent law to submit to a breath test; refusal to cooperate will lead to license revocation.

In the 1980s, as states and localities searched for more effective anti-drunk driving strategies, some police departments mounted roadblocks at which every car (or every *n*th car) was briefly stopped and the driver briefly observed and sometimes questioned. If the officer detected alcohol, the driver was pulled over and required to submit to a breath test. Since these drunk-driving roadblocks were not based upon probable cause, they were challenged. In 1990, however, the U.S. Supreme Court upheld drunk-driving roadblocks under its *administrative search* doctrine (*Michigan Dept. of State Police v. Sitz*, 110 S. Ct. 2481). The Court ruled that as long as the roadblocks are situated in a fixed location, overseen by high-level officials, and operated nondiscriminatorily, they do not violate the Fourth Amendment.

DETERRING THE DRINKING DRIVER

Deterrence based on the threat of arrest, conviction, and punishment remains the chief strategy in the attack on drunk driving. During the 1980s, state and local governments have established dozens of strike forces and passed hundreds of laws aiming to raise the costs to the offender of driving while intoxicated. In a series of empirical evaluations of police crackdowns and elevated maximum punishments in the United States and abroad, the sociologist H. Laurence Ross found that this type of law-enforcement escalation usually produces a reduction in drunk driving (as measured by single-vehicle fatalities), but not a long-term reduction. "No such policies have been scientifically demonstrated to work over time under conditions achieved in any jurisdiction . . . the option of merely increasing penalties for drinking and driving has been strongly discredited by experience to date."

While Ross has done far more empirical research than anybody else on deterring the drunk driver, his conclusion is not uncontroversial. One criticism is that he uses single-vehicle automobile fatalities to measure the amount of drunk driving; however, this kind of accident might not be strongly associated with the full range of drunk driving, but only with a narrow group, the most drunken and reckless of drunk driving. Possibly, while law-enforcement escalations cannot affect the kind of drunk drivers who kill themselves in single-vehicle crashes, they might be effective in the far more numerous non-fatal drunk-driving episodes that are engaged in by less pathological alcohol abusers and sociopathological persons.

The number of traffic fatalities has fallen from the late 1980s into the 1990s; drunk-driving fatalities seem to have fallen more than non-alcohol-related accidents. There may be reasons for this other than deterrence, including general re-

ductions in alcohol consumption and abuse and more responsible public attitudes toward sober driving—however, a marginal deterrence effect cannot be ruled out.

OTHER ANTIDRUNK-DRIVING STRATEGIES

In addition to deterrence, states and localities have implemented many other anti-drunk driving strategies. Since all these strategies are being used simultaneously, it is impossible to attribute any reductions to one strategy over another.

Some courts have made punitive damages available in drunk-driving cases. This allows the victim of a drunk driver to recover any amount of money a jury deems appropriate for punishment. Some states permit insurance coverage of punitive damages, thereby negating whatever deterrent effect such damages might produce, but not negating a windfall for the victim.

In some states, legislatures and courts have expanded civil (tort) liability for causing drunk-driving injuries to include commercial hosts and package sellers of alcohol. While these DRAMSHOP LAWS vary from state to state, they essentially make purveyors of alcohol to underage or intoxicated persons liable for the injuries caused by such persons to themselves or others. A few state courts have even made social hosts liable for the alcohol-related traffic injuries caused by their guests.

An essential strategy for incapacitating drunk drivers is taking away their licenses to drive. Several studies have shown that drunk drivers who lose their drivers' licenses are less likely to have a recurrence than drunk drivers who are fined, sent to jail, or assigned to mandatory treatment programs (actually, all these sanctions can be imposed together). Nevertheless, when licenses are suspended or revoked, a good deal of licenseless driving takes place—which is not surprising in a society where people depend on automobiles for their economic and social lives. Several states also have laws that authorize vehicle impoundment or forfeiture, but these sanctions are rarely used, perhaps because of the sacred status of the automobile as expensive private property.

Opportunity blocking refers to anti-crime strategies that change the environment to reduce the opportunities of committing particular offenses. The best opportunity-blocking strategy for drunk driving involves fixing the defendant's vehicle so that it cannot be started until he blows alcohol-free breath into a tube affixed to the vehicle. Such equipment is now available, and several jurisdictions have implemented experimental programs. Other opportunity-blocking strategies include the twenty-one-year-old drinking age and a spate of new laws and regulations on bars, taverns, and package-goods stores.

The anti-drunk driving movement has spawned a large number of educational strategies. These include public-service announcements on radio and television and educational materials for primary and secondary schools. The effects of such programs are very difficult to evaluate. Rehabilitation strategies for drunk drivers are closely linked to the matrix of community alcoholism and alcohol-abuse services. Drunk drivers are regularly screened for alcohol problems, and those who are identified as abusers are typically channeled into treatment through a probationary sentence.

DYNORPHIN Dynorphin is a neuropeptide transmitter; it is an OPIOID peptide, a member of the endorphin family of peptides. All neurotransmitters like Dynorphin have receptors. Its greatest affinity is for the Kappa opioid receptor. Dynorphin's role in drug abuse was originally anticipated based on its location in anatomical areas strongly associated with the mechanism of action of drugs of abuse. It is localized in the NUCLEUS ACCUMBENS, AMYGDALA, and VENTRAL TEGMENTAL AREA.

Dynorphin induces feelings of dysphoria, or despair. This was first documented in animals, and later confirmed in humans. It is surprising because the best known opiate-like drugs are morphine and heroin, and they present great abuse liability since they illicit feelings of euphoria and absence of pain. However, there seem to be two opioid systems controlling behavior one influencing feelings of REWARD (through-endorphins) and one influencing feelings of AVERSION, (through dynorphin). The physiological substrate underlying the effects of dynorphins is believed to be at the level of the MESOLIMBIC DOPAMINE neurons in the ventral tegmental area. Dynorphin tonically inhibits the firing of dopamine neurons, thus preventing its release in the striatum. Elevations of dopamine levels in the nucleus accumbens are believed to underlie the reinforcing properties of many PSYCHOSTIMULANT-like drugs, as well as OPIATES.

Due to the ADVERSE feeling associated with WITHDRAWAL from many drugs of abuse, the dynorphin system has been implicated in contributing to this state. Studies have found that there are long-term changes in dynorphin levels in brain areas associated with drug abuse, and that these changes also exist during withdrawal. Prenatal exposure to cocaine also effects the levels of dynorphin in the brain. These changes are present in both animal and human models of drug abuse. Since drugs modulate dynorphin systems, we can gain an understanding of how drugs work in the brain by studying the dynorphin system.

ECONOMIC COSTS OF ALCOHOL ABUSE AND ALCOHOL DEPENDENCE

Alcohol abuse and alcohol dependence continue to be major health problems in the United States. The terms *alcohol abuse* and *alcohol dependence* are based on the diagnostic criteria as stated in the American Psychiatric Association's DIAGNOSTIC AND STATISTICAL MANUAL *of Mental Disorders, Third Edition, Revised* (1987). As such, they cost the nation billions of dollars in health-care costs and reduced or lost productivity each year. Since the mid-1980s, researchers have issued studies that estimate the economic costs associated with alcohol and alcohol abuse in the United States. In 1985, alcohol abuse and dependence cost an estimated 70.3 billion dollars and in 1988 an estimated 85.8 billion dollars (Rice et al., 1990, 1991). In 1998, the National Institute on Drug Abuse (NIDA) and the National Institute on Alcohol Abuse (NIAAA), which are parts of the National Institutes of Health (NIH), released a study on these costs based on 1992 survey data. This report, which also analyzed drug abuse, forms the basis of this article.

EXTENT OF THE PROBLEM

The economic cost to society from alcohol and drug abuse was $246 billion in 1992. Alcohol abuse and alcoholism cost an estimated $148 billion, while drug abuse and dependence cost an estimated $98 billion. When adjusted for inflation and population growth, the alcohol estimates for 1992 were very similar to cost estimates produced over the past 20 years. The 1992 estimates were significantly greater than the 1985 estimate for alcohol: 42 percent higher for alcohol over and above increases due to population growth and inflation. Between 1985 and 1992, inflation accounted for about 37.5 percent and population growth for 7.1 percent increases. Over 80 percent of the increase in estimated costs of alcohol abuse was attributed to changes in data and methodology employed in the new study. This suggests that the previous study significantly underestimated the costs of alcohol abuse.

In 1992, there were an estimated 107,400 alcohol-related deaths in the United States. Many of the alcohol-related deaths were among persons between ages twenty and forty, because the major causes of death, such as motor vehicle crashes and other causes of traumatic death are concentrated among younger-aged people. However, alcohol is also involved in numerous premature deaths among the older population because of long-term, excessive alcohol consumption. Total costs attributed to alcohol-related motor vehicle crashes were estimated to be $24.7 billion. This included $11.1 billion from premature mortality and $13.6 billion from automobile and other property destruction.

In 1992, total estimated spending for health care services was $18.8 billion for alcohol problems and the medical consequences of alcohol consumption. Specialized services for the treatment of alcohol problems cost $5.6 billion. This included special-

ized detoxification and rehabilitation services as well as prevention, training, and research expenditures. Costs of treatment for health problems attributed to alcohol were estimated at $13.2 billion.

An estimated $67.7 billion in lost potential productivity was attributed to alcohol abuse in 1992. This accrued in the form of work not performed, including household tasks, and was measured in terms of lost earnings and household productivity. These costs were primarily borne by the alcohol abusers and by those with whom they lived. About $1 billion was for victims of fetal alcohol syndrome who had survived to adulthood and experienced mental impairment. This study did not estimate the burden of drug and alcohol problems on work sites or employers.

The costs of crime attributed to alcohol abuse were estimated at $19.7 billion. These costs include reduced earnings due to incarceration, crime careers, and criminal victimization; and the costs of criminal justice and drug interdiction. Alcohol abuse is estimated to have contributed to 25 to 30 percent of violent crime.

The study estimated that 3.3 percent of social welfare beneficiaries in 1992 received benefits because of an administrative determination of drug- or alcohol-related impairment. While 1996 federal welfare reform legislation has largely terminated alcohol or drug dependence as a primary cause for benefit eligibility, these impairments resulted in transfers of $10.4 billion in 1992, with administrative and other direct service expenses of $683 million for those with alcohol problems.

A large amount of the economic burden of problems falls on the population that does not abuse alcohol. Governments bore costs of $57.2 billion (38.6 percent) in 1992, compared with $15.1 billion for private insurance, $9 billion for victims, and $66.8 billion for alcohol abusers and members of their households. Costs are imposed on society in a variety of ways, including alcohol-related crimes and trauma (e.g., motor vehicle crashes), government services, such as criminal justice and highway safety, and various social insurance mechanisms, such as private and public health insurance, life insurance, tax payments, pensions, and social welfare insurance.

CONCLUSION

Alcohol abuse and alcohol dependence are costly to the United States in resources used for care and treatment of persons suffering from these disorders, lives lost prematurely, and reduced productivity. Data show clearly that the measurable economic costs of alcohol abuse continue to be high.

ED50 The ED50 is the median effective dose—the dose of a drug that is required to produce a specific effect (e.g., relief from headache) in 50 percent of a given population. The ED50 can be estimated from a dose-effect curve, where the dose of the drug is plotted against the percentage of a population in which the drug produces the specified effect. Therefore, if the ED50s for two drugs in producing a specified amount of relief from headache are 5 and 500 milligrams, respectively, then the first drug can be said to be 100 times more potent than the second for the treatment of headaches.

NICK E. GOEDERS

EDUCATION AND PREVENTION American adolescents increased their use of most illicit substances throughout the 1990s after a significant drop in the previous decade, and in 1999 Drug Czar Barry McCaffrey responded to the recent Monitoring the Future study by saying drug use "remains unacceptably high" (University of Michigan Institute for Social Research, 1999). Data on special populations such as infants, the homeless, the ELDERLY, and those with HIV/AIDS indicate increasing needs for prevention and education throughout the life span. COCAINE and HEROIN patients in emergency rooms have also increased since 1990 and the American Lung Association estimates that 430,700 Americans die each year from diseases directly related to smoking. Clearly, the use of ALCOHOL, TOBACCO, and other drugs—whether licit or illicit—by various age groups and special populations continues to be a problem in the United States.

The concept of *prevention* has evolved since the 1960s to become much broader, one that has shifted from a focus primarily on adolescents to a life-span perspective that includes all ages from the fetus through the elderly. Prevention services recognize all potentially addictive substances—including alcohol, tobacco, MARIJUANA, cocaine, OPIOIDS, INHALANTS, HALLUCINOGENS, and prescription and nonprescription (OVER-THE-COUNTER, OTC) medications. Linkages have been developed with several services to include PREVENTION, intervention, and TREATMENT. Prevention programs now emphasize comprehensive long-term systematic programming for individuals, peer groups, FAMILIES, and/or communities. Such programs utilize prevention concepts based on the positive results of controlled experiments and quasi-experimental studies. They contain a core of pro-social skills central to the prevention of substance abuse as well as other social problems—SUICIDE, unwanted pregnancies, and VIOLENCE.

CONTEMPORARY PRINCIPLES OF PREVENTION

Several authorities have analyzed prevention programs for substance abuse and have listed principles of effective prevention programs (Dryfoos, 1990; Falco, 1992; Hawkins et al., 1992; The U.S. General Accounting Office, 1992; and The Higher Education Center for Alcohol and Other Drug Prevention, 1999). The principles in this section emerged from this literature as well as other sources. This type of "lumping," of necessity, ignores many subtle points applicable to specific programs or to particular issues. Nonetheless, widespread agreement exists that these principles provide a foundation for planning effective, cost-effective, prevention programming.

1. Effective prevention programs provide for comprehensive, coordinated services to individuals and their families along a continuum of care.

Comprehensive prevention programming in a community includes services for all age groups, with multiple forms of programming for any age group. Comprehensive services are arrayed along a continuum to include education, prevention, intervention, and referral to treatment when necessary. Further, most people in high-risk substance-abuse environments need a variety of other services—health, nutrition, prenatal care—along with sub-

stance-abuse prevention services. All of these services need to be coordinated for maximum effect and efficiency. In any community, pregnant women, children, adolescents, workers and/or elderly, some are in need of intervention rather than prevention; a comprehensive strategy provides for intensive services as required.

Effective prevention programs also involve the families of the target populations, either as the focus of the service or as a tangent to a service array. Such programs include training in relationships and parenting skills, while reinforcing family awareness of the purposes and procedures of substance-abuse prevention programs. Bry, Conboy, and Bisgay (1986) reported reduced substance use and fewer problems in programs for youth that taught their parents needed parenting skills.

Student-assistance programs and EMPLOYEE-ASSISTANCE PROGRAMS (EAPs) have emerged to fill an important gap in the care continuum. Such programs identify those whose performance (academic or work) deteriorates, to assist them in obtaining the most appropriate help. They are considered by businesses to be beneficial (U.S. Department of Labor, 1991), and schools perceive them as essential to their total programming (Swisher et al., 1993).

2. Effective prevention programs are developmentally appropriate, culturally relevant, and sensitive to ethnic minority members, females, and persons in special circumstances (e.g. homeless persons).

They must also be developmentally appropriate and adjusted to the emotional and mental development of the individual or group. Too often prevention programs have attempted to provide a diluted version of a program to a younger age group without considering the developmental stage. Programs must be adapted to an individual's needs in the various transitions of our lives. Some programs, for the oldest members of a community, must be designed for their particular needs and frequent involvement with chronic illness (Garrity & Lawson, 1989).

Prevention programs are most effective when they are culturally relevant to the norms and assumptions of the various ethnic and minority groups. Role models and media materials must be culturally sensitive or they will be rejected by the audience either consciously or subconsciously. Several authorities have compiled examples of successful experiences that a variety of programs have had with participants from diverse racial and ethnic orientations (e.g., Resnick & Wojcicki, 1991; Marcus & Swisher, 1992). A recent novella aimed at Hispanic youths and their families received accolades for cultural sensitivity and scope, and reader responses suggested the work had some positive impact on Hispanic youth attitudes toward alcohol (Lalonde, Rabinowitz, Shefsky, & Washienko, 1997).

Those in special circumstances (e.g., the homeless) require different approaches in the effective delivery of prevention services. For example, reaching and engaging the homeless requires different strategies (Federal Task Force on Homelessness and Severe Mental Illness, 1992) and some researchers have been successful (reduced drug use) with prevention programming for the homeless (Botvin and Dusenbury, 1992).

3. Effective prevention programs use behavior change technology to equip people with life skills, knowledge of substance abuse, and awareness of the services available to them.

Equipping people with life skills includes decision making; coping; knowledge about the effects of alcohol, tobacco, and other drugs; awareness of services; and assertiveness/refusing. This cluster of skills also equips people with the ability to manage their immediate situations with the healthiest outcomes. Such strategies teach people to understand that they are engaging in risky behaviors and give them the skills to resist peer pressure and other influences, such as ADVERTISING. Recent studies have shown that alcohol advertising may increase consumption, while counter-advertising and bans decrease alcohol use to some degree (Saffer, 1997).

There is somewhat dated but nonetheless relevant literature of prevention technologies, such as *Life Skills Training* (e.g., Botvin & Tortu, 1988) or *Normative Education* (Hansen, 1990), which provide intensive instruction in a variety of competencies. Similarly, there are several comprehensive curricula offered sequentially from kindergarten through twelfth grade (Center for Health Promotion, 1990). Only two of these comprehensive school curricula have had positive outcomes based on experimental evaluations; these are the *Here's Looking At You* editions (Comprehensive Health Education Foundation, 1990) and *Growing Healthy* (e.g., Connell, Turner, & Mason, 1985). *Growing Healthy* is a comprehensive health curric-

ulum that includes a limited focus on alcohol, tobacco, and other drugs, whereas *Here's Looking at You: 2000* is an alcohol, tobacco, and other drug-use-prevention curriculum.

The results of a groundbreaking study were released in 1996, when the U.S. Department of Education published the results of a word association test called the Environmental Assessment Initiative (EAI). The EAI looks at the language people use and from that determines attitudes and beliefs about alcohol—indeed, the EAI study reported 80 percent accuracy in noting differences between users and nonusers regarding perceptions about drugs and alcohol (Katz, 1996). The study suggests increasing the influence of students who do not overindulge in alcohol as a way of improving campus life. Possible steps include offering numerous activities that do not involve alcohol, as well as developing strategies and rules that shed romanticized views of alcohol abuse.

Effective PREVENTION PROGRAMS must provide accurate information that there are risks associated with the use of various substances. This scientifically based information—highlighting the relationships between an abused substance and its consequences—has been an important component in changing behavior in all age groups (Johnston, Bachman & O'Malley, 1993).

4. Effective prevention programs emphasize the early identification of risks and resiliency factors and program accordingly.

Effective substance abuse prevention programs emphasize early identification and intervention to reach a substance abuser and his or her family as early as possible, even in preschool programs. Risk status assessment coupled with interventions have become standard in effective prevention programs (Lorion, Bussell, & Goldberg, 1991).

Some communities are expanding programs such as Drug Abuse Prevention Education (DARE) from elementary classrooms into the junior high schools as well, hoping to send youths a positive message early and often—and at an age when many children are first exposed to drugs and alcohol.

Research by Hawkins and Lishner (1985) lists risk factors for school-age youth. These risk factors are important to a total process in planning for prevention services.

1. family history of alcoholism
2. family history of antisocial behavior or criminality
3. family management problems
4. early antisocial behavior and hyperactivity
5. parental drug use and positive attitudes toward use
6. academic failure
7. little commitment to school and education
8. alienation, rebelliousness, and lack of social bonding to society
9. antisocial behavior in early adolescence
10. friends (peers) who use drugs
11. favorable attitudes toward drug use
12. early first use of drugs

Risk factors for other age groups need to be researched if prevention practitioners are to be maximally effective in addressing all populations in a given community. Efforts have also focused on developing resilience in people at high risk (Northeast Regional Center for Drug-Free Schools and Communities, 1992).

5. Effective prevention programs operate in communities that establish positive norms through enforcement of clear policies.

Communities that establish positive norms regarding alcohol, tobacco, and other drug use have also been successful in delaying the onset of use. Such communities have changed their policies toward access to substances by children and adolescents, including the location of advertisements and beverage-serving establishments; they have also promoted positive lifestyles. Gerbner (1990) has underscored the importance of communities reducing their ambivalence about communicating about all substances, licit or illicit.

Prevention services and policy changes have reduced the regular use of alcohol, tobacco, and other drugs, and there has been a concurrent reduction in consequences—including reduced highway ACCIDENTS because of alcohol; improved general health because of tobacco prevention; and reduced criminal activity because of illicit substance abuse. A 1992 report from the Office of the Inspector General confirmed an almost total lack of enforcement efforts by state agencies to control cigarette access, despite numerous provisions in existing state laws. In a study of media programming targeted to specific audiences and combined with community follow up, significant differences in the use of alcohol, tobacco, and other drugs were found between ex-

perimental and control groups (Flay & Sobol, 1983).

Pentz and colleagues (1989) demonstrated the effectiveness of community immersion in prevention through a program that included policy changes, refusal-skill training for junior high students, parent training, and mass media coordination. In this program, community groups monitored the availability of alcohol, tobacco, and other drugs and, in turn facilitated enforcement of existing policies or implemented new policies where needed.

An example of an ambitious prevention initiative is The Higher Education Center for Alcohol and Other Drug Prevention, created by the U.S. Department of Education in 1993. Alarmed by a Harvard study that confirmed almost half of U.S. college students engaged in heavy episodes of drinking, The Center formed the Presidents Leadership Group in 1997. This collaboration marked the first time in a decade that a group of college and university leaders joined forces to review alcohol abuse and develop a plan of prevention.

The Group published a report in 1997 that asked university presidents to acknowledge three major facts: student alcohol abuse is a problem all institutions of higher education share; student substance abuse is a problem of the community as a whole, not simply the campus; and student drinking is a problem that will never completely go away. The Group then listed their thirteen Proposals for Effective Prevention, among them: college presidents should use every opportunity to speak out and write about alcohol and other drug prevention to reinforce it as a priority concern and to push for change; college presidents should work to ensure that all elements of the college community avoid providing mixed messages that might encourage alcohol and other drug abuse; college presidents should appoint a campus-wide task force; college presidents should offer new initiatives to help students become better integrated into the intellectual life of the school, change student norms away from alcohol and other drug abuse, and make it easier to identify students in trouble with substance abuse; and college presidents should take the lead in identifying ways to effect alcohol and other drug prevention through economic development in the community (The Higher Education Center for Alcohol and Other Drug Prevention, 1997).

In November, 1996, forty-nine college presidents in Ohio decided to address the problem of student binge drinking by signing a letter of commitment. Institutions soon formed action teams to develop prevention plans. Educators found that communities reacted positively to university commitment against alcohol abuse.

6. Effective prevention programs provide staff development and training.

Effective prevention programs provide training for staff at all levels. The behavior-change and the other intervention techniques require constant upgrading of staff skills, supervision, and feedback. New prevention and intervention techniques require intensive training for proper implementation. This specialized training should be available at colleges, universities, and vocational training centers. Moreover, there is a world of information on alcohol and drug abuse education available on the Internet, including home pages for DARE and The Higher Education Center for Alcohol and Other Drug Prevention, as well as dozens of support sites.

The results of the several controlled-outcome studies of teacher training have been summarized by Swisher and Ashby (1993). They concluded that for each negative result (e.g., increase in beer use) there were five positive findings (e.g., reduced use of various substances). The training involved a ten-day retreat in which teams of teachers were given planning skills and prevention techniques. The planning skills led to an action plan to be implemented upon return to one's school; the prevention techniques were designed to be immediately implemented and reinforced with additional training sessions and technical assistance. Students in these schools have reported an improved school climate and improved academic functioning.

ENDURING MYTHS

Myths about prevention of substance abuse continue to impede progress toward more effective services. Some of the myths that need to be addressed as part of an advocacy for effective prevention principles include the following: (1) substance abuse cannot be prevented because it is caused by genetic and other biological phenomena; (2) there is no evidence that prevention works; and (3) scarce resources should be given to increasing availability of treatment for those in need.

Instead, most problems in this area are seen as being caused by the interaction of the biology, psychology, and social environment of the individual and the term that is emerging is *biopsychosocial problems*, indicating an interaction of these domains in social problems. There is clear evidence that genetic and other biological factors play a role in substance abuse, but more important is the social environment at all ages, which plays a significant role in increasing risk for the onset of a disorder. In some cases, it is possible to provide at-risk individuals with coping skills before a crisis occurs—to better enable them to avoid or manage the event (Institute of Medicine, 1989).

A large number of studies indicate that prevention works. For example, an issue of the *Journal of Community Psychology* (Lorion & Ross, 1992) included a series of articles that clearly demonstrated that prevention services for high-risk youth can reduce alcohol, tobacco, and other drug use as well as related social problems. The American Psychological Association published a well-documented listing of successful prevention programs (Price, Cowen, & Lorion, 1988). An outstanding longitudinal study was reported by Botvin (1993), in which he outlined a successful six-year follow-up of life-skills training.

CONCLUSION

Providing prevention services at any point along a continuum reduces demand while reducing costs for subsequent services. It also reduces related costs, such as accidents, illness, death, and crime. It is most cost effective to provide services as early as possible. However, budget priorities continue to emphasize law enforcement and treatment over prevention.

For prevention to play an appropriate role in responding to the problem of drug use and abuse, the federal, state, and local governments need to establish standards and ensure that the best practices in prevention and education are provided to all ages. The major obstacle remaining is the lack of means to train professionals and volunteers in what is known and to assist them in implementing the best practices. Unfortunately, most of the very limited government monies available for prevention of substance abuse are allocated to a flowthrough blockgrant mechanism or to the development of new models—without a follow-up system of disseminating or replicating what is already known about effective prevention.

EIGHTEENTH AMENDMENT *See* Alcohol: History of Drinking; Temperance Movement; Women's Christian Temperance Union

ELIMINATION OF THE DRUG ADDICTION AND ALCOHOLISM CATEGORY IN SOCIAL SECURITY DISABILITY PROGRAMS Since 1950, the federal government of the United States has provided income support by welfare or social insurance mechanisms to individuals with work disabilities unrelated to military service. Currently, the Social Security Administration operates two programs for the disabled: Social Security Disability Insurance (DI) and Supplemental Security Income (SSI). The differences between them reflect a fundamental schism in the American welfare state, which is divided into "tracks" along the line of labor force attachment. As it name implies, DI is an "insurance-like" program: Workers make payroll deductions that over time qualify them for benefits based on average lifetime earnings should they ever become disabled. SSI, on the other hand, is a "welfare" program designed for individuals with little history of employment and few resources. Whereas income and wealth are no bar to the receipt of DI, SSI is "means- tested." Excluding (mainly) the value of a home and an automobile, no SSI recipient can have assets valued at more than $2000 (or $3000 in cases where two beneficiaries are married). Some people collect both SSI and DI (they get "concurrent benefits") because although they qualify for DI, their benefit level is so low that it is augmented by SSI.

Typical of income maintenance schemes in liberal welfare states, the American system emphasizes economic returns to work, and thus social insurance offers more substantial benefits than welfare. In March 1999, the average monthly benefit for DI recipients was $773, whereas the federal minimum SSI benefit for sighted individuals under 65 years old and living in their own households was $500 per month. Some states (notably Alaska, California, and Connecticut) augment the federal minimum with a state supplement, but even in states the value of SSI is substantially less than the average DI payment.

For both SSI and DI, statue defines disability as "the inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to result in death or has lasted or can be expected to last for a continuous period of not less than 12 months." The rules and procedures used to determine if a case falls within this definition are also the same for both programs. Substantial gainful activity is defined as the performance of significant physical or mental activities for remuneration of profit at the level of $700 per month. Since a series of federal court rulings in 1993 and 1994 (codified by statue in 1994), illegal activities such as prostitution and drug dealing have been included in its meaning. Thus, an addict supporting a $700 per month heroin habit through prostitution, for example, may on this evidence be ruled able to work.

GROWTH OF THE DRUG ADDICTION AND ALCOHOLISM IMPAIRMENT CATEGORY

From the advent of SSI in January 1974, until March 1996, drug addiction and alcoholism (DA&A) were treated as potentially disabling impairments. The DI program adopted the more liberal SSI addiction standard in 1975. In Social Security lingo, beneficiaries who qualified on this basis were known as "DA&As." In the SSI program, DA&As were obliged to be in treatment and to have a "representative payee," a third party who received their checks and managed their funds. "DA&As in the DI program were not subject to such requirements until 1994. This disparity reflected the historical reference tendency for American income maintenance programs to combine material aid and moral surveillance in welfare programs (Welfare Policy and Substance Abuse in the United States), but to treat the beneficiaries of the "insurance-like" programs as though they were the recipients of an insurance benefit for which they had paid premiums in full.

Because there were no practical consequences of DA&A classification for DI recipients, the Social Security Administration had no accurate count of them until 1995. In the SSI program there were fewer than 10,000 DA&As as late as the end of 1986. By mid-1996, however, there were almost 166,000 SSI DA&As (including concurrent beneficiaries) and almost 43,000 DA&As on DI—a total of about 209,000. Overall, the two disability pro-

grams grew substantially during this period, but the DA&A category swelled disproportionately.

Most of the growth in the DA&A category occurred after 1989. Some of it was artifactual, stemming from the Social Security Administration's more accurate identification of DA&A cases after 1991. However, most of the growth was real and seems to have resulted from four additional factors, the precise contributions of which cannot be specified. First, federal circuit court decisions during the mid-1980s removed substantial technical obstacles to claimants seeking benefits on the grounds of addiction. Second, in the wake of these decisions many state and county governments set out to transfer to SSI (a program funded almost entirely by the federal government) recipients of General Assistance, a welfare program supported entirely with state and local funds. To promote this process, some states (like Illinois) contracted with private non-profit legal advocates to support applications and appeals. This very effective "cost-shifting" strategy was also appealing in view of the spiraling costs of medical care that were overwhelming many public hospital systems supported substantially by state and local tax revenues. As SSI beneficiaries automatically qualified for Medicaid (a federally supported, means-tested medical assistance program) in 39 states and the District of Columbia, and as DI recipients qualified for Medicare (Medicaid's non-means-tested counterpart) after a waiting period, this represented a second important source of savings for state and local governments. When the DA&A SSI population is disaggregated by state, it is clear that California, Michigan, Illinois, and a few others made much higher per capita use of the DA&A category than did other states. For example, by 1996 Oregon had as many DA&As on SSI as Texas, a state with several times the adult population of Oregon.

The last two contributors to the growth in the DA&A rolls are related to a famous Reagan-era controversy concerning the Social Security disability programs. During the early 1980s, responding in part to a Carter Administration initiative and also drawing on a similar tactic applied during his governorship of California between 1967 and 1974, President Reagan's Social Security administrators launched a roll-cutting campaign that relied on "continuing disability reviews" (CDRs). As a result, over 500,000 people lost federal disability benefits, a large percentage of them people with mental illness. Subsequent backlash from the courts and Congress restored many to the rolls, further liberalized eligibility criteria, and all but paralyzed the CDR process for years to come. As a result of perennially backlogged CDRs, many DA&As who regained their ability to work remained on the rolls, particularly as the economic conditions of the late 1980s and early 1990s provided few opportunities for poor, unskilled, ill-educated people. In part as the result of this episode, and in part due to the dramatic rise in homelessness during the 1980s (HOMELESSNESS, ALCOHOL AND OTHER DRUGS ENTRY), the Social Security Administration was charged with increasing its outreach efforts, especially among homeless people. This brought more DA&As into the application process.

CONTROVERSY AND DEMISE

Throughout the history of the DA&A program, the Social Security Administration relegated it to the Agency's backwaters. With no specific appropriations from Congress to ensure that DA&As received treatment or were separated from the rolls for failing to participate, and with no resources to thoroughly investigate the relationship of representative payees to beneficiaries, the Agency allowed the program to drift. However, it attracted a great deal of critical and unwanted attention as it began to grow rapidly. Beginning in 1991, the program was the subject of unflattering reports from federal watchdog agencies and a mounting number of highly publicized incidents involving DA&As using benefits to purchase drugs and signing up representative payees (like bartenders) with little fiduciary interest in them. The more scandalous claims about the program were largely unfounded, but the DA&A program was repugnant to many legislators and representatives of the alcohol and drug treatment community who saw it to be "enabling" addiction. Moreover, the program's rapid growth, and the Social Security Administration's apparent inability to curb it, lent credence to the claim that it was an entitlement program "out of control" in an era of bipartisan fiscal retrenchment.

In August 1994, after Congressional hearings and national media coverage (almost exclusively negative), Congress limited DA&A benefits to three years, reiterated the necessity to participate in treatment, and made DI DA&As subject to treat-

ment and representative payee requirements for the first time. Although Social Security Administration made no efforts to defend the DA&A program, it worked very hard to implement treatment referral and monitoring arrangements in all of the states. But as it did so, the November 1994 elections shifted control of the House of Representatives to conservative Republicans who were hostile to the DA&A program. As house welfare reform legislation shaped up during 1995, it became clear the DA&A program would be terminated.

On March 29, 1996 Congress eliminated the DA&A category in the Social Security disability programs, the first time any qualifying impairment had been legislated out of existence. The benefits of 209,000 recipients of SSI and DI were to cease after 1996 unless they applied for redetermination and were reclassified on the basis of other impairments (mental illness, for example). Only 34 percent had been reclassified to the rolls by the end of 1997.

CONCLUSION

In retrospect, the demise of the DA&A program seems to have been over-determined. It was at once culturally problematic and thus deprived of a unified constituency; extremely difficult to administer (and thus distinctly unloved by the Social Security Administration); and as a result of its administrative problems, susceptible to discrediting scandal. The program left behind a legacy of mandatory treatment and representative payee provisions that may become common features of state and local welfare reform measures, but no observers see any chance of its resurrection at the federal level in the foreseeable future.

EMPLOYEE ASSISTANCE PROGRAMS (EAPS) An Employee Assistance Program (EAP) consists of employer-sponsored services intended to aid employees with personal problems that may adversely affect their job performance. Initially developed to address alcohol-related problems, over the last fifteen years EAPs have emerged as a common response to the problems of ALCOHOL and drug abuse in the workplace. In addition, they provide a variety of services to help employees and their families resolve health, emotional, marital, family, financial, or legal concerns.

While the exact mix of services provided depends on a number of variables, such as size and type of company, EAPs generally offer, at a minimum, confidential client counseling, problem assessment, and treatment referral. A comprehensive EAP offers

1. assessment and referral—EAPs conduct psychosocial assessments to guide decisions to refer clients to treatment and the choice among treatment alternatives
2. treatment follow-up—client follow-up and reintegration into the workplace is an essential EAP function
3. supervisor, management, and union representative training—training provides the information needed on how and when to use the program and how to best assist employees who use it
4. employee education—information on a broad range of problems and how to use the EAP.

The delivery of EAP services may take several forms, depending on such factors as the organization's size and structure. Large companies and organizations, unions, and employee groups often operate their own programs. These services are most often housed within the human resources or medical departments. Smaller organizations, or organizations with dispersed worksites may find it more advantageous to contract with an independent EAP provider located outside the company. A newer trend among small employers is the development of consortium EAP arrangements in which a number

of small employers contract with an external provider to provide EAP services.

In the 1980s and 1990s, the number of EAPs grew dramatically. The Employee Assistance Professionals Association estimates that by the 1990s, 20,000 EAPs were in place in organizations throughout the United States. The Department of Labor's Bureau of Labor Statistics reported that nearly 12 percent of the nonagricultural establishments they sampled offered EAP services. Further, they found that of those sampled, the probability of an establishment offering EAP services increased as a function of establishment size, ranging from 79 percent of employers with over 250 employees, to 9 percent of employers with fewer than 50 employees.

Rapid growth in the number of EAP progams has led to heightened scrutiny concerning their cost effectiveness; in the current economic climate, EAP programs will experience increased pressure to conduct evaluation studies that provide empirical evidence of their efficacy. More research is needed to identify and improve the most essential program components and to aid in tailoring programs to fit specific needs.

Costs incurred in providing EAP services vary widely, but their presence has been clearly tied to overall savings in a number of areas. For example, the McDonnell Douglas Corporation of St. Louis found that employees utilizing their EAP services betwen 1985 and 1988 for an initial assessment before being referred to treatment had 44 percent fewer lost work days, 81 percent lower termination rates, and lower total four-year medical claims per person than employees seeking treatment for chemical dependence without first consulting the EAP.

For many companies, the approach taken to minimize the impact of drugs in the workplace incorporates a number of additional elements that complement EAPs and constitute a comprehensive strategy. These include a clearly stated formal policy prohibiting drug use, consequences for violating the policy, and alternative strategies to deter drug use.

ENDORPHINS Endorphins are a group of peptides with potent ANALGESIC properties that occur naturally in the brain. The word *endorphin* is a contraction for the words *end*ogenous and *morphine*; it was coined by narcotics researchers in 1975 as the preferred term for a then hypothetical natural substance capable of action at RECEPTORS for OPIATES (such as HEROIN). The underlying hypothesis was that an endorphin NEUROTRANSMITTER utilized the receptors at which morphine and related drugs exerted their actions. After extensive and intensely competitive research by many groups, three distinct types of such endogenous opioid peptides were found (*peptides* are segments of linked amino acids that can act as neurotransmitters). By 1999, additional peptides able to act at opioid receptors as well as to regulate pain sensitivity through nonopioid receptors had been identified.

Each type of opioid peptide gives rise to one or more opioid peptide prohormones, which are then modified by enzymes in tissues to convert the larger inactive peptides into smaller active ones. For example, the pro-opiomelanocortin prohormone is synthesized in the corticotropes in the anterior pituitary gland and separately in hypothalmic and medullary neurons is cleaved in those cells to β-endorphin, a 31 amino-acid peptide with the greatest intrinsic opioid activity. Each active natural opioid peptide contains the tetrapeptide tyrosine-glycine-glycine-phenylalanine at its amino terminus. The fifth amino acid is either methionine (resulting in the so-called Met^5 enkephalin) or leucine (resulting in leu-enkephalin). Opioid peptides derived from plants—for example, caseimorphin—have also been described. The opioid peptides, of which the proenkephalin- and prodynorphin-derived peptides are most widespread, are found in specific neurons in the brain.

ENFORCEMENT STRATEGIES AND TACTICS *See* Drug Interdiction

ENKEPHALIN Enkephalin is either of two pentapeptides (containing five amino acids) with OPIATE and ANALGESIC (painkilling) activity, occurring naturally in the brain, with a marked affinity for opiate receptors. ENDORPHIN was initially the name for all opioid-like NEUROTRANSMITTERS in the brain; the research team of Hans Kosterlitz and John Hughes gave their own name, enkephalin (a variant of *en-cephal* ["of the brain"]), to the two opioid pentapeptides that they had purified from ox brains (ca. 1977). They confirmed their discovery by showing that the effects of synthetic peptides were the same in bioassays using opiate RECEPTORS and that both Met^{5}enkephalin and Leu^{5}enkephalin were authentic endogenous opioid peptides.

EPIDEMICS OF DRUG ABUSE Hearing the word *epidemic*, one often thinks first of the flu, measles, the ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS), or some other contagious disease spreading through a community. In epidemics with person-to-person spread of infection and disease, people become infected and fall victim to the disease, and in the process they come into contact with other people, who in turn get the infection and disease. Often, what is being spread from person to person is not the disease itself, but rather an agent of the disease—for example, one of the viruses that accounts for influenza, the measles virus, or the human immunodeficiency virus (HIV) that causes AIDS.

In EPIDEMIOLOGY (the study of epidemics), it is not the agent, the person-to-person spread of a disease, or the intentional or unintentional nature of acquiring the infection or disease that defines an epidemic. Instead, an epidemic is defined as an unusual occurrence of an infection, disease, or other health hazard in a population. The contrast between "usual" and "unusual" most often is determined by looking at the number of cases that have been occurring within the population over time. If the number of cases occurring in the population this month (or year) is notably greater than the number of cases that occurred in the population during each of the prior months (or years), then it is legitimate to talk of a growing epidemic.

An epidemic may be most obvious when the number of cases goes from zero to a much greater number in a relatively short span of time. For example, before the middle 1970s, the U.S. population apparently had no cases of HIV infection or AIDS. For those years, the usual number of cases per year was zero. Since then, the country has seen a mounting number of HIV infections and AIDS cases each year, and it has become a raging epidemic. Compared to the previous usual number of cases per year, the United States faces an unusual occurrence of disease in the form of thousands of cases per year.

The same concept can be applied on a smaller scale. In the mid-1990s there still are small cities and communities where apparently no one in the population has yet acquired the HIV infection. Health officers who watch over these populations may speak legitimately of an HIV epidemic once the number of cases occurring in the population begins to mount, and there is no need to wait until there are hundreds or thousands of cases before describing the epidemic situation. This is because epidemics are not defined by the absolute number of cases that are occurring. In the early 1990s, there was an epidemic outbreak of hantavirus infection

and hantavirus-related deaths in the southwest United States. Because the usual number of hantavirus-related deaths in this region was zero, the situation was declared to be an epidemic well before 100 cases had occurred. Sometimes an epidemic that is limited to a certain place or time will be called an *outbreak*, but this distinction is not a technical one.

There are also epidemics even when no person-to-person spread is involved. For example, in the middle of the twentieth century, there was an epidemic of infant blindness due to retrolental fibroplasia, induced when premature infants were kept in incubators with excessively high concentrations of oxygen. These very high concentrations of oxygen were not a result of machine failure. Instead, the number of cases of retrolental fibroplasia and associated blindness kept growing as ever more hospitals raised the oxygen concentration within incubators in a misguided effort to increase survival of the infants by enriching their oxygen supply. Later, clinical and epidemiologic studies showed that this effort to save lives actually led to the increased occurrence of blindness.

Sometimes people object to the usage of the term *epidemic* as applied to drug dependence because it is believed that people bring drug problems down upon themselves by their careless behavior. Epidemiologists, however, typically do not recognize the distinction between "careless" and "careful" behavior when it comes to epidemics. For this reason, they have no trouble speaking about epidemics of syphilis and AIDS, which in some degree are linked to unprotected sexual behavior, something that many would regard as careless behavior.

In summary, the evenhanded application of the concept of epidemic makes it clearly legitimate to speak of an epidemic of smoking-related lung cancer or emphysema, an epidemic of liver cirrhosis due to drinking of alcoholic beverages, an epidemic of leukemia induced by ionizing radiation, an epidemic of mental retardation due to rubella (German measles) infection during gestation, an epidemic of motor vehicle crashes, and an epidemic of deaths by homicide, as well as epidemics of drug use and drug abuse. In order to use the term *epidemic* to describe the health-related experience of a nation, state, or community, it is necessary to demonstrate an *unusual* occurrence of the condition in the population during some specified span of time, relative to the number or rate of cases that occurred in the population during the immediately prior time spans. There is no need to limit usage of the term to infectious diseases with known agents such as rubella or HIV: nor is there a need to limit its usage to diseases spread by person-to-person contact or to be concerned whether the spread of the disease involves careful or careless behavior.

EPIDEMICS IN THE UNITED STATES

An unusual occurrence of drug use or an unusual occurrence of problems connected with drug use can be referred to as epidemics of drug use and drug abuse. In the mid-1990s in the United States, there were multiple indications that the nation had gone through its second major epidemic of COCAINE use and now was in the end-stages of that epidemic.

The first U.S. epidemic of cocaine use started in the late nineteenth century and early twentieth century when cocaine was marketed widely in a variety of forms, including Coca-Cola, Vin Mariana (a wine containing cocaine), and other cocaine products sold without a doctor's prescription. That epidemic subsided, in part because of increased federal and state restrictions on importation and marketing of cocaine, as well as new labeling requirements for patent medicines and other over-the-counter products.

From 1920 through the early 1960s, cocaine use in the United States was not a usual occurrence outside of relatively small circles of HEROIN users, movie and television stars, jazz musicians, and others who came into contact with illicit suppliers of the drug. In the early 1970s, when the federal government began supporting a series of national and state surveys of illicit drug use, cocaine use was found so rarely that it was difficult to get a reliable impression of the characteristics of the cocaine users—there were too few of them in the survey samples.

By studying the series of survey reports from 1972 through the mid-1990s, it is possible to plot the growth of this second U.S. epidemic of cocaine use from what had been typically low levels of use to increasingly greater numbers of cocaine users. The peak years of the epidemic use seem to have been in the late 1970s, which were followed by declining numbers of cocaine users in subsequent years, notwithstanding a small rally in the mid-1980s in connection with the emergence of crack-cocaine smoking.

Although the number of active cocaine users in the U.S. population has dropped back toward the levels observed in the early-to-middle 1970s, it seems that an epidemic of cocaine dependence is still very much in evidence, if the definition of cocaine dependence is meant to encompass very frequent cocaine use as well as the cocaine dependence syndrome described in the more formal terms of clinical research. That is, as the epidemic of cocaine *use* subsided in the late 1980s and early 1990s, there was no parallel falling off in the numbers of daily or other frequent cocaine users, and there was no clear drop in the number of people actively affected by cocaine dependence. Indeed, in the mid-1990s, the number of active cases of cocaine dependence in the population seems to be greater than it ever has been in the nation's history. Thus, it can be said that the epidemic of cocaine dependence is not yet over, for there continues to be an unusually large number of cocaine-dependence cases in the population. There is not yet enough evidence to say whether fewer newly occurring cases of cocaine dependence are developing in the U.S. population. Once it can be shown that the new occurrence of cases has fallen off, it can then be said with more confidence that the nation has entered a declining phase in this most recent epidemic of cocaine dependence.

With their attention focused upon a declining number of cocaine *users* in the early 1990s, the American public and politicans seemed to turn their attention away from the nation's cocaine problems. At the same time, the level of support for treatment of drug dependence dropped from relatively high levels of expenditures in the mid-1980s, even though the number of people suffering from cocaine dependence had remained about the same as it was during the late 1980s. This set of circumstances underscores the political importance of drawing a distinction between epidemics of drug use versus epidemics of *drug dependence or drug-related problems*. It is likely that many Americans equated declines in the number of cocaine users with declines in the number of cocaine-dependent persons: they were not aware that the epidemic of cocaine dependence continued even as the epidemic of cocaine use was subsiding dramatically.

Coincident with decline of cocaine use within the United States, several other drugs have been the subject of increased attention and use, including drugs whose past popularity has re-emerged in recent years. This comeback of older drugs might be due to newer cohorts of drug users with no experience of friends suffering the adverse consequences associated with the drug, or possibly due to a change in either the availability, purity, or administration of the drug which would make its use more attractive, accessible, or reinforcing. Two examples of this re-emergence are methamphetamine and heroin.

Methamphetamine, a subgroup of amphetamines, was widely used in the 1960s and 1970s. Also known as "speed," "crank," "meth," "zip," and "ice," the medical and nonmedical uses of methamphetamine have included appetite suppression for weight loss, staying awake, and recreation. The stimulant effect is similar to that of cocaine, but with longer duration.

Methamphetamine use has appeared in outbreak and epidemic form in Asia, the Pacific Islands, and primarily southwestern parts of the United States since the middle of the 20th century, often in the form of "ice" smoking (i.e., inhalation of volatile fumes). In the early 1990s less than two percent of the population over the age of twelve had tried methamphetamine, according to national estimates. This number increased fifty percent in the later part of the decade and now remains relatively steady as we enter the 21st century. Among teenagers, the number of methamphetamine users doubled during the1990s. Emergency room admissions associated with methamphetamine use increased nearly 350 percent from the early to the middle of the 1990s; admissions to treatment increased nearly four hundred percent from the early to the late part of the decade. Outbreaks of "ice" smoking have spread northward and eastward from the southwestern United States, suggesting an epidemic pattern in the United States in the 1990s, still persisting in the year of publication.

Prevalence estimates of heroin use had been relatively consistent during the 1980s, but early in the 1990s the purity of the drug increased dramatically, as did its availability. The heightened purity allowed for modes of administration other than injection, such as snorting and "smoking" (inhalation of volatile fumes), opening a door to heroin use for the drug users who otherwise might abstain due to an aversion toward injection.

Initiation of heroin use among youths in the mid-1990s was at its highest level in nearly 30 years. From the mid-1990s to the end of the dec-

ade, the proportion of heroin users using needles remained unchanged while the proportion sniffing or snorting increased from 50 percent to 75 percent. Much of the new heroin use is within the population under age 25. Heroin use started to increase in the early 1990s and continued through the end of the decade. It now seems to have stabilized.

OTHER PAST DRUG EPIDEMICS

An epidemic during the third century B.C. of "hanshi" use at the end of the Han dynasty in China and the spread of tea drinking prior to 900 B.C., might be the earliest documented epidemics of PSYCHOACTIVE DRUG use in the world, not counting outbreaks of excessive ALCOHOL use (see ASIA, DRUG USE IN).

In the 1600s, in Europe, there were epidemics of CHOCOLATE (cocoa) consumption, TOBACCO consumption, and COFFEE consumption. These epidemics followed shortly after colonization of the Americas by Europeans and were sustained by ever-increasing supplies of these products shipped from the cash-poor colonies.

During the nineteenth century, many Europeans became enthusiastic about the inhalation of ether, an intoxicating volatile substance that was investigated for its medical uses by John Snow, one of the fathers of modern epidemiology. Although definitive statistics are not available, it appears that nonmedical inhalation of ether spread through Ireland in an epidemic fashion during the nineteenth century, as did inhalation of NITROUS OXIDE (laughing gas) in the United States. Also during the nineteenth century, China and several other countries experienced epidemics of OPIUM consumption, especially opium smoking. In part, an increased spread of opium smoking in the Americas prompted passage of antiopium legislation, which ultimately produced international agreements that curbed the supply and distribution of opium and opium products worldwide.

It has been said that the international agreements on these drugs were less effective than the public-health and punitive actions taken within countries to curb opium smoking. For example, harsh jail sentences were imposed for violation of city, state, and federal laws concerning opium, and a tradition of executing "drug criminals" was started in some countries. In Communist China, according to some stories, capital punishment of drug dealers and drug users account for the virtual disappearance of drug problems in that country. The truth of these stories cannot be known.

About the same time that the international agreements on opium and opium products were passed, the United States experienced an increase in tobacco smoking, ultimately with peak population levels of tobacco smoking occurring during World War II and the following years, before declines occurred in conjunction with the surgeon general's 1962 report on smoking and health and other publicity about the health hazards of smoking. When one considers the social climate of the 1990s, a time when tobacco smoking was not at all a socially approved drug-use practice, it may be difficult to imagine that during World War II Lucky Strikes and other cigarettes were passed out to soldiers as part of their daily food rations. This turned out to be an effective way to sustain the epidemic of tobacco smoking, but one cannot be sure whether the tobacco industry's intent was primarily to boost the morale of soldiers or to create and build market strength for tobacco cigarettes. Someone interested in the history of epidemiology might be able to sort this issue out, if industry records from that time were opened for inspection.

A more definitive case can be built for the marketing strategies that have been used to increase and build market strength for smokeless tobacco products such as snuff. There was a tremendous increase in the youthful usage of smokeless tobacco between 1970 and 1985. This increase has been traced to deliberate marketing strategies, including formulation of relatively low-cost, "unit dose" supplies of tobacco snuff that had been flavored to increase palatability.

While tobacco consumption was increasing worldwide, Japan's population was affected by an epidemic of METHAMPHETAMINE use during and especially after World War II; later distribution of this drug was seen throughout other countries of the world, including the Scandinavian nations and the United States. At one point in the 1950s, it was estimated that 2 percent of Japan's population had taken methamphetamines nonmedically. It also has been said that especially harsh jail sentences and other criminal penalties accounted for the termination of the amphetamine epidemic in Japan, but as noted in regard to capital punishment and prior Asian drug epidemics, there is no good evidence on

this issue. Between 1945 and 1965, other countries saw amphetamine epidemics come and go without the implementation of especially harsh criminal penalties.

The prevalence of nonmedical STIMULANT use in the 1950s did not reach the 2 percent level in the United States as it had in Japan, but it was sufficiently widespread to yield congressional hearings that focused especially upon AMPHETAMINE use by long-distance truckers (e.g., those who used the drug to promote vigilance and stamina for lengthy trips) and by homemakers (e.g., those who took amphetamines to curb their appetite or because of their mood-altering effects). In part, these epidemics should be understood in relation to the relatively widespread availability of amphetamines in a context of limited regulation of supplies and distribution. These epidemics resulted in legislation and social action to reduce the supply and control the distribution of the amphetamine drugs. In the United States, two especially relevant pieces of federal legislation were the Drug Abuse Control Amendments of 1965 and the CONTROLLED SUBSTANCES ACT of 1970; these laws were directed at controlling the use of the amphetamines as well as the use of other drugs.

The usage of marijuana and the psychedelic drugs (e.g., LSD) grew during the 1960s and seems to have peaked during the 1970s. In the 1990s, there were conflicting reports of increasing consumption of these drugs, especially LSD. By some accounts, the nation entered a new phase of LSD usage. It appears, however, that this nationwide increase was not detectable in population estimates from the NATIONAL HOUSEHOLD SURVEY ON DRUG ABUSE, and it is possible that the apparent nationwide epidemic actually remains quite limited in scope.

Several noteworthy developments occurred in relation to HEROIN and the OPIOID drugs during the late 1960s and early 1970s. One important clinical and epidemiological research group based at the University of Chicago developed important innovative strategies for community-level intervention directed at outbreaks of heroin use and heroin dependence. An important element in the group's intervention plan was to employ outreach workers, including staff in recovery from heroin dependence, who would spend enough time on the street corners to identify both new and old users of heroin and to help them get into treatment and stay in treatment. In addition, in Britain, Richard de Alarcon adapted classical methods of epidemiologic research to study the diffusion of injecting drug use (especially injecting heroin use) as an epidemic phenomenon, by plotting the person-to-person spread of the epidemic over time and across the cities of that country.

In 1971, President Richard M. Nixon declared a "war on drugs" following a period of increased heroin use in the United States: he did this partially in association with the return of Vietnam veterans, many of whom had become users of heroin and other opioid drugs during their overseas tours of duty. This epidemic of the late 1960s and early 1970s was documented most readily by examining statistics on clients entering treatment for heroin dependence, including the lag of several years that separated users initial injection of heroin to their first admission for treatment. Despite the war on drugs, a decline in heroin use in the early 1970s was followed by another smaller epidemic of heroin use or dependence during the mid-1970s, followed by apparent decreases in the occurrence of heroin dependence during the late 1970s and early 1980s. The early decrease appears to have coincided with the decrease in importation of heroin to the United States from supplier countries such as Turkey and the mid-1970s increase with the emergence of Mexico and Southeast Asia as suppliers of illicit opiates.

When heroin is the drug of choice and heroin availability declines, users often take other drugs that provide the same functions—either opiate drugs derived from the opium poppy such as morphine or synthetic opioids derived in the chemistry lab and not requiring cultivation products from poppy fields. One example of a synthetic opioid is the so-called China White, which spread through the United States, especially on the West Coast. The number of overdoses linked to China White and related synthetic opioid drugs seemed to increase until the mid-1980s. Since then, there have been declines in the incidence of this type of overdose, possibly because of the increased supplies and street-level purity of poppy-derived heroin.

In addition to the cocaine epidemics already mentioned, there was a cocaine epidemic in the late twentieth century, which might have been sustained by the introduction of CRACK-cocaine, another unit-dose formulation of a psychoactive drug that reduces cost to a level that can be afforded (at least, initially) by many people. Other articles in

this encyclopedia discuss reasons that crack-cocaine smoking might have helped sustain the epidemic of cocaine use, including differences in the pharmacologic, pharmacokinetic, and reinforcement profiles of crack-smoking versus nasal insufflation of cocaine hydrochloride powder. In this context, it is interesting to note that the epidemics of crack smoking and cocaine use ended when they did, during a period of widespread availability of cocaine in a low-cost formulation. In epidemiologic terms, this development carries three very important implications. First, given widespread availability, many Americans had opportunities to smoke crack or take cocaine powder and did not do so. In some important way, these were Americans who were not susceptible to widespread media publicity and other conditions that otherwise might have promoted the use of crack or other forms of cocaine.

Second, for many Americans who tried crack or cocaine powder, the use of these drugs did not compete well with alternative behaviors that were as readily available to them in their home and community environments. They found that there were other, more reinforcing ways with which to occupy their daily lives. This signifies that within the population, for those who have used cocaine, there are differences in the users' susceptibility to becoming cocaine dependent.

Third, within the American population, the balance of these several kinds of susceptibility must have changed over the course of the 1980s. For example, during many other epidemics of contagious disease, as the balance of susceptibility changes, the people who are more susceptible become surrounded by people who are less susceptible. Sometimes, the balance of susceptibility changes without any active and organized public health intervention, as in the case of a typical influenza epidemic in an elementary school population. Sometimes, the balance of susceptibility is changed quite deliberately by organized public-health action, as in the successful worldwide effort to eradicate deadly smallpox by making sure that susceptible persons were immunized against smallpox, and by making sure that infected individuals were surrounded by those who were not susceptible by virtue of either immunization or past infection.

In the case of a drug epidemic, as the more susceptible individuals in the population start to become surrounded by people who will not or do not take the drug, it must be increasingly difficult for them to come into contact with the drug at an individual level, even when the drug supply is great at the societal levels. Furthermore, as the balance of the several kinds of susceptibility changes within the population, there must be an evolution of the social-influence processes that promote the spread of drug use from person to person: Fewer people are being pressured by peers to use the drug; fewer people are talking about the drug in favorable terms; more people are talking about how they had a chance to use it, but it just didn't seem worth it; more people are talking about how they have used the drug but it just didn't do very much for them.

This sort of process must have taken place with regard to the cocaine epidemic for the balance of susceptibility to have changed within the population; otherwise, the epidemic of cocaine use would have persisted. Because we do not have an effective biological vaccine that would reduce susceptibility to cocaine use the way the smallpox vaccine reduced susceptibility to smallpox infection, this change in the balance of susceptibility had to have been caused by something else. *Before* the epidemic of cocaine use had started to decline, the social demographer K. Singh hypothesized that it would decline simply because of demographic changes in the U.S. population caused by a declining birth rate fifteen to twenty-five years earlier. Singh apparently reasoned that, numerically, there would be fewer and fewer people aged fifteen to twenty-five, and this by itself would change the balance of susceptibility in the population because the developmental period from age fifteen to twenty-five is one that is at especially high risk for starting illicit drug use.

Later, and *after* the epidemic of cocaine use had started to decline, two other main hypotheses emerged. One of these took note of the demographic changes to which Singh had pointed but also drew on three other interrelated epidemiologic observations, namely that (1) cocaine use almost always starts after MARIJUANA use has started; (2) a history of marijuana use probably is the strongest indicator of susceptibility for trying cocaine; and (3) most marijuana users try cocaine once or a few times but do not go on to become dependent upon it (i.e., they are in the second kind of susceptibility group already mentioned). These three epidemiologic observations were also linked with an observation from ethnographic research: When a young

person is presented with an opportunity to try marijuana or cocaine, it very often is a slightly older person with a history of marijuana use who presents the opportunity. It might thus have happened that the cocaine epidemic had stopped growing and had started to end once the supply of cocaine had increased to a level where a large proportion of former and current marijuana users had been presented with an opportunity to use cocaine. When these marijuana users either declined to use cocaine or tried and then stopped using cocaine, they then no longer could serve as sources of diffusion to younger persons. That is, the change in balance of susceptibility within the population was related to the number of individuals who previously had tried marijuana and to whether they had completed the normative passage of (1) declining to use cocaine when it was offered to them or (2) trying cocaine a few times without becoming dependent upon it, thereby ceasing to be part of the vanguard of cocaine experimenters who in the glow of their first cocaine experiences would enthusiastically be offering cocaine to others.

According to the other main post-epidemic hypothesis, trends in the perceived danger or risk of harm associated with taking cocaine affected trends in cocaine use. Particularly after basketball star Len Bias died after smoking crack, more young people reported that they perceived there to be substantial risks of harm associated with taking cocaine. Concurrently, there were declines in reported levels of cocaine use. For a number of years, as surveys showed more and more young people reporting that they perceived cocaine use to be dangerous, the levels of cocaine use declined even further, despite increasing or stable levels of cocaine availability. These trends gave rise to the optimistic observation that perhaps it was the increases in perceived dangerousness of cocaine use that accounted for the declines in cocaine use. If such an observation were true, society might be able to stop or curb future epidemics by educating youths to perceive the harmfulness of drug use.

DRUG EPIDEMICS IN THE FUTURE

Singh's prediction based on an analysis of demographic changes in the population and the two main hypotheses that emerged after the epidemic of cocaine use had started to decline have historical importance. Although it was not possible to test these hypotheses about the 1975-to-1994 epidemic of cocaine use in the United States in any rigorous fashion, and it cannot be known for certain that any of them is correct, they may help in the plans for coping with future epidemics of drug use and drug dependence; they also offer pointers what kind of societal response might be needed if a rising line is perceived in the plotted curves of new epidemics. Nonetheless, until a more certain knowledge is acquired about the dynamics of epidemics of drug use, it will be premature for politicians or anyone else to ride to glory on the descending line of these curves. There is enough knowledge to take action, but not enough to say what specific combinations of public-health actions will be effective.

The array of public-health actions to stop or curb future drug epidemics have not yet been exhausted. In the 1970s, Dr. Jerome H. Jaffe and other experts suggested developing prevention strategies that would be based on concepts of reducing susceptibility to drug dependence. This might sound like science fiction, but recent new developments in molecular biology, immunology, pharmacology, and neuroscience have made a viable strategy of this type more plausible.

A relatively sharp increase in the use of steroids among youths towards the end of the 1990s suggests that investigation into its use, especially among males, might identify an emerging epidemic. Similarly, "club drugs" such as MDMA ("ecstasy"), Rohypnol, ketamine, and others, have shown increases in use and availability throughout the 1990s, primarily among youths and young adults.

Because of the novelty of these types of drugs, surveys designed to estimate the number of users have difficulty keeping up with their emergence in isolated outbreaks until use has persisted long enough and has become sufficiently prevalent to warrant inclusion in the survey assessments. For this reason, there are no definitive sources of epidemiological evidence on epidemics of drug use, akin to the evidence available for notifiable diseases such as syphilis and HIV infection. Readers interested in local area outbreaks and epidemics will find useful and sometimes definitive evidence in the periodic reports of Community Epidemiology Work Groups established by the United States National Institute on Drug Abuse, and its counterpart institutions in other countries.

In seeking to understand the future of drug epidemics in society, it will be necessary to complete more thorough studies of some predicted epidemics that did not materialize. For example, following the 1990/91 Persian Gulf war and 1992 posting of U.S. troops to Somalia in East Africa, it was said that the United States would suffer a khat-cathinone epidemic as soon as the veterans returned with the experience of seeing khat used by the people of the Middle East and Somalia—and when cathinone (one of khat's active ingredients) was extracted or synthesized by underground chemists for distribution. So far, however, the prediction of the nationwide KHAT-cathinone epidemics has been wrong. There have been isolated epidemics in a few communities but apparently no widespread use, and it is not altogether clear what curbed the spread to other communities.

As of the early 21st century, many countries have conducted epidemiological surveys to estimate the number of drug users in their populations, and some countries maintain substantial surveillance efforts to assess whether and when drug epidemics are occurring. No country, however, has made a substantial investment in the empirical study of drug epidemics. Most of the hypotheses and theories about drug epidemics remain untested against epidemiologic evidence, including a recently stated and fairly elaborate theory that incorporates what might be the necessary conditions for the expansion, the maintenance, and the decline of drug epidemics. It must thus be said that the present stage of applying epidemiology to the study of drug epidemics is a fairly primitive one.

EPIDEMIOLOGY OF DRUG ABUSE One of the best ways to introduce an article on the epidemiology of drug use and drug dependence is to ask some basic questions that epidemiologic studies can answer but laboratory and clinical studies cannot. Here are some examples:

In the late 1990s in the United States, about how many ages 12 to 17 had used cocaine at least once?

In the late 1990s, within which U.S. population subgroups were active cocaine users most likely to be found?

Within the United States in the early 1990s, among those aged 15 to 24 who had used cocaine, what proportion had become dependent on it?

In the early 1990s, which age group within the U.S. population was most likely to have experimented with cocaine, and which age group was most likely to have developed cocaine dependence?

For a young adult living in the United States, what is the risk of developing the problem of alcohol abuse or dependence between one year and the next?

Is the risk for alcohol dependence greater for some young adults than for others?

Which subgroups of young adults are at especially high risk for alcohol dependence?

Are these same subgroups of young adults at especially high risk of becoming dependent on psychoactive drugs such as marijuana or cocaine?

To answer questions of this type, it is necessary to step outside the laboratory and clinical settings where drug users receive treatment. This step can be taken during the course of epidemiologic surveys that seek information about all aspects of the population's drug experience; the surveys take into account not only the relatively modest numbers of drug users who have received counseling and treatment, but also those who never have received any kind of health care or social services. The answers to these questions, based on epidemiologic surveys conducted in the United States between 1980 and the present, are as follows:

In the late 1990s, among those aged 12 to 17 in the United States, an estimated 496,000 to 682,000 had used cocaine at least once. As a proportion, this amounted to about 2.5 percent of those 12 to 17 in the United States at that time.

Within the United States in the late 1900s, young adult men aged 18 to 29 were more likely to be active cocaine users than any other population subgroup categorized by age and sex. For example, slightly more than 2.5 percent of men 18 to 25 were active cocaine users, as compared with 1.4 percent of men 26 to 34, 1.3 percent of women aged 18 to 25, and 0.9 percent of women aged 26 to 34.

Within the United States in the early 1990s, among those aged 15 to 24 who had used cocaine, an estimated 25 percent had become dependent on it. That is, for every four who had experimented with cocaine, one had become dependent on it.

Within the United States in the early 1990s, people of the 25 to 34-year age group were most likely to have experimented with cocaine; within this age group, about 30 percent of men had tried cocaine at least once, and about 21 percent of women had tried cocaine at least once. Cocaine dependence also was most prevalent in this age group: it affected about 4 percent of all persons aged 25 to 34. Among cocaine users aged 25 to 34, an estimated 16 percent had become dependent on it.

For those 18 to 29 living in the United States, the best available estimate for the risk of developing alcohol abuse or dependence between one year and the next is about 2 to 4 percent.

The risk of succumbing to alcohol abuse or dependence for males aged 18 to 29 is an estimated 6 percent per year, as compared with about 1 percent per year for females aged 18 to 29.

Males between the ages of 18 and 25 are at especially high risk of succumbing to alcohol abuse or dependence.

These same subgroups of young adults are at especially high risk of becoming dependent on psychoactive drugs such as marijuana or cocaine. When all the abuse or dependence syndromes attributable to nonmedical use of these drugs are considered, the estimated risk for males aged 18 to 29 of developing clinically recognizable drug problem is estimated at 4.4 percent per year; for females aged 18 to 20, it is about 1.6 percent.

There is, of course, good reason to wonder whether epidemiologic surveys of drug use and drug dependence have sufficient validity to be trusted. On the one hand, especially among young people, there may be a tendency to exaggerate drug taking, and to falsify survey responses in the direction of more drug taking than has really occurred. On the other hand, some people may be hesitant to disclose their histories of drug taking or drug problems; they might not agree to participate in the survey, or they might falsify their answers in the

direction of less drug taking or fewer problems than have actually occurred.

There fortunately is a body of methodologic research that provides some general assurance about the accuracy of estimates in epidemiologic surveys. Accuracy of the survey results seems to be enhanced considerably when special care is taken to guarantee confidentiality of responses, to protect the privacy of the survey respondents, and to develop trust and rapport before asking survey questions about sensitive behavior, alcohol and drug problems, or illegal activities. In particular, except in poorly conducted surveys of very young respondents, there seems to be very little exaggeration of drug involvement, and older adolescents and adults rarely report drug use unless it actually has happened. Moreover, the accuracy of the estimates does not seem to be distorted too much when the surveys concentrate on household residents and do not extend their samples to include homeless or imprisoned segments of the population. Even though homeless people and prisoners often have significant and special needs for alcohol- and other drug-dependent treatment services that society cannot ignore without peril, the number of homeless and incarcerated persons is small relative to the considerably larger number of persons living in households.

It also is important to note the relatively large size of the survey estimates obtained in these epidemiologic surveys. For example, in 1998, as part of the HIGH SCHOOL SENIOR SURVEY (Monitoring the Future), almost 16,000 high school seniors were asked to fill out confidential questionnaires about their use of such drugs as marijuana and cocaine; more than 38 percent reported having taken these drugs illegally, 80 percent reported consuming alcoholic beverages, and more than 60 percent reported having consumed alcohol to the point of getting drunk. In 1998, more than 25,500 American household residents aged 12 years and older participated in a U.S. government-sponsored NATIONAL HOUSEHOLD SURVEY ON DRUG ABUSE and were asked to answer an interviewer's questions about the use of these drugs; illegal drug taking was reported by an estimated 21 percent of those 12 to 17 years, 48 percent of those 18 to 25, 51 percent of those 26 to 34, and 32 percent of older adults. Furthermore, between 1990 and 1992, almost 9,000 Americans aged 15 to 54 completed confidential interviews as part of a U.S. government-sponsored National Comorbidity Survey. According to this survey, one in three tobacco smokers had tobacco problems, signs, and symptoms consistent with their having become dependent on tobacco and one in seven drinkers had alcohol problems, signs, and symptoms consistent with their having developed the clinical syndrome of alcohol dependence. Among those who reported use of marijuana, heroin, or other controlled substances, one in seven reported drug problems, signs, and symptoms consistent with their having become dependent on these drugs. These survey-based estimates are already high enough to provoke social concern. They would be even higher if corrections were to be made to account for respondents who were hesitant to report either their consumption of these drugs or the problems associated with drug use that they had.

DRUG-SPECIFIC ESTIMATES FOR THE U.S. POPULATION

It may be useful if, bearing in mind these potential limitations in the survey methods, one considers each broad drug class one by one, in order to convey the relative frequency of use of tobacco, alcohol, and other drugs in the United States, and to identify population subgroups within which drug use or drug dependence is most common. (From this point on, estimates based on the 1999 survey of high school seniors are labeled MF estimates; those from the 1998 National Household Survey on Drug Abuse are labeled NHSDA estimates; and those from the 1990–1992 National Comorbidity Survey are labeled NCS estimates.) In view of recent attention to the CAFFEINE-dependence syndrome and other health hazards of drinking COFFEE or TEA or consuming other caffeinated products, estimates concerning the use of caffeine and caffeine dependence might seem warranted. There is not yet a stable base of epidemiologic data on caffeine use and caffeine dependence, however; these remain topics that ought to be examined in future epidemiologic studies.

Tobacco Smoking in the Late 1990s. Monitoring the Future (MF) estimates show that about 65 percent of high school seniors have smoked TOBACCO cigarettes at least once. An estimated 35 percent of high school seniors smoked tobacco cigarettes at least once during the month

prior to the survey, and 23 percent had become daily tobacco smokers.

According to the National Household Survey on Drug Abuse (NHSDA), which included household residents age 12 years and older, an estimated 68 to 71 percent smoked tobacco cigarettes at least once, for a total of about 149,021,000 to 155,515,000 smokers. An estimated 29 to 32 percent had smoked in the year prior to the survey, for a total of 64,012,000 to 69,522,000 recently active smokers; most of these had smoked in the month prior to the survey (57,811,000–63,072,000).

There was an important age and sex-related variation in these estimates. For example, among adults past age 34, males were more likely than females to have been recent tobacco smokers (26.9% versus 23.4%). Among those 18 to 25, within the limits of survey error, there essentially were no differences between the sexes in prevalence of smoking, and both estimates were in a range from 37.5 to 45.3 percent. Among those 12 to 17, there also were no statistically reliable differences between the sexes, and the estimated proportions were between 17 and 21 percent; although estimates from earlier years show the proportion of girls smoking in this age group to be numerically greater than that for boys of the same age (NHSDA estimates).

Using data from the National Comorbidity Survey of Americans aged 15 to 54, it has been possible to estimate the proportion of tobacco smokers and other drug users who have developed drug-dependence syndromes, as defined in relation to a set of diagnostic criteria for drug dependence that were developed by the American Psychiatric Association in 1987. Before the diagnoses of drug dependence are made, the survey must produce evidence that drug users experienced signs or symptoms of dependence such as going through withdrawal or taking drugs to avoid withdrawal symptoms. Applied to the tobacco smokers identified in the Naitonal Comorbidity Survey, these diagnostic methods indicated that almost one-third of tobacco smokers in the survey population had developed tobacco dependence. That is, for every three tobacco smokers, one had developed tobacco dependence and was found to have met the American Psychiatric Association's diagnostic criteria for dependence on this drug. Of the more than 70 percent of respondents who had smoked tobacco at least once, a truly remarkable proportion of about 24 percent was found to have a history of currently active or former tobacco dependence (NCS estimates).

Smokeless Tobacco Use in the Late 1990s. An estimated 23 percent of high school seniors had tried smokeless tobacco at least once, and about 8.4 percent had used it during the month prior to the survey (MF estimates). Household survey estimates indicate somewhat lower values, except among males aged 18 to 25. For example, among 12- to 17-year-olds, an estimated 8.9 percent had tried smokeless tobacco, and just over 1 percent had used it in the month prior to the survey. By comparison, slightly more than 24 percent of 18- to 25-year-olds had tried smokeless tobacco; corresponding estimates for 26- to 34-year-olds and those over age 34 were 23.4 and 15.6 percent, respectively. Males aged 18 to 25 were also more likely to be recent smokeless tobacco users; more than 10 percent had used it during the month prior to the survey, while an additional 16 percent had used it at some time before the past month (NHSDA estimates).

Alcohol Use in the Late 1990s. An estimated 80 percent of high school seniors have consumed ALCOHOL at least once. About 74 percent had consumed alcoholic beverages in the year prior to the survey, and 51 percent had done so during the month prior to the survey. About 3.4 percent had become daily drinkers (MF estimates).

An estimated 62.3 percent of high school seniors had been drunk at least once—almost 53 percent during the year prior to the survey and almost 33 percent during the month prior to the survey. About 3.4 percent reported having become daily drinkers (MF estimates).

Among household residents aged 12 and older, an estimated 80 to 82 percent have consumed alcoholic beverages; this represents from 174,928,000 to 179,975,000 individuals. During the month prior to the survey, an estimated 51 percent had consumed alcohol. As might be expected, the prevalence values for 18- to 25-year-olds were somewhat higher than they were for the high school seniors, especially in relation to recent drinking: Almost 60 percent of the 18- to 25-year-olds had consumed alcoholic beverages during the month prior to the survey. The values for 12- to 17-year-olds were lower: About 37 percent in this age group had tried alcoholic beverages at least once, and about 19 percent had consumed alcohol during the month prior to the survey (NHSDA estimates).

An estimated 22.4 percent of respondents of all age groups from 12 years upward reported drinking at least once per week or more during the year prior to the survey. Corresponding estimates for respondents aged 12 to 17, 18 to 25, 26 to 34, and 35 + were 4.6, 24.5, 23.8, and 24.6 percent, respectively (NHSDA estimates).

Alcohol dependence was found to have affected 15 percent of those who had consumed alcoholic beverages: Out of every six or seven persons who had tried alcohol, about one had become dependent on alcohol. In relation to the total survey population that included drinkers as well as abstainers, an estimated 14 percent were found to qualify for the diagnosis of drug dependence, according to the American Psychiatric Association's criteria (NCS estimates).

Other Illicit Drug Use in the Late 1990s. When controlled substances such as MARIJUANA, cocaine, and heroin, as well as INHALANT drugs, were considered, it was found that an estimated 55 percent of respondents had used these drugs on at least once occasion, 42 percent during the year prior to the survey. About 26 percent had taken one or more of these drugs during the month prior to the survey (MF estimates).

The National Household Survey on Drug Abuse reported that an estimated 34 to 37 percent of the population aged 12 and older had engaged in illicit drug use at lease once: this amounts to about 75 to 81 million drug takers. The number of recently active drug takers was lower; they represented 6 to 7 percent of the population (NHSDA estimates).

According to the National Comorbidity Survey estimates, out of every seven persons who had tried marijuana, cocaine, or other controlled substances and inhalant drugs, one had developed drug dependence (14.7%). In light of the fact that about 51 percent of this survey population of 15- to 54-year-olds reported a history of illicit drug use, the resulting estimate for the prevalence of dependence on controlled substances was 7.5 percent. That is, in the total population of individuals (including both drug users and never users), about one in fourteen had fulfilled the criteria for drug dependence (NCS estimates).

Cannabis Use in the Late 1990s. An estimated 50 percent of high school seniors had tried marijuana or HASHISH (*Cannabis*) on at least one occasion, and about 38 percent had smoked cannabis during the year prior to the survey. An estimated 23 percent had smoked cannabis during the month prior to the survey, and an estimated 6 percent reported daily cannabis use (MF estimates).

Within the age ranges of 12 to 17 and among persons aged 35 and older, there are many individuals who have not yet started to use illicit drugs such as cannabis, as well as many others who never will start to use these drugs. As a result, one might expect lower prevalence values in these age groups as compared to the values for other age ranges. In fact, this is precisely what the national survey estimates indicate. Overall, an estimated 32 to 34 percent of respondents reported having tried cannabis, but among 12- to 17-year-olds the estimate was only 18.9 percent, and among those aged 35 years and older it was 29.4 percent. Prevalence of cannabis use was most common among 26- to 34-year-olds (47.9%) and among 18- to 25-year-olds (44.6%). This also was true for recent cannabis use during the month prior to the survey: There was a prevalence of 5.0 percent for the population overall, 8.3 percent for 12- to 17-year-olds, 13.8 percent for 18- to 25-year-olds, 5.5 percent for 26- to 34-year-olds, and 2.5 percent for older adults (NHSDA estimates).

Among cannabis users, about 9 percent were found to have developed cannabis dependence. Among *all* 15- to 54-year-olds (including both users and never users), 4.2 percent had become dependent on cannabis (NCS estimates).

Inhalant Use in the Late 1990s. INHALANTS had been used by an estimated 15 percent of high school seniors—about 6 percent within the year prior to the survey and about 2 percent during the month prior to the survey. Very few respondents (well under 1 percent) reported daily inhalant use (MF estimates).

The National Household Survey on Drug Abuse indicated that about 5.8 percent of its survey population had tried inhalants at least once; about 1 percent had done so during the year prior to the survey, and from 0.3 to 0.4 percent had used these drugs during the month prior to the survey. It was found, when considering age and sex, that the subgroup most likely to have used inhalant drugs during the month prior to the survey was that of males aged 18 to 25; in this group, 1.9 percent reported recently active inhalant use (NHSDA estimates).

An estimated 2.3 to 5.1 percent of the inhalant users have been found to qualify for the diagnosis

of dependence on inhalant drugs. Translated into an overall prevalence estimate for both users and nonusers, this amounts to about 0.3 percent prevalence of inhalant dependence in the total survey population (NCS estimates).

Use of Psychedelic Drugs in the Late 1990s. PSYCHEDELIC drugs (primarily LYSERGIC ACID DIETHYMIDE, or LSD) had been used by an estimated 14 percent of high school seniors. Almost two-thirds of these users (9.4%) had used them in the year prior to the survey, and about one-quarter (3.5%) had used them during the month prior to the survey. PHENCYCLIDINE (PCP) users were in the minority within this group of drug users; only 3.4 percent of the high school seniors had ever tried PCP (MF estimates).

Among persons aged 12 years and older, from 9.1 to 10.7 percent of individuals had tried psychedelic drugs such as LSD, but for the most part these drug experiences were not recent: Only 0.5 to 0.9 percent reported taking psychedelic drugs during the month prior to the survey. Peak prevalence values for recent use of the psychedelic drugs were observed in the years of adolescence and early adulthood; only for 12- to 17-year-olds and 18- to 25-year-olds did these values exceed a threshold of 1 percent (1.8 and 2.7%, respectively); otherwise, they were at the 0.4 percent level or lower (NHSDA estimates).

About 5 percent of the users of psychedelic drugs were found to qualify for the diagnosis of a dependence syndrome, defined in relation to the American Psychiatric Association criteria. Thus, about 0.5 percent of the survey population of 15- to 54-year-olds had become dependent on psychedelic drugs.

Cocaine Use in the Late 1990s. Among high school seniors, an estimated 9.8 percent had tried cocaine; within this group of COCAINE users, roughly one-half had tried CRACK-cocaine. About 6 percent of high school seniors had used cocaine (including crack) during the year prior to the survey, and just over 2.6 percent had used it in the month prior to the survey. In the MF sample of about 16,000 high school seniors, daily cocaine smoking was too rare to estimate precisely (MF estimates).

An estimated 10 to 11 percent of the National Household Survey's population reported having tried cocaine or crack smoking (or both) at least once. The corresponding value for 12- to 17-year-olds was only 2.2 percent, and there was age-related variation: 10.0 percent of the 18- to 25-year-olds had taken cocaine (including crack); 17.1 percent of the 26- to 34-year-olds had done so, and the prevalence estimate for older adults was 10.4 percent. Translated into absolute numbers, an estimated 21 to 25 million Americans aged 12 and older had tried cocaine or crack smoking. Recent use was substantially less common: Only 0.7 to 1.0 percent of the survey population reported having used these drugs during the month prior to the survey; this represented about 1.4 to 2.1 million recently active cocaine users in the survey population.

By the early 1990s, the second American epidemic of cocaine use had peaked and waned. Crack smoking had sustained the epidemic for a time, but in the early 1990s it became clear that crack smoking had not diffused broadly through the U.S. population. The relatively low prevalence values for crack smoking among high school seniors was reflected in the National Household Survey on Drug Abuse, which found that only 1.8 to 2.3 percent of its survey population had tried crack smoking; this amounted to 3.9 to 5.1 million individuals. The age groups with most crack-smoking experience were the 18- to 25-year-olds, with a prevalence value of 2.7 percent, and the 26- to 34-year-olds, with a prevalence value of 3.9 percent. Prevalence of crack smoking during the month prior to the 1998 survey was uniformly under 1 percent for all age and sex groups under study (NHSDA estimates).

For every six individuals who had tried cocaine at least once, one had developed cocaine dependence. That is, among these cocaine users, an estimated 15.2 to 18.2 percent had become sufficiently dependent upon cocaine to qualify for the American Psychiatric Association diagnosis. In relation to all persons in the survey population, whether they had tried cocaine or not, an estimated 2.7 percent qualified for the diagnosis of cocaine dependence (NCS estimates).

Use of Non-Cocaine Stimulants in the Late 1990s. The nonmedical use of stimulants other than cocaine (such as AMPHETAMINES) was actually more prevalent than cocaine use among high school seniors. An estimated 16.3 percent of high school seniors had taken these stimulant drugs without any doctor's orders; 10 percent had done so in the year prior to the survey, and 4.5 percent had done so during the month prior to the survey. Metham-

phetamine or "ice" smoking reemerged among youth in the 1990s. Among high school seniors, 4.8 percent had ever tried "ice," 1.9 percent had done so in the year prior to the survey, and 0.8 percent had used during the prior month (MF estimates).

For reasons not well understood, the Monitoring the Future sample of high school seniors yields prevalence estimates for non-cocaine stimulant usage that are considerably larger than corresponding estimates from the national household survey. Overall, the household survey population estimate for nonmedical use of these stimulant drugs was 4.4 percent, and the age group with the highest prevalence value was that made up of 26- to 34-year-olds, at 5.1 percent. Nonetheless, within the survey population, recent use of the stimulant drugs was found to be 3.2 to 4.9 percent for the 18- to 25-year-olds, the age group whose level of use most resembled that of the high school seniors (NHSDA estimates).

Slightly more than 11 percent of the persons who had used these stimulant drugs were found to have become dependent on them. This number of stimulant-dependence cases represents about 1.7 percent of all persons in the survey population aged 15 to 54 (NCS estimates).

Use of Anxiolytic, Sedative, and Hypnotic Drugs in the Late 1990s. About 9 percent of high school seniors had used tranquilizers (anxiolytic) or SEDATIVE-HYPNOTIC (e.g., BARBITURATE) drugs without a doctor's orders. About 5.8 percent had done so during the year prior to the survey, and 2.5 percent had done so during the month prior to the survey (MF estimates).

About 3 to 4 percent of the national household survey population reported nonmedical use of tranquilizers or anxiolytic drugs, while 2 to 3 percent reported nonmedical use of sedative-hypnotic drugs without a doctor's orders. For tranquilizers, this amounted to 6.8 to 8.8 millions of nonmedical users. For sedative-hypnotics, the total was 4.0 to 5.4 millions of nonmedical users. The estimated number of recently active users was less substantial; they represented less than 0.5 percent of the survey population for tranquilizers (under 1 million nonmedical users) and for the sedative-hypnotics (under 500,000 nonmedical users).

Grouping the users of the tranquilizer or anxiolytic drugs together with the users of the sedative and hypnotic drugs, the National Comorbidity Survey team found that about 9 percent of these drug users had become dependent on them. In considering this prevalence value, it is important to note that in this survey nonmedical drug use was defined to include not only use of the drug to get high, but also taking more of the drug than was prescribed or in ways not consistent with accepted medical practice. Overall, the prevalence of dependence on these drugs was at a level of 1.2 percent in the survey population (NCS estimates).

EPIDEMIOLOGY OF DRUG USE AND DRUG DEPENDENCE OUTSIDE THE UNITED STATES

Each year, the United States allocates more resources to epidemiologic surveys of drug use than does any other country in the world. For this reason, it has been possible to assemble a wealth of epidemiologic survey data on the prevalence of drug use and drug dependence within the United States. Other countries also have conducted surveys of this type and have produced valuable evidence about their experience with tobacco, alcohol, and other drugs. (See the bibliography for some references that can be consulted to gain more information about the results of these surveys.)

OTHER ASPECTS OF EPIDEMIOLOGY AS APPLIED TO DRUG USE AND DRUG DEPENDENCE

A broad range of research questions must be answered in order to gain a complete understanding of the epidemiology of drug use and drug dependence. The focus in this article has been on *quantity*: How many people in the population (or what proportion) have been affected by drug use and by drug dependence? Although many epidemiologists now devote their research careers to surveys that are needed to answer this kind of basic question, more stress ought to be placed on the other central questions for epidemiology, especially when the answers to these questions can guide society toward effective strategies for prevention of drug use and drug dependence. These questions are:

Where in the population are the affected cases located (in which subgroups, in which places, during which seasons, years, or epochs)? This is a question of *location*.

What accounts for some people becoming affected, whereas others do not become affected? This is a question about CAUSES.

By what processes or sequence of conditions do people become dependent on drugs? This is a question about *mechanisms* and linked sequences of causal conditions.

What can we do to prevent and reduce the suffering? This is a question about *prevention* and *amelioration*.

At its best, epidemiology provides critically important answers to each of these questions, and it works to ensure that new findings are translated rapidly into effective strategies for prevention. This is the future agenda for epidemiologic research on drug use and drug dependence.

ETHANOL/ETHYL ALCOHOL *See* Alcohol: Chemistry and Pharmacology

ETHCHLORVYNOL This is a complex alcohol that causes depression of the central nervous system (CNS). It is a SEDATIVE-HYPNOTIC drug typically used on a short-term basis to treat insomnia and is prescribed and sold under the name Placidyl. Because of its depressant effects on the brain, it can impair the mental and/or physical abilities necessary to operate machinery, such as an automobile.

Continued use of ethchlorvynol can result in TOLERANCE AND PHYSICAL DEPENDENCE leading to abuse. Since the risk of abuse is not very great, it is included in Schedule IV of the CONTROLLED SUBSTANCES ACT. Withdrawal signs, not unlike those seen after ALCOHOL (ethanol) or BARBITURATES, occur upon termination of its use in addicts. Ethchlorvynol should never be combined with other CNS depressants, such as ethanol or barbiturates, because their depressant effects are additive. Because of their greater safety, the widespread use of BENZODIAZEPINES as sedative/hypnotics has largely supplanted the use of ethchlorvynol.

ETHINAMATE This is a short-acting Sedative-Hypnotic drug typically used to treat insomnia. It is prescribed and sold as Valmid. Structurally, it does not resemble the Barbiturates, but it shares many effects with this class of drugs; the depressant effects of ethinamate are, however, generally milder than those of most barbiturates. Continued and inappropriate use of ethinamate can lead to Tolerance and Physical Dependence, with withdrawal symptoms very similar to those of the barbiturates. Because of their greater safety, the widespread use of Benzodiazepines as sedative/hypnotics has largely supplanted the use of ethinamate.

ETHNIC ISSUES AND CULTURAL RELEVANCE IN TREATMENT Differences exist among ethnic and cultural groups in their use—and abuse—of drugs and alcohol, as well as among risk factors that precede use and responses to treatment. Research suggests that an approach known as cultural congruency—when a patient and counselor share the same ethnic background or gender—can significantly improve the outcome of public health interventions and treatment. Drug and alcohol abuse treatment programs are no exception, and a number of recent studies have shown that careful attention to a special population's variant cultural framework can decrease recidivism and enhance treatment efficacy. The basic conceptual background for these tailored approaches begins with an examination of the cultural values held by the target community. Questions the treatment provider must ask when developing a targeted program include (Amodeo et al., 1997): At what point is the use of alcohol or other drugs considered a problem in this culture? At what point is a user deemed to require treatment? Who is perceived as owning this problem (e.g., the individual, the family, the community)? To what extent is any stigma attached to the problem? Are certain individuals more stigmatized (e.g., women)? This article will outline treatment approaches and considerations both general to the concept of cultural congruency and specific to some major ethnic groups.

ADDICTION: A MULTICULTURAL PROBLEM IN NEED OF MULTICULTURAL SOLUTIONS

Just as addiction is a global, rather than a national or regional, phenomenon, so addiction problems in the United States are multicultural. The whole fabric of successful treatment needs to be woven around cultural realities. In this society, twelve-step fellowships, such as Alcoholics Anonymous (AA), Narcotics Anonymous, and Cocaine Anonymous, are increasingly seen as the primary means to ensuring long-term abstinence and sobriety through addiction recovery.

Outside the United States there is strong professional resistance to both the Disease Concept and twelve-step recovery. In France, for example, where the *toxicomanes*, physicians dealing with chemical dependency, are heavily invested in a psychotherapeutic approach, there is professional denial that twelve-step programs exist or, if they do, are effective with French clients. Several *toxicomanes* maintained that even if they, themselves, championed twelve-step recovery and attempted to refer clients to such programs, the French, with their heritage of individual freedom and idiosyncratic behavior and beliefs, would never abridge their freedom by joining such fellowships as AA.

Health professionals in such wine-producing and -consuming countries as Italy, Spain, and France also express concern over the issue of addicts needing to abstain from all psychoactive sub-

stances. Wine, they maintain, is a food, and should not be included in such a blanket prohibition.

It has been suggested that twelve-step fellowships and their success provide credibility to addiction treatment as the bridge between active addiction and active recovery. While this may be increasingly true for the mainstream of white, European-American cultures, it may be less true for other cultures.

Countering the Perception That Twelve-Step Fellowships Have an Exclusively White, Male, Christian, Middle-Class Focus. From its beginnings, elements within the "group conscience" of AA began working to broaden the scope and flexibility of their fellowship. AA may have had its specific beginnings in the Christian Oxford Movement and the personal interaction between its cofounders, Bill W. and Doctor Bob, but its basic tenets reflect a spectrum of cultural antecedents. Throughout history and within various cultures, attempts have been made to deal with addiction and associated human problems. The most generally successful of these have involved in some way the development of individual spiritual maturity within a supportive environment. In that context, the Twelve Steps developed by AA and adapted by other twelve-step fellowships can be seen as a blueprint for developing spiritual maturity, which is similar in intent to the Buddhist Four Noble Truths and Eightfold Path, the Hindu *Vedas*, and the Zen Oxherding Panels.

Individuals with certain religious backgrounds may have particular problems relating to certain tenets of the Twelve Steps. Many Buddhists, for example, venerate the Buddha as a fully enlightened being to be followed and emulated, but do not see him as a "higher power." Not utilizing a concept of God or a higher power in their cultural background, they see their faith as a philosophy and a way of life rather than as a religion. Points of reference need to be established in order for twelve-step recovery to become meaningful for these individuals.

Culture and Spirituality in Twelve-Step Fellowships. While there are many meetings that have a distinct Christian orientation that goes far beyond joining hands and reciting the Lord's Prayer, there are many others that do not. Definitions of God and a "higher power" can and do include an open range of options. Essentially, a belief in God as represented in any particular religion is unnecessary for the workings of twelve-step recovery. However, belief in a power outside oneself that is capable of bringing one to sanity in terms of one's addiction is necessary, even if this power is characterized as the meeting group.

From a recovery standpoint, addiction can be seen as a disease of self-centered fear that depends on isolation and deeply held convictions regarding the nature and effects of the addicts' drugs of choice; that isolation renders the addict incapable of understanding the disease and its personal effects, which is the basis of denial. So long as the addict attempts to fight the addiction through personal willpower alone, he or she is fighting a losing battle, trapped in emotional gridlock in a state of "white knuckle sobriety," where increasing anxiety from the stress will inevitably result in relapse. The reason for this is that the convictions about use are buried within the individual's spiritual belief system, where they can be reached only if the addict is willing to accept that there is something outside his or her own immediate being that can lead him or her to sanity—a power higher than oneself.

Surrender and Powerlessness. The concept of surrender, given its many war-related connotations of occupation, rape, loss of freedom, and so on, is hard enough for anyone to accept, but it is particularly hard for cultural groups that have, over time, suffered more than their share of occupation, rape, loss of freedom, and so on. African-Americans and Native Americans, for example, may feel that they have been in a state of individual and cultural powerlessness for many generations, and have no desire for further surrender. Native Americans also have difficulties with that aspect of twelve-step recovery because it runs counter to tribal mores of self-reliance and stoicism. Adolescents, although their cultural cohesion is transitory, are in the process of developing their own individuality and are often loath to appear to be giving up something they have so recently gained. Muslims may have the least problem with the concept of surrender. "Islam" literally means "submission to God's will."

In explication, and to some degree expiation, of the term "surrender" as it is used in recovery, members of the community speak in such terms as "joining a winning team," and urge newcomers to "hang out with the winners." In admitting powerlessness over the disease, addicts are in effect gaining the power, through enlisting the support of their higher power and the fellowship itself, to be responsible for their own recovery. A misunder-

standing of this process can lead to an interpretation that people in twelve-step recovery are somehow "copping out" from personal responsibility. The point is that while the addict may not be responsible for having a disease that involves physiological and possibly genetic, psychological, and environmental components, in twelve-step fellowships the addict is most certainly responsible for his or her own recovery.

The African-American Extended Family Program is a good example of how the precepts of twelve-step recovery can be adapted to the needs a specific community. In it, African-American cultural mores and traditions are taken into consideration and made primary to recovery. Culturally, African-Americans strongly value communalism, or a collective identity (Longshore et al., 2000). In many treatment modalities targeted to African-American populations, drug addiction and use are related to slavery. For example, many African-Americans see methadone, a common treatment for opiate addictions, as a type of chemical slavery (Longshore et al., 1998). The HAIGHT ASHBURY FREE CLINICS, Inc. (HAFCI)/Glide Memorial Methodist Church African-American Extended Family Program (AAEFP), described in detail in Reverend Cecil William's book, *No Hiding Place*, represents an important collaboration that has made possible an effective intervention in the inner-city crisis of CRACK-cocaine use.

The key to this intervention has been the adaptation of TWELVE-STEP principals of supported recovery to the AFRICAN-AMERICAN inner-city culture. In the HAFCI/Glide program, the basic practicalities of recovery are utilized in a model that is uniquely meaningful in terms of the African-American experience.

The "Big Book" of ALCOHOLICS ANONYMOUS uses the terms "spiritual experience" and "spiritual awakening," manifesting in many different forms, to describe what happens to bring about a personality change sufficient to induce recovery. While some of these may involve an "immediate and overwhelming God consciousness," most are what William James called an "educational variety" of revelation, developing slowly over time. According to a "Big Book" appendix titled "Spiritual Experience," the core of this process is the tapping of an "unexpected inner resource" by members who identify this resource with "their own conception of a Power greater than themselves."

Many members of the African-American community afflicted with crack-cocaine addiction have been raised in the church. There is a tradition of revelation; many who have been "saved" now believe they are sinners because they have used and sold crack-cocaine to their own people. God has been described in a strict denominational sense. Spiritual awakening in a recovery model within a church program may produce conflict with traditional religious definitions, particularly the third step: "Made a decision to turn our will and our lives over to the care of God *as we understood him*." Religious leaders, such as Reverend Williams, have played a role in presenting a model of recovery theology that helps mobilize the church as a sleeping giant to better respond to the nation's drug epidemic. In his model, Williams employs self-definition within a spirituality of recovery.

In keeping with the IBCA's African-American cultural approach, it was generally agreed that the best site for the new program would be a church. In a Glide conference panel debate on religion and spirituality, Richard Seymour pointed out that under the best of conditions, religion equals spirituality plus culture. This is particularly true in the African-American community, within which the church provides a point of cohesion and a center for both spiritual and community values and, thus, a common ground for positive community activity. For a number of reasons, the clear choice was Glide Memorial Methodist Church in San Francisco's Tenderloin, a neighborhood that, though it includes a number of ethnic minorities, is predominantly African-American, low-income, and hard hit by the onslaught of dealing and abuse of crack-cocaine.

Under the leadership of Reverend Williams, Glide had been providing services for indigent and homeless residents, including addicts, for 25 years. Because of his growing concern over the crack-cocaine problem, Reverend Williams and his wife, Jan Mirikitani, executive director of Glide, attended a twelve-step recovery conference conducted by David Smith and Millicent Buxton. Following this conference, they decided to develop a culturally specific recovery program at Glide Church because of the resistance of people of color to participating in the twelve-step process.

Specific problems of the African-American target population as identified by various studies

(HAFCI, 1990; Jackson, 1995; Longshore et al., 1998 and 2000) include the following:

- Low self-esteem
- Late introduction into recovery
- Focus on short-term abstinence rather than long-term recovery
- Dialect of African-Americans
- Institutionalized racism
- Internalized racism
- A unique, often dysfunctional family structure: many classical African cultures have been matrilineal, and look to the "grandmother" for spiritual direction and values. African-Americans developed a matriarchal family structure to survive during slavery, but this structure has proved unable to address problems of alcohol and other drug addictions. America is based on a patriarchal family structure, the opposite of the African-American model. It is therefore difficult for African-Americans to relate to systems and to address dysfunctional families when their model is not the norm. The most extreme injury is seen in children being taken from mothers by the system.
- Women's meetings: For those who have lost children, the comparison between now and the capture of children in Africa during the slave trade is made. Particular emphasis is placed upon the role of women in the more matriarchal African-American family. For many the most positive role model is a grandmother who passed on the traditions of the family and represents a "higher power."

The first and foremost priority is bringing to intervention and recovery an approach and nature that members of a target culture can identify and live with. Culturally responsive activities need to be identified and developed. Most research to date has been conducted with African-American populations, but the treatment models developed in conjunction with these studies can be transliterated to other ethnic and cultural populations.

Implicit within these modalities is the recognition that treatment is more than the prescribing of medication or the providing of basic and generic counseling based on a homogeneous model of what constitutes addictive disease.

Does establishing culturally congruent treatment produce results? Another example of a treatment intervention designed to be congruent with the cultural values and mores of the group process is the Engagement Project developed by Longshore et al., which is used for the purposes of scientific measurement of the effects of cultural congruency. Treatment began with a traditional African-American meal of fried chicken, ribs, greens, potatoes, and red beans and rice, to establish a culturally-specific framework for the intervention. The participant shared this meal with a counselor and a former drug user, called a "peer." This group then together watched a video featuring still photos, footage, and clips from commercial films about African-Americans. The third and final phase of the intervention consisted of a counseling session to review the participant's commitment to recovery. By situating drug abuse as both an individual problem and a community problem seated in power inequalities between the African-American community and dominant institutions, the intervention proved statistically effective in terms of participants reporting being drug abstinent one year afterwards.

Cultural Characteristics of Other Ethnic Groups. *Asian Americans.* Asian Americans have been traditionally treated as a conglomerate group, a "model minority" whose drug problems have often been overlooked (Nemoto, 1999). However, this is patently not the case, as Japanese Americans, Filipinos, Vietnamese Americans, and Chinese Americans all come from differing cultural backgrounds and retain variant attitudes toward substance abuse, illness, and disease. Some cultural constructs that are shared among most Asian Americans regarding the use of drugs and alcohol are a fear of addiction, fear of injecting drugs, and a strong stigma attached to drug users in the community (Nemoto, 1999). Immigrant Asian Americans are more likely to use drugs than American-born people of Asian descent (Nemoto, 1999); such cultural factors often inform a user's response to treatment. It is necessary that treatment providers be not just bilingual, but also bicultural, in the sense that they are equipped to understand the unique family structure and pressures present in Asian American culture.

Native Americans. The traditionally tribal orientation of Native American society is in stark contrast to dominant institutional norms. For many Native Americans, an effective approach to the treatment of drug and alcohol problems involves a strong

spiritual component. A 1998 report by Christine T. Lowery asserts that four broad concepts comprise an intellectual understanding of "healing the spirit" for Native Americans. These concepts, addressing the concepts of spiritual health and wellness, are:

- Balance and wellness.
- The colonization experience and addiction as a crisis of spirit.
- Issues of abuse (including sexual abuse).
- A time of healing.

Careful consideration of these principles illustrates the unique spiritual perspective Native Americans have on addiction and recovery. The intersection of the concepts outlined above should be the focus for intervention in these communities. For Native Americans, healing is traditionally a multidimensional, spiritual, relational, and intergenerational endeavor.

Hispanic Americans. Studies indicate that there is a positive correlation between length of time in the United States and drug usage among Hispanic Americans (Ma et al., 2000). Moreover, degree of acculturation and immigration status may affect treatment-seeking behaviors (Amodeo, 1997). An illegal immigrant is less likely to seek drug or alcohol treatment intervention because of the perceived threat of deportation.

Acceptance of disease-concept-related treatment and recovery outside the United States has differed from culture to culture, from country to country, in some cases from community to community. In Scandinavia, for a studied example, Finland, Iceland, and SWEDEN have experienced phenomenal multiplication of AA groups since the 1970s, whereas Denmark and Norway have experienced a decline in groups over the same period. With the advent of glasnost, narcologists in the former Soviet Union discovered AA. Since that time, treatment has been increasingly linked with recovery in Russia and other republics.

Overcoming Points of Resistance and Concern. The distance between cultures may seem like a chasm at times, but it is being bridged by such projects as the AAEFP that provide both recovery and a means to developing cultural parity. Society is changing rapidly, and fortunately, recovery has the flexibility to change along with it. Many groups within AA have learned that if there is no meeting that fits their special need, they can form their own meetings. The challenge is to adapt the process of treatment and recovery to all cultures and races, to counter stereotypes that recovery works only with certain groups.

REVISED BY SARAH KNOX

ETHNICITY AND DRUGS In national statistics for the United States, it is common to see information about different segments of the population. For example, data from the U.S. Census and many national surveys on drug use often are subdivided in relation to four racial groups: (1) white, (2) black, (3) Asian or Pacific Islander, (4) American Indian or Alaska native. In concept, "racial heritage" refers to biologically inherited origins, but most people appreciate that these categories of race are determined more by social ideas and customs than by sharp genetic distinctions among these four groups. Some people even change their racial affiliation as they change their social perceptions.

In some national statistics and survey data, it also is common to see subdivisions in relation to "ethnic heritage," which sometimes refers to a person's country of origin but more generally refers to shared social and cultural characteristics. For example, people with recent or distant family origins in Spain or Portugal, or former colonies of Spain and Portugal (e.g., Mexico, Brazil), are called Iberian, Hispanic, or Latino; in North American statistics, it has been typical to subdivide the racial groups in relation to ethnicity as well: (1) White-not Hispanic, (2) Black-not Hispanic, (3) White-Hispanic, (4) Black-Hispanic, and so on. Here, too, the designation of Hispanic or Latino refers more to a social characteristic than to a specific family-genetic background. For example, American Indians from Mexico may be classified as Hispanic-American on the basis of their Mexican ancestry or as Native American on the basis of their North American Indian ancestry. The utility of these classifications of ethnicity and ethnic heritage depends on the degree to which they reflect sameness of social customs and learned behavior. People who are being compared within different ethnic groups ought to exhibit similarities in social customs and learned behaviors, and sometimes a shared sense of affiliation with that particular group. People across different ethnic groups ought to demonstrate more variation in social customs and learned behaviors than are to be seen among people within these groups.

There are many reasons for national reports to present statistical data on the population classified in relation to racial and ethnic heritage. Anyone reading historical documents for the period during and preceding the nineteenth century will find it difficult to escape a conclusion that these classifications were motivated in part by prejudice and racist thinking. Since the nineteenth century—from the earliest days of the U.S. Census—government officials have been interested in knowing the ethnic origins, as well as the size, of different racial and ethnic groups within the population for various policy and planning purposes.

Despite their somewhat questionable origins and uses, racial and ethnic classifications are important measures of social and historical phenomena in the United States. For example, in the area of public health, when national statistics on liver cirrhosis

are examined, it can be seen that Americans who describe themselves as African-American are more likely to develop liver cirrhosis compared with Americans of predominantly European heritage. This type of information can guide public health action directed at preventing and treating liver cirrhosis. It is a help in targeting early detection and intervention efforts intended to reduce the suffering associated with liver cirrhosis. It may help identify specific environmental conditions such as poor nutrition or infectious diseases that might account for the higher risk of liver cirrhosis in the African-American segment of the population.

National statistics on alcohol and other drug use in relation to racial and ethnic heritage also have helped the nation's policymakers to see that some segments of the population have a greater need than others for alcohol and drug treatment and prevention services. Through block grants and other funding mechanisms, the federal, state, and local governments can provide support for services that target the special population groups with more needs for these services.

Although statistics on ALCOHOL and other drug use in relation to race and ethnic heritage can be used for the benefit of the population, it must be said that this topic has been understudied and the evidence often misrepresented. On the one hand, the topic is understudied in the sense that differences can be observed in alcohol and other drug use across racial and ethnic subgroups of the population, but it is not known whether they are due to differences in inherited predispositions or to other differences. On the other hand, the evidence of racial and ethnic differences in alcohol and drug use can be misrepresented and interpreted prejudicially as data showing one group to be inferior to another.

The complicated nature of this topic can be illustrated by considering liver cirrhosis among African Americans in the United States. In part, the occurrence of liver cirrhosis is determined by long-term heavy drinking of alcoholic beverages, but liver cirrhosis is also caused by prior infections or by autoimmune reactions, and vulnerability to alcohol-related liver cirrhosis is also influenced by cofactors such as poor nutrition. In the United States, African Americans historically have been at great social disadvantage. On average, they are not as wealthy as other Americans, and, in addition, they more often live in poverty, with associated poor nutrition, underutilization of health care services, and compromised health status. Hence, it might be these socioeconomically related conditions that account for the excess occurrence of liver cirrhosis among African Americans rather than any inherited characteristics or personal characteristics related to drinking.

Within the United States, many other racial and ethnic minority groups also live with social disadvantages similar to those endured by African Americans. For this reason, it is easy to misinterpret national statistics on alcohol and drug use among racial and ethnic minority groups if they are taken strictly at face value. Instead, one must look beneath the surface and ask whether social or economic conditions might account for the statistics.

While studying racial and ethnic differences in CRACK smoking and other COCAINE use, some public health scientists have attempted to hold constant the social and neighborhood conditions that also could explain these differences. Once social and neighborhood characteristics had been taken into account, these studies found very little evidence to support the idea that African Americans or Hispanics were more likely to smoke crack or to take cocaine.

Although the importance of social and environmental influences in people's use of alcohol and other drugs has been clearly illustrated, it is important to keep in mind that biological factors may also play a role in determining one's preference for alcohol or particular drugs. For example, Asian Americans, as a group, consume less alcohol than any of the other racial or ethnic groups. Their lower drinking rates have been attributed, in part, to the fact that a majority of Asians possess a particular form of an alcohol-metabolizing enzyme whose action results in unpleasant side effects after drinking alcohol.

It also is interesting to find variation *within* large racial and ethnic groups, because this draws attention to the fact that not all African Americans are alike, nor all Hispanic Americans, Native Americans, Asians, or Pacific Islanders. For example, studying occurrence of alcohol abuse and dependence in different countries of Asia, epidemiologists found that men in South Korea had an extremely high prevalence of these conditions but men in Taiwan an extremely low prevalence. In addition, epidemiologists found more crack smoking among Hispanic Americans whose behavior showed that

they had become acculturated to mainstream customs (e.g., by choosing to speak English rather than Spanish) and less crack smoking among other Hispanic Americans (e.g., those who chose to speak Spanish rather than English). This relationship was more pronounced among Hispanic Americans from Mexico than among those from Cuba, however, and this is an additional indication of variation within the large and growing Hispanic segment of the U.S. population.

Studies conducted on alcohol and other drug use by Native Americans provide another example of the variation that can exist within a large racial group. For instance, there is considerable variation in alcohol and other drug experiences from tribe to tribe, from one part of the country to another, and even from one residential location to another (e.g., boarding school students versus other young people). It becomes difficult, therefore, to summarize the alcohol and drug experiences of Native Americans in a few sentences. For many Native-American young people and adults living in urban environments, and sometimes on reservation lands as well, the use of alcoholic beverages and also INHALANT drugs is associated with several social and health problems. Researchers have speculated that the disintegration of Native-American culture has contributed to high rates of STRESS and that this in turn is related to a disproportionately high use of alcohol among this segment of the American population. These statistics alerted the attention of public health workers and government officials, and through their efforts many programs have been initiated to draw Native Americans with alcohol abuse problems into treatment.

Racial and ethnic patterns of alcohol and other drug use and related problems vary by age, gender, and drug. National surveys of high school seniors conducted since the early 1970s, and more recent surveys that included eighth- and tenth-graders, reveal that some minority youth use less alcohol and other drugs than Caucasian youth. Specifically, Caucasians, Native Americans, and Mexican Americans have the highest frequency of reported alcohol use whereas African Americans and Asian Americans have the lowest. Because these surveys include only in-school youth and not children who have dropped out of school, it may be that the true proportions of alcohol and other drug use have been underestimated.

In general, males report using drugs more frequently than females, and this gender difference cuts across racial and ethnic boundaries. For example, African-American males and Caucasian males are more likely than African-American and Caucasian females to use alcohol. It is also true that people in different age groups vary in relation to their reports of using alcohol and other drugs. When researchers carefully divide different racial and ethnic groups by age, some interesting trends in alcohol-use patterns appear. For Caucasian adults, drinking tends to increase until mid to late life, with older people drinking less as a group than younger adults. African Americans, however, tend to be heavier drinkers later in life and to exhibit more alcohol-related health problems (e.g., cirrhosis, esophageal cancer). For some drugs other than alcohol, a similar picture exists. For example, Caucasians and Hispanic Americans report using cocaine earlier in life whereas African Americans report using it later in life. Cigarette SMOKING is more common among young Caucasians (12–17 years old) than it is among Hispanic Americans or African Americans of the same age; however, a higher proportion of the latter groups report smoking later in life.

It is sometimes difficult to interpret findings that point to differences in drug use between minority and nonminority subgroups within the U.S. population. It must be kept in mind that socially shared environmental conditions (e.g., availability of drugs, neighborhood conditions, economic resources) rather than race or ethnic identity may be underlying patterns of drug use. Other factors such as social status and community norms for coping with life stresses may account for reported racial or ethnic differences in drug use.

Continued research is needed to track patterns of alcohol and other drug use in the population and to find out the mechanisms or the reasons that put some groups at higher risk than others for problematic involvement with alcohol and other drugs. Some of the most current information is limited. For instance, minority intravenous drug users are known to have higher rates of exposure to HIV than Caucasian drug users, but no clear explanation for this observation has been determined. Perhaps learning more about barriers to obtaining treatment for intravenous drug use in certain minority populations will contribute to an understanding of this problem.

Researchers, as well as policymakers, need to be culturally sensitive; that is, they must appreciate the social, cultural, and economic conditions that underlie racial and ethnic differences in alcohol and drug use. It is important to realize that racial and ethnic identification can serve as a source of strength to those who design targeted prevention and intervention programs for certain segments of the population.

ETHNOPHARMACOLOGY This branch of pharmacology studies the use and lore of drugs that have been discovered and developed by sociocultural (or ethnic) groups. It involves the direct observation and report of interactions between the societies and the drugs they have found in their natural environments and the customs that have evolved around such drugs, whether ceremonial, therapeutic, or other. These drugs, usually found in plants (hence similar study by ethnobotanists as well as ethnologists), are described—as are their effects within the customs, beliefs, and histories of a traditional culture or a specific society.

Examples include descriptions of the use of coca leaves (*Erythroxylon coca*) by indigenous populations of Colombia and Peru, for increased strength and endurance in high altitudes; the ceremonial use of PEYOTE (*Lophophora sp.*) by Native Americans of the Southwest and Mexico; and the use of KAVA (*Piper methysticum*) in ceremonial drinks by the indigenous populations of many South Pacific islands.

EXCLUSIONARY RULE In legal proceedings, the exclusionary rule prohibits the use of any evidence obtained in contravention of the U.S. Constitution. The rule is frequently invoked when government authorities seize evidence in violation of the Fourth Amendment's prohibition against unlawful searches and seizures. Evidence may be illegally obtained when government officials do not have a warrant to search an individual's premises or the warrant is defective. Law enforcement officers may also lack sufficient probable cause to arrest a person. In addition, the courts may invoke the exclusionary rule when they find a violation of an individual's Fifth Amendment right against self-incrimination or a violation of a defendant's Sixth Amendment right to counsel. Courts often refer to evidence obtained in violation of the Fourth, Fifth, or Sixth Amendment as "tainted" or "the fruit of a poisonous tree."

The U.S. Supreme Court established the exclusionary rule in the early 1900s. It applies to all federal courts through the Fourth Amendment and to all state courts through the Due Process Clause of the Fourteenth Amendment. Before the rule was created, any evidence was admissible in a criminal trial if the judge found it relevant. It made no difference how the police had obtained it. In *Weeks v. United States*, 232 U.S. 383, 34 S.Ct. 341, 58 L.Ed. 652 (1914), the Supreme Court barred the use of evidence secured through a warrantless search of a defendant's house by federal agents. However, for almost 50 years the exclusionary rule only applied to federal courts.

The Supreme Court broadened the rule's coverage in *Mapp v. Ohio*, 367 U.S. 643, 81 S.Ct. 1684, 6 L.Ed.2d 1081 (1961). It held that the due process clause of the Fourteenth Amendment requires states to exclude evidence obtained from an unconstitutional search or seizure. The Court has often cited an individual's right to privacy and the deterrence of unreasonable police conduct as the primary reasons for excluding evidence obtained from an unreasonable search and seizure.

A criminal defendant who claims an unreasonable search and seizure is usually allowed to make the claims in a suppression hearing that is conducted before the trial. At this hearing the judge must determine what evidence will be suppressed, or excluded from trial.

A number of exceptions to the exclusionary rule have emerged to reduce the effects of the doctrine, such as a police officer's "good-faith" belief that an otherwise defective warrant is valid, evidence obtained in "hot pursuit," or evidence seized in "plain view" of the law enforcement officer's sight and reach. There are other exceptions to the exclusionary rule. Evidence seized by private parties is not excluded from trial if the search was not at the direction of law enforcement officers. If a criminal defendant testifies in his or her own defense, illegally seized evidence may be used to discredit the defendant's testimony. Illegally seized evidence can also be used in grand jury proceedings and civil proceedings. However, a grand jury cannot use illegally seized evidence if it was obtained in violation of federal wiretapping statutes.

IMPORTANCE IN DRUG CASES AND ENFORCEMENT

The exclusionary rule prohibits the introduction of constitutionally tainted evidence. The effect of the doctrine has often been the exclusion of evidence that might be used to convict a suspected drug trafficker or abuser. Courts have excluded evidence of drug PARAPHERNALIA or supplies illegally seized, admissions obtained by coercion or without notifying the party of the right to remain silent, and evidence obtained in violation of a defendant's Sixth Amendment right to counsel, such as a lineup identification. The Supreme Court has determined that it is preferable to allow a drug trafficker to go free than to permit law enforcement officers to violate a citizen's constitutionally protected rights.

Two recent Supreme Court cases illustrate the polarities in Fourth Amendment exclusionary rule cases. In *Minnesota v. Carter*, 525 U.S. 83, 119 S.Ct. 469, 142 L.Ed.2d 373(1998), the Court had to balance law enforcement and privacy interests in assessing the reasonableness of a drug search and seizure. The key issue was whether a police officer who looked in an apartment window through a gap in a closed window blind violated the privacy of the drug dealers in the apartment because they had an expectation of privacy that is protected by the Fourth Amendment. The Supreme Court held that the police officer did not violate the Fourth Amendment because the occupants of the apartment did not have an expectation of privacy. Therefore, the drugs that the police officers saw and later seized did not have to be excluded from evidence.

The outcome was much different in *Bond v. U.S.*, ___U.S. ___, 120 S.Ct. 1462, 146 L.Ed.2d 365(2000). In this case, the Court ruled that police cannot squeeze the luggage of bus passengers to try to find illegal drugs. The U.S. Border patrol routinely squeezed carry-on luggage of bus passengers traveling near the Texas-Mexico border. Border patrol officers discovered a brick of methamphetamine after feeling the defendant's soft-sided bag. The Supreme Court noted that the Fourth Amendment provides that a person's "effects" are protected from unreasonable searches and seizures. A traveler's piece of luggage was clearly an "effect" protected by the amendment. It found that a "bus passenger clearly expects that his bag may be handled. He does not expect that other passengers or bus employees will, as a matter of course, feel the bag in an exploratory manner." Because the agent did manipulate the bag, he violated the Fourth Amendment. In addition, the Court ruled that the defendant's expectation of privacy was reasonable. It distinguished prior rulings that defeated exclusionary rule challenges because they were based on visual inspections, not tactile inspections.

EXISTENTIAL MODELS OF ADDICTION *See* Values and Beliefs: Existential Models of Addiction

EXPECTANCIES The beliefs a person has about the effects a drug will have are called *expectancies*. The study of expectancies began with the employment of the experimental balanced-placebo design in alcohol research in the early 1970s (see Marlatt & Rohsenow, 1980, for a review). Research on people ranging from light drinkers to inpatient alcoholics revealed that expectancies are predictive of some of the behaviors exhibited when people use a drug. These studies revealed that both the beliefs an individual has—about whether a drink contains ALCOHOL and the specific outcomes that individual expects from consuming alcohol—are in many cases more predictive of subsequent behavior than the pharmacological effects of the drug.

EXAMPLES OF RESEARCH STUDY

An example of research using balanced-placebo design is as follows: In a simulated bar setting, half the participants in a study are told they will receive a drink containing vodka and tonic, and half are told they will receive a drink containing only tonic. After this expectation is established, half of each group does receive vodka and tonic, while the other half receives only tonic, resulting in four groups: (1) those who expect vodka and tonic and receive vodka and tonic, (2) those who expect vodka and tonic and receive only tonic, (3) those who expect tonic and receive vodka and tonic, and (4) those who expect tonic and receive tonic. Thus, some of the people who expect alcohol receive only tonic, and some who expect only tonic receive a mix containing alcohol.

Behavioral observations following this manipulation reveal that the most powerful predictor of behavior after consuming the assigned drink is not whether the person actually receives alcohol, but whether that person *believes* he or she is drinking alcohol: People who expect alcohol in this experimental situation consume significantly more drink than those who are not expecting alcohol, regardless of whether or not they do receive alcohol in their drink. With the discovery of this phenomenon, even in people who are considered dependent on alcohol, this finding has been interpreted as providing contrasting evidence to the disease model's notion that "loss of control" is caused exclusively by the pharmacological effects of alcohol; the findings introduced the idea that cognitive factors are influential in a person's drug-related behavior. The presence of expectancy effects have also been identified in research on drugs other than alcohol, including TOBACCO and MARIJUANA (Marlatt & Gordon, 1985).

Most of the research on expectancies during the 1970s and 1980s was conducted on college students, with samples ranging from light to heavy social drinkers who were primarily Caucasian. This research has shown that the effect of a person's expectancies depends on whether the behavior involved is socially mediated: Stronger expectancy effects are found for social behaviors (e.g., aggression or sexual arousal) than for nonsocial behaviors (e.g., beliefs concerning motor coordination or memory skills); they are stronger for outcomes that are perceived as positive (e.g., sexual arousal) than as negative (e.g., poor motor coordination).

For socially mediated behaviors, expectancy research has revealed that college students of both sexes show less anxiety in social situations if they believe they have consumed alcohol. In addition, males show heightened sexual arousal when exposed to an erotic environment if they believe they have consumed alcohol (Marlatt & Gordon, 1985). Men and women of college age have also both been found to respond more aggressively when provoked after they believe they have consumed alcohol. Sex differences have been found on the effects of alcohol on anxiety with persons of the opposite sex: Women of college age have shown more anxiety in the company of an unfamiliar man when they believe they have consumed alcohol, while men of college age have shown reduced anxiety when in the company of an unfamiliar female. The results have been interpreted as reflecting gender differences regarding the acceptability of alcohol in social situations with a stranger of the opposite sex.

OTHER STUDIES

Other experimental work has revealed that specific outcomes can vary with the personal beliefs an individual holds regarding alcohol and with the phase of intoxication of an individual (Southwick et al., 1981). Overall, the results based on expectancy research point to the likelihood that people may have established cultural beliefs regarding the effects of alcohol in social situations and that these beliefs play some role in the behavioral effects of alcohol.

Research has also found that expectancies do predict drinking behavior over a one-year period for early adolescents (Christiansen et al., 1989); that expectancies tend to crystallize in people at a young age and that they tend to be resistant to change (Miller, Smith, & Goldman, 1990). Other studies on Caucasian adolescents and young adults have found that those who have mostly positive and only few negative outcome expectancies tend to experience more alcohol-related problems than those whose outcome expectancies are more evenly divided between positive and negative effects (Brown, Christiansen, & Goldman, 1987).

Since the late 1980s, researchers have begun to examine ethnic and racial differences in the expectancy variable. One study of college-age students (Daisy, 1989) revealed that Native-American students had significantly stronger expectancies for the positive social and physical effects of drinking than did Asian-American students. Caucasian students were found to have stronger positive expectancies for social and physical effects than did Asian-American students, but less than did Native-American students. These beliefs concerning the effects of alcohol were also found to be highly associated with the drinking patterns of the study participants: those people whose drinking pattern was considered heavy had stronger beliefs in the above expectancies than individuals who drank less. The study strongly suggests that ethnic differences exist in alcohol-related expectancies, and it confirms that expectancies are related to the amount of alcohol consumed.

The association between expectancies and drinking pattern has been consistent in the research and has therefore become targeted in substance-abuse treatment. Expectancies have been found to influence the way a person copes with high-risk situations after treatment aimed at abstinence (Marlatt & Gordon, 1985; Condiotte & Lichtenstein, 1981). In RELAPSE PREVENTION, positive-outcome expectancies are viewed as the source of urges or cravings for a substance. Treatment according to this perspective therefore includes changing a client's outcome expectancies: If a person believes that drinking will provide immediate relief from stress, then treatment focuses on helping that person consider the long-range implications of drinking—helping the person by adding the negative outcomes of drinking to the anticipated positive results of drinking—and thereby changing the composition of the person's outcome expectancies.

Self-efficacy expectancies, or how effectively one feels he or she can cope with a high-risk situation, are also examined in treatment. If a client lives a stressful lifestyle and believes that only alcohol provides relief from that stress, the therapist helps the client develop and utilize alternative methods for coping with stress. For example, clients can be taught to look forward to meditation or exercise or other positive-reward situations to help cope with stress and to reduce urges and the resulting temptation to drink. Treatment focuses on developing alternative coping strategies for a client's individual high-risk situations, and therefore includes an ongoing assessment of each client's high-risk situations.

Self-efficacy differs from overall motivation to quit or reduce substance use, since perceived control will vary across situations. In research on relapse prevention, self-efficacy has been found to be predictive of the first use of the substance after abstinence-based treatment: Those people who do not believe they can cope with either a specific situation or cope, in general, with the temptation to use a substance are more likely to relapse in the face of a high-risk situation than are people who believe that they are able to maintain their goal of abstinence in the same situation (Condiotte & Lichtenstein, 1981).

The Alcohol Expectancy Questionnaire (AEQ), developed in the late 1980s, became the most commonly used alcohol expectancy instrument. Criticisms of the AEQ led to a conceptual model of drinking expectancy grounded in social learning theory. In this model, people acquire a set of alcohol expectancies regarding how alcohol will affect them during what is called the acquisition phase of the model. The behavioral outcomes of these beliefs

were then hypothesized to be regulated by a process involving Drinking Refusal Self-Efficacy (DRSE).

In 1996, the Drinking Expectancy Profile (DEP) was developed, which had two interrelated subtests, the Drinking Expectancy Questionnaire (DEQ) and the Drinking Refusal Self-Efficacy Questionnaire (DRSEQ). When compared to the AEQ in a study, the DEP showed better predictive ability on the Alcohol Dependence Scale and for quantity of drinking and frequency of drinking in a student sample. Furthermore, the DEQ contained both negative and positive outcome expectancies, which yielded better information on alcohol-related outcomes.

Further research in the 1990s showed that alcohol expectancies can develop independently of the actual drinking experience, developing from vicarious learning before even tasting alcohol. Actual drinking behavior could later reinforce or modify the existing beliefs. Drinking refusal self-efficacy beliefs were also show to develop prior to one's drinking history.

A study in 2000 considered the 1992 Temptation Restraint Inventory (TRI) and DEP as indicators of problem drinking across a range of drinking parameters. It yielded a more comprehensive picture of the complex interrelationship between the variables that make up the individual drinker's motivation for risky and dependent drinking. The results showed that drinking restraint and related control and impaired-control issues were the strongest predictors of alcohol problems. Alcohol expectancies and drinking refusal self-efficacy, while reflecting some of these loss-of-control factors, tended to focus more on choices of whether to drink or not and thus predicted more frequent usage of alcohol. This study suggested that restraint, alcohol expectancy, and self-efficacy measured different cognitive domains (Connor, et al, 2000).

Another study in 2000 looked at psychosocial and behavioral factors as predictors of heavy drinking among adolescents and assessed students' expectancies about drinking. The study found that boys who reported positive drinking expectancies were over seven times more likely to become heavy drinkers than boys who had negative drinking expectancies. In fact, positive alcohol expectancy was the single strongest predictor of later heavy drinking among boys. However, the expectancy variables were not associated with later heavy drinking for the girls in the study (Griffin, et al, 2000).

REVISED BY MARY CARVLIN

F

FAMILIES AND DRUG USE One major debate in the area of families and drug use continues to be whether dysfunctional family life creates drug addiction or whether drug addiction produces dysfunctional families. In other words, are ALCOHOLISM and other drug addictions diseases of individuals or are they products of disorganized families and other social systems? The former is an "individual-focused" view, often held by drug counselors who favor SELF-HELP groups such as AA, Al-Anon, NA, and the like. The latter is a "systemic" view held by professionals who prefer to treat drug addictions by working with families, in order to change family systems into more healthy environments.

Whatever one's position in this debate, almost everyone agrees that the family is the primary socializing agent in society. However, Glick (1988), a senior family demographer, observed that during the past fifty years American families have been undergoing significant transformations. Social acceptance of various forms of families is steadily replacing the older, normative view of a family as comprising only two parents and their children, with the father as a breadwinner and the mother as a homemaker. In the 1960s and 1970s, decades of social protests, Americans witnessed increasing numbers of cohabiting couples, families being maintained by single parents, and many adults living alone. As a result, divorce, single-parenthood, childlessness, and living alone have become more acceptable. Significant transformation has also occurred in gender attitudes, which moved toward greater egalitarianism and resulted in increased percentages of young men and women who perceived fatherhood as a fulfilling experience (Lewis, 1986; Thornton, 1989).

These changes continued to occur until the early 1980s when they began to level off, and by 1987 a quarter of all children under eighteen years of age no longer lived with both of their parents. Eighty-two percent of these children lived with stepfathers, whereas only 18 percent lived with stepmothers. The late eighties and early nineties, however, seem to have been a period of stabilization, during which all trends flattened (Glock, 1988; Thornton, 1989).

No systematic analysis has been conducted to assess the association between these social and demographic changes in the family and trends in drug abuse. If one looks at the statistics closely, however, one sees that the trends in families and in drug use look similar. A dramatic increase in the abuse of all kinds of drugs by all age groups was observed during the early 1970s to early 1980s. These trends in drug use also flattened in the early eighties and, as was observed in 1988, are beginning to drop significantly, especially among youth aged twelve to seventeen years.

This line of reasoning is not meant to suggest that the changes in attitudes toward families and the changes in family structures and forms in the last three decades directly caused the current trends in drug use. It may suggest, however, that the instability of families either allows there to be or

imposes greater stresses upon individuals and society. Similarly, the stabilization of families provides more secure environments for individuals, who may then more effectively cope without the abuse of substances.

There is nevertheless some evidence and much speculation about a reciprocity between an individual's drug addictions and "family illnesses," since the latter often appear to be passed from one generation to another.

Although recent reductions in the use of illicit drugs present a somewhat optimistic picture of the future of American families, the overall number of drug casualties is still grim and the consequences are debilitating. Every year, 100,000 Americans die as the result of drug abuse. That number should increase with the spread of AIDS. Alcohol, nicotine, and illicit drug abuse are number-one health problems, especially among the young. Life expectancy has steadily risen over the past seventy-five years in all age groups except that for youth aged fifteen to twenty-four, who now have a higher death rate because of injuries and disappearances related to drug use. Long-term substance abuse is associated with DEPRESSION, hostility, malnutrition, lower social and intellectual skills, broken relationships, mental illness, economic losses, and growing CRIME rates.

FAMILY PREDICTORS OF DRUG ABUSE

Family factors that predict drug use may be put into three interrelated categories: structural, historical, and interpersonal. The structural factors pertain to family composition, such as single- or two-parent families, the number of children, sibling spacing, and gender composition. Family historical factors specifically refer to intergenerational patterns, such as the extent and influence of drug usage in the family of origin. Finally, interpersonal factors relate to interpersonal dynamics in the family, such as those reflected in the quality of marital relationships or the quality of parent-and-child or sibling relationships.

Family Structural Factors. Three structural factors—parental composition, family size, and birth order—are the most often included variables referred to in drug and family research. Although these factors seem to contribute to the etiology of drug abuse, one needs to look at the findings more critically to try to evaluate the extent of their influence.

The literature on drug abuse is replete with findings that suggest that, compared with traditional nuclear families, disorganized, especially single-parent families are more vulnerable environments for children. These families are associated with an earlier onset and greater degree of drug and alcohol abuse. Information regarding the role of family size and birth order, however, is currently insufficient. According to the data, there are very limited indications that an only child is the least at risk, whereas families with seven or more children are at greater risk for drug abuse. However, there seem to be fewer cases of drug abuse involving first-born children compared with the number of cases involving subsequent, especially last-born, children (Barnes, 1990; Glynn, 1984).

Stanton (1985), Hawkins et al. (1987), and Wells and Rankin (1991) have argued that family structural factors do not contribute much to our understanding of drug-abuse behavior. More important risks for children, they suggest, lie in family processes and the quality of family environments.

Divorce, for example, may be a healthy way of ending a hostile marital relationship. The separation of parents may only be the culmination of hostile relationships, painful negotiations, and the draining of family resources prior to the family breakup. Sessa and Steinberg (1991) argue that the most important impact of divorce on children is how much it disturbs the children's developmental tasks—for example, their autonomy. Most children experience relatively brief adjustment problems following a divorce, but continued development of the adjustment process depends on many more factors, such as the age of the children, the gender, the custodial parent, and the quality of life in the home after the divorce.

Different forms of families may possess varied abilities to exercise certain parenting practices, like monitoring and supervision. Dishion, Patterson, and Reid (1988) found interesting linkages between living in a single-parent family, poor parental monitoring, and greater adolescent involvement with drug-abusing peers. In a supportive family relationship, however, parental composition is not a predictor of adolescent drug use.

Variations in family size may impose certain restrictions and may afford opportunities for the utilization of family resources, such as parental

support and finances. Birth order seems to expose each child to different opportunities for social learning (e.g., in regard to role models) and different behavioral expectations, depending on one's family traditions. It is therefore important to look at family processes and the quality of family environments as well as at the family structure.

Family History Factors. Some well-established evidence indicates that drug use by any member of the family is related to drug use by other family members. In couple relationships, the initiation of a female partner into illicit drug use and her progression toward drug dependency are related to patterns of drug use in the male partner, whereas illicit drug use by the male partner is more independent of spousal drug use (Weiner, Wallen, & Zankowski, 1990).

Parental and sibling drug use have consistently been found to be associated with ADOLESCENT drug-abusing behavior (Hawkins et al., 1986). The transmission of the problem behavior, however, is perceived differently by different scholars. Although there is an increasing fascination with GENETIC explanations, more research is needed to validate genetic assumptions (e.g., Cadoret, 1990; Searles, 1990, 1991). In their view of the literature, Hawkins et al. (1986) concluded that the evidence from behavioral genetic research was limited to male ALCOHOLISM and the lack of convergent evidence from adoption, twin, and biological response studies. Similar criticism has been presented by Searles (1990, 1991), who also argued that only 20 percent of children of alcoholics become alcoholics and that half of all alcoholics do not have a family history of alcoholism. Research on the family clustering of OPIATE and ALCOHOL abusers indicates that a genetic explanation is inadequate when it is considered that the community or environment affects the choice of the substance of dependence.

A systemic (family) approach presents more compelling explanations. Research focusing on the role of parental attitudes and values has revealed a high congruence between parents' and adolescents' perceptions of the use and abuse of drugs (Barnes, 1990). When parents use drugs such as CIGARETTES and alcohol, it indicates to the children that such use is expected (or at least allowed) in the family.

Heavy drug use in the family, especially by parents, also disrupts functional properties of the family system (e.g., care and support, problem solving, etc.), and this, in turn, provides a conducive environment for drug use and abuse by other members of subsequent generations (Steinglass et al., 1987). Dishion and Loeber (1985) argued that parental drug use diminishes parental ability to exert effective monitoring and supervision, thus allowing children to mingle with peers who abuse drugs frequently. Clinical observation also suggests that parental drug use blocks effective communication, alters modes of interpersonal relations, and is associated with all kinds of child abuse (Barnes, 1990; Leonard & Jacob, 1988).

Interpersonal Factors. There are at least two broad dimensions of interpersonal dynamics in the family—support and control—and one facilitating dimension—communication (Barber, 1992; Rollins & Thomas, 1979). The support dimension refers to the positive affective experience associated with relationships, such as acceptance, encouragement, security, and love. The control dimension pertains to the extent to which children's behavior is restricted by the caregiver(s), and this ranges from establishing rules and discipline to varieties of physical coercion (e.g., hitting and yelling). Familial support is regarded as the most robust variable in the prevention of all kinds of delinquent behaviors in children and adolescents (Baumrind, 1991; Gecas & Seff, 1990). Different aspects of support have recently been identified, such as general support, physical affection, companionship, and sustained contact (Gecas & Seff, 1990), all of which are negatively associated with socially unacceptable behaviors. Coombs and Landsverk (1988), for example, found consistent evidence that maintaining a rewarding parent-child relationship deters substance abuse during childhood and adolescence (see also reviews by Glynn, 1984; Hawkins et al., 1986). Parental praise and encouragement, involvement and attachment or perceived closeness, trust, and help with personal problems are all characteristics of the families of abstainers, whereas parental rejection, conflicts, manipulative relations, and overinvolvement are related to the earlier onset and continued use of drugs (Baumrind, 1991; Hawkins et al., 1986).

The control dimension is more complex than the support dimension, since one needs to differentiate between types of control. Baumrind (1987, 1991), for example, distinguished between authoritative and authoritarian controls. The first is characterized by a combination of warmth, supervision, and

opportunity for negotiation; this type of control is associated with positive outcomes. In her study of drug-abusing adolescents, Baumrind found that authoritative control characterized the families of abstainers and soft experimental drug users. Authoritarian control, on the other hand, is based on force, threats, and physical punishment; this is the type of control that characterized the families of dependent drug users. Other studies have revealed that sexual abuse and physical abuse are prevalent in the families of drug abusers.

It has been especially well documented that families with inconsistent or no clearly defined rules also have adolescents who abuse drugs (see Baumrind, 1987; Coombs & Landsverk, 1988; Hawkins et al., 1986; Volk et al., 1989). The constantly changing rules in some families jeopardize parental ability to monitor and supervise children and make it difficult for the children to adapt to family expectations.

In order to function within these two dimensions, families must rely on their communication mechanism. To give support or exert control over others, it is necessary to communicate one's intents. Watzlawick, Beavin, & Jackson (1967) believe that when people communicate, the communication also defines their relationships with other persons. They also believe that to be able to define the relationship, those who communicate should be able to understand each other's perceptions regarding what they talk about and regarding their relationship. In a family where drug use is prevalent, communication is heavily loaded with interpersonal misperception and exchanges of negative affect. Studies also indicate that communication in these families is frequently blocked either by the use of drugs or feelings of not being understood (Hawkins et al., 1986; Jurich et al., 1985; Piercy et al., 1991).

The Family and Other Systems. The peer group and school are two other systems to be considered when the adolescent member of the family who is involved in drug abuse. These systems intervene with their own parenting practices, because they provide much of the environment for learning VALUES, attitudes, and norms as far as expected behaviors are concerned (behaviors that may or may not be expected by the adolescent's family).

It is well known that most new drug users are introduced to drugs by peers and that peers help maintain patterns of use, including greater dependent use. To assess the influence of peers, one should assess the following indicators (Agnew, 1991): (1) time spent with peers, (2) the degree of attachment to peers, and (3) the extent of peer delinquency or drug use.

Although researchers find consistent evidence of the relationship between school DROPOUTS, low performance and underachievement in school, and drug abuse, it is not known when school factors become developmentally salient as possible predictors of drug abuse (Hawkins et al., 1986). Some research indicates that a low grade-point average and dropping out of school are strongly associated with children's involvement with drug-abusing peers. It is clear, on the other hand, that parental involvement in children's schoolwork and activities reduces the changes of a child being seriously involved in drug use.

Hawkins et al. (1987) documented limited evidence with regard to the association of drug use and the social isolation of the family. The 1990 NATIONAL HOUSEHOLD SURVEY indicated that drug users were concentrated within underprivileged families of lower social economic status and within communities of color.

IMPLICATIONS FOR PREVENTION

In the last ten years, those responsible for drug-PREVENTION efforts have discovered that (1) the most effective programs are multilevel programs; (2) it is most cost-effective to target youth aged twelve and younger; (3) the family is the most influential context within which to set programs, especially with drug users who are younger and female; and (4) LIFE-SKILL programs rather than knowledge-oriented programs are most effective in preventing drug abuse.

In the assessment phase, one can determine the risk status of a family by looking at the intergenerational history of drug usage, reported child abuse, the children's academic performance, the degree of parental involvement in schools, and the characteristics of the community in which the family lives (e.g., population density, extent of economic and social deprivation, rates of criminal activity and drug abuse behavior).

In the program development phase, one may well consider issues embedded in (1) individual and family development (Baumrind, 1991; Steinglass et al., 1987), (2) culture and gender (Weiner et al., 1990), and (3) health and economy,

both of which affect the individual and the family (Bush & Iannotti, 1987; Conger et al., 1991). One could also determine how these issues are interconnected in order to come up with the best possible program for specific populations.

In the implementation phase, matching of staff and target group and the ways in which the programs are delivered may affect the outcomes. It may be wise to staff prevention programs delivered in cultures other than the mainstream culture with personnel of similar backgrounds or with those who have an adequate knowledge of that specific culture. Positive and nonthreatening approaches that combine both information and life-skill building are most effective. Parental or significant-other involvement with involvement by the school give programs the most credibility to youth.

FAMILY TREATMENT

As described earlier, dysfunctional family life is one potential contributor to the development of drug addictions in family members. The reciprocal nature of addictions and disorganized families, however, is evident in that not only may dysfunctional families produce addictive behaviors in their members, but these addictions, in turn, may affect the quality of family life, thus negatively impacting the behavior of family members and devitalizing or fracturing family relationships. The most demoralizing aspect of this reciprocity is that drug addictions are often passed from earlier generations to later generations, unless this pattern can be ended by successful treatment or intervention.

Until the mid-1980s, very few drug treatment programs *directly* utilized spouses, parents, or other family members in their treatment of the identified patient. After that time, family therapy became the treatment of choice for most drug abusers, especially in the area of alcoholism treatment. A growing body of research findings has shown that family-centered drug interventions are very effective in getting family members off drugs and keeping them off (Lewis & McAvoy, 1984).

There is evidence, for example, that family groups given systemic family interventions have a higher treatment success rate—that is, decreased drug dependence and less recidivism (Stanton & Todd, 1982). In contrast, if adolescents are treated individually and their family system has not changed, they often return home to resume the same roles and behaviors that had earlier fostered their addictive behaviors.

The inclusion of other family members in an adolescent's drug treatment does add to the complexity of the treatment. Yet this addition often gives a family therapist greater leverage for sustained and successful drug treatment (Lewis & McAvoy, 1984), because of the drug abuser's wish to maintain family love and relationships. Strengthening family relationships may therefore help to reduce or eliminate an individual's addictive behaviors.

Some of the better known interventions currently used in the field of alcoholism treatment are treatments based on family systems. For instance, research has revealed that the spouses of alcoholics often play roles that support their spouse's addiction (through co-dependency). Changes in the spouse's behavior and roles, however, can also contribute to the effective treatment of the spouse's alcoholism (Steinglass et al., 1987).

Systemic family treatment has also been widely utilized in the treatment of adolescents' drug abuse, according to the successful research conducted by Stanton and Todd (1982) with adult heroin addicts. In this programmatic research, one of the best controlled studies of family therapy, the researchers found a significant decrease in the heroin usage of young adults when family-focused therapy was employed.

A longitudinal study of 136 adolescents (Lewis et al., 1991) also documents the relative effectiveness of a family therapy program as compared to a family education program and treatment-as-usual (i.e., individual counseling). In this study, the two brief family-based drug interventions together reduced the drug use of nearly one-half (46%) of the adolescents who received them. This success is thought to be due primarily to the fact that both of these outpatient interventions focused on the systemic treatment of entire family groups. In contrast, the family therapy intervention seemed to have been more effective in significantly reducing adolescent drug use for a greater percentage of the adolescents (54.6% compared with 37.5%). Thus family-based interventions (especially family therapy) can be potent and viable drug-treatment programs.

The best drug treatment, however, may be a combined treatment (Lewis, 1989), in which individual treatment focuses on the teaching of social

skills and strategies for coping with stress, whereas the emphasis of the family treatment component is on increasing the nurturance and parenting skills of other family members. It is at the intersection of these two approaches that much of the current creativity seems to be taking place. Even though their focus and methods may differ, it is good for these two arenas of inquiry to become better known to each other, since each has a wealth of understanding to contribute to the other.

FAMILIES IN ACTION *See* Prevention Movement

FAMILY VIOLENCE AND SUBSTANCE ABUSE Substance abuse has a profound impact on Americans of all ethnic groups. Many people are concerned about substance abuse, especially because it is believed that it has the major consequence of increasing rates of crimes such as robbery and ''drive-by'' homicides. Yet the physiological, psychological, and social effects of substance abuse extend well beyond acts by individuals against strangers; substance abuse has especially adverse effects on families.

Most individuals' illicit drug use occurs between the ages of eighteen to thirty-five, the childbearing years (National Institute on Drug Abuse, 1993). About 10 million children reside in households that have a substance abuser (Blau et al., 1994), and a minimum of 675,000 children per year are neglected or abused by drug- or alcohol-dependent caretakers (Bays, 1990). At the same time that substance abuse increased, foster care placements increased by 30 percent between 1986 and 1989 (Kelley, 1992).

The extent of spousal abuse by substance abusers is more difficult to document. Although there is much more focus on men as perpetrators and women as victims, women in conjugal relationships do assault their male partners (Halford & Ogarsby, 1993). Recent estimates suggest that annually about 10 percent of married women experience some level of assault (Dutton, 1989) and that between 12 percent to 25 percent experience more serious assault such as being hit or kicked (Andrews & Brown, 1988; Randall, 1990). Physical abuse has been identified as the main reason that between 20 percent and 33 percent af all women seek treatment in emergency rooms (Randall, 1990). Rates for violence against men by their female partners are similar to those reported for violence by men against female partners, but whereas women are believed to commit about 10 percent of murders of nonspouses, they commit 48 percent of murders of husbands and partners (Strauss & Gelles, 1990). Thus, domestic violence by women against men appears much more likely to be lethal when it does occur, whereas domestic violence by men appears more likely to result in severe injuries. Few studies, however, have inquired as to whether either the perpetrator or the victim was a substance abuser or was under the influence of alcohol or drugs at the time of a precipitating incident.

Public awareness of child abuse and neglect has increased dramatically since the mid-1980s, but awareness of spousal abuse has lagged behind. Until recent years, adult victims rarely acknowledged their predicament, attributed signs of physical abuse to other causes, excused perpetrators, and resisted recommendations that they use the legal system to try to deter perpetrators. There are several reasons for reluctance to prosecute. In many instances, wives are dependent on their male partners for economic support, fear loss of their children as a result of custody suits, or conceal abuse to avoid criticism by family, friends, or the community. The still-popular notion that women "deserve" abuse prevails and will only diminish as popular beliefs are replaced with information about the complex circumstances facing abused women.

There are few reliable estimates of abuse of elderly people by family members (Pillemer & Suitor, 1988). Many cases may go unreported. One survey reported that 1.5 million elderly persons in the United States were abused in 1989, but others estimate that the range could be somewhere between 4 percent to 10 percent of the elderly population (Boudreau, 1993). Low rates of spousal abuse (3.3%) have been noted for persons over the age of sixty-five, but only 55 percent of this population is married (Strauss & Gelles, 1990). Since women live longer than men, study of the abuse of elderly people by their children or children's spouses focuses mainly on the abuse of mothers. In relationships between adult children and their parents that have become abusive, predisposing factors include health status, dependency status, social isolation, intergenerational transmission of violent behavior, and external stressors. Anecdotal reports indicate that in 30 percent to 45 percent of cases reported to service providers, perpetrators have mental health or substance abuse problems, but the topic requires more systematic study, especially for rates in the general population.

Most studies of family violence involving children have focused on intergenerational relationships. Much less information is available about abuse among siblings or by other children. For example, research emphasis in studies of childhood sexual abuse has examined characteristics of adult male perpetrators who are stepfathers or other relatives, with sexual abuse by brothers identified as the least frequent occurrence.

SUBSTANCE ABUSE AND FAMILY LIFE

It has been estimated that abuse is associated with psychological disorders in about 20 percent of cases (Stark & Flitcraft, 1988). The family plays an important role in factors relating to the development, maintenance, and treatment of substance abuse. The fundamental significance of families as dynamic systems has been recognized and studied (Wolin et al., 1980). Today, treatment plans for substance abusers typically involve family members or significant others. The disorganizing impact of alcoholism on families is perhaps the addiction that has been best delineated, but information about the impact of other drug use is increasing (Kosten, Rounsaville, & Kleber, 1985; Bernardi, Jones, and Tennant, 1989).

Disrupted family dynamics can occur irrespective of socioeconomic status and ethnic group membership. Research involving a large cross-sectional sample found that offspring of substance abusers were more likely to experience marital instability and psychiatric symptoms, especially if they had experienced physical and sexual abuse (Greenfield et al., 1993), and it has also been found that alcohol abuse often co-occurs with domestic violence (Fagan, Barnett, & Patton, 1988; Dinwiddie, 1992). Construction of "family trees," or genograms, are now in common use as clinical tools to depict the degree to which abuse of various substances has had effects on several generations in a family, the extent that support is available from family members, and the emotional "valence" of kinship relationships (Lex, 1990). Background factors significant for women include childhood violence experiences, violence from a cohabiting partner, and presence of concurrent antisocial and/or borderline personality disorders (Haver, 1987).

Substance abuse and child abuse may co-occur under similar family conditions and dynamics, or substance abuse can lead to child abuse (Kelley, 1992). Mediating factors, such as social support and education, income, alternative sources of nurturing, and parents' own histories of familial substance abuse and histories of neglect and abuse are important. It is likely, however, that when mothers who use drugs or alcohol are primary caregivers, they will be unable to fulfill some aspects of their children's emotional or physical needs (Tracy & Farkas, 1994).

One typical factor in family lives of substance abusers is the absent father, who usually is affected in some way by substance abuse and whose familial role has had to be reallocated among other relatives (Bekir et al., 1993; Hayes & Emshoff 1993). Often this pattern is transmitted from the grandparental generation to the parental generation. Involuntarily or out of necessity, the missing role is frequently assigned to a child, who has to assume responsibilities inappropriate to his or her age and generation (that is, to act as a spouse or parent). Some children recall having had to raise themselves, since their parents neglected to nurture them or abused or scapegoated them or controlled their activities excessively. Children's responses can include acting out through anger, antisocial behavior, and estrangement, or compliance and assumption of housekeeping, care for siblings, and other domestic tasks. In adulthood, resentment because of the burdens of these childhood role reversals can promote depression in individuals and affect their adjustment to adult roles, and it can, in turn, damage their relationships with their own offspring. In some cases, the onset of substance abuse in children occurs at the age or life-cycle stage when a parent began substance abuse. Substance abusers often appear to expect parental unconditional love from their spouses that includes unquestioned acceptance of their substance abuse and irresponsible behavior (Bekir et al., 1993). Unstated expectations and other communication difficulties occur when the moods and behaviors of substance abusers are closely tied to those of family members (McKay et al., 1993). "Low autonomy" (emotionally dependent) substance abusers, however, appear to respond well to treatment if family members provide more nurturing and support. Conversely, male substance abusers whose attitudes and actions are independent and detached from family concerns seem to exhibit a pernicious individualism that is associated with a poor outcome in treatment.

CONSEQUENCES OF ADDICTION IN CHILDREN

Infants exposed to drugs in utero can present problems for caretakers, such as the consequences of prematurity, low birth weight, retarded intrauterine growth, and developmental delays (Blau et al., 1994; Scherling, 1994). Cocaine-exposed infants can be irritable and easily overstimulated, exhibit increased muscle tone, and resist attempts at soothing (Kelley, 1990). There is also a large literature on alcohol effects in utero, which may affect at least 2.6 million infants annually (for review of this literature, see Finnegan & Kandall, 1992). For drug-dependent mothers, these babies sometimes present overwhelming challenges that are often interpreted as "personal" rejection. Mothers' emotions can include guilt about exposure of their child to drugs as well as anger that their efforts at parenting hyperactive babies with feeding difficulties and abnormal sleep patterns seem unsuccessful and only generate more stress. The attachment between mother and child may be disrupted because mothers experience these infants as being highly demanding and ignore and withdraw from them or continue to use drugs. All too often, the consequences of disrupted attachment lead to child neglect and abuse.

PRECIPITATING FACTORS

Alcohol, Drugs, and Aggression. It is popularly believed that alcohol use facilitates the commission of violent acts. Although there is an association between alcohol (and drug) use and aggression, it is not appropriate to attribute all family violence to substance abuse, and substance abuse does not inevitably result in violence (Hayes & Emshoff, 1993; Taylor & Chermack, 1993). Individual, familial and environmental factors are all implicated in family violence. Controlled studies in research laboratories constitute one means of disentangling the important interrelationships of these factors. One series of laboratory experiments that used electric shocks between competitors as a proxy for aggressive behavior (see Taylor & Chermack, 1993) showed that both the quantity of alcohol that has been consumed and the social environment encouraging aggression are two major contributing factors. Results should be interpreted cautiously, since the extent to which controlled laboratory conditions, and the stimulus of a shock, can be generalized to the events in daily domestic life in households with a person who meets the diagnostic criteria for substance dependence or abuse remains to be demonstrated (Leonard & Jacob, 1988).

Experiments were designed to identify factors that could instigate aggression in persons intoxicated with alcohol. In an interactive setting, re-

search subjects were tested while sober and while intoxicated (i.e., about 0.10 blood alcohol level, or the limit for intoxication while driving in many jurisdictions). Since actual violence could not be condoned ethically, the experiment could only give the illusion that a subject would compete with an "opponent" who could signal intention to send a shock of intense magnitude.

Unless their opponents indicated willingness to administer a strong shock, 80 percent of the sober subjects and 40 percent of the intoxicated subjects were reluctant to retaliate by increasing the magnitude of the shock presumably to be received by the opponent. An additional important factor was pressure from bystanders. In another experiment, two accomplices of the experimenter encouraged both sober and intoxicated subjects to use high-magnitude shocks against their opponents. Under this condition, escalation of shock strength occurred for 10 percent of sober subjects and 50 percent of intoxicated subjects. Once escalation had occurred, however, intervention by a third party was generally ineffective. Instead, the strategies best suited to averting aggression in intoxicated persons were to show the opponent to be nonthreatening, to announce a conventional limit on aggressive behavior (in this instance, magnitude of shocks), or to divert attention from aggression to more socially acceptable behaviors. Although intoxicated subjects expected opponents to be more aggressive than did sober subjects, using a video camera to project an image of the sober opponent's behavior diminished the aggressive responses.

Effects of other drugs on aggression also were evaluated by using this type of laboratory experiment. These studies are important because some tranquilizers are prescribed for anxiety and irritable behavior (Ratey & Gordon, 1993). Low doses of marijuana could result in aggressive behavior, but high doses suppressed it. The use of low doses of benzodiazepines increased aggression, but amphetamines did not augment aggression, and these results were contrary to prevailing expectations. Other studies showed that pretreatment with nicotine, dextroamphetamine, or propranolol (which lowers blood pressure) inhibited aggressive behavior. Furthermore, when individuals were evaluated on an aggression rating scale, the nonaggressive group did not respond to provocation while intoxicated with alcohol, but persons in the moderate- and high-aggression groups responded with aggression.

Thus, pharmacological action of drugs, dosage, characteristics of the consumer, and the social factors surrounding drug taking are all important factors contributing to aggressive behavior. Disturbance of higher-order information processing, or reasoning, appears to be the factor that best explains escalation in aggression while intoxicated. Intoxicated subjects were likely to continue aggressive behavior once it had begun, unless they were strongly prompted to engage in self-reflection. Weak suggestions to limit aggressive behavior apparently are not perceived. Having crossed a behavioral boundary may make it easier to continue to do so.

It also should be noted that alcohol and other drugs have a pharmacological effect on sexual arousal and sexual behavior. Among men, alcohol can cause secondary impotence and heroin use can delay ejaculation. There also is evidence to support the notion that cocaine use can increase sexual interest for men and women, and marijuana use has become associated with uninhibited sexual activity. Some women find that heroin use by their partner prolongs intercourse, and once heroin is used as an adjunct to sexual activity, couples are prone to relapse to drug use (Lex, 1990).

Pharmacological effects of alcohol and drugs can also distort communication. For example, large doses of alcohol consumed in short periods of time can result in blackouts, or disrupted short-term memory. A person in a blackout is unlikely to remember what was said and done during the episode. Excessive cocaine consumption can result in suspicion, hostility, and paranoia. A person in a state of withdrawal from alcohol or drugs can be irritable, and oscillation between withdrawal and intoxication distorts communications, thereby leading to inconsistency, unpredictability, and mistrust (Hayes & Emshoff, 1993).

Social Context of Domestic Violence. Many sociologists have assumed that domestic violence is a relatively rare event, and until the 1980s anthropologists had only a limited perspective on the occurrence of family violence in other societies. In a major analysis of data from ninety societies (Levinson, 1987), it was found that wife beating was nearly ubiquitous and predictably associated with social and cultural factors. The frequency of wife beating was analyzed, and societies were clas-

sified according to whether wife beating was absent or rare, occurred in less than half of households occurred in more than half of households, or was present in almost all households. Using these criteria, it was found that wife beating occurred in 84 percent of the societies in the sample. Occurrence of this behavior was best explained by both social acceptance of violence and economic dominance of men. In a restudy by Erchak and Rosenfeld (1994), additional societies were selected for analysis and when wife beating was coded as simply being either present or absent; it was found that that it occurred in 80 percent of the sample. However, social isolation occurred in 47 percent of societies without wife beating, in contrast to occurrence in 94 percent of nonisolated societies. Socially isolated societies were typically smaller, and their members need to be mutually interdependent for the purposes of survival. In comparison, societies where raiding or warfare against outsiders was common—that is, where disputes with outsiders were resolved by physical force—had a wife-beating rate of 85 percent, versus 29 percent for societies without warfare. In societies that strongly emphasized men's role as warriors, rates of wife beating were 94 percent, in contrast to rates of 56 percent in societies lacking these attitudes and behaviors. Neglect or abuse of children co-occurred with wife beating. Other associated values were beliefs about women's inferiority, the lack of value of women's lives, and a widow's ability to choose a new spouse. Additional associated behaviors included tolerance for homosexuality, control of female sexuality, and competition for economic resources. Thus, the current prevailing desire of women for equality between men and women in the United States may be counterproductive and result in more violence, because of increased economic competition between the sexes and increased confusion about appropriate gender-related social behaviors (Erchak & Rosenfeld, 1994).

For impoverished members of minority groups, attributes of the community and neighborhood can adversely affect family life (Wallace, Fullilove, & Wallace, 1992). In a number of urban areas, deterioration of housing, decreases in levels of services such as housing inspections and response by firefighting and arson units, and diminished police presence have permitted the dynamics of urban decay to operate. As buildings deteriorate, are further damaged by vandalism, and are destroyed by fire, the impact is much like the spread of a contagious disease. Adjacent buildings may be affected as landlords abandon housing stock and businesses leave or fail. Whole blocks may be damaged, and, finally, entire districts of a city may deteriorate completely.

The quality of life diminishes accordingly. Abandoned buildings are taken over by substance users and sellers or used for other illicit activities such as prostitution. Adolescents can gain ready access to drugs and alcohol, and their behavior may go unchallenged. As people move away, there remain fewer persons available to notice children's behavior, and more unsupervised locations become available where children can engage in disapproved acts. When an area lacks former types of social control, such as sanctions from neighbors, acts such as smoking tobacco cigarettes may escalate to greater deviance, such as using marijuana or crack cocaine. As a consequence, antisocial behaviors may go unchecked, and feelings of anger and hostility can grow. It should be noted, however, that urban settings are not the only locations in which deviance can increase. Contexts that permit anonymity, including ready accessibility of transportation, can also separate perpetrators from persons who know them or would report deviance to authorities.

Perpetrators of Domestic Violence. Much recent attention has been focused on the psychopathology of both perpetrators and victims. One review (Dinwiddie, 1992) suggested that perpetrators had poor communication skills, higher levels of hostility, and, predictably, less control over their anger. Perpetrators studied for personality problems were more likely to be antisocial, passive-aggressive, or narcissistic. The picture is less clear regarding substance abuse, although men meeting criteria for alcohol abuse or dependence (American Psychiatric Association, 1980) were more likely to hit or throw objects at their wives. Studies of community samples have generally found that perpetrators also meet the criteria for diagnoses of depression and antisocial personality disorder.

In one study, rates of spousal abuse and other problem behaviors were studied in 380 married male relatives of alcoholics (Dinwiddie, 1992). Only 16 percent of the men were self-reported spouse abusers, and 30 percent of these were separated or divorced at the time of the interview, in contrast with 14 percent of the nonabusers. When

effects of single diagnoses were examined, alcoholism was the most commonly diagnosed psychological disorder (87%) and was associated with an almost fourfold increase in likelihood of abuse. Diagnoses of antisocial personality disorder (46%) or major depression (33%) were associated with an almost double increased likelihood of spousal abuse. Only four abusers (7%) had no psychological disorder. Most abusers, however, had more than one diagnosis of psychological disorder. Antisocial personality disorder or depression usually co-occurred with alcoholism. Among nonabusers, 65 percent were alcoholic, 23 percent were drug dependent, 20 percent had major depression, and 31 percent had an antisocial personality disorder. Aggressive childhood behaviors were poor predictors of abuse in adulthood, but as adults 95 percent of all abusers reported having physical fights, about half reported marital infidelity, 23 percent had been divorced one or more times, and 17 percent had made attempts at suicide.

Alcohol problems and marital distress appear to be highly interrelated (Halford & Osgarby, 1993). Drinking outside of the home increases marital dissatisfaction, and marital disputes can provoke a relapse in abstinent alcoholics. Divorce rates for alcoholics are thought to be highest among persons with psychological disorders, and divorce or marital problems diminishes the likelihood that alcohol treatment will succeed for individuals. Treatment efforts directed at increasing marital stability, however, can successfully promote abstinence (McCrady et al., 1979). Accordingly, many therapists who treat people for alcoholism suggest conjoint treatment for alcoholism and marital problems. In contrast, few marital therapists address issues of alcohol abuse (Halford & Osgarby, 1993).

A sample of eighty-four women and fifty-six men seeking marriage counseling were identified in a marriage guidance clinic (Halford & Osgarby, 1993). All subjects were still married and cohabiting. The subjects were mainly in their thirties, had about two children, and had been married about nine years. One-third were involved in second or later marriages. The subjects completed questionnaires that probed for information about amounts of alcohol consumption, occurrence of physical violence, and frequency of disputes about alcohol use. About half of the men, but less than 20 percent of the women, met the criteria for a diagnosis of alcoholism. More than 80 percent of the entire sample reported having repeated arguments about alcohol intake, and almost 70 percent reported the occurrence of physical violence. Men and women taking steps leading to divorce were more likely to report disagreements about alcohol use. Women mentioned male violence as a factor in marital dissatisfaction, but men who had been abusive were more likely to seek divorce. In this sample, alcohol abuse was significantly associated with couples taking steps toward divorce, but few other common sources of marital dissatisfaction, such as allocation of household tasks, communication, finances, use of leisure time, and parenting issues, were reported to any significant extent. At the very least, these data suggest that marital therapists should routinely screen their clients for alcohol intake and alcohol-related problems, and that they should assess the extent to which these factors interact with domestic violence. It also is possible that abuse by a husband signals a desire to terminate the relationship rather than to exert greater control over the wife's behavior within the context of marriage.

Disentangling cause-and-effect sequences between alcohol or drug abuse and family violence is an important and necessary step in understanding factors that promote or maintain any interrelationships. There are several ways of approaching these questions, and researchers with competing theories have attempted to explain the relevant issues (Fagan et al., 1988; Strauss & Gelles, 1990). One theory termed "deviance disavowal" has argued that drinkers are not responsible for their actions while they are intoxicated (McAndrew & Edgerton, 1969). Drunkenness is used as an excuse, and it is possible that some persons seek an intoxicated state so as to be able to engage in violent behaviors (Gelles, 1974). According to another theory, alcohol acts on the central nervous system to create a "disinhibition" that releases aggression. Although this reflects a popular belief about the effects of alcohol, it is the social environment promoting or discouraging aggression that is an important contributing factor (Strauss & Gelles, 1990; Taylor & Chermack, 1993). Social learning theory has been applied to a wide variety of behaviors, and the proponents of this theory argue that social meaning becomes attached to behaviors, such as alcohol use, with the result that people come to expect certain behaviors in association with alcohol. Researchers who support a more focused approach have suggested that drinking and violence become associ-

ated within the family context, and that discussion of drinking behavior acts as a cue or trigger that escalates verbal hostility and culminates in physical aggression (Fagan, Barnett, & Patton, 1988).

Characteristics of Perpetrators and Victims. One study used a Relationship Abuse Questionnaire to assess levels of marital violence among abusive and control subjects, including happily married men, maritally dissatisfied men, and men convicted of a violent offense who had not committed acts of domestic violence (Fagan, Barnett, & Patton, 1988). Men in the marital-violence group were young males from minority groups, with limited education and a high rate of unemployment. All members of these groups had been married for an average of four years, had about two children, and were between one to two years older than their wives. Maritally violent men were more likely to consume whiskey and beer, drink daily, drink at lunch on workdays, and drink at home—after work and in the company of their children or by themselves. In addition, maritally violent men indicated that their female partners also drank, but to a lesser degree than they did. These men in the maritally violent group reported that they drank to "deaden the pain in life," to "cheer up a bad mood," to "relax," to "celebrate special occasions," to "forget worries," "to forget everything," and to allay feeling "tense and nervous." They said their female partners drank to "celebrate special occasions" and to "be sociable." Maritally violent men reported that drinking accompanied abuse about one-third of the time but occurred without drinking occasionally, about one-fourth of the time. Female partners were said to drink on about one-fourth of occasions when abuse occurred. Maritally violent men were most likely to report that in the aftermath of violence they felt "sexy" or "wanted to make love," "tried to stop abuse through reasoning," or "took drugs/had a drink." In sum, these men drank more, drank in many social contexts, perhaps continuously but in low amounts, drank to "escape" unpleasant emotions and events, and had female partners who also drank. Drinking or drug taking could be an outcome, however, rather than the cause of a violent episode. It also should be noted that a violent episode could precipitate sexual activity.

A classic study (Kantor & Strauss, 1989) investigated whether drug or alcohol use by victims increased the likelihood of assault by their partners. Information about violence was obtained from 2,033 married or cohabiting women who responded to the 1985 National Family Violence Survey. Research was stimulated by empirical observations that cultural acceptance of violence was the strongest factor in violence directed at wives. This study was designed to test the hypothesis that victims of violence might in some way precipitate violent episodes. Several studies had indicated that people were more likely to attribute blame for violent episodes to women who had violated the cultural attitude that fosters disapproval of women who are intoxicated and another culturally shaped attitude that excuses intoxicated men from the consequences of their alcohol use, including violence. Specific questions included in the interview asked whether women's alcohol or drug use increased the risk of violence from male partners, whether drinking or drug use by male partners increased the risk of violence, whether intervening variables, such as socioeconomic status, explained the occurrence of violence, and whether minor violence and severe violence had different antecedents.

Events were classified as nonviolent, minor violence (throwing objects, pushing, slapping, or grabbing), and severe violence (kicking, hitting, beating, choking, threatening with knives or guns, or using knives or guns). Subjects also were asked whether they used drugs to the extent of being "high" and alcohol to the extent of being "drunk." Predictably, high rates were obtained for alcohol use. Among nonviolent couples, 16 percent of wives and 31 percent of husbands were reported to use alcohol to the extent of being drunk. In contrast, 36 percent of women and 50 percent of men involved in minor-violence episodes used alcohol, and 46 percent of women and 70 percent of men involved in severe-violence episodes had used alcohol. Correlation of violence with drug use (marijuana) was less than half that of alcohol, but the illegal status of marijuana might have encouraged underreporting. Among nonviolent couples, only 4 percent of wives and 5 percent of husbands were reported to use marijuana. In contrast, 14 percent of women and 18 percent of men involved in minor-violence episodes had used marijuana, and 24 percent of women and 31 percent of men involved in severe-violence episodes had used marijuana. Minor-violence episodes were related to the husband's use of marijuana and to violence in the family of origin of the victim. Drunkenness by the wives and by their

husbands, low income, and the wives' acceptance of male violence were significant factors, but wives' marijuana use was unimportant. Severe-violence episodes showed a more restricted pattern. Violence in the women's families of origin and husbands' drunkenness were somewhat stronger factors than husbands' marijuana use. Income level, wives' acceptance of abuse, and wives' drunkenness or being high did not affect the severity of violence. In this study, pregnancy or employment status were not relevant factors.

Some have argued that pregnancy is a factor in the precipitation or escalation of abuse episodes. A recent study examined the extent of physical abuse in a multiethnic sample of pregnant women (Berenson et al., 1991). Of 501 women using services at a prenatal clinic, about 20 percent reported physical abuse, and of this group, 29 percent had been abused while pregnant. However, only 19 percent had ever sought medical help, thus indicating that emergency-room statistics might seriously underreport the prevalence of physical abuse. Abuse occurred typically within the context of a primary relationship, with 92 percent of women reporting abuse by only one person, usually (83% of the time) a male partner. Women who had been abused were more likely to report having a partner who abused alcohol or drugs. Abused pregnant women had significantly more pregnancies and more living children than other pregnant women. Across ethnic groups, white non-Hispanic women were 3.5 times more likely than Hispanic women and 1.6 times more likely than black women to experience physical abuse. Substance abuse increased risk of abuse for white non-Hispanic women to two times that of non-abused women, but for black women, almost four times. Other characteristics were important. Traditional values, as exemplified by speaking Spanish, appeared to be a protective factor for Hispanic women. Divorced or unemployed black women, however, were at higher risk for abuse than either Hispanic or white women. Thus, alcohol or drug use are important factors in the abuse of pregnant women, but black women appear to be at highest risk for abuse when these factors were involved.

There is no single cluster of characteristics that typify men who abuse women. Some studies, however, have indicated that witnessing violence in the family of origin may have taught men to use violence as a coping mechanism. Others have argued that alcoholic abusers also may have had a family history of alcoholism, thereby blurring the relationships between causes and effects in families of origin. In a study of men in a treatment program for family violence (Hamberger & Hastings, 1991), comparisons of marital adjustment, coping with conflict, and personality characteristics were made among alcoholic and nonalcoholic men in treatment and control subjects drawn from the community. The average age of the men was about thirty-five, and they had similar education levels. Nonalcoholic men were more likely to be employed and less likely to have witnessed violence in their families of origin. Alcoholic men who had abused their wives were more likely to have been abused as children, but parental alcohol abuse and parental alcoholism appeared to have no direct role in provoking violence by adult abusers who were alcoholic. As might be predicted, the alcoholic abusers had significantly higher personality-disorder scores for avoidant (passive-aggressive) behaviors, aggression, and negativism, and lower scores for conformity. Both alcoholic and nonalcoholic abusers had a large number of symptoms of pathology, thus scoring high on scales measuring anxiety, hysteria, and depression. Alcoholic abusers had the highest scores on psychotic thinking, psychotic depression, and borderline behaviors. As predicted, abusers had higher scores for personality disorders, and alcoholic abusers had the highest scores in this regard. Alcoholic abusers had witnessed more violence in their families of origin and had themselves been victimized by abusers in their families of origin. Overall, alcohol abuse was significantly related to psychopathology as well as to the degree of harm conferred by abuse. Unemployment as a factor operated in some unknown way to bring abusers to the attention of authorities, but the effect of socioeconomic status was not included in the characteristics examined in this study. Clearly, alcoholic abusers identified through agencies had more severe problems, thus suggesting that treatment programs should carefully assess referral sources of clients. A finding of co-morbidity with depression, anxiety, borderline behaviors, and thought disorders suggests that a program focused on abuse alone would be less successful than a more comprehensive approach that offered services for severe psychological disorders.

In another line of investigation, researchers examined women's histories of victimization and

their alcohol use together with characteristics of their partners. The reasoning behind this approach was the consideration that when abusive behavior was modeled, excused, or condoned, children would perpetuate these behaviors as being appropriate to gender roles. Thus boys would devalue women and consider abuse a conventional way to deal with conflict, and girls would expect to be devalued and would tolerate abuse. One study investigated these background factors among forty-nine abused women and eighteen male abusers (Bergman & Brismar, 1992). Abusers were not identified through their female partners, since many of the women were afraid to permit contact with them and many of the abusers refused to participate. Abusers were selected from men who had been sentenced to prison for assault and battery of their female partners. The extent of injuries inflicted by the selected men and experienced by the women were comparable as a result of matching reports from the abused women and those from the convicted abusers. It was intriguing to find that both the men and the women reported having been raised without fathers in their families of origins, that about half of the absent fathers were alcoholic, and that most of the mothers were abstainers. As children, about 80 percent of both men and women had witnessed domestic violence in their families. Moreover, 29 percent of the women and 11 percent of the men had experienced sexual abuse as children. As adults, almost all of the women (94%) had experienced previous abuse, and 49 percent had been abused by former partners. About half of the men and one-fourth of the women had used marijuana, 62 percent of the women and 44 percent of the men had used sedative-hypnotic prescription drugs, and 55 percent of the women and 61 percent of the men acknowledged that both partners had been drunk at the time of the precipitating episode of abuse (only 20% of the women and 11% of the men had been sober). Roughly two-thirds of the men and of the women indicated that the abusive incident probably would not have happened in the absence of alcohol. Transgenerational perpetuation of abuse patterns seemed likely, since 25 percent of episodes were witnessed by the children of the women and the rate of the parents' alcohol and drug abuse was high. Thus, information about histories of alcohol and drug abuse as well as exposure to domestic violence should be evaluated for each partner in a couple involved in domestic violence.

Less information is available about drug use (see Miller, 1990). Abuse is not uniformly associated with drug use, however. Psychopharmacological factors have been implicated in domestic violence in the case of some drugs, such as cocaine (Maher & Curtis, 1992), and for economic reasons, such as when a drug abuser resorts to appropriation of family funds to purchase drugs. Systemic violence, related to the hazards of illicit transactions, may spill over into the domestic area if a drug abuser is concerned or suspicious that a partner may be an informer or may be adulterating drugs. Female drug users may find themselves devalued on the basis of both their gender and their behavior, and because some women are involved in prostitution to obtain drugs for themselves or their partners, their risk of exposure to violent behavior is increased substantially. Intoxicated women also may be more verbally aggressive and thus violate the cultural norm that values the "soft-spoken" woman (Miller, 1990).

Studies of alcohol abuse as it is associated with the abuse of women have not been able to identify a sequence of cause and events. More definitive studies are needed, but one informative study of alcohol and drug abuse by eighty-two male perpetrators and victims sought important linkages. The perpetrators were parolees, and data about psychological disorders, substance abuse, modes of conflict resolution, and frequency of violent events were obtained from them and their female partners. About three-quarters of the perpetrators, and a surprising 56 percent of their female partners had alcohol problems, and 73 percent of perpetrators and 40 percent of their partners acknowledged using illegal drugs. Similarly, 78 percent of parolees and 72 percent of their female partners reported perpetrating a moderately violent episode, and 33 percent of parolees and 39 percent of their female partners reported perpetrating a severely violent episode at least once during the three months before the interview. About one-third of the episodes were considered severe, and about three-fourths were considered moderate. Neither alcohol nor drug use was involved independently, but concurrent use contributed significantly to violent events, and the separation of drugs into different classes by pharmacological action did not change the effect of alcohol and drug interaction. When combined, however, cocaine and alcohol had a strong effect on violence. In addition, couples with more substance

abuse-related problems had a higher incidence of violent episodes, but, overall, alcohol problems most strongly increased the likelihood that violence would occur. Additional studies of women with concurrent alcohol and drug abuse problems are needed to clarify the temporal relationships.

TREATMENT FOR ABUSERS

Shame, guilt, and denial are powerful emotions that impede both the recognition of problems and the admission of the need for help. It is popularly believed that perpetrators enter treatment only under coercion and with considerable reluctance. Given the strong association between substance abuse and marital violence in some individuals, questions arise as to whether treatment of alcohol or drug abuse alone will concomitantly diminish violent acts. Behavioral marital therapy teaches improved communication skills and has been used to improve the marital relationships of patients as their drinking abates (O'Farrell & Murphy, 1995). This treatment modality, however, does not directly address the problem of violence. A comparison was made between eighty-eight couples with a newly abstinent husband and a nonalcoholic control sample of eighty-eight couples undergoing marital therapy. The study covered the year before treatment and the year after it. Acts of domestic violence occurred between four to six times more frequently during the year before treatment. Rates for violent episodes during the year after treatment remained elevated for both men and their wives, and they were higher than the rates among control couples. In instances of relapse, rates were higher than those for couples who had not relapsed. In turn, rates for couples who had not relapsed were comparable to those for controls. Consequently, effective treatment for alcoholism appears to reduce the frequency of domestic violence, although a study that uses a control group of conjugal pairs not receiving behavioral marital therapy is needed for conclusive results. The cause-and-effect relationships between the release of emotions and relapse still need to be disentangled, however, since the former may provoke the latter or have an additive effect.

Another study examined rates of violent acts among seventy-four persons who completed a treatment program for spousal-abuse abatement and thirty-two who relapsed from this program. Men were referred by themselves or the courts, but neither source of referral nor amount of criminal activity had an effect on outcome. Alcohol problems persisted in 32 percent of the men who completed this program successfully, but 56 percent of recidivists had persistent alcohol problems. Recidivists also had higher levels of drug abuse and less empathy as measured on standardized scales. Recidivists also were found to be significantly more narcissistic (self-centered) and gregarious. These findings suggest that alcohol and drug abuse must be addressed when they occur among perpetrators of domestic violence.

COMMENTARY

Numerous studies that use standardized criteria generally support the prediction that substance abuse and domestic violence co-occur in the majority of violent episodes. Roughly one-fourth to one-fifth of episodes, however, occur without substance abuse as a possible co-factor or precipitant. Some additional studies suggest that verbal hostility can escalate domestic conflict to domestic violence (Lindman et al., 1992), but some episodes of verbal hostility may stem from response to life stress and others may be a result of social learning. In other instances, conflict over a child's or a partner's alcohol or drug consumption may prompt the substance abuser to "protect" the behavior through vehement denial, thereby leading to an escalation of hostility that spirals out of control.

Although any suggestion that women's behaviors might contribute to abuse may seem to take the currently unacceptable position of blaming the victim, there is some evidence that women who express aggression verbally may have had abusive families of origin, and that alcohol abuse may have played a role in fostering a climate of tension and hostility within their households (Gomberg, 1993; Hayes & Emshoff, 1993). This pattern may emerge when women who feel devalued have no behavioral alternative through which to express their frustration. Unfortunately, many potentially interesting and informative laboratory experiments that investigate aggressive behaviors are conducted with undergraduate college students and thus may not disclose important information about effects that stem from income level, social class, educational level, or ethnicity.

Data from alcoholic and drug-abusing women in treatment suggest that younger women may be more verbally aggressive, thus reflecting society-wide changes in gender-role behavior. Other data (Miller, Downs, & Testa, 1993) reveal that women who were victimized as children are more likely to develop alcohol and drug problems in adolescence and adult life. In contrast to women with other psychological disorders, women who require substance-abuse treatment recall more abuse during their childhood. Some contribution to this outcome could be diminished self-esteem and increased alienation from typical childhood socialization processes, as well as limited development of social skills for negotiation and compromise.

It is also possible that the contexts of substance-abuse treatment generate a social expectation that a client must have a family history of substance abuse as well as a background that includes emotional, physical, or sexual abuse. It is clear that additional research is needed and that subject samples need to be drawn from different sources, with different prevalence rates of various types of violence. Longitudinal research that would follow a cohort of children through adolescence, young adulthood, and marital life might hold sorely needed answers. Lacking the answers obtained from definitive research, it is reasonable to continue to screen abuse victims and perpetrators for substance-abuse problems, and to screen substance abusers for perpetration of or victimization through family violence. Because both substance abuse and family violence engender denial that anything is wrong, careful assessment is a prerequisite for effective prevention, intervention, and treatment.

BARBARA LEX

FERMENTATION Fermentation is a natural metabolic process that produces energy by breaking down carbohydrates (such as sugars) in the absence of oxygen. It occurs in many microorganisms (such as yeasts), and the end product can be either ethyl alcohol (ethanol) or lactic acid; energy is typically given off in the form of heat. The chemical reaction of this process was first described in 1810 by the French chemist Joseph Louis Gay-Lussac. Fermentation is important to the production of many foods and beverages, the most popular of which are bread, butter, cheese, beer, and wine.

Figure 1
Grapes

Fermented foods first occurred naturally, when stored or forgotten caches were found to be altered but edible. In ancient times, wheat and barley were domesticated, farmed, stored, and used to make breads and porridges—some of which fermented and formed brews. Since that time, the process of fermentation has been used worldwide. Industrial means provide huge quantities of fermented foods, as well as alcohol, which is obtained by DISTILLATION from fermented juices of fruits, grains, vegetables, and other plants.

SCOTT E. LUKAS

FETAL ALCOHOL SYNDROME Fetal alcohol syndrome (FAS) is a constellation of behavioral, growth, and facial abnormalities resulting from prenatal alcohol exposure. Diagnosis is made by a specially trained physician and is based on the following criteria: growth deficiency; a pattern of distinct and specific facial abnormalities; and central nervous system (CNS) damage. In other cases, where there are no related physical findings, but a pattern of cognitive and behavioral deficits exist concurrent with confirmed prenatal alcohol exposure, a diagnosis of static encephalopathy may be given. Due to confusion, this term and fetal alcohol related conditions (FARC) are used in the place of fetal alcohol effects (FAE). The characteristics listed above and discussed later in this entry must occur in conjunction with confirmed maternal alcohol consumption. Racial, genetic, and familial influences must also be considered when such a diagnosis is made.

HISTORY

The term fetal alcohol syndrome was first used in 1973 to describe the physical problems seen in the offspring of alcoholic women. There have been admonitions against women drinking during PREGNANCY for literally thousands of years—in biblical verses and in the writing of the ancient Greeks. The physical and social implications of women drinking during pregnancy first became highly noticeable during the gin epidemic of the 1750s. At that time, gin became a cheap and easily accessible beverage among low-income women. It was noted that there was a correlation between women who were consuming large amounts of gin and problems among their offspring.

A formal study was conducted in the 1890s by an English physician named Sullivan. He identified the offspring of 120 female "drunkards" in the Liverpool jail and compared them to the children of their nondrinking female relatives. From this study, Sullivan noted a perinatal mortality rate that was two and one half times higher in the offspring of the female alcoholics.

In 1968, Dr. Paul Lemoine published a study on the children of women alcoholics in a French medical journal. This article did not receive much attention until the landmark articles published in the *Lancet* by Jones, Smith, Ulleland, and Streissguth in 1973. Since 1973, more than five thousand articles have been published detailing the effects of prenatal alcohol exposure from birth through middle age. There can be no doubt that alcohol is a powerful teratogen (causative agent in fetal malformations) with lifelong after-effects (sequelae).

DISTRIBUTION

The prevalence of FAS ranges widely from community to community and is determined by the number of women consuming alcohol in any particular community. It is estimated that FAS is now the leading cause of mental retardation in the United States, surpassing Down's syndrome and spina bifida. The prevalence estimates for FAS range from 1 in 600 to 1 in 750 births. However, few prevalence studies have been conducted and many experts have differing views as to the accuracy of the prevalence figures available. New Centers for Disease Control (CDC) studies suggest that drinking during pregnancy is actually on the increase, despite public-health information designed to prevent FAS. This trend may lead to a higher number of babies born with FAS/FARC.

PHYSICAL EFFECTS

Scientific research indicates the likelihood that there is no level of alcohol consumption guaranteed free from risk for any period during pregnancy. Individuals react very differently to alcohol and it is difficult, if not impossible, to predict which women will produce a child with FAS. The exception to this is the woman who has already given birth to a child with FAS or FAE. If this woman continues to drink at the same or an increased level, it is highly likely that her subsequent pregnancy will be affected to the same or a greater degree.

Drinking alcohol during pregnancy produces different effects, depending on *when* the alcohol is consumed. During the first trimester, there is a chance of major physical abnormalities and central nervous system (CNS) damage. During the second trimester, alcohol consumption leads to an increased rate of spontaneous abortion and CNS damage, as well as more subtle physical abnormalities. During the third trimester, alcohol consumption can lead to pre- and postnatal growth retardation and CNS damage. These characteristics are detailed below.

As was mentioned above, three major indices are used in diagnosing FAS. First are the common facial abnormalities: These include short palpebral (eye-slit) fissures; a long smooth philtrum (upper lip groove); and thin upper lip. Other common physical problems associated with prenatal alcohol use include cardiac (heart) malformations and defects; pectus excavatum (hollow at the lower part of the chest due to backward displacement of xiphoid cartilage); clinodactyly and camptodactyly (permanent curving or deflection of one or more fingers); fusion of the radius and ulna at the elbow; scoliosis (lateral curvature of the spine); kidney malformations; and cleft lip and palate.

Growth deficiency in FAS is noted in three parameters: height, weight, and head circumference. Many of the prepubescent patients experience growth retardation; they are generally short and skinny in appearance. Significant changes in weight are noted as the female patients enter puberty; although the growth deficiency remains in height and head circumference across the lifespan, the girls frequently gain weight and appear plump. The male patients seem to remain fairly short and slender until their late twenties or thirties.

CNS damage is frequently manifested in cognitive and memory deficits, sleep disturbances, developmental delays, hyperactivity/distractibility, a short attention span, an inability to understand cause and effect, lower levels of academic achievement, impulsivity, and difficulty in abstracting. The difficulties noted in infancy and early childhood are often precursors to psychosocial deficits in later life.

PSYCHOSOCIAL AND EDUCATIONAL ISSUES

Ages Birth to 5 Years. Diagnosis of alcohol-related birth defects is possible at birth but many physicians are either not trained to identify FAS or do not consider it a possibility. Perinatal behavioral manifestations of FAS include the following: poor habituation, an exaggerated startle response, poor sleep/wake cycle, poor sucking response, and hyperactivity. Failure to thrive, alcohol withdrawal, and cardiac difficulties have become medical concerns frequently noted in this patient population.

Developmental delays in walking, talking, and toilet training are often observed. Concerns such as hyperactivity, irritability, difficulty in following directions, and the inability to adapt to changes are commonly reported. The damage done the brain makes it problematic for children with FAS to learn in a timely and consistent fashion. The more abstract the task, the more apparent this learning gap becomes, particularly as the child enters adolescence and then adulthood.

Recommended interventions at this age focus on the family as well as the child. Many children with FAS are removed from the care of the biological mother owing to abuse, neglect, and/or premature maternal death. Newborns and infants with FAS often have trouble feeding; when this is coupled with a mother who may be deeply involved in substance abuse(s) and not attentive to the needs of her infant, it can lead to medical crises. Therefore, it is necessary to provide the following services and interventions:

- Monitoring of health and medical concerns
- Safe, stable, structured residential placement with services provided to the mother, father, patient, and other family members, such as substance-abuse treatment and parenting training
- Directions given to the caregivers in a simple, concrete fashion, one at a time; directions given to the child in similar fashion
- Adaptation of the external environment to fit the child's level of ability to handle stimulation
- Setting by caregivers of appropriate goals and expectations for their child
- Respite care and ongoing support for caregivers

Ages 6 to 11 Years. Some of the problems noted earlier, primarily health issues, become less severe as others become more severe—with greater implications for negative social functioning. These are hyperactivity, impulsivity, memory deficits, inappropriate sexual behavior, difficulty predicting and/or understanding the consequences of behavior, difficulties in abstracting abilities, and poor comprehension of social rules and expectations. Children with FAS may show decreasing ability to function in school as they get older. The abstracting deficits become more apparent when the child reaches the third and fourth grades and is expected to perform multiplication and division. A summation of suggested interventions at this stage include the following:

- Safe, stable, structured residential placement
- Establishment of reasonable expectations and goals
- Clear physical/behavioral limits and boundaries
- Establishment of reasonable expectations and goals
- Listing of chores and expectations in writing
- Structuring of leisure time and activities
- Education of parents, caregivers, and the patient regarding age-appropriate sexual and social development
- Appropriate educational placement that focuses on an activity-based curriculum, development of communication skills, development of appropriate behavior, and basic academic skills embedded with functional skills

Ages 12 to 17 Years. Children with FAS have the same emotional needs as others this age. Adolescents with FAS may exhibit cognitive deficits, impulsivity, low motivation, lying, stealing, DEPRESSION, suicidal thoughts and attempts, and significant limitations in their adaptive behavior skills. Other concerns include faulty logic, pregnancy/fathering a child, and the loss of residential placement. Social deficits noted encompass financial/sexual exploitation and substance abuse. It is frequently difficult for people with FAS to articulate their feelings and needs. This is commonly the time when they reach their intellectual ceiling.

Despite these problems and deficits, adolescents with FAS should not be infantilized. In addition, this is commonly the time where they reach their academic ceiling. The following are some suggested interventions to help them reach their social, emotional, and adaptive potential:

- Changing the focus from academic to vocational and daily-living skills training
- Structuring of leisure time and activities, such as involvement in organized sports and social activities
- Education of the patients, parents, and caregivers regarding sexual development and the need for birth control or protection against sexual exploitation and sexually transmitted diseases (STDs)
- Planning for future vocational training and placements, financial needs, and residential placement
- Increasing responsibility based on the patient's skills, abilities, and interests

Ages 18 through Adulthood. The problems, deficits, and difficulties seen prior to the age of 18 are precursors to those seen in young adulthood

and middle age. An additional problem experienced by people with FAS is the increased expectations placed on them by others. Not only can people with FAS often not meet these expectations but their impulsivity and poor judgment have more serious consequences than during their younger years. Issues such as poor comprehension of social rules and expectations, aggressive and unpredictable behavior, and depression coupled with impulsivity, may lead to suicide attempts, antisocial behavior, hospitalization, and/or incarceration.

Other concerns noted in adults with FAS include social isolation and withdrawal; difficulties in finding and sustaining employment; poor financial management; problems accessing and paying for medical treatment or child care; and a need for help with social/sexual exploitation and unwanted pregnancy. The hyperactivity and distractibility seen in small children with FAS/FARC manifest in the adult not being able to learn job skills or to meet the requirements of many jobs. The following is a brief outline intended to help adults with FAS deal with problematic issues in a productive fashion:

- A guardianship for or systematic help with whatever funds may be received, since arithmetic skills in this population seldom exceed the third grade
- Subsidized residential placements to help ensure physical safety
- Medical coupons for care, along with birth-control planning
- Homebuilders or community housing to help them live as independently as possible
- Child-care and parenting classes, as needed
- Education to others about FAS, including its limitations and skills, to foster acceptance
- Long-term residential/vocational/psychosocial support for both the patient and/or caregivers

SUMMARY

FAS is a preventable birth defect; once it exists it has life-long consequences. Special programs involving planning for future vocational, educational, and residential needs should be implemented as early in childhood as possible. Education on the harmful effects of alcohol use, focusing on young women and men of childbearing years, is critical to help prevent, or at least reduce, this significant public-health problem.

FETUS, EFFECTS OF DRUGS ON THE

The pregnant drug-dependent woman subjects her developing infant to a host of problems. When assessing the effects of drugs, especially illicit drugs, on newborn infants (neonates) and young children, two factors must be considered: (1) the duration and concentration of the drug exposure on the developing fetus, and (2) any preexisting medical complications in the mother. These factors are interactive and together will influence, in varying ways, the eventual capabilities of the child. Therefore, the long-term outcome of children exposed to drugs during fetal development should be assessed.

EFFECTS ON THE NEWBORN

A pregnant drug-dependent woman puts her developing fetus at risk for a number of diseases, including hepatitis, ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS), tuberculosis, and sexually transmitted diseases (STDs). A number of these diseases may be acquired through needle sharing. Mothers who are infected with these diseases are likely to deliver prematurely.

In pregnant women who inject HEROIN, the placenta, for example, shows microscopic evidence of oxygen deprivation. The infants are small for their gestational age, with all their organs affected. In heroin-dependent women, a significant portion of the medical complications seen in their newborns is due to prematurity and low birthweight. Such complications include immature lungs, difficulties in breathing at birth, brain hemorrhage, low sugar and calcium levels, infections, and jaundice.

Women on METHADONE MAINTENANCE (an oral NARCOTIC used for the treatment of heroin addiction) are likely to give birth to normal- or almost normal-sized babies. Because they are in treatment, the complications in their infants are not as severe and generally reflect: (1) the amount of prenatal care the mother has received; (2) whether the mother has suffered any complications, including hypertension or infection; and (3) most importantly, any multiple drug use that may have produced an unstable intrauterine environment for the fetus, perhaps complicated by WITHDRAWALS and/or OVERDOSE.

Multiple drug use may cause a series of withdrawals, when the pregnant woman cannot obtain the drug she needs. This series of extreme physical conditions in the pregnant woman can severely affect the oxygen and nutrients that feed the developing fetus, causing various birth defects, depending on when in each trimester the withdrawals occur. If the mother overdoses, a decreased oxygen supply to the fetus can cause aspiration pneumonia—if the mother survives the overdose to give birth.

Laboratory and animal studies have shown that narcotics (OPIOIDS) may have an inhibitory effect on enzymes that influence oxygen metabolism. They also alter the passage of oxygen and nutrients to the fetus by constricting the umbilical vessels and decreasing the amount of oxygen delivered to the developing fetal brain. Such metabolic side effects may cause a derangement in the acid/base balance (acidosis). In contrast, increased maturation of organ systems and certain enzymes have been seen in heroin-exposed infants, including maturation of the lungs, tissue-oxygen unloading, sweat glands, and liver enzymes. The stressful life of the pregnant woman probably contributes to this enhanced maturation in heroin-exposed infants.

The genetic risks to the offspring of addicts on heroin *and* methadone include an increase in the frequency of chromosome abnormalities; infants exposed predominantly to methadone in utero do not. The adverse environmental factors that may contribute to the abnormal findings in heroin-exposed infants may be less prominent in methadone mothers, since drug addiction is compounded by poor maternal nutrition, extreme STRESS, infectious disease, and a lack of early and consistent prenatal care. However, in the absence of specific clinical abnormalities, it is impossible to isolate ei-

ther methadone or heroin as agents linked to GENETIC damage.

Given the obstetrical and medical complications, the lack of prenatal care, and the prematurity of the infants at delivery, it is not surprising that the death rate for ADDICTED BABIES is higher than for infants born to nonaddicts.

NEONATAL OPIOID WITHDRAWAL SYNDROME

This syndrome is described as a generalized disorder, characterized by signs and symptoms of central nervous system hyperirritability, gastrointestinal dysfunction, respiratory distress, and autonomic nervous system symptoms that include yawning, sneezing, mottling, and fever. At birth, these infants develop tremorous movements, which progress in severity. High-pitched crying, increased muscle tone, irritability, and exaggerated infant reflexes are common. Sucking of fists or thumbs is common, yet when feedings are administered, the infants have extreme difficulty and regurgitate frequently—because of an uncoordinated and ineffectual sucking reflex. The infants may develop loose stools and are therefore susceptible to dehydration and electrolyte imbalance. At birth, the blood levels of the drug(s) used by the mother begin to fall, so the newborn continues to metabolize and excrete the drug, and withdrawal signs occur when critically low levels have been reached.

Whether born to heroin-addicted or methadone-dependent women, most infants seem physically and behaviorally normal. The onset of their withdrawal may begin shortly after birth to two weeks of age, but most develop symptoms within seventy-two hours of birth. If the mother has been on heroin alone, 80 percent of the infants will develop clinical signs of withdrawal between four and twenty-four hours of age. If the mother has been on methadone alone, the baby's symptoms usually appear by forty-eight to seventy-two hours.

In summary, various studies have shown that the time of onset of withdrawal in the individual infant will depend on: the type and amount of drug used by the mother; the timing of her dose before delivery; the character of her labor; the type and amount of anesthesia and pain medication given during labor; and the maturity, nutrition, and presence or absence of systemic diseases in the infant.

Studies indicate that more full-term infants require treatment for withdrawal than do preterm infants. Withdrawal severity appears to correlate with gestational age; less mature infants show fewer symptoms. Decreased symptoms in preterm infants may be due to either (1) developmental immaturity of the preterm nervous system, or (2) reduced total drug exposure because of short gestations.

The most severe withdrawal occurs in infants whose mothers have taken large amounts of drugs for a long time. Usually, the closer to delivery a mother takes heroin, the greater the delay in the onset of withdrawal and the more severe the symptoms in her baby. The duration of symptoms may be anywhere from six days to eight weeks. The maturity of the infant's own metabolic and excretory mechanisms plays an important role. Although the infants are discharged from the hospital after drug therapy is stopped, some symptoms such as irritability, poor feeding, inability to sleep regularly, and sweating may persist for three to four months.

Not all infants born to drug-dependent mothers show withdrawal symptoms, but investigators have reported that between 60 and 90 percent of infants do show symptoms. Since biochemical and physiological processes governing withdrawal are still not fully understood, and since multiple drugs are often used by the mothers in an erratic fashion—with vague or inaccurate maternal histories provided—it is not surprising to find varying descriptions and experiences in reports from different centers. Seizures, a severe outcome in withdrawing infants, are rare in narcotic-exposed infants. One report found that 5.9 percent of 302 newborns exposed to narcotics during pregnancy had seizures that were attributed to withdrawal. Other reports found even rarer occurrences of seizures.

Drug-exposed infants show an uncoordinated and ineffectual sucking reflex as a major manifestation of withdrawal. Regurgitation, projectile vomiting, and loose stools may complicate the illness further. Dehydration, due to poor intake and coupled with excessive losses from the gastrointestinal tract, may occur, causing malnutrition, weight loss, subsequent electrolyte imbalance, shock, coma, and death. Neonatal withdrawal carries a risk of neonatal death when these complications are untreated. The infant's respiratory system is also affected during withdrawal: excessive secretions, nasal stuffiness, and rapid respirations are sometime

accompanied by difficulty breathing, blue fingertips and lips, and cessation of breathing. Severe respiratory distress occurs most often when the infant regurgitates, aspirates, and develops aspiration pneumonia.

The increased sensitivity to recognition, the accuracy of clinical and laboratory diagnosis, and treatment have essentially eliminated neonatal mortality attributed to withdrawal per se.

ASSESSMENT AND MANAGEMENT OF NEONATAL OPIOID ABSTINENCE

With proper management, the neonate's prognosis for recovery from the acute phase of withdrawal is good. If symptoms of withdrawal appear, simple nonspecific measures should be instituted, such as gentle, infrequent handling, swaddling, and demand feeding. Careful attention to fluid-electrolyte balance and calorie support is essential in opioid-exposed infants undergoing withdrawal, since they display uncoordinated sucking, feed poorly, often develop vomiting and diarrhea, and have increased water losses due to rapid respirations and sweating.

Indications for specific treatment, dosage schedules, and duration of treatment courses have varied widely. As a general guide, if, in spite of nonspecific measures, babies have difficulty feeding, diarrhea, marked tremors, irritability even when undisturbed, or cry continuously, they should be given medication to relieve discomfort and prevent dehydration and other complications. The dosages must be carefully regulated so that symptoms are minimized without excessive sedation. Several drugs appear to be effective in treating neonatal narcotic withdrawal, but there has been little controlled comparison of their safety and effectiveness. Drugs such as PAREGORIC or tincture of OPIUM are effective in treating narcotic withdrawal symptoms in the infant, and PHENOBARBITAL is useful, but less so when opioid exposure has occurred in high doses.

NEUROBEHAVIOR IN THE NEWBORN

The Brazelton Neonatal Assessment Scale has been used extensively for evaluating newborn behavior. This instrument assesses reaction to stimuli such as a light or a bell, responsivity to animate and inanimate stimuli (face, voice, bell, rattle), state (sleep to alertness to crying), the requirements of state change (such as irritability and consolability), and neurological and motor development. When using this scale in evaluating drug-exposed infants, it was noted that they were less able than nondrug-exposed infants to be maintained in an alert state and less able to orient to auditory and visual stimuli, most pronounced at forty-eight hours of age. Drug-exposed infants were as capable of self-quieting and responding to soothing intervention as normal neonates, although they were substantially more irritable. These findings have important implications for caregivers's perceptions of infants and thus may have long-term impact on the development of infant-caregiver interaction patterns.

Abnormalities in the interaction of drug-dependent mothers and their infants, on measures of social engagement, have been shown. Abnormal interaction was explained by less positive maternal attachment, as well as difficult infant behavior, which impedes social involvement. Many of these interactive abnormalities reverted to normal by four months of age, but the need for "parenting training" is obvious.

OPIOIDS AND SUDDEN INFANT DEATH SYNDROME (CRIB DEATH)

Sudden infant death syndrome (SIDS) is defined as the sudden and unexpected death of an infant between one week and one year of age, whose death remains unexplained after a complete autopsy examination, full history, and a death-site investigation. Compared to an incidence of approximately 1.5 per 1,000 live births in the general population, narcotic-exposed infants appear to have an increased risk of SIDS. Other high-risk factors for SIDS, such as low socioeconomic status, low birthweight, young maternal age, black racial category, and maternal smoking are all overrepresented in the drug-using groups that are studied. In a most extensive study, New York City SIDS rates were calculated in 1.2 million births from 1979 to 1989. Maternal opiate use, after control for high-risk variables, increased the risk of SIDS by three to four times that of the general population.

LONG-TERM OUTCOME OF CHILDREN WHO HAVE UNDERGONE IN UTERO EXPOSURE TO OPIOIDS

Despite the fact that a drug-exposed newborn may seem free of physical, behavioral, or neurolog-

ical deficits at the time of birth, the effects of pharmacological agents (used or abused) may not become apparent for many months or years. Although heroin abuse during pregnancy has been recognized for more than forty years, and methadone treatment has been employed for more than twenty years, follow-up of opioid-exposed infants is still fragmentary. The difficulties encountered in long-term follow-up of this population include an inability to fully document a mother's drug intake, separation of the drug effects from high-risk obstetric variables, problems in maintaining a cohesive group of infants for study, and the need to separate drug effects from those of parenting and the home environment.

The easiest part of caring for the neonate is actually over when drug therapy has been discontinued and the infant is physically well. The most difficult parts then begin—the care involved in discharge planning and assuring optimal growth and development throughout infancy and childhood. Because there is no standard for the disposition of these infants, some may be released to their mothers, some to relatives, and others placed in the custody of a state agency. Still others may be voluntarily released by the mother to private agencies for temporary or permanent placement.

In the United States, pressure recommending separation of infants from their addicted mothers has been growing. This solution may not be practical in cities where social services and courts are already understaffed and overworked. Decent foster care is expensive and hard to find. Pediatricians basically feel that the mother-infant association should not be dissolved except in extreme situations. Aside from intensive drug rehabilitation and medical treatment, these women need extensive educational and job training—to become the productive citizens and loving mothers who will positively socialize their children. Supportive therapies such as outpatient care or residential treatment may help eliminate some of the medical and social problems experienced by drug-dependent women and their children.

Most of the children evaluated for long-term development have been exposed to methadone. Evaluations have occurred at various intervals—at six, twelve, eighteen, and twenty-four months; then at three, four, and five years of age. Testing procedures utilized have been the Gesell Developmental Schedule, the Bayley Scales of Infant Development, the McCarthy Scales of Infant Abilities, and the Stanford-Binet and the Wechsler Preschool and Primary Scale of Intelligence. Infants have shown overall developmental scores in the normal range but a decrease in scores at about two years of age—which suggests that environment may confound long-term infant outcome: low socioeconomic groups suffer from this factor particularly, because of poor language stimulation and development.

The developmental scores in these early years, although useful in identifying areas of strength and weakness, may not predict subsequent intellectual achievement. More and more studies have proposed multiple-factor models to assess infant outcome following intrauterine drug exposure. One such postnatal influence involves maternal–infant interaction. Drug-exposed infants are often irritable, have decreased rhythmic movements, and may display increased muscle tone (tensing) when handled. Such behaviors may be interpreted by the mother as "rejecting" behavior, leading to inappropriate maternal caretaking and possible neglect of the infant. Studies of mother—infant interactions show that: (1) infants born to narcotic-addicted women show deficient social responsiveness after birth; (2) this deficient mother—infant interaction persists until the infants' treatment for withdrawal is completed; and (3) maternal drug dosage may affect that interaction.

Based on available data, at five years of age, children born to women maintained on methadone, in contrast to heroin-exposed babies, appear to function within the normal range of their mental development. In addition, no differences in language and perceptual skills were observed between them and children of mothers not involved with drugs and of comparable backgrounds. Difficulty in following large cohorts of drug-exposed infants has led to the study of very limited samples, however.

Positive and reinforcing environmental influences can significantly improve drug-exposed infant development. Women who show a caring concern for their infants are most likely to pursue follow-up pediatric care and cooperate in neurobehavioral follow-up studies. Lacking a large data base, there is an obvious need for comprehensive studies assessing the development of large populations of drug-exposed infants.

COCAINE

The effects of maternal medical and obstetrical complications seen in opioid-exposed infants are similar to those of COCAINE exposure—although cocaine is a stimulant, not a depressant drug (like the opioids). The infants are frequently small in weight, length, and head circumference as a result of preterm birth and/or retardation of fetal growth. The effects of blood-vessel constriction, a characteristic pharmacologic effect of cocaine, is one of the main reasons for adverse effects—since it results in lack of oxygen and nutrients to the fetus. This predisposes the infant to growth problems, brain hemorrhage, abnormal organ development, and crib death.

The many studies on cocaine effects in the newborn need further clarification because of inadequate sample size, research methodology, and actual drug intake; these include studies that have evaluated brain hemorrhage, structural abnormalities, crib death, and long-term development. Although cocaine-exposed infants have been reported to have some irritability and perform poorly on neurobehavioral tests in the first few days of life, no evidence shows that they have a withdrawal syndrome as described previously in infants exposed to opioids. The symptoms have been related to a cocaine toxicity reaction rather than to a withdrawal syndrome. Infants with opioid *and* cocaine exposure, as compared to opioid exposure alone, have had milder symptoms. This may be a result of interactions between the depressant *and* stimulant properties of these drugs. No treatment has been found necessary to alleviate the symptoms of infants exposed to cocaine, whereas opioid-exposed infants may need treatment in about 40 to 50 percent of cases.

Although a number of reports in medical literature have described babies who have structural abnormalities related to cocaine exposure, an equal number of studies have found no increased incidence of abnormalities. The abnormalities reported have been those of the urinary tract, intestines, and extremities—all of which are related to the vascular disruption caused by cocaine's ability to constrict blood vessels. The most recent review of the clinical studies describing abnormalities in cocaine-exposed infants shows a very low incidence of occurrence.

Studies evaluating cocaine's effects on the occurrence of SIDS (crib death) have shown diverse results. Although inadequate methodologies and small numbers have accounted for these differences, cocaine-exposed infants have also experienced most of the factors that predispose any child to SIDS. These include low birthweight, POVERTY, neonatal complications, minority ethnicity, low maternal age, and maternal cigarette smoking. When these factors are controlled in the research, cocaine exposure accounts for only a very modest increase in the rate of SIDS.

As with all drugs of abuse, cocaine has properties that permit it to be transmitted through the breast milk. Since a significant portion of drug-using women in the United States may be HIV-positive, until the role of breast feeding in HIV transmission is clarified, breast feeding should be discouraged.

Recent reports indicate that cocaine exposure may even occur in young infants after they leave the hospital. The evidence for the postulated route of cocaine toxicity (passive inhalation of smoked cocaine—"crack") is circumstantial, and the range of occurrences in reported series is 2 to 4 percent. Symptoms involve abnormal neurologic findings, including seizures, drowsiness, and unsteady gait.

Much concern has been voiced regarding the ultimate neurobehavioral outcome of infants following intrauterine exposure to cocaine. Based on multiple-risk factors, it appears reasonable to voice these concerns. Commonly, the parents may be of poor socioeconomic status and culturally deprived. The mother may be poorly nourished, may carry medical and sexually transmitted diseases, including AIDS, and may receive little or no prenatal care. After birth, neurologic and neurobehavioral abnormalities may be present in the infant. Stimulation for intellectual growth may be lacking because of prolonged hospital stays, infrequent and inappropriate parental contact, placement in a group-care facility, or discharge to a home in which intellectual nurturing is lacking.

Follow-up studies of large numbers of cocaine-exposed babies are lacking as of the early 1990s. The lay press has reported anecdotal experiences with the first cohort of three- to five-year-old children born of the crack epidemic. Such cocaine-exposed babies have been characterized as showing significant deficits in environmental interactions during play groups and in nursery schools. These

babies have also been described as showing less representational play, decreased fantasy play and curious exploration, and lesser quality of play. Others have described these children as "joyless"—unable to fully participate in either structured or unstructured situations, with attention deficits and flat apathetic moods. Developmental evaluations show, however, that the majority of children who were exposed to cocaine in utero and who now have stable environments score in the normal range.

NICOTINE

Prenatal exposure to smoking has been linked with a number of impairments to the fetus, including impairments to memory, learning, cognition, and perception. Such impairments may result from chronic fetal hypoxia, a loss of oxygen to the cells that may impair normal development of the central nervous system. Maternal smoking during pregnancy also affects the respiratory system of a fetus, and newborns of smokers tend to have reductions in expiratory flows. It may also alter the developing lung and result in respiratory illness in the infant.

Low birth weight is another factor commonly associated with prenatal exposure to smoking, and even passive smoking—that is, from the father or another person in the vicinity of the mother—seems to affect an infant's weight. Some studies have shown an average decrease in birth weight of about 200 grams in newborns whose mothers smoked throughout pregnancy. The risk of a low-birth-weight infant has also been estimated to be two to four times greater for mothers who smoke. In general, women who stop smoking in pregnancy prevent the full effects of low birth weight associated with smoking, and studies have shown that the earlier a woman stops smoking during pregnancy, the lower the risk of a low-birth-weight baby. An infant's birth weight also appears to be "dose dependent," with heavy smokers being at the greatest risk for low-birth-weight babies.

Behavioral studies have also been conducted with children exposed to prenatal smoking. Some research has also shown that a child whose mother smoked during pregnancy is at increased risk of becoming a smoker. Because smoking activates neurotransmitters in the brain, including dopamine, which is involved in reinforcing the effects of addictive drugs, researchers have speculated that nicotine may have an effect on the developing dopamine system of the fetus and put the child at greater risk of addictive behavior in later life.

Prenatal exposure to cigarette smoking may affect a growing fetus in several ways. Carbon monoxide and high doses of nicotine obtained during inhalation of tobacco smoke can interfere with the oxygen supply to the fetus. Nicotine readily crosses the placenta, and it likely causes vasoconstriction of the umbilical arteries and impedes placental blood flow. Carbon monoxide can bind with hemoglobin to reduce the capacity of the blood to transport oxygen. These factors, combined, likely account for the developmental delays commonly seen in the fetuses and infants of smoking mothers.

One of the most striking risks associated with prenatal smoking is that of Sudden Infant Death Syndrome (SIDS). A higher mortality rate exists for infants whose mothers have smoked compared to those who have not. Maternal smoking during pregnancy has also been cited as a major risk factor in almost every epidemiologic study of SIDS. The risk of sudden infant death syndrome is greater among infants exposed to both prenatal and postnatal smoking compared to those only exposed to postnatal smoking. The increase in SIDS risk also appears to be related to the "dose" of passive-smoke exposure—the greater the exposure to smoke both before and after birth, the higher the risk of SIDS. The link between cigarette-smoke exposure and SIDS is not fully understood.

FLY AGARIC A poisonous mushroom of Eurasia (*Amanita muscaria*), having typically a bright red cap with white dots. A preparation, consisting primarily of the dried mushroom, is ingested by the people of Siberia as a HALLUCINOGEN. Intoxication by ingestion of several mushrooms moistened with milk or fruit juice leads to a progression of symptoms—beginning with tremors, continuing through a period of visual hallucination that may be interpreted as having religious significance, and finally ending in deep sleep. A similar preparation

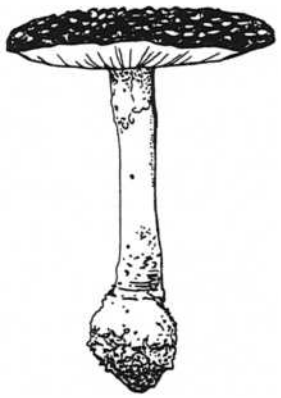

Figure 1
Fly Agaric

may be identified with the deified intoxicant *soma* of the ancient Hindus. In some cultures, the urine of intoxicated individuals is ingested by others to induce intoxication, since the active components of the preparation pass unmetabolized through the body.

The active components found in fly agaric are ibotenic acid and several of its metabolites. The predominant metabolite is muscimol, which has agonist properties at a subset of receptors recognizing the NEUROTRANSMITTER GABA. Ibotenic acid itself has agonist properties at certain excitatory amino acid receptors and has been shown to be neurotoxic.

FOOD AND DRUG LAWS *See* U.S. Government: The Organization of U.S. Drug Policy

FOREIGN POLICY AND DRUGS Drug control is a relative newcomer to the list of global issues that are now an integral part of U.S. foreign policy. While arms control and human rights were already important international issues in the

1970s, drug control lagged behind. In 1971–1972 some members of Congress tried to use foreign-aid restrictions to stop the entry of Turkish HEROIN, but the government did not want to risk hurting relations with an important defense ally over heroin, which was not considered a mainstream drug. The U.S. government found a compromise through diplomatic efforts, which led to the Turkish government severely limiting the cultivation of OPIUM POPPIES (from which heroin is made) and changing the way in which poppies were processed into legitimate medicinal opium. Parallel diplomatic negotiations with MEXICO resulted in cooperation on MARIJUANA eradication efforts. On the international front, the U.S. government pressed hard for the ratification of the 1971 United Nations Convention on Psychotropic Drugs and created the United Nations Fund for Drug Abuse Control (UNFDAC), the predecessor of today's United Nations Drug Control Program (UNDCP). During the rest of the decade, however, drug control gradually declined as a key U.S. foreign policy objective.

Drug control only gained full diplomatic legitimacy in the 1980s when COCAINE use became widespread among entertainers, athletes, and stockbrokers. The government's inability to stop the EPIDEMIC at home prompted Congress to take the issue abroad.

In 1986, in the first of a series of comprehensive international antidrug laws (the Anti-Drug Abuse Act of 1986), Congress placed the burden of halting drug flows on the governments of the drug-producing countries. Using a traditional carrot-and-stick approach, the law required the major drug-producing and TRANSIT COUNTRIES to cooperate fully with the United States in drug matters in order to receive American foreign aid. Half of all assistance was withheld every year until the president certified that the country concerned had met the criteria for receiving aid. Subsequent laws have expanded the requirement, obliging the major drug-producing and transit countries also to comply with the 1988 United Nations Convention Against Illicit Traffic in Narcotics Drugs and Psychotropic Substances. Countries that do not comply not only lose U.S. assistance but incur U.S. opposition to loans from the World Bank and other international financial institutions. For many countries in the developing world, losing access to these loans is an even greater hardship than losing U.S. assistance. Though the certification process has raised tensions with some foreign governments, by 2000 it had become an accepted part of U.S. foreign policy. However, critics noted that the U.S. has recertified countries such as Mexico and Columbia, even when political corruption in these nations has seriously undercut narcotics enforcement efforts.

In earning its diplomatic legitimacy, drug control has had to overcome the same obstacles encountered by other global issues, such as human rights or nuclear nonproliferation. The U.S. foreign-policy establishment favors strategic issues affecting vital U.S. national-security or trade interests over law enforcement or scientific endeavor. It has been reluctant to allow multilateral "functional" questions to affect traditional bilateral negotiations. Congress, however, has left no doubt that it intends to keep drug control high on the list of U.S. foreign-policy issues. By denying virtually all forms of aid—excluding humanitarian and drug-control assistance—to countries that refuse to cooperate, Congress has devised an effective form of leverage over drug countries. Since the law also allows the president to waive sanctions when clearly stated national interests are at stake, Congress has made it difficult for foreign-policy agencies to evade their drug-control responsibilities.

RESPONSIBLE AGENCIES

The U.S. Department of State is responsible for formulating international drug policy. Its Bureau for International Narcotics and Law Enforcement Affairs oversees the annual certification process and prepares an annual report. Since 1989, formal coordination authority has rested with the White House Office of National Drug Control Policy (ONDCP) and the National Security Council. Drug control programs, however, involve a broad spectrum of government agencies including the Central Intelligence Agency, the Department of Defense, the U.S. CUSTOMS SERVICE, the Coast Guard, the Department of Treasury, the Justice Department, the DRUG ENFORCEMENT ADMINISTRATION, and the Department of Health and Human Services. A small percentage of the U.S. drug-control budget is spent on international programs. The bulk of the money goes to domestic law enforcement, drug treatment, and public education.

THE REALITIES OF DRUG CONTROL

As presidential administrations have discovered, an effective drug policy is easier to design than to carry out. The drug issue is a typical chicken-and-egg problem. Does supply drive demand or vice versa? The drug-consuming countries traditionally blame the suppliers for drug epidemics, while drug-producing countries allege that without foreign demand, local farmers would not be growing the drug crop at all. Planners must therefore strike the right balance between reducing drug supply and demand. In theory, eliminating drug cultivation in the source countries is the most economical solution, since it keeps drugs from entering the system and acquiring any value as a finished product. Few SOURCE-COUNTRY governments—all of which are in developing nations—will, however, deprive farmers of a livelihood without substantial compensation from abroad. And the price they seek is usually more than the U.S. government is prepared to pay.

THE NATURE OF THE THREAT

Today's illegal drug trade is one of the most lucrative, and therefore powerful, criminal enterprises in history. Drugs generate profits on a scale without historical precedent—especially given their abundance and low production costs. Such financial resources, which are well beyond those of most national budgets, give drug traffickers the means to buy sophisticated arms, aircraft, and electronic and technical equipment available to few countries. More importantly, illegal drug revenues allow trafficking organizations to buy themselves protection at almost every level of government in the drug-producing and drug-transit countries, where drug-related corruption remains the single largest obstacle to effective control programs.

As for the drugs themselves, there is a superabundance. Opium is in especially great supply. In Southeast Asia, Myanmar (formerly Burma) could supply the world's needs several times over with 257.5 metric tons annually. Estimates of heroin consumption in the Unites States range only between 6 and 20 metric tons, less than 10 percent of Myanmar's potential output. In South America, coca production dropped in the 1990s, yet it is enough to satisfy world demand twice over. This surplus is so large that the drug trade easily absorbs losses inflicted by drug-control authorities and still makes enormous profits.

Traffickers have the option of expanding cultivation of drug crops into new areas. For example, although coca plants are currently confined to Latin America, coca once flourished in Indonesia and could do so again if market conditions were right. Opium poppy cultivation is spreading into nontraditional areas, including South America. Gambling on the resurgence of expanding heroin use in the 1990s, South American cocaine-trafficking organizations have been diversifying into opium poppy cultivation. Without active government anti-drug programs, production will grow until the new expanding market is saturated.

CURRENT POLICY

The U.S. government's first priority is to stop the flow of cocaine, which still poses the most immediate threat to potential drug users. Because of rising heroin use promoted by the new, cheaper Latin American producers, the United States must also focus on opium-producing countries. The United States goal is to limit the cultivation of drug crops to the amount necessary for international medical applications. Since all the cocaine that enters the United States comes from coca plantations in Peru, Bolivia, and Colombia, the U.S. government has active drug-control programs in the three countries. During the 1990s, the U.S. has assisted Bolivia and Peru in their efforts to reduce coca cultivation. While these efforts have dramatically reduced production, drug traffickers increased coca production in Colombia. This resulted in increased political corruption and political destabilization. In 2000, the U.S. approved a $1.3 billion emergency assistance package to Colombia to help the Colombian government. The aid package contains money for police and military training, administration of justice programs, and economic development programs. The U.S. has also increased its military assistance to Latin America to help fight narcotics trafficking, yet many critics question the effectiveness of this approach. Others have expressed concern that direct U.S. military involvement may be requested by Colombia, which could lead to problems similar to those encountered by the U.S. in Southeast Asia in the 1960s and 1970s.

Opium control is more difficult than coca suppression, since most of the world's opium poppy

grows in countries where the United States has minimal diplomatic influence (Myanmar, Afghanistan, Laos, Iran, etc.). There also appears to be increasingly important opium poppy cultivation in China, Vietnam, and the Central Asian countries. Left unchecked, this opium expansion will make effective heroin control virtually impossible in drug-consuming countries, as Europe is already aware.

AN INTERNATIONAL APPROACH

Since bilateral programs seldom provide solutions to global problems, the United States has been an active proponent of collective action under the 1988 UN Convention. This latest agreement covers not only the traditional aspects of drug production and trafficking, but requires signatories to control drug-processing chemicals and outlaw drug-money laundering. The MONEY-LAUNDERING provisions are critical innovations, since they target the enormous international cash flows that sustain the drug trade. As astronomical as drug profits may be, drug money is useless unless it can enter the international banking system. The major industrialized countries are therefore pressing for uniform laws and regulations to exclude drug money in all key financial centers. If honestly implemented, strict money-laundering controls, along with better use of existing programs to suppress drug supply and decrease consumption, offer the hope of reducing the drug trade from an international threat to a manageable concern.

FORFEITURE LAWS *See* Legal Regulation of Drugs and Alcohol; Mandatory Sentencing

FREEBASING The illicit practice of smoking COCAINE is generally referred to as freebasing. The hydrochloride form of cocaine (powder) is highly soluble in water and, therefore, is efficiently absorbed by the mucous membranes when taken intranasally (snorted) or via blood when injected intravenously (shot up). This form of cocaine is, however, destroyed when it is heated to the temperatures required for smoking it. Therefore, the cocaine alkaloid, called "CRACK" or "freebase," is the form that is smoked. Although not always differentiated, freebase actually refers to cocaine in the base state with all the adulterants removed (Inciardi, 1991). Cocaine hydrochloride is combined with an alkaline substance, such as sodium hydroxide or ammonia, to remove the hydrochloride. The *free* cocaine *base* is then dissolved in ether, and pure cocaine-base crystals are formed. It has been estimated that approximately 560 milligrams of cocaine freebase can be extracted from one gram of street cocaine hydrochloride (Siegel, 1982). Cocaine freebase has a melting point of 208°F (98°C) and is volatile at temperatures above 194°F (90°C), therefore providing an active drug for smoking. Crack, in contrast, although also in the base state and used for smoking (or freebasing), does not have the adulterants of the street cocaine removed. Cocaine base is soluble in alcohol, acetone, oils, and ether—but is almost insoluble in water.

Cocaine freebase is usually smoked in a water pipe containing fine mesh screens, which trap the heated cocaine as it melts. A temperature of 200°F (93°C) is the most efficient. Although the amount of cocaine absorbed by the smoker varies—depending on the kind of pipe used, the temperature of the heat source, and the inhalation pattern of the user—under optimal conditions approximately 30 to 35 percent of the cocaine placed on the mesh screen is absorbed by the smoker.

COMPARISON OF COCAINE AND METHAMPHETAMINE SMOKING

Vapor inhalation of the (+) isomer of methamphetamine hydrochloride, colloquially known as *ice* has several differences when compared to vapor inhalation of cocaine freebase. Although both methamphetamine and cocaine freebase have their origin as a salt, cocaine hydrochloride must be pretreated with an alkaline substance to remove the hydrochloride, thus creating the freebase of cocaine that can be heated and inhaled as vapor. In contrast, methamphetamine hydrochloride can be heated and inhaled without adulterating the original compound.

When heated, cocaine freebase has a melting temperature of 208°F while methamphetamine hydrochloride melts at 268°F. Once the appropriate melting temperature is met for each substance, vapors will form and can be inhaled. Significant amounts of cocaine freebase vapor are lost through pyrolysis (chemical change caused by heat) and little condensation appears on the water pipe, suggesting decreased amounts of inhaled vapor. Methamphetamine hydrochloride, however, condenses as a crystalline solid on the cooler areas of the glass pipe. It is thought that this same phenomenon occurs in the mouth and throat of the user, leading to rapid methamphetamine absorption through the lungs as well as delayed absorption through the oral mucosa.

These differences in drug absorption have been demonstrated by comparisons of plasma levels of cocaine and methamphetamine after smoking the individual substances. Plasma levels of cocaine peak and decline rapidly, with a half-life of approximately forty-five to sixty minutes. Methamphetamine plasma levels also rise rapidly, but the half-life is approximately eight to twelve hours. The delayed absorption of methamphetamine from the oral mucosa is thought to play a role in the extended half-life. Differences in the metabolism of cocaine and methamphetamine also contribute to the disparity in plasma half-life. Cocaine is quickly degraded to inactive metabolites by plasma esterases (enzymes) and cleared from the bloodstream. Methamphetamine is eliminated by enzymes with limited plasma distribution and limited activity and, unlike cocaine, is converted to active metabolites that prolong the action of the drug. These active metabolites can accumulate, and repeated smoking of methamphetamine and its active metabolites can lead to dangerous levels of methamphetamine in the plasma.

In summary, differences between cocaine freebase vapor inhalation and methamphetamine hydrochloride inhalation include method of preparing the substance, melting temperature, metabolism, and length of plasma half-life. These differences can have important clinical implications. For example, methamphetamine can cause paranoid symptoms that last considerably longer than those ordinarily seen after cocaine smoking. Distinguishing between drug-induced paranoia and other causes of paranoia thus requires a different length of drug-free observation depending on which drug was inhaled. Understanding the differences between cocaine freebase inhalation and methamphetamine inhalation, particularly the difference in duration of action of the two drugs, can be important in the evaluation and management of patients with stimulant abuse.

Although in use since the mid-1970s, freebasing cocaine became popular in the United States in the early 1980s. The popularity of this route of administration was responsible for the rise in U.S. cocaine use during the mid-1980s. When cocaine is smoked, it is rapidly absorbed and reaches the brain within a few seconds. Thus, users get a substantial immediate rush and an almost instant "high," comparable to that after intravenous cocaine. This is in contrast to intranasal use of cocaine, which engenders a high with a much slower onset. Freebasing is thus a convenient way of taking cocaine, with the possibility of repeated and substantial doses. Since the likelihood of abuse is related to the rapidity with which a drug reaches the brain, smoking cocaine makes it more likely that use will lead to abuse than does snorting the drug. Despite losses of more than half of the cocaine when it is smoked, sufficient cocaine rapidly

reaches the brain, providing an intense drug effect—which users repeat, often to toxicity. The danger of freebasing, in addition to the inherent danger of cocaine use, lies in what some users perceive to be the greater social acceptability of a route of administration that requires minimal PARAPHERNALIA and can achieve toxic levels of cocaine with relative ease.

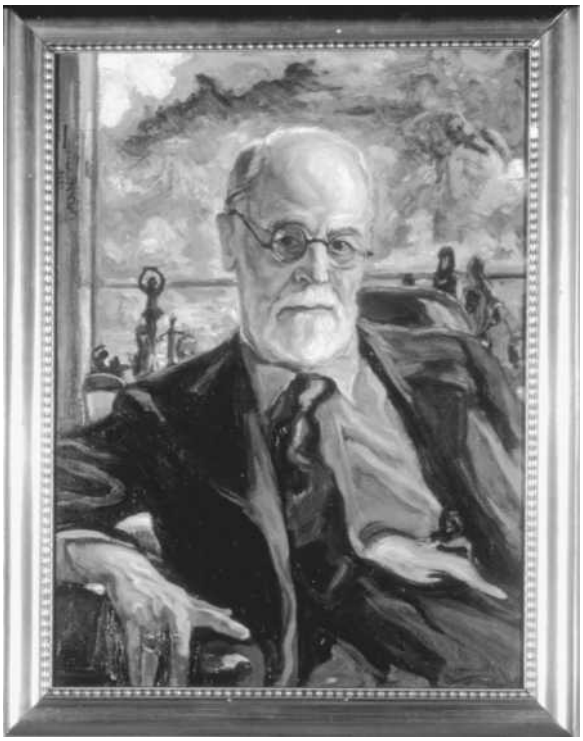
FREUD AND COCAINE Sigmund Freud (1856–1939), Austrian neurologist and founder of



Sigmund Freud performed a number of cocaine experiments on himself and reported the results in his Contribution to Knowledge of the Effects of Cocaine. (The Library of Congress)

PSYCHOANALYSIS, became interested in COCAINE in the early 1880s. At the time he was in his late twenties and was a medical house officer at the Vienna hospital called the Allgemeine Krankenhaus. He was able both to gain access to the literature about cocaine and, at some expense, to the substance itself (which was not illegal at that time). There had been articles in the American medical literature describing cocaine used in the treatment of various ills and for drug dependencies as almost a panacea. The ability of cocaine to fend off fatigue and enhance mood also came to Freud's attention. He was particularly taken by suggestions that cocaine might be an adjunct to, or even a cure for, ALCOHOL or OPIOID dependencies. His interest was heightened because one of his close teachers and friends, Ernst von Fleischl-Marxow, had become an opiate addict. Using cocaine, Freud treated him with almost disastrous results. At the time, there was no opprobrium attached to the use of cocaine and relatively little concern about any adverse effects.

Freud performed a number of cocaine experiments on himself and reported the results in his experimental paper, "Contribution to Knowledge of the Effects of Cocaine." These were reasonable studies that provided useful data about the physiological and psychological effects of cocaine. Biographies of Freud, such as Ernest Jones's *The Life and Work of Sigmund Freud,* have tended to disparage his experimental paper and other works on cocaine. Although his work was done on himself and was limited in its scope, it has been confirmed in modern replications. Freud was initially skeptical about the possible "addictive" properties of cocaine in normal individuals, but later, in the face of evidence and criticism, he was less vehement on the subject. He became, in later life, very sensitive to criticism of his earlier views on cocaine.

From 1884 to 1887 Freud wrote four papers concerning cocaine, including a definitive review ("Über Coca") in 1884. He obviously felt comfortable in both taking cocaine and writing about it in his letters. He mentions and discusses his use of and dreams about cocaine in the *Interpretation of Dreams* (1889). The true extent and duration of his self-experiments is not known, since access to his correspondence has been severely restricted.

Freud is sometimes credited with the discovery of local anesthesia because of his proposal in his cocaine review paper that the substance could be used for this purpose. He also claims suggesting the idea to both Koenigstein and Carl Koller prior to their experiments in ophthalmology, which led to the initial papers on local or topical anesthesia. There is a semantic problem in understanding these claims. Almost all investigators of cocaine had noticed the numbing properties of the drug when placed on the tongue. The idea that this property had a practical use in ophthalmological surgery does belong to Carl Koller, a friend and colleague of Freud's, who did the proper experiments and published them promptly. The controversy about the discovery between Koller and Koenigstein with Freud's mediation is well covered in the article by Hortense Koller Becker, "Carl Koller and Cocaine," in *Psychoanalytic Quarterly*.

Extreme viewpoints that attribute Freud's behavior and writings to the influence of the toxic effects of cocaine are unsubstantiated by evidence. Clearly, he used cocaine as a psychotropic agent on himself and this experience led to his faith in its relative safety. Despite this, there is no real support for a viewpoint that he was an addict or that his thought was markedly affected by his drug usage. The combined notoriety of both Freud and cocaine has led to speculative exaggerations that make better newspaper headlines than history.

GABA *See* Gamma-Aminobutyric Acid

GAMBLING ADDICTION: ASSESSMENT With the legalization and spread of gambling across North America over the last twenty years of the twentieth century, problem gambling emerged from out of the shadows into the mainstream of serious personal and social problems.

BEGINNING OF TREATMENT

In the United States, the first organized program to deal with problem gambling occurred in 1957 with the founding of Gamblers Anonymous, a self-help/mutual support program. The first professional treatment program for compulsive gamblers was begun in 1972 by a psychiatrist, Robert Custer, in an inpatient alcohol program in a Veterans Administration hospital. The first state funded treatment program for compulsive gamblers began in Maryland in 1978.

ASSESSMENT AND TERMINOLOGY

Gamblers Anonymous developed 20 screening questions to help individuals decide whether they are compulsive gamblers. This questionnaire was the primary instrument utilized by professionals until 1980, when the mental health establishment recognized a gambling problem as a psychiatric disorder, naming it pathological gambling. Diagnostic criteria for this disorder were specified in the Diagnostic and Statistical Manual (DSM III) used by mental health and addiction clinicians (American Psychiatric Association, 1980). The most widely used term in society referring to this disorder is still compulsive gambling, while the terms addictive, chronic and disordered gambling are also currently in use. The term *problem* gambling is used generically to refer to an unspecified level of severity and is also used in an assessment context to refer to a gambling problem of mild to moderate severity, encompassing those at risk for developing pathological gambling.

DSM IV DIAGNOSIS

The diagnostic criteria were modified in DSM III-R (American Psychiatric Association, 1987) and in DSM IV (American Psychiatric Association, 1994). The diagnostic criteria for pathological gambling in DSM IV are provided below.

A. Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:
   1. is preoccupied with gambling, e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble

2. needs to gamble with increasing amounts of money in order to achieve the desired excitement
3. has repeated unsuccessful efforts to control, cut back, or stop gambling
4. is restless or irritable when attempting to cut down or stop gambling
5. gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)
6. after losing money gambling, often returns another day to get even ("chasing" one's losses)
7. lies to family members, therapist, or others to conceal the extent of involvement with gambling
8. has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
9. has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
10. relies on others to provide money to relieve a desperate financial situation caused by gambling

B. The gambling behavior is not better accounted for by a Manic Episode.

Key features in these criteria include: obsessive preoccupation (including craving); progressive inability to control all aspects of gambling; and continuation of gambling despite increasing negative consequences of gambling.

To assist certified clinicians who are not experts in pathological gambling in making a reliable diagnosis of pathological gambling, several DSM IV based structured interviews have been developed but no validation studies have been reported.

It would be clinically useful to include in the future revision of DSM the less severe category of gambling abuse to parallel the current substance abuse diagnostic categories in DSM IV.

DEVELOPMENT OF SCREENING INSTRUMENTS

Pathological gambling is a progressive disorder with very serious life consequences at the later stages. Early identification is especially important because of the devastating individual, family and social impacts of high rates of bankruptcy, suicide, and crime and other individual and societal problems related to pathological gambling (Blaszczynski, et al., 1989; Lesieur, 1998; Phillips, et al., 1997).

The first valid and reliable screening instrument for pathological gambling was the South Oaks Gambling Screen (SOGS) developed in 1987 and still the primary instrument in the field for clinical screening and prevalence research (Lesieur & Blume, 1987). As the SOGS has twenty items, there is a need for a briefer screening instrument which is rapidly scorable. Screening instruments which have been developed to assess problem and pathological gambling in youth are the MAGS (Shaffer, et al., 1994), DSM IV-J (Fisher, 1992) and SOGS-RA (Winters, et al., 1993). Self-report instruments are useful for self-screening and initial professional screening but are not to be used for diagnostic purposes.

ASSESSMENT OF THE FAMILY SYSTEM

In addition to conducting an assessment of the gambler in the clinical context, assessment of other key family members is important for the following reasons (Steinberg, 1993):

- Identification of current and imminent crises.
- Orientation of family members to the treatment setting in preparation for potential involvement in the process.
- Gaining the perspective of significant others provides a more accurate picture of the nature and extent of the gambler's problem.
- Observation of family dynamics provides a clearer understanding of family deficits and strengths.
- Opening an avenue of communication with family members provides earlier detection of signs of relapse.
- It increases the likelihood of help for the family even if the gambler drops out of treatment.
- The impact of the gambling on children in the family can be better determined.

PROGRESSION OF THE DISORDER

Assessment of problem gamblers in less advanced stages is more difficult. Increased public awareness of the signs of pathological gambling

coupled with more human services professionals receiving training in the disorder is resulting in detection of a gambling disorder early in its progression. Instruments that identify the degree of current problem and risk for developing pathological gambling are still needed.

Custer and Milt (1985) identified in clinical practice three stages in the progression of a gambling disorder (for almost exclusively male action gamblers).

Winning stage: Characterized by an initial large win.

Losing stage: Losses are chased with increased gambling until a major problem occurs which is temporarily resolved by a financial bailout, followed by a higher level of gambling and increased crises.

Desperation stage: The gambler further withdraws from family and work responsibilities into gambling, often resulting in criminal and suicidal behavior. Help may or may not be sought.

Hopelessness stage: Rosenthal added the fourth stage for some gamblers who no longer care and continue to gamble without hope of winning. Custer's (1985) chart below depicts the progression and recovery cycle for those who seek help.

PATHOLOGICAL GAMBLING, SUBSTANCE DEPENDENCE, AND OTHER CO-MORBID DISORDERS

While pathological gambling is classified as an impulse disorder, it is increasingly viewed as part of the family of addictions. In fact, the criteria for pathological gambling in DSM III-R were modeled after the criteria for psychoactive substance dependence in DSM III-R. The DSM IV criteria for problem gambling blend DSM III and DSM III-R criteria. There is increasing clinical research evidence for sequential and simultaneous dual addictions involving gambling and substances e.g., alcohol, cocaine, tobacco (Lesieur & Blume, 1996). Brain chemistry research and preliminary genetic research have both pointed to biochemical and etiological commonalities for pathological gambling and substance dependence. While not as extensively researched, relationships have also been found between pathological gambling and food, sex, and work addictions. Co-morbidity has also been found between pathological gambling and other psychiatric disorders, including clinical depression and other mood disorders, anxiety, attention deficit hyperactivity disorder (ADHD), and personality disorders (Blaszczynski & Steel, 1998; Carlton, et al., 1987; McCormick, et al., 1984).

A theory is developing which places pathological gambling in a compulsive-impulsive spectrum with problem gambling as one of the impulse (ego syntonic) disorders at one end of the spectrum and obsessive-compulsive disorders (ego dystonic) at the other end (Cartwright, et al., 1998). Different degrees of impulsivity and compulsivity are experienced by pathological gamblers, depending upon the stage of the development of the disorder with impulsivity primarily at the early stage and growing compulsion at the later stage.

MULTIPLE CONTRIBUTING CAUSATIVE FACTORS

As the twenty first century begins, there is not widespread agreement as to the exact cause(s) of pathological gambling. However, as with many other disorders, a broad model is emerging which includes four major areas of risk factors for developing this disorder: biological, social, psychological, and spiritual (Rugle, 1993).

Biological. Genetic research in the late 1990s has provided preliminary evidence of a genetic link among pathological gambling and other addictive and impulse control disorders (Comings, 1998). This is mediated by neurotransmitters which control impulsivity, emotion and the experience of pleasure. Advances in brain imaging in the late 1990s began to identify areas of deficit in brain functioning which are related to deficits of behavior functioning (e.g. attention deficit hyperactivity disorder [ADHD] (Cartwright, et al., 1998)).

Social/Environmental. Research has provided evidence that early environmental factors in the home such as exposure to a parents excessive gambling or abuse is linked to a later gambling problem. Further, it is likely that trauma in adulthood, including losses later in life, increase vulnerability to developing a gambling problem. Such environmental factors as proximity to gambling, widespread gambling advertisements and the absence of significant education about responsible gambling and the warning signs of problem gam-

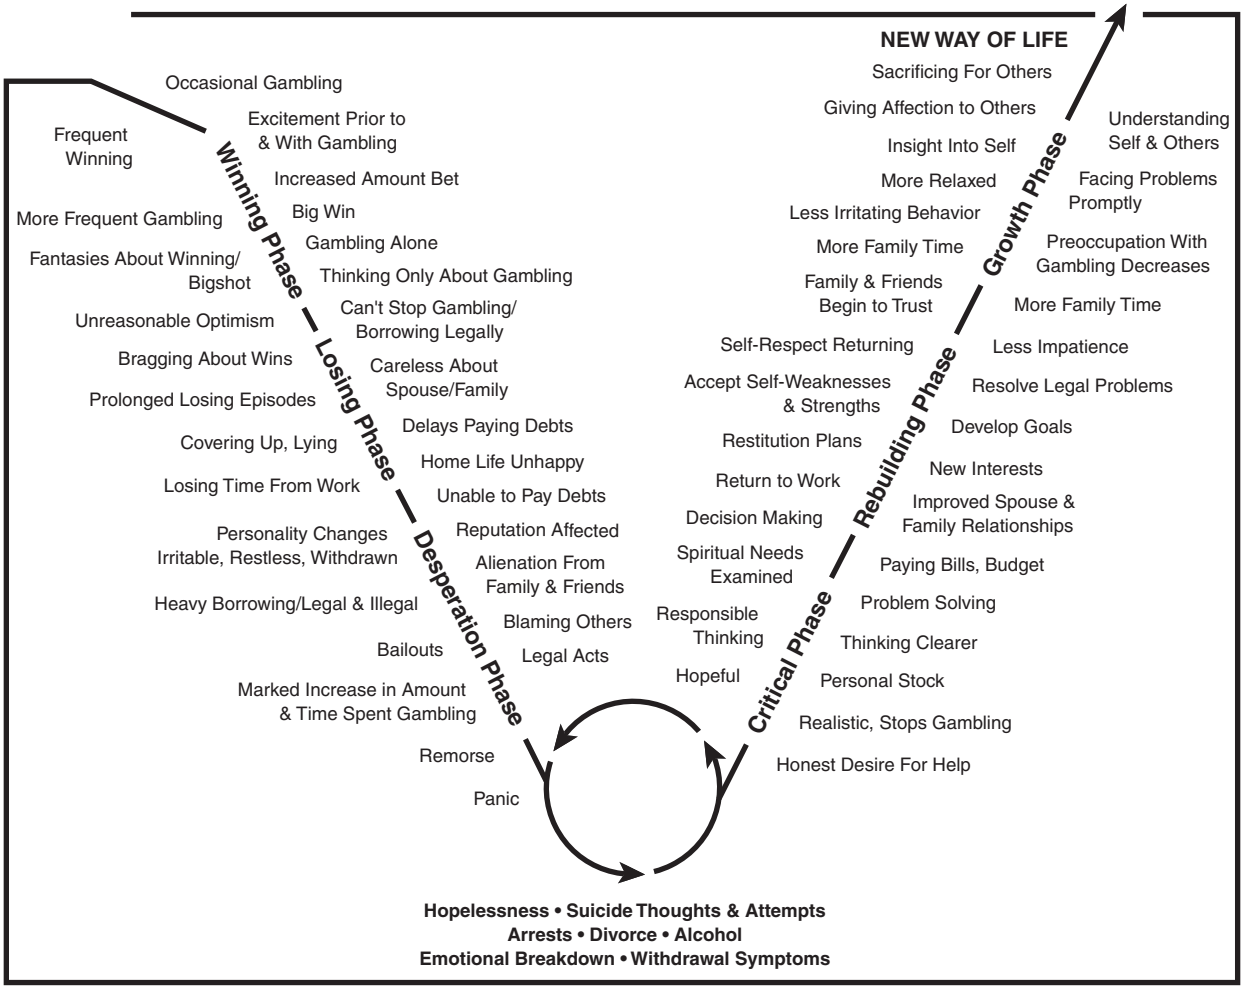

Figure 1
A chart of compulsive gambling and recovery.

bling are likely contributors to higher prevalence rates in certain communities.

Psychological. Recognizable differences between pathological gamblers and non-pathological gamblers have been identified in personality patterns (low frustration tolerance, self-centeredness, mood changes), dissociation and fantasy, as well as irrational and magical thinking. Gender differences have been linked to choice of gambling activities. Men tend to more often be "action" gamblers seeking competition and games of skill (e.g., cards, sports) and women are more likely to be "escape" gamblers seeking solitary and non-competitive activity (e.g., electronic gaming machines).

Spiritual. The 12-Step Recovery programs of Gamblers Anonymous and Gam-Anon, for family members of addicted gamblers (patterned after Alcoholics Anonymous and Al-Anon) attempt to bolster the recovery process by searching for and relying on a higher power to give new meaning to life. Addictions, including pathological gambling, involve substitution of quick fix activities for intimate relations and a spiritual life.

While it has become clearer that the above factors increase the risk of developing a gambling problem, progress toward the development of valid and reliable measures of these factors is evolving slowly but with a quickening pace.

MARVIN A. STEINBERG

GAMBLING ADDICTION: EPIDEMIOLOGY GAMBLING is a form of risk taking that may be defined as risking (betting or wagering) something of monetary value on the unknown outcome of a future event in order to gain something else of monetary value. Evidence of gambling has been found in early civilizations as well as throughout history. For example, many references to gambling can be found within the Old and New Testaments. However, as with ALCOHOL, wide cross-cultural differences have existed in the degree of acceptability and extent to which gambling is integrated into a culture.

RAPID GROWTH OF LEGALIZED GAMBLING

Historically, gambling in the United States had not been integrated into the larger culture as a major legal recreational pastime until the largest continuous expansion of legalized gambling that began during the last quarter of the twentieth century. Gross gambling revenues dramatically increased in the 1990s. For example, in 1996, $47.6 billion in revenues surpassed the $40.8 billion of combined revenues from movies, recorded music, cruise ships, live entertainment, and spectator sports (Christiansen, 1998). In the 1990s, there

were major increases in the availability of some forms of gambling (casino and lottery) as well as new locations (riverboats and Native American reservations), many of which were immediately accessible (convenience stores). By the end of the twentieth century, gambling in the public mind had moved away from being associated with immorality, personal deviance, and crime and had become a major socially acceptable form of entertainment. At the turn of the twentieth-first century, lottery and casino gambling are the prominent forms of legal gambling in the United States, and there is no indication that this trend is slowing down.

The factors contributing to increased gambling include the perceived need by governments for lottery revenue to avoid raising taxes and to stimulate economic growth in distressed areas. Also contributing are the efforts of gambling entrepreneurs in the private sector and the simultaneous development of new forms of gambling technology, principally electronic gaming devices.

The private gaming industry and state governments trumpet gambling as exciting entertainment that also brings the benefits of more jobs and lower taxes. However, gambling is not solely a societal plus. When gambling is legalized and made more accessible, the number of people who try it increases and a certain percentage of those new gamblers who are vulnerable to addiction develop a problem. Social costs of pathological gambling, such as addiction, bankruptcy, divorce, and crime have been found to be severe in clinical samples of pathological gamblers. Assessment on a large scale of these social costs has only just begun (Lesieur, 1998).

PREVALENCE OF PROBLEM GAMING

The first national study of gambling and problem gambling in 1974 indicated that .77 percent of the sample had at some time in their lifetime been probable pathological gamblers, with another 2.33 percent potential compulsive gamblers (University of Michigan Survey Research Center, 1976). The second federally supported national study was conducted by the National Gambling Impact Study Commission (NGISC) in 1999. It was found that 1.20 percent (2.5 million) of the adult population were probable pathological gamblers in their lifetime and 1.50 percent (3 million) were lifetime problem gamblers (National Research Council, 1999). An additional fifteen million adults were identified as being at risk for developing a gambling problem. As compared to these statistics for the telephone sample where a total of 2.70 percent were lifetime problem and pathological gamblers, this study also surveyed patrons at gambling facilities (regular gamblers) and found that 13.00 percent met criteria for lifetime problem and pathological gambling. The NGISC report estimated that the annual cost for problem and pathological gambling is $5 billion, plus $40 billion in lifetime costs associated with decreased productivity, social service costs, and creditor losses (Gersten et al., 1999).

The prevalence of gambling problems is affected by many factors including the number of legal (and illegal) forms of gambling that are available and accessible. Prevalence rates may also be affected by the increasing availability of forms of electronic gaming. These machines are intrinsically engaging and even mesmerizing for many people. This form of gambling involves an insulated person–machine interaction, which provides the opportunity for more frequent play and reinforcement than other forms of gambling. For the individual susceptible to a gambling addiction, the time in which addiction may occur is foreshortened, especially when such machines are available 24 hours a day. However, any form of gambling may result in addiction for an individual who is vulnerable.

Higher prevalence rates for problem gambling are also likely to result when there is an increased acceptance in society of financial risk taking as gambling. In today's financial world financial resources are gambled away in ways that have not been traditionally considered forms of gambling. For example, excessive and destructive risks are being taken in the business world by pathological gamblers who are not aware that they are acting out a gambling problem. Slightly greater awareness is developing that the stockmarket and other financial markets are also arenas for problem gambling. Despite the fact that most people invest prudently in the financial markets, enormous sums are gambled daily in the markets. In 1997, the United States Securities and Exchange Commission acknowledged for the first time that problem gambling occurs in the financial markets by way of its agreement to distribute a pamphlet on investor problem gambling (Connecticut Council on Prob-

lem Gambling, 1997). However, the brokerage industry has not yet acknowledged problem gambling as a concern.

An additional fact that may influence the prevalence rate of problem gambling is the dramatic increase of accessibility to gambling via the Internet. The number of gambling sites available and number of online gamblers have been increasing rapidly, as indicated by the more than doubling of Internet gambling revenues from $445.4 million in 1997 to $919.1 million in 1998 (Barry, 1998). People at risk for a gambling problem will find it more difficult to avoid gambling and youth will be further tempted with increased accessibility by way of home computers. Even if the federal bill in the year 2000 to prohibit Internet gambling in the United States is enacted, online gambling will still be available on the Internet emanating from many other locations. Regardless of the legal status of Internet gambling, Intranet gambling sites involving *pari-mutuel* wagering will continue to be available to subscribers on home televisions and computers.

PREDISPOSING FACTORS

The National Opinion Research Center (NGISC, 1999) reviewed the available literature on problem gambling and concluded that the following are major predisposing factors to the development of a gambling problem:

- Problem gambling often occurs jointly with substance abuse, mood disorders, and personality disorders.
- Pathological gamblers more often than nonpathological gamblers report having a parent who is a pathological gambler.
- The earlier gambling starts, the more likely pathological gambling will occur.

SUBGROUPS AT RISK

The identification and modification of risk factors have been hampered by the confusion from the mixed messages the public receives. On the one hand, private and government sponsers of gambling on a large scale encourage gambling. On the other hand, consumers receive strong but less frequent messages that gambling to excess or inappropriate gambling can create addiction and related negative life consequences.

Evidence suggests that certain groups are at risk, such as older people, youth, women, and people with low income. Seniors are gambling more frequently and they are one of the major groups being targeted by casinos in their promotional efforts. There is building evidence that people of low income gamble a higher percent of their income than people with higher income. The rate of problem gambling among women appears to have dramatically increased in the 1990s, growing from a small percentage to more than 25 percent of all identified problem gamblers. Statewide prevalence studies have consistently identified teenagers as having a greater number of problem gamblers than adults in the same states (National Research Council, 1999).

These emerging facts raise many more questions that need to be investigated. For example, although seniors are a vulnerable group because of declining physical heath and mental capacity as well as depression due to loss and isolation, it is not known whether seniors as a whole experience a greater rate of problem gambling than adults in general. Perhaps the social contact available in a gambling environment and the alertness and required in concentration on gambling have positive mental health benefits for seniors? Research with subgroups in the population, especially groups at risk, across a wide range of geographical areas is needed.

GROWTH OF COUNCILS ON PROBLEM GAMBLING

To meet the challenges of problem gambling, which have increased with the growth of gambling in the last quarter of the twentieth century, councils on problem gambling have been created in the United States and Canada. As spiritual advisor to Gamblers Anonymous, Monsignor Joseph Dunne, along with recovering compulsive gamblers and family members, founded the National Council on Problem Gambling (NCPG) in 1972. Connecticut became the first state affiliate of the NCPG in 1980 and by 2000 there were thirty-four state affiliate councils. The NCPG was the first professional organization to educate the public about compulsive gambling as a serious public health problem and to advocate for treatment services. Other major priorities of the NCPG and its affiliates include the following: sponsoring helplines, conducting prevention programs, training human services person-

nel, conducting surveys on problem gambling, and collaborating with a variety of relevant organizations, including the public and private gaming industry.

GAMING INDUSTRY'S RESPONSIBLE GAMBLING PROGRAMS

The American Gaming Association (AGA), the national trade association for casinos, in 1996 took a major voluntary step forward in creating the Responsible Gaming Resource Guide, which provided a blueprint for establishing a responsible gaming program. In 1997, AGA also established the National Center for Responsible Gaming that is a significant funder of basic research into problem gambling (American Gaming Association, 1998). In the late 1990s, a few state gaming regulatory bodies began to require responsible gaming programs in order for private sector gambling operators to be licensed. Native American-owned casinos have also developed innovative responsible gambling programs. Although most state lotteries have responsible play programs in the year 2000, government efforts to promote responsible gambling (with a few exceptions) are not as progressive as those of the private sector. This may be due to the inherent difficulty of serving as both the regulator and operator of the lottery or because the lottery is incorrectly viewed as a relatively benign form of gambling. Funding for treatment, prevention and research programs by state governments began gradually in the late 1970s and by the end of the twentieth century approximately half the fifty states funded significant programs.

RECOMMENDATIONS OF THE NGISC

The NGISC's (1999) two-year examination of gambling in the United States has been the most extensive and systematic study of the state of seventy-four recommendations for changes in policies and practices for the public and private and Native American sectors of the gambling industry, state regulators, and the federal government. Some of the major recommendations include:

- A pause in the processing of all new gambling applications to allow for adequate assessment of the gambling already in place
- A rollback of all convenience gambling in communities and a halt to authorization of all new convenience gambling
- A restriction of the minimum legal gambling age to 21
- A ban on betting on collegiate and amateur athletics
- A ban on all aggressive gambling advertisements, and the creation of responsible gambling advertisement guidelines
- Prohibition of Internet gambling not already authorized
- A ban on ATM and credit card machines within or near the immediate gambling area
- Gambling establishments policies to ensure the safety of children and prevent underage gambling
- School programs from the elementary through college level should include warning of the dangers of gambling

NEED FOR A COMPREHENSIVE PLAN

Few epidemiological studies have been undertaken primarily due to an underestimation of gambling's impact on all levels of the community. Most communities lack a comprehensive approach and systematic methodology to determine the overall value of gambling to the community. Given the rush to profit from the popularity of gambling, most state and local governments have not systematically planned (e.g., articulated-short and long-term goals) and conducted a comprehensive study of the likely impact of new or significantly expanded gambling on their communities. Economic projections and gambling regulation have been the primary interests. Consequences can be enormous if initial assessments are not comprehensive, thorough, and accurate. Once gambling is introduced, it is very difficult to roll it back as governments become highly dependent on the revenue. Further, evaluation and monitoring programs have typically not been set up to assess the impact of gambling on communities over time. Needed are the short- and long-term assessment of social costs, the extent to which projected economic benefits have been met and sustained, and the extent to which gambling has changed the communities in other positive and negative ways (NGISC, 1999).

GAMBLING AS AN ADDICTION Human beings have indulged in games of chance since before recorded history. Archeological sites in both the Old World and the New World yield gambling bones, dice, and counters. The Old and New Testaments mention the casting of lots to determine the distribution of property, presumably as an expression of God's will. In addition, the classical literature of both Eastern and Western cultures includes many accounts of gambling, often with dramatic consequences. Lotteries have been popular in Asia and Europe for centuries. The first European government-sponsored lottery was established by Queen Elizabeth I in sixteenth-century England. The thirteen American colonies and the early American universities—including Harvard, Yale, Princeton, and Columbia—were all supported in part by lotteries.

Gamblers play the slot machines at the Casino Sandia, a gaming facility at the Sandia Pueblo north of Albuquerque, New Mexico, January 10, 1997. (© Miguel Gandert/CORBIS)

Most societies have recognized the popularity of gambling and its potential for generating social good and personal harm. Therefore, governments have sought ways to regulate gambling. Some governments have prohibited all gambling, while others have established laws limiting the availability of gambling to particular locations, establishing a minimum age, specifying types of games allowed, and regulating the gaming industry to prevent fraud and raise revenues. In the United States, government attitudes toward legalizing gambling have changed radically over time. By the mid-twentieth century, some state governments increasingly looked to state lotteries as a fertile source of revenues. In addition, casino and riverboat gambling, sports betting, card rooms, and bingo games were variously legalized, taxed, and regulated. By 1994, some form of gambling was legal in all states but Hawaii and Utah, and several American Indian nations were operating gambling establishments on tribal land. In 1997, an estimated 639 billion dollars was wagered annually in the United States, generating a profit of more than 41 billion dollars—with the vast majority of the total legally bet. Illegal gambling has its own special set of subcultures—with rules, limits, and penalties for its devotees.

With the increases in gambling have come mounting concerns about gambling-related personal and social harm. In 1997, the President and

Congress appointed a National Gambling Impact Study Commission to analyze both the positive and negative impacts of gambling in the United States, and to recommend policy initiatives. The Commission made its report in 1999, estimating a five billion dollar cost to American society. Among its many recommendations were freezing or reducing so-called *convenience gambling* (video gambling machines in retail outlets or taverns), and banning gambling on the Internet. In regard to problem gambling, the report called for more treatment, better health insurance coverage and, state funding for treatment, more and better efforts at prevention, and an increased investment in research.

For most people gambling is a pleasurable, if not very profitable, occasional recreation. For a significant minority, however, gambling has the potential to become a compulsive behavior and a ruinous destructive problem. Compulsive gambling has also been known for centuries. The classic Hindu epic, *The Mahabharata*, tells the story of a wise and just king whose single flaw, the inability to control his gambling, leads him to gamble away his wealth and kingdom in a dice game. Still unable to stop, he gambles his brothers, his wife, and himself into slavery. This critical game of chance sets off a train of events that mark the beginning of division and strife in human society.

Famous people among the ranks of compulsive gamblers include sports figures, entertainers, and artists. Fyodor Dostoyevsky, who wrote his novella, *The Gambler*, to restore his finances, was a self-described compulsive gambler. Sigmund Freud's 1928 essay about Dostoyevsky was one of the first attempts to understand compulsive gambling as a psychopathological process. This conceptualization and its further development guided the treatment of compulsive gamblers with psychoanalytic therapies.

Until 1980, the term *compulsive gambling* was used to describe the syndrome of apparent loss of control in gambling. At that time, the American Psychiatric Association published the third edition of its DIAGNOSTIC AND STATISTICAL MANUAL (DSM-III). For the first time, the DSM-III established standard criteria to diagnose this disorder, which was renamed *pathological gambling*. The term was coined to avoid confusion with other diagnoses in which the word "compulsive" appeared, such as obsessive-compulsive disorder and obsessive-compulsive personality disorder; these disorders were thought to be unrelated to compulsive gambling. Pathological gambling was grouped under the heading Impulse Control Disorders Not Elsewhere Classified, along with such diagnoses as kleptomania (shoplifting) and pyromania (arson). In 1987, the American Psychiatric Association's *Diagnostic and Statistical Manual* was again revised (to be abbreviated DSM-III-R). In this revision, the term *pathological gambling* and its classification as an impulse-control disorder were retained, but the diagnostic criteria were significantly altered in response to new knowledge about the disorder. Likewise, the fourth edition of the *Diagnostic and Statistical Manual* (DSM-IV) has additional changes reflecting additional research.

THE ADDICTION MODEL OF PATHOLOGICAL GAMBLING

The early psychoanalytic literature often referred to compulsive gamblers as ADDICTS, but it was not until the founding of Gamblers Anonymous (GA) in 1957 that the addictive-disease model became a basis for recovery. GA was initiated through the efforts of a recovering alcoholic who was both an ALCOHOLICS ANONYMOUS (AA) member and a compulsive gambler. GA adapted the TWELVE STEPS of AA, the fellowship's traditions, its spiritual base, and the general format of its meetings to aid in the recovery of gambling addicts. Gam-Anon, a twelve-step group for the friends and families of compulsive gamblers, modeled on Al-Anon Family Groups, was established shortly afterward. Local chapters of Gamblers Anonymous are increasingly available in U.S. communities as well as in treatment units, work settings, and prisons.

The growth of the alcoholism- and drug-addiction-treatment system in the 1960s gave rise to a variety of professional program models that incorporated a cooperative working relationship with twelve-step groups such as Alcoholics Anonymous. In 1971, using one of these models, Dr. Robert Custer developed the first inpatient addiction-oriented treatment unit for compulsive gamblers at the Brecksville, Ohio, Veterans Administration Hospital. Custer's approach proved useful and has been adopted with various modifications by other mental-health and addiction-treatment facilities.

COMMON CHARACTERISTICS WITH OTHER ADDICTIVE DISORDERS

The addiction model conceptualizes pathological gambling as a disease characterized by a dependence on what gamblers refer to as "being in action." The term describes their aroused euphoric state—experienced while gambling. Pathological gamblers who are also users of other drugs compare being in action to the "high" derived from COCAINE or other STIMULANTS. The addiction model is also supported by the many similarities between pathological gambling and substance dependence in risk factors, symptoms, the course of the disease, the nature of relapse triggers, treatment goals, and the process of recovery. A core symptom for both types of disorder is a loss of control over the substance use or gambling behavior. There is also an important comorbidity between the various addictive disorders. For example, a 1986 study of 458 adult inpatients admitted for alcohol and other drug (AOD) dependence to South Oaks Hospital in New York found that 9 percent satisfied diagnostic criteria for pathological gambling and an additional 10 percent had some gambling problems. These rates are many times higher than are found among the general public. In a parallel study of 100 younger AOD inpatients (average age 17), 14 percent met criteria for pathological gambling and an additional 14 percent had some gambling problems. In a later study of cocaine-dependent outpatients, Dr. Bruce Rounsaville at Yale University found pathological gambling in 19 percent of the male and 5.5 percent of the female subjects. Failure to recognize and address gambling problems during treatment for alcohol or other drug dependence often leads to relapse to substance use in a gambling situation. Less frequently, the result is a switch of addictions from alcohol or another drug to gambling.

EPIDEMIOLOGY OF PATHOLOGICAL GAMBLING

Epidemiological studies conducted during the 1980s in New York, New Jersey, Maryland, and Quebec yielded similar estimates. Approximately 1.5 percent of adults were found to be probable pathological gamblers and an additional 2.5 percent were found to have some gambling-related problems. In contrast, a lower prevalence was found in Iowa. Unlike the other jurisdictions studied, in which legal gambling was well established, Iowa had just initiated a state lottery at the time of the survey. The Iowa rate climbed over the next few years, and subsequent studies by Dr. Rachel Volberg found that the prevalence of gambling problems in several states correlated with the state's per capita lottery sales and the number of years of exposure of the state's population to legal gambling.

Dr. Howard Shaffer of Harvard and his colleagues conducted a meta-analysis of 120 epidemiological studies of gambling problems in the scientific literature to try to approximate an overall prevalence rate. They found that among adults, about 1.6 percent had a diagnosis of pathological gambling at some time in their lives and an additional 3.9 percent had gambling problems. Criteria for a current diagnosis was met by about 1.1 percent, while 2.8 percent had current gambling problems of a lesser severity.

In general-population studies in the United States, males outnumber females among probable pathological gamblers by a ratio of about two to one. This is in sharp contrast to male to female ratios observed in treatment programs and GA groups, which are closer to eight or nine males to one female. Some general-population studies in the United States have also found an overrepresentation of nonwhite adults (blacks and Hispanics) among probable pathological gamblers; but these groups, like women, are also underrepresented in treatment and GA populations.

Although less is known about the prevalence of pathological gambling among adolescents than among adults, several surveys of high school students revealed that the vast majority gamble to some extent and that many have problems. For example, a New Jersey study of nearly 900 students found that over 90 percent had gambled at some time in their lives and about 35 percent did so at least weekly. Approximately 5.7 percent of these eleventh- and twelfth-grade students—9.5 percent of boys and 2 percent of girls—were classified as probable pathological gamblers. The Shaffer study found consistently higher rates of both gambling problems and pathological gambling in adolescent and college-age populations.

Established risk factors for pathological gambling include being male, having a family history of heavy or problem gambling or of parental alcoholism, and early interest and participation in gam-

bling activities. In addition, some studies show higher rates of problems in people who are non-Caucasian, unmarried, have less than a high school education, have less than average income, or are under the age of thirty.

CLINICAL CHARACTERISTICS

Gambling usually begins in adolescence, although women may begin gambling later in life. Pathological gambling often develops in three phases, originally described by Custer (1985): (1) the winning phase; (2) the losing phase; and (3) the desperation phase. Female pathological gamblers tend to have a later onset of the illness than males, and may never experience a winning phase.

The Winning Phase. Pathological gamblers often start as winners. Also, in a minority of cases, a significant upsurge in gambling activity begins with a "big win"—a sum equal to half a year's income or more. With or without the big win, individuals developing a dependence on gambling often begin with some success. In this context, they develop an intense interest in gambling and derive an increasing proportion of their self-esteem from feeling smart or lucky. The high derived from being in action becomes a major source of pleasure, a solution to life problems, a remedy for boredom, anger, anxiety, depression, and other uncomfortable feeling states. Bets must be gradually increased in size, in frequency, and sometimes in riskiness to produce the desired psychological effects. This phenomenon parallels the development of tolerance in the substance-dependent patient who must continue to increase the alcohol or drug dosage to reach the preferred feeling state. At this stage of the illness, the gambler devotes a great deal of time and effort to handicapping, studying the sports page, selecting a lottery number, or following the stock market, as well as to the gambling itself. As one gambler put it, "When I'm not occupied with gambling I'm preoccupied with it." Even if the gambler is winning more often than losing, time and emotional investment are withdrawn from friends, family, work, and other interests. The gambler's spouse often senses that something is wrong, but may not identify gambling as the problem. Marital counseling is sometimes sought.

An unreasonable attitude of optimism is also common during the early phase of pathological gambling, sustained by concentrating on wins and making excuses for (or even denying) losses. Because of this denial, the gambler often cannot account for money claimed to have been won. Pathological gamblers who begin with a winning phase are often those who state they gamble for excitement or stimulation.

The Losing Phase. All gamblers know that when on a losing streak it is wise to stop wagering, at least temporarily. For the compulsive gambler, however, losses are experienced as a severe injury to self-esteem. This produces an intense drive to continue gambling in an effort to recoup the money that has been lost, called *chasing losses*. Chasing losses is an important characteristic of this disease and an example of the pathological gambler's impaired control of gambling behavior. Chasing losses accelerates the gambler's losing and initiates a downward spiral. As the gambling debts mount, the pathological gambler will use any and all money available—take out loans, sell property, and gamble with money meant for family necessities. When these sources are exhausted, extended family members or friends may be approached for a "bailout," in the form of a loan or gift to relieve immediate financial pressure. In return, the pathological gambler often promises to give up gambling. However, part of the bailout money is usually gambled in the hope of another big win, and the downward spiral resumes. Although there are both wins and losses during the losing phase, the overall result is mounting emotional and financial distress as well as interference with social, vocational, and family functioning. Serious depression and a variety of stress-related somatic disorders are often experienced. Pathological gamblers report insomnia, gastrointestinal symptoms, dizziness, headache, hypertension, palpitations, chest pains, and breathing problems. Medical help may be sought, but again the connection to gambling behavior is seldom recognized. Family problems become more intense and divorce often results. Alcohol and other drug abuse may accompany gambling and/or function as a substitute when gambling is temporarily interrupted.

Pathological gamblers also describe a WITHDRAWAL syndrome when they are prevented from gambling. Symptoms include craving, restlessness, irritability, insomnia, headache, weakness, gastrointestinal symptoms, shakiness, and muscle aches.

Those pathological gamblers who do not experience a winning phase often describe themselves as

gambling for "escape" (from life problems that seem insoluble). However, by the time the disease is well-developed, most pathological gamblers report gambling for both escape and excitement.

The Desperation Phase. The desperation phase often begins when all legitimate sources of funds are exhausted. The gambling now takes on a desperate quality. The gambler's behavior during this phase may be characterized by activities inconsistent with the individual's previous moral standards, such as lying, embezzling, larceny, and forgery. These activities are justified as temporary expedients until the next big win. Pathological gamblers are often imprisoned both for white-collar crime and for illegal gambling activities such as bookmaking. Violent crime is less common. Studies of prison populations have found gambling problems in 15 to 30 percent of inmates.

An irrational belief in the inevitability of a big win sustains hope to some degree during this phase. Family problems become more intense and mood swings are common. Severe anxiety, major depression, and suicidal behavior are increasingly noted during the late stages of the disease. Manic or hypomanic states are also seen in some cases. Most pathological gamblers who enter treatment or Gamblers Anonymous do so in the desperation phase. Surveys of Gamblers Anonymous have reported suicide attempts by 17 to 24 percent of members.

PATHOPHYSIOLOGY

Several studies have examined neurochemical changes in pathological gamblers. One study measured levels of NEUROTRANSMITTERS and their metabolites in the body fluids of male pathological gamblers, comparing these to levels in normal male subjects. The researchers found an elevated level of a NOREPINEPHRINE metabolite in the gamblers' urine and cerebrospinal fluid, presumably caused by an increased production of the neurotransmitter norepinephrine within the brain. Furthermore, a psychological measure of extraversion in the gamblers was correlated with levels of norepinephrine and its metabolites in their body fluids. Other, less direct evidence suggests the involvement of additional neurotransmitters, including DOPAMINE and SEROTONIN. A single study of beta ENDORPHINS in pathological gamblers found lower baseline levels in those who bet on horse races than those who played poker-machines or those who were not gamblers. Although research on the pathophysiology of this disease is still preliminary, commonalities with other addictions through central nervous system mechanisms are being sought.

IDENTIFICATION AND TREATMENT

Since 1987 a valid and reliable paper-and-pencil test, the South Oaks Gambling Screen (SOGS), has been available for screening general or clinical populations for gambling problems. The maximum score on this screening test is 20. A score of 5 or more indicates probable pathological gambling, while a score of 1 to 4 signals some gambling problem. Following screening a formal diagnosis must be established. A thorough assessment of physical, psychiatric, addictive, family, social, financial, and legal problems is also necessary because multiple problems are common. Alcohol and drug dependencies, psychiatric disorders and physical problems are most effectively treated at the same time as the gambling addiction. Several psychoactive medications have been tried as adjuncts to the treatment of pathological gambling. Among them, fluvoxamine, a selective serotonin reuptake inhibitor (SSRI), has shown some promise. However, definitive studies have not yet been reported.

Treatment may be provided in both inpatient and outpatient settings. Psychoeducation, individual and group therapies, psychodrama, relaxation training, family counseling and RELAPSE PREVENTION training are commonly used treatment techniques, usually combined with an introduction to Gamblers Anonymous. Family treatment and long-term follow-up are important as well. Abstinence from all forms of gambling is one of the treatment goals, along with improved physical and psychological well-being.

Addiction model treatment may be organized either in a separate facility or as part of a combined substance-dependence and pathological-gambling program. Studies of patients involved in both models of the addiction program have yielded positive outcomes, with gambling abstinence in 56 to 64 percent of the patients who were followed, and improvement in many other aspects of their lives.

American society has paid little attention to the development and application of methods to prevent gambling problems. Most efforts to date involve regulation of the availability of gambling (e.g., minors are forbidden to buy lottery tickets or play in

casinos) and posting notices of the availability of help, usually in the form of a toll-free helpline number. The government has made almost no effort to educate youth or the general public about risk factors for pathological gambling and its dangers, in spite of the high prevalence of gambling problems among adolescents. Although children of problem gamblers and alcoholics are known to be at higher risk than others, they have not been the target of organized prevention programs. Since the 1980s, makers of trading cards (e.g., baseball or basketball cards) have begun to insert valuable so-called *chase cards* at random into the packets of cards at pre-determined rates (e.g., one special card per 700 cards), to stimulate interest in purchasing the product. Because this is similar to a lottery, there has been concern about its immediate and future effects on the children who buy these packets in hopes of finding the valuable cards.

OTHER MODELS OF PATHOLOGICAL GAMBLING

Pathological gambling has been explained using models other than addictive disease. It has been considered, for example, a symptom of some other psychiatric disorder, a behavior disorder, learned behavior that can be "unlearned", a moral problem, or the result of a faulty gambling strategy. Based on behavioral principles, several types of behavior therapy have been applied to gambling problems. The addiction model has, however, proved a useful framework for research, intervention, treatment and self-help. As future research clarifies the neurophysiological mechanisms that underlie alcohol and other drug addiction, both the neurochemical basis of pathological gambling and a "common pathway" of addiction in the brain may also be discovered.

GAMMA-AMINOBUTYRIC ACID (GABA)

This is an amino acid derived by a single-step decarboxylation from GLUTAMATE. GABA is the most abundant (in micromolar concentrations/mg of protein) inhibitory NEUROTRANSMITTER—and it is found throughout the animal kingdom. Its role as a neurotransmitter was first defined for the inhibitory nerve in lobster muscle, where GABA accounted for the total inhibitory potency of nerve extracts. A central inhibitory neurotransmitter role for GABA

was securely established only when selective ANTAGONISTS, such as bicuculline, discriminated GABA receptors and pathways from glycine, a related inhibitory amino acid neurotransmitter. GABA actions and receptors for GABA have been linked to central nervous system sedatives such as ALCOHOL and BENZODIAZEPINES.

GANGS AND DRUGS Youth gangs have been part of the U.S. urban landscape for over 200 years. From the earliest mentions of gangs in the social commentaries of post-Revolutionary War America, gangs have been linked to the use and trafficking of illicit intoxicants. In the late eighteenth century, for example, gangs such as the Fly Boys, the Smith's Vly gang, and the Bowery Boys were well known in the streets of New York City (Sante, 1991). As European immigration increased in the early nineteenth century, gangs such as the Kerryonians (from County Kerry in Ireland) and the Forty Thieves formed in the overcrowded slums of the Lower East Side (of New York City). Gangs proliferated quickly in that time, with such colorful names as the Plug Uglies, the Roach Guards, the Hide-Binders (comprised mainly of butchers), the Old Slippers (a group of shoemakers' apprentices) and the Shirt Tails. Many of these gangs were born in the corner groceries that were the business and social center of the neighborhoods. These groceries also hid the groggeries that were important features of neighborhood life, and guarding them provided a steady income for the gangs. Although not involved in theft, robbery, or the unsavory professions of GAMBLING or tavern-keeping, these gangs warred regularly over territory with weapons—including stones and early versions of the blackjack. They occasionally joined forces to defend their neighborhood, and nearly all were united in their opposition to the police.

Throughout the nineteenth century, gangs emerged in the large cities of the Northeast, in Chicago and in other industrial centers of the Midwest. In the early twentieth century, gangs also formed in the Mexican immigrant communities of California and the Southwest. In what still is widely regarded as the classic work on youth gangs, Thrasher (1927) identified over 1,300 street gangs in the economically disadvantaged neighborhoods of industrial Chicago in the 1920s. He interpreted the rise of Chicago's gangs as symptoms of deteriorating neighborhoods and the shifting populations that accompanied industrialization and the changing populations that lived in the interstitial areas between the central city and the industrial regions that ringed it. Wherever neighborhoods in large cities were in transition, gangs emerged, and their involvement in drinking and minor drug use was a regular feature of gang life.

In the 1990s, gangs became present in large and small cities in nearly every state. They reflect the ethnic and racial diversity of American society (Klein, 1992). Gangs are no longer colorful, turf-oriented groups of adolescents from immigrant or poor neighborhoods. Whereas gangs in the past were likely to claim streetcorners as their turf, gangs today may invoke the concept of turf to stake claims to shopping malls, skating rinks, school corridors, or even cliques of women. Gangs use graffiti and "tagging" to mark turf and communicate news and messages to other gangs and gang members

(Huff, 1989). The participation and roles of young women in gangs has also changed. Through the 1960s, women were involved in gangs either as auxiliaries or branches of males gangs, or they were weapons carriers and decoys for male gang members. Today, female gangs have emerged that are independent of male gangs. Fights are common between the new female gangs. There also is some evidence of sexually integrated gangs, where females fight alongside males (Taylor, 1993).

Traditionally, stealing and other petty economic crimes have long been the backbone of gang economic life. For example, Saint Francis of Assisi commented that nothing gave him greater pleasure than stealing in the company of his friends. English common law in the 13th century accorded especially harsh punishments to the roving bands of youths who moved across the countryside stealing from farmers and merchants. The House of Refuge, the first U.S. residential institution for boys, opened in New York City in 1824, largely in response to the unsupervised groups of youths who roamed the city stealing and drinking. For some contemporary gangs, however, entrepreneurial goals, especially involving drug selling, have replaced the cultural goals of ethnic solidarity and neighborhood defense that historically motivated gang participation and activities. A few gangs have functional ties to adult organized crime groups. Other gangs have become involved in drug selling and have developed a corporate structure that has replaced the vertical organization that in the past regulated gang life.

This article examines recent data on the drug and alcohol involvement of street gangs. Recent changes in the social structure of cities has led to a new generation of gangs and gang cities. We look to these changes in cities and neighborhoods to explain the new patterns of substance use and drug distribution among gangs. Changes in the conception of work, the institutionalization of drug selling, and cultural shifts in gangs and ganging, have influenced gang involvement in drugs and alcohol. This article discusses the relationship between political and economic factors that shape the social structure of communities, the neighborhood effects that result from those forces, and the mediating effects of neighborhood processes on the formation of gangs and their use of substances.

DRUG AND ALCOHOL USE AMONG YOUTH GANGS

ALCOHOL and MARIJUANA use have always been, and continue to be, the most widely used substances among both gang and non-gang youths (Fagan, 1989, 1990; Sheley, Smith, & Wright, 1992). Drinking and other drugs (primarily marijuana) consistently are mentioned as a common part of gang life throughout gang literature. For instance, Short and Strodtbeck's (1965) study of Chicago gangs showed that drinking was the second most common activity of gang members of all races, exceeded only by hanging out on the streetcorner. Although COCAINE may be trafficked by some gang members, it is not often used in either its powder or smokeable forms (Fagan, 1990).

Ethnographic studies of gang life (Hagedorn, 1988; Campbell, 1990; Stumphauzer, Veloz & Aiken, 1981; Vigil, 1988; Padilla, 1992; Moore, 1978, 1992a, 1992b; Taylor, 1993) also show the commonplace occurrence of drinking and its place in a broad pattern of substance use. Dolan and Finney (1984) and Campbell (1990) illustrated the commonplace role of drug use in gang life among both males and females. Stumphauzer et al. (1981) noted that use patterns varied within and among Los Angeles gangs, but changed for individuals over time. MacLeod (1987) noted high rates of drinking among white gang members but only occasional beer use among the Brothers, a predominantly black (but somewhat integrated) gang. Sanchez-Jankowski (1991) found that all members of all gangs drank regularly, using gang proceeds for collective purchases. Although they used drugs in varying patterns, alcohol was mentioned consistently. But Sanchez-Jankowski also mentioned that the Irish gangs least often used illicit drugs, since access was controlled by nonwhites with whom they did not want to engage in business.

Vigil (1985, 1988) described a variety of meanings and roles of substances among Chicano gang members in East Los Angeles, from social "lubricant" during times of collective relaxation to facilitator for observance of ritual behaviors such as *locura* acts of AGGRESSION or VIOLENCE. In these contexts, drug use provided a means of social status and acceptance, as well as mutual reinforcement, and was a natural social process of gang life. Vigil (1988) notes that these patterns are confined to substances that enhance gang social proccesses—

alcohol, marijuana, PHENCYCLIDINE (PCP), and CRACK-cocaine. There is a sanction against HEROIN use among Chicano gangs. Heroin involvement is seen as a betrayal of the gang and the barrio; one cannot be loyal to his addiction and the addict ("tecato") culture while maintaining loyalty to the gang. Vigil noted that gang members prepared for imminent fights with other gangs by drinking and smoking PCP-laced cigarettes. During social gatherings, the gang members used the same combinations to "kick back" and feel more relaxed among one another. Evidently, gang members had substantial knowledge about the effects of alcohol (and its reactivity to PCP), and they had developed processes to adjust their reactions to the mood and behaviors they wanted.

Feldman el al. (1985) observed three distinct "styles" among Latino gangs in San Francisco that in part were determined by the role and meaning of substances in gang social processes. The "fighting" style included males in gangs who were antagonistic toward other gangs. They aggressively responded to any perceived move into their turf by other gangs or any outsider. Drinking and drug use were evident among these gangs, but this was only situationally related to their violence through territoriality. Violence occurred in many contexts unrelated to drug use or selling and was an important part of the social process of gang affiliation. The "entrepreneurial" style consisted of youths who were concerned with attaining social status by means of money and the things money can buy. They very often were active in small-scale illegal sales of marijuana, pill amphetamines, and PCP. While fighting and violence were part of this style, it was again situationally motivated by concerns over money or drugs. The last style was evident in gangs whose activities were social and recreational, with little or no evidence of fighting or violence but high rates of drinking and marijuana use.

Padilla's (1992) study of a Puerto Rican gang in Chicago described how alcohol and marijuana often accompanied the rituals of induction and expulsion of gang members. These ceremonies often were tearful and emotional, with strong references to ethnic solidarity. Padilla described how emotions intensified as the ceremony progressed, and drinking was a continuous process during the events.

Drinking or drug use also is disallowed in some youth gangs, regardless of the gang's involvement in drug selling. Chin (1990) found that intoxication was rejected entirely by Chineses gangs in New York City. Although they used violence to protect their business territories from encroachment by other gangs, and to coerce their victims to participate in the gang's ventures, "angry" violence was rare; violent transactions were limited to instrumental attacks on other gangs.

Taylor (1990a) and Mieczkowski (1986) described organizations of adolescent drug sellers in Detroit who prohibited drug use among their members but tolerated drinking. Leaders in these groups were wary of threats to efficiency and security if street-level sellers were high and to the potential for co-optation of its business goals if one of its members became involved with consumption of their goods. The gangs were organized around income and saw drug use (but not alcohol) as detracting from the selling skills and productivity of their members. Expulsion from the gang resulted from breaking this rule, but other violent reprisals also were possible. However, gangs in both studies accepted recreational use of substances by members, primarily alcohol, marijuana, and cocaine in social situations not involved with dealing.

In the Mieczkowski study, the sellers particularly found danger in being high on any drug while on the job. Gang superiors enforced the prohibition against heroin use while working by denying runners their consignment and, accordingly, shutting off their source of income. Violence was occasionally used by superiors (crew bosses) to enforce discipline. Gang members looked down on their heroin-using customers, despite having tried it at some point in their lives, which in part explains the general ideology of disapproval of heroin use.

Buford (1980) depicted crowd violence among English football (soccer) "supporters" as an inevitable consequence of the game's setting and the dynamics of crowds of youths. Expectancies of both intoxication and violence preceded the arrival of the "lads" at drinking locations surrounding the stadiums. The expectancies were played out in crowd behavior through rituals that were repeated before each match. Alcohol consumption before and during episodes of unrestrained crowd violence was an integral part of the group dynamic, but Buford does not attribute to alcohol an excuse function, nor is alcohol a necessary ingredient for the relaxation of social norms. In fact, he pointedly notes that the heaviest drinkers were incapacitated by inebriation and were ineffective rioters, while

the crowd leaders were relatively light drinkers. In this context, alcohol was central but hardly necessary to the attainment of the expected behavior—the setting itself provided the context and cues for violence.

GANGS AND DRUG SELLING

In the 1980s, the confluence of social problems involving gangs, violence, and drug trafficking changed both popular and political perceptions of gangs. Beginning with the crack-cocaine crisis, youth gangs have been confounded with new forms of drug distribution organizations that involve young men and women in "underclass" neighborhoods. This terminology has been interchangeably used to describe these groups as gangs. Indeed, the growth in cocaine use in the 1980s did coincide with more visible gang involvement in drug selling and drug-related violence (Huff, 1992). Although drug use and selling have been central features of gang life for decades, gangs were often blamed for many of the new drug problems (Newsweek, 1986; U.S. Department of Justice, 1989; Conley, 1992; Los Angeles County District Attorney, 1992). Once seen as streetcorner groups protecting "turf" and neighborhood, gangs were portrayed in the 1980s by the popular press and criminal-justice officials as nascent organized-crime groups focused on the distribution of drugs, with elaborate intercity networks well-financed by drug income.

Several trends contributed to this changing characterization of gangs. First, gangs became highly visible. Although gangs traditionally have been active in larger cities, gangs emerged in the 1980s in smaller cities—with populations as low as 25,000 (U.S. Department of Justice, 1989). Among the 100 largest U.S. cities, gangs have emerged in 42 cities since 1980 (Klein, 1992). Their recent emergence may belie their stability, however, since gangs are well known to often be temporary groupings with short half-lives (Spergel, 1989). The validity of police reports of gang activity itself remains a difficult measurement problem.

Second, gang violence has become more visible if not more prevalent. Gang-related homicides in Los Angeles grew sharply throughout the 1980s, exceeding 500 annually after 1989 (Los Angeles County District Attorney, 1992). In 1991, record homicide rates were set in both Los Angeles and Chicago, two cities with extensive youth-gang networks (FBI, 1992). Yet the classification of homicides as "gang-related" is quite sensitive to definitions; and this trend, too, may reflect anomalies in definition and measurement of gangs and gang incidents. Maxson and Klein (1989) showed that the Los Angeles Police Department rates, based on the gang affiliations of victims or perpetrators, could be halved by applying the motive-based definition used by the Chicago Police Department.

Third, gang involvement in drug trafficking reportedly grew in the 1980s (U.S. Department of Justice, 1989; Spergel, 1990; but see Moore, 1992a). Spergel (1990) found that 75 percent of gang members on probation in San Diego County were convicted of drug offenses at one time or another. Among the 1,200 youths in Chicago, Los Angeles, and San Diego interviewed by Fagan (1990), 32 percent of the gang members reported they were involved in drug selling, compared to fewer than 8 percent of the nongang youths. Based on 45 interviews with California prison inmates Skolnick et al. (1989) claimed that linkages existed between prison gangs and street gangs around drug distribution. But Klein et al. (1991) showed that adolescent participation in rock-cocaine selling in Los Angeles grew equally for gang and nongang youths.

Drug selling also contributed to changes in the organization and meaning of gangs. Taylor (1990b) and Mieczkowski (1986) illustrated the transformation of Detroit gangs from streetcorner groups protecting territory to highly efficient drug-selling organizations. Padilla (1992) describes how Puerto Rican youths in a Chicago gang refocused the gang to drug dealing as the primary source of income. Hagedorn (1991) showed that twenty-two of thirty-seven African-American gang members in Milwaukee went on to become involved in adult drug organizations.

Fourth, reports of gang migration contributed to the perception of gangs as highly disciplined entrepreneurs intent on establishing intercity drug networks to expand their profits. Gang members are alleged to have set up "franchises" or branch offices in remote cities for selling drugs. Huff (1992) reports arrests of Los Angeles gang members in large and small Ohio cities and Detroit gang members in Cleveland (1989); members of Los Angeles gangs have been arrested on drug charges in cities as far east as Columbus (Ohio) (U.S. Department of Justice, 1989). This diffusion of gang activity

from the major gang centers of Los Angeles and Chicago is often cited as a bellwether of the evolution of gangs to a new and more dangerous form.

The temporal proximity of these trends led to their confounding in the popular and sociological literatures, with hasty assumptions that they were causally linked. Few phenomena have been stereotyped as easily as gangs, violence, and drug use, especially in conjunction. These perceptions were amplified in the popular culture through movies and hip-hop music depicting gang life as a stew of violence, drug money, police repression, and the exploitation of women (Taylor, 1992). These perceptions were fueled by gang-related violence in the theaters at the opening of recent films depicting gang life (*Colors*, *Boyz 'n the 'Hood*), as well as reports of violence at rap concerts and in local clubs specializing in "house" and "hip-hop" music (Huff, 1992). These cultural vehicles falsely signaled a transformation of youth gangs from streetcorner groups to more sophisticated crime groups reaping great profits from drug distribution and specializing in lethal violence. In the context of the crack crisis of the mid-1980s and the violence that accompanied it, these portrayals also created a perception that there was an increase in gangs—with more youths in gangs and more violent gangs in urban centers throughout the United States.

The 1980s' changes in drug-use trends, together with earlier changes in labor markets, income dynamics, and demographics in urban centers, suggest that the drug-gang nexus is part of a larger, more complex process of urban change tied to the economic and social transformation of cities. This was a significant era because of the sharp reduction in wholesale cocaine prices, the emergence of crack, and the expansion of street-level drug markets for cocaine and crack distribution (Fagan, 1992a). Reports from law-enforcement agencies suggest that by 1980 gangs formed in smaller cities not traditionally known as gang centers (Klein, 1992), and having little to do with drugs (Fagan & Klein, 1992). This was also an era marked by the emergence or persistent poverty in urban centers and the growth of an "urban underclass" (Wilson, 1987, 1991; Jargowsky & Bane, 1990; Ricketts & Sawhill, 1988; Jencks, 1991). In fact, the emergence of gangs in the 1980s was motivated by broad changes in economic and social conditions during the 1970s, changes that reflected deindustrialization and growing social and economic isolation in large U.S. cities (Jackson, 1991; Hagedorn, 1988; Sullivan, 1989; Fagan & Klein, 1992).

Despite the historically uneven relationship between gangs and drug use or selling (Klein, Maxson, & Cunningham, 1991; Spergel, 1989; Fagan, 1989), recent studies contend that the lucrative and decentralized crack markets in inner cities have created a new generation of youth gangs (Skolnick et al. 1989; Taylor, 1990b). Young drug sellers in these gangs have been portrayed as ruthless entrepreneurs, highly disciplined and coldly efficient in their business activities, and often using violence selectively and instrumentally in the service of profits. This vision of urban gangs suggests a sharp change from the gangs of past decades, and much of the change is attributed to the dynamics of the inexpensive, smokeable cocaine market.

The empirical data suggest otherwise (Fagan, 1989, 1990; Klein et al. 1991; Vigil, 1988; Padilla, 1992; Moore, 1992b; Hagedorn, 1988). Drug selling has always been a part of gang life, with diverse meanings tied to specific contexts and variable participation by gangs and gang members (Fagan, 1990). For example, Fagan (1989) found diverse patterns of drug selling within and across three cities with extensive, integenerational gang traditions, while Klein et al. (1992) reported variability within and across Los Angeles gangs in crack selling.

GANGS, DRUGS, AND NEIGHBORHOOD CHANGE

What are the changes that occurred in cities and communities to explain variation and change in gang participation in drug selling? Two factors have in particular contributed to changes in gangs and the substitution of instrumental and monetary goals for the cultural or territorial affinities that unified gangs in earlier decades. First, cocaine markets changed dramatically in the 1980s, with sharp price reductions. Before cocaine became widely available, drug distribution was centralized, with a small street-level network of heroin users responsible for retail sales (Curtis, 1992; Johnson et al., 1985). The heroin markets from the 1970s were smaller than the mid-1980s crack market, both in total volume of sales and the average purchase amount and quantity. Street-level drug selling in New York City, for example, was a family-centered heroin and marijuana business until the 1980s,

when new organizations developed to control the distribution of cocaine (Curtis, 1992; Johnson et al., 1990). The psychoactive effects of HEROIN (a depressant) and its methods of administration (by injection) limited its sales volume and number of users.

Cocaine was different in every way—a stimulant rather than a depressant, ingested in a variety of ways (nasally, smoked, or injected), and with a shorter half-life for the "high." The price declined as cocaine became widely available, and the discontinuity in distribution systems across successive drug eras created new opportunities for drug selling, and may even have encouraged participation in it. The sudden change in cocaine marketing, from a restricted and controlled market in the 1970s to a fully deregulated market for crack, spawned intense competition for territory and market share (Fagan, 1992a; Williams, 1989). Law-enforcement officials in New York City characterized the crack industry as "capitalism gone mad" (New York Times, 1989).

In inner-city neighborhoods that since the 1970s had grown more socially isolated, and where legal economic activity was declining quickly, drug selling became a common form of labor market participation. Young men began to talk about drug selling and crime as "going to work" and the money earned as "getting paid" (Padilla, 1992; Sullivan, 1989). In the closed milieu of these neighborhoods, the tales of extraordinary incomes had great salience and were widely accepted, even if the likelihood of such riches was exaggerated (Bourgois, 1989; Reuter, MacCoun, & Murphy, 1990; Fagan, 1992a, 1992b). The focus of socialization and expectations shifted from disorganized groups of adult males to (what was perceived as) highly organized and increasingly wealthy young drug sellers. Many other sellers kept one foot in both licit and illicit work, lending ambiguity to definitions of work and income (Reuter et al., 1990; Fagan, 1992a, 1992b).

Second, profound changes in the social and economic makeup of cities (Tienda, 1989; Wacquant & Wilson, 1989) combined to disrupt social controls that in the past mediated gang behavior (Curry & Spergel, 1988). In this context, gangs became less concerned with cultural or territorial affinities and instead became focused on instrumental and monetary goals (Taylor, 1990; Padilla, 1992; but see Moore, 1992a). The interaction of these two trends provided ample opportunities for gangs to enter into the expanding cocaine economy of the 1980s.

As drug selling expanded into declining local labor markets, it became institutionalized within the local economies of the neighborhoods. Whether in storefronts, from behind the counters in *bodegas* (groceries), on streetcorners, in crack or "freak" houses, or through several types of "fronts," drug selling was a common and visible feature of the neighborhoods (Hamid, 1992). Young men and, increasingly, women had several employment options within drug markets—support roles (lookout, steerer), manufacturing (cut, package), or direct street sales (Johnson et al., 1990). Legendary tales, often with little truth, circulated about how a few dollars' worth of cocaine could be turned into several thousand dollars within a short time. Such quick riches had incalculable appeal for people in chronic or desperate poverty.

THE IMPACT OF DRUGS ON GANGS AND GANG CULTURE

The transition from streetcorner group to ethnic enterprise profoundly shaped the social organization of youth gangs. Money became the driving force and organizing principle for these groups. Greed was elevated to a set of beliefs, expressed consistently among gangs and gang members in the neighborhoods with extensive drug markets (Padilla, 1992). The use of the language of work ("getting paid," "going to work") to describe drug selling signals an ideological shift in the social definition of work and the confounding of illegal and legal means of making money. For the young men using this language, there was no particular meaning assigned to drug selling: they pursued commodities that offered instrumental value as signs of wealth (Sullivan, 1989; Padilla, 1992). Any high-demand contraband consumable commodity would likely have inspired the same behavior (as for example weapons, guns).

Not surprisingly, "materialism" is evident in the motivations expressed by young people participating in drug selling—the attainment of wealth as a manifestation of individual power and achievement. Within the isolated, concentrated poverty areas in inner cities, the absence of mediating social definitions allowed the pursuit of material wealth to become transformed into the very substance of so-

cietal bonds and conventional values. Americans always have looked up to the Horatio Algers, whose "self-made" business success defied social odds. As these models were elevated to societal icons, the attainment of wealth seemed to supersede the importance of law or the collective societal good (Wall Street Journal, 1989).

The interaction of drug selling, violence, and material goals often are combined in an emerging set of sociocultural processes within gangs. Padilla (1992) describes how older gang members reoriented the gangs to become business organizations to fuel increases that were disproportionately taken by the older members. In effect, the older members became local employers themselves. Since the older members were no longer the keepers of the culture and regulators of gang organization, they used traditional appeals to ethnic and neighborhood loyalties to recruit and motivate younger gang members. However, they added money incentives to the mix to strengthen their controls over young gang members.

The emphasis on money, individual gain, and quick wealth was so strong that gang members in Detroit (Taylor, 1990a) and Padilla's Chicago neighborhood themselves regarded low-level drug sellers, even their own "homeboys," as "working stiffs" who were being exploited by other gang members. In the past, such denigration of gang work was heretical: entry level jobs in the service of the gang typically would be seen as serving the gang's collective interest. Padilla describes how the new pattern of exploitation of lower-level workers (street sellers) in the gang was obscured by appeals to gang ideology (honor, ethnic solidarity, and neighborhood loyalty) combined with the lure of income to control them. Taylor (1990a) also talks about the use of money as social control within Detroit drug-selling gangs—if a worker steps out of line, he simply is cut off from the business, a punishment far more salient than threats to physical safety. Moore (1992b) describes similar age-related exploitation within chicano gangs in Los Angeles but with little involvement in drug selling.

The exaggerated, almost ideological emphasis on money and material wealth interacts in a very complex fashion with ethnicity and local context. It marks a dramatic shift from the gangs of 1970 to 1985. It is difficult to disentangle the order of events. Did drugs bring in more money, and did money take on greater importance (raised the stakes) because of the economic transformation of the cities? Or did the loss of economic structures make drugs more salient? Did the increased stakes/money bring in guns, which in turn increased the lethality of gang violence? Or did the guns come as a manifestation of power for those who are rejected from any other source of economic or personal power?

In Chicago (Padilla, 1992) and Detroit (Taylor, 1990a, 1990b, 1992), gangs superficially are ethnic enterprises, but more substantively serve as economic units with management structures oriented toward the maintenance of profitability and efficiency. For the African-American gangs in Detroit, there was little concern with the neighborhood or the traditional meaning of gang life. Although forms of internal control varied, money was manipulated along with appeals to ethnic solidarity to maintain loyalty and discipline within groups that otherwise had evolved from gangs or streetcorner groups to become economic organizations. Among the "Diamonds" in Chicago, appeals to Puerto Rican solidarity were used by older gang members to maintain order and motivation within the gang, while these older members kept the lion's share of the gang's profits from drug sales.

GANG MIGRATION

The appearance of Crips, Bloods, Vice Lords, Black Gangster Disciples, Latin Kings, and other well-known gang names in new gang cities across the country has created concerns that gangs are expanding and migrating. Migration is a term that actually includes several distinct patterns: franchising, opening "branch offices," or acquiring and operating local subsidiaries. Gang migration was virtually unknown until the 1980s, when law enforcement and media reports claimed that gang members were setting up illegal businesses in other cities to expand their drug-selling territories.

There are few instances of gangs operating directly in other cities. Migration seems to be concentrated along interstate highway routes, such as I-75 ('Caine Lane, named for its volume of cocaine traffic) connecting Detroit with Ohio cities, or the I-5 route from Los Angeles through California's Central and San Joaquin valleys (Huff, 1992). Others (Waldorf, 1992) found no evidence of gang migration among San Francisco gangs, either in-migration from Los Angeles gangs or reports of

gang members doing gang "business" in other cities.

More often, what appears as migration reflects natural social dynamics of residential relocation, court placements, mimicry, and other forms of gang diffusion. Gang migration also has been confused with the enterprising behavior of individual gang members. There have been sporadic incidents of deliberate migration, isolated among specific gangs in specific cities. But most often, local gangs are composed of local youths who may have adopted the names, graffiti, and other symbols of established gangs from the larger cities.

There are few documented instances of gang migration. Hagedorn (1988) reported that Milwaukee gangs adopted the name of the Vice Lords, a Chicago gang, but had little contact with them. Some Crip or Blood members relocating from Los Angeles may have organized small crews to sell drugs, but law-enforcement officials interpreted this as evidence that Crip chapters had opened in their cities. Chicago gang graffiti appeared in Mississippi as young males were sent away to live with relatives to escape gang violence; but this event was viewed as signs of Chicago gang expansion into the South (Lemann, 1991).

Critics suggest federal initiatives and funds to control gangs have created incentives (and funds) for zealous law-enforcement agencies to identify streetcorner groups or drug gangs as interstate gang conspiracies. Indeed, there have been isolated instances of what Carl Taylor (1990b) calls gang "imperialism," where gangs have established business locations in other cities. Most often, this includes drug selling—and nearly always among entrepreneurial or corporate gangs. Their motives appear to be simply market expansion and increasing profits. Chicago gangs have influenced the gang scene in nearby Evanston. Chinese street gangs operate both regionally throughout the New York metropolitan area and in cities in the Northeast including Philadelphia, Albany, and Hartford (Chin, 1990). The Chinese gangs are not involved in drug trafficking, but their multiple enterprises include extortion and the smuggling of illegal aliens.

SUMMARY

Few phenomena have been stereotyped as easily as gangs, violence, and drug use, especially in conjunction. Drug use has always been a part of gang life, as has peddling of small quantities of whatever street drugs were popular at the time. Many gangs also adopted codes prohibiting drug use, fearing that loyalty to one's drug habit conflicts with loyalty to the gang or efficiency in drug selling. The cocaine and crack crises of the 1980s created opportunities for gang and nongang youths alike to participate in drug selling and increase their incomes. There is little evidence that gang members have become involved in drug selling more so than nongang adolescents. Malcolm Klein and his colleagues, based on police arrest reports following the appearance of crack in Los Angeles in 1985, found no evidence that gang members were arrested more often than nongang members for crack sales, or that drug-related homicides were more likely to involve gang members than nongang members.

Among gangs, involvement in the drug trade varies by locale and ethnicity. Chicano gangs in Los Angeles do not sell cocaine but sell small quantities of other drugs. The crack and cocaine trades are dominated by African-American youths, both gang members and nongang youths. Crack sales began in Chicago more than five years after Los Angeles gangs began selling drugs. As in Los Angeles, both gang and nongang youths are involved. Crack sales in New York flourished beginning in 1986, but there was no discernible street gang structure that participated in drug selling. Instead, loosely-affiliated selling crews provided an organizational structure for drug sales. Chinese gangs have remained outside the cocaine and crack trades. However, some members (but not the gangs themselves) have been involved in transporting or guarding heroin shipments from Asia.

Not all gang members sell drugs, even within gangs where drug selling is common. Drug-selling cliques within gangs are responsible for gang drug sales. These cliques are organized around gang members who have contacts with drug wholesalers or importers. Among the "Diamonds," Padilla (1992) describes how drug selling is a high-status role reserved for gang members who have succeeded at the more basic economic tasks of stealing and robbery. Despite public images of gang members using drug profits for conspicuous consumption of luxury items, drug incomes in fact are quite modest for gang members who sell drugs. Drug incomes are shared within the gang, but the bulk of the profits remain with the clique or gang member

who brought the drugs into the gang. The profits from drug selling, combined with the decline in economic "exits" from gang life, provide some incentive for older gang members to remain in the gang.

JEFFREY FAGAN

GANJA Ganja is a Hindi word (derived from Sanskritic) for the HEMP plant, *Cannabis sativa* (marijuana); the term *ganja* entered English in the late seventeenth century. Ganja is a selected and potent preparation of MARIJUANA used for smoking.

The hemp plant was introduced into the British West Indies by indentured laborers from India who arrived in Jamaica in 1845. Considered to be a "holy" plant, ganja is often used in religious ceremonies in both countries. The Indian Hemp Drug Commission traced the origin of ganja use to India.

Although usually smoked, *Cannabis* may also be mixed with foods or drinks; it is considered a remedy for many ailments in herbal medicine. A medical-anthropological study of ganja users in Jamaica was conducted in 1972; the results revealed little evidence of a deleterious effect among users, as compared with nonusers. These conclusions were criticized, however, by investigators who claim that the tests of maturation and mental capacity that were used were not sensitive enough to detect decrements in higher level mental skills or motivation.

GATEWAY FOUNDATION *See* Treatment Programs/Centers/Organizations: An Historical Perspective

GENDER AND COMPLICATIONS OF SUBSTANCE ABUSE Does gender have an influence on whether a drug has complications? There is limited research available to answer this question, for many studies include men only. In general, women drink less often and in smaller amounts than men do, and they suffer fewer ALCOHOL-related problems and less dependence (WITHDRAWAL) symptoms. Women use illicit drugs less often than men do, although women have a higher consumption of prescription tranquilizers, sleeping pills, and over-the-counter drugs. Thus, the differences seen between the genders in complications largely reflect the differences in the respective patterns and prevalence of their alcohol and drug use.

The effects of the drugs are relatively similar between men and women. For example, in a heavy drinking and heavy SMOKING sample population, there is little difference in the mortality rates between men and women. Alcohol- and drug-using women are more likely to have partners who are alcohol and drug users. Such women are often victims of violence. Illicit-drug-using women frequently support their drug habits by prostitution, putting themselves at risk for sexually transmitted diseases (STDs) including HUMAN IMMUNODEFICIENCY VIRUS (HIV) and hepatitis B, even if they are not needle users. Accidents and trauma related to substance abuse are more common in men. The skid-row lifestyle is more common in men. Men report DRINKING AND DRIVING more often than women.

ALCOHOL

Women appear to be more susceptible than men are to alcohol-related LIVER damage. For women, cirrhosis may develop with consumption of 20 grams of alcohol (1–2 drinks) per day—as compared to 80 grams (6 drinks) per day for men. Women alcoholics have death rates 50 to 100 percent higher than their male counterparts. Women develop hypertension, obesity, anemia, malnutrition, and gastrointestinal hemorrhage at lower alcohol consumption levels and with a shorter time course of drinking. Women become intoxicated after drinking smaller quantities of alcohol than do men. For an equivalent dose of alcohol corrected for body weight, women absorb alcohol faster and reach a higher peak BLOOD ALCOHOL CONCENTRATION compared to men. These differences can be explained, in part, by the lower total body water of women compared to men. With a higher percentage of fat and lower water content, there is less volume in which to dilute the alcohol, and its concentration is therefore increased. Women also produce less stomach alcohol dehydrogenase—the enzyme re-

sponsible for breaking down alcohol. This leads to higher blood alcohol levels, since less is metabolized as it passes through the wall of the stomach and, therefore, as compared to men, more alcohol gets into the bloodstream. There may also be some hormonal or immune effects that account for the increased damage in women.

TOBACCO

Women are at risk for all the same health complications of smoking as are men. The differences seen in the 1990s largely reflect the lower prevalence of women smokers in past generations. For example, as smoking rates have increased in women, lung cancer rates have also increased.

REPRODUCTION

A woman's drinking pattern may be influenced by the mood changes associated with the phases of the menstrual cycle, and her blood alcohol level actually measures higher during the premenstrual period for any given amount of alcohol. This may make it difficult for a woman to predict the effects of her drinking. Oral contraceptives interact with cigarette smoking in contributing to coronary heart disease in women. Cigarette smoking is also correlated with an earlier onset of menopause. In her role as childbearer, a woman's substance use may have harmful effects on the FETUS and newborn. These effects may be related to her lifestyle, such as poor nutrition and poor prenatal care, or to the toxic effects of the drugs themselves resulting in fetal growth retardation, at-birth neonatal abstinence syndrome (withdrawal), and neurobehavioral abnormalities in the child.

Alcohol, tobacco, and illicit drugs like COCAINE and HEROIN are all associated with decreased fertility, increased rate of spontaneous abortion (miscarriage), and decreased birthweight in the newborn. The severely dependent woman may stop menstruating altogether. Menses resume, however, when abstinence or stabilization on methadone maintenance is achieved.

JOYCE F. SCHNEIDERMAN
REVISED BY REBECCA J. FREY

GENE A gene is a unit of heredity that confers some trait or function on the organism. Most genes are thought to be essential to development and normal functioning. Genes are often a primary determinant of interpersonal differences; for example, they determine whether you have blue or brown eyes. A disrupted or mutated gene can cause serious, even fatal problems. Genes are composed of DNA and found in the chromosomes in the nucleus of a cell. At present, we are on the verge of identifying all the human genes due to the efforts of the genome projects.

MICHAEL J. KUHAR

GENE REGULATION: DRUGS To understand the regulation of genes, the following sequence of events must be appreciated: A gene, made of DNA, is "transcribed" to produce a messenger RNA, or mRNA, that is "translated" to produce a protein product. Gene regulation refers to the regulation of production of mRNA from the gene.

Although every organism contains a collection of genes necessary for its survival and reproduction, not every gene is turned on or is producing mRNA at any given moment. At any moment or stage of development such as in the adult, only a subpopulation of genes is expressed (i.e., producing mRNA). During the development and growth of an organism, certain gene products guide and program growth. Because only a subgroup of the genome is expressed at any stage of the life cycle, gene regulation must occur. Gene regulation also occurs during a life cycle as in the adult brain.

A gene contains an important part called the "promoter" that controls the rate at which mRNA is produced. A human gene, for example, can be expressed or turned on when the promoter is activated. For the purposes of our discussion here, the promoter of a gene is the site of gene regulation. Perhaps a reasonable analogy is that a promoter is like a light switch; the switch must be "activated" or turned to "on" before light can be produced, and not every light has to be turned on. There are many different kinds of promoters, each of which is turned on or off by its own "transcription factor", which is a protein that binds to the promoter region of a gene and alters the rate of transcription (production of mRNA).

The brain has evolved such that receptors for drugs and neurotransmitters, through complex biochemistry, can affect the state of the promoters for genes by activating transcription factors. The active transcription factor then regulates gene expression by binding to the promoter region of the gene.

A simplified summary of the events involved in gene regulation is as follows: A drug is taken and it goes to the brain where it interacts with its receptor; the activated receptor, through biochemical pathways, can activate transcription factors; the transcription factors then bind to the promoter of the gene; binding of the transcription factor to the promoter changes the rate (faster or slower) at which the gene produces mRNA, which ultimately changes the level of the protein product in the cell. The most important point for consideration here is that drugs of abuse can change the biochemical composition of the brain by this mechanism or pathway. Many scientists believe that change in brain composition by this mechanism are one of the bases for drug addiction. It is often said that the drug dependent brain is a changed brain, and this is what that statement means. Drugs change the balance of proteins in the brain and that influences how the brain functions.

Understanding how drugs change brain protein composition by altering gene regulation is an important area of research, because this is a key to understanding what makes a brain (and, of course, a person) addicted. Once that is understood, then we can begin to repair the addicted brain by intervening in various ways or by reversing such changes in brain protein composition. If gene regulation can be controlled or influenced, then the protein composition of the brain can be influenced, and the way the brain functions can be correspondingly influenced. Science does not have the knowledge or skill to do this now, but it is one of many hopes for the future.

GENETICS *See* Causes of Substance Abuse: Genetic Factors; Vulnerability as Cause of Substance Abuse: Genetics

GENOME PROJECT The project with the goal of sequencing the human genome, which is the collection of all human genes. In the 1990s, a scientific commitment was made to identify all the genes in human chromosomes, and some other organelles such as mitochondrion. This involved international cooperation and a very significant effort by many laboratories. Genes are made of DNA, which is composed of sequences of four different nucleotides, with perhaps as many as three billion nucleotides total in the genome. The genome project's goal is to determine all the nucleotides and their sequence, and then make this information available through the Internet. A gene is a functional segment of this DNA sequence that produces a product, an mRNA, which in turn guides the formation of a protein. Estimates of the number of genes in humans vary widely, with the averages falling in the range of 70,000 to perhaps 120,000. It is believed that identifying the genome sequence is the first step necessary for producing dramatic advances in biology and medicine. In addition to the human genome project, there are similar on-going projects attempting to sequence the genomes of other organisms as well.

MICHAEL J. KUHAR

GINSENG Ginseng is the most revered and well-known plant of Chinese herbal medicine; it is sold over the counter in Asian apothecaries and groceries worldwide. This plant of the family Araliaceae grows on both sides of the Pacific, with *Panax schinseng* the Asian form and *Panax quinquefolius* the North American form. It is a perennial herb with five-foliate leaves, and its fleshy aromatic root is valued as a tonic and a medicine.

The root has been used by Native Americans, Siberians, Chinese, and other Asians for millennia. Usually it is taken as a tea—once a day as a general preventative tonic, more frequently for therapeutic purposes. Since the North American form is considered the most potent, it is now grown in ASIA along with the local variety. American ginseng is also exported to Asia, then sometimes reimported into the United States as a Chinese or Korean herbal. Both the wild and cultivated forms are used. Roots older than five years are needed for good effect, and the older and larger the root (seven to fifteen years is prized), the more the ginseng costs. Dried roots

Figure 1
Ginseng

are heated and sliced thinly to make tea, but pieces may be kept in the mouth, sucked, and eaten. The many ginseng products now sold (sodas, candies, etc.) have no real tonic or therapeutic value.

Ginseng has a bittersweet aromatic flavor, contains ALKALOIDS, and is said to be good for mental arousal and general well-being. It has not been established in Western medicine and pharmacology, although it contains properties that might be isolated and used pharmacologically.

GLUE/GLUE SNIFFING *See* Inhalants

GLUTAMATE Glutamate (GLU) is a dicarboxylic aliphatic amino acid. Chemically symbolized as $COOH\text{-}CH_2\text{-}CH_2[NH_2]\text{-}COOH$, it is abundant (micromolar concentrations/mg protein) in NEURONS (nerve cells) as well as in almost all other cells of the body. Its role as the major excitatory NEUROTRANSMITTER in the brain was recognized reluctantly; its universal ability to excite all neurons was considered too nonspecific for a neurotransmitter, so it awaited the development of drugs that antagonized GLU and the specific neuropathways from which it was released.

Its source for this special role in NEUROTRANSMISSION is unknown, but the synaptic vesicles of glutamatergic neurons have a selective ion-ex-

change mechanism to compartmentalize GLU from other metabolic pathways. Excessive GLU-receptor activation can lead to neuronal death.

FLOYD BLOOM

GLUTETHIMIDE Glutethimide was introduced into clinical medicine in 1954. It was prescribed to treat insomnia and sold as Doriden. It was first acclaimed as a safer "nonbarbiturate" hypnotic—implying that it was free of the problems of abuse, addiction, and withdrawal that were, by then, recognized drawbacks of the older barbiturate SEDATIVE-HYPNOTICS. Within ten years, however, it was recognized that, in most respects, its actions are like those of the BARBITURATES and it shares the same disadvantages.

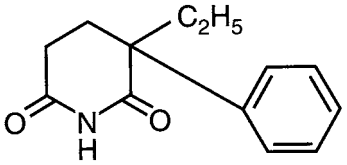

Figure 1
Glutethimide

Glutethimide is structurally related to the barbiturate drugs and, like the short-acting barbiturates, it depresses or slows the central nervous system. Side effects from its proper use are relatively minor, but a rash is often seen. Like barbiturates, it can produce intoxication and euphoria; TOLERANCE and DEPENDENCE can result with daily use. Glutethimide is metabolized somewhat differently than barbiturates, and OVERDOSE is often far more difficult to treat than barbiturate overdose; fatalities are not uncommon. As a consequence of this and its ABUSE POTENTIAL, glutethimide is included in Schedule III of the CONTROLLED SUBSTANCES ACT. Since the introduction of the BENZODIAZEPINES to treat short-term insomnia, the use of glutethimide has decreased considerably.

SCOTT E. LUKAS

GOLDEN TRIANGLE AS DRUG SOURCE The world's largest illicit OPIUM-growing area is the Golden Triangle—a region in Southeast Asia of some 150,000 square miles (388,500 sq km). The Golden Triangle extends from the Chin hills in the west of Myanmar (formerly Burma), north into China's Yunnan province, east into Laos and Thailand's northern provinces, and south into the Kayah state of Myanmar. It encompasses all the Shan state in Myanmar and supplied some 35 percent of the HEROIN used in the United States between the 1960s and early 1990s. Between 1990 and 1999, however, changes in heroin trafficking greatly reduced the importation of heroin from Southeast Asia. In 1990, Myanmar, Thailand, and Laos supplied about 56 percent of the heroin consumed in the United States. By 1999, Latin America supplied most of the heroin to the United States, accounting for 82 percent of the heroin seized in the U.S. The Southeast Asian opium crop, which was on the rise in the early 1990s, suffered a sharp decline due to adverse weather in the later 1990s.

The United States Government has supplied millions of dollars to Myanmar and Thailand in an effort to reduce OPIUM-POPPY (*Papaver somniferum*) cultivation and interdict heroin destined for the United States. As they have done for years, disenfranchised tribal people cultivate opium as a medicinal and cultural product, as a cash crop to buy food and supplies and improve living conditions, and as a means to procure weapons. Political events in Southeast Asia are complex and are changing constantly. The U.S. government has managed a limited success in helping to reduce opium cultivation in Laos and Thailand; it is anxious over the increased production in Myanmar and the increasing flow of heroin exiting that country

via China to Hong Kong, through Rangoon toward Malaysia and Singapore, and through India and Bangladesh.

THE OPIUM SUPPLY

The Golden Triangle had favorable weather in the early 1990s, which resulted in record opium crops. By far the largest producer is Myanmar, which until 1988 had attempted to reduce illicit opium production, strike at illicit refineries, and interdict shipments of illicit drugs. In 1988, however, the military government shifted its police and military away from drug-control efforts, to suppress domestic political opponents. This policy did not shift during the 1990s, despite constant efforts by the United States to have Myanmar take more effective antidrug actions. Myanmar produces over 50 percent of the world's opium.

Laos, isolated and largely ignored by the West since 1975 when the Communist Pathet Lao seized power, cultivated opium in its nine northern provinces—about 20 percent of Myanmar's production. Partly because of the 1990 collapse of the Soviet Union, Laos's principal trading partner and ally, the Laotian government has entered into a number of cooperative agreements with Western nations. Opium production decreased by 16 percent from 1998 to 1999, due mostly to severe weather. However, Laos still accounted for 11 percent of the production in the region.

Thailand is more important as a TRANSIT COUNTRY for Myanmar's opium and heroin. Thailand's already marginal production dropped 38 per cent in 1999, accounting for less than one percent of Southeast Asia's potential production. A traditional producer of opium since the mid-1800s and a net importer of heroin, Thailand's opium is grown in the northern highlands by nomadic hill tribes who are not tied to Thailand culturally, religiously, or politically. Opium cultivation in Thailand remains illegal, so the government has sponsored both eradication and crop-substitution efforts in the north.

China has become a major narcotics transit point because of its open border with Myanmar, its location adjacent to the Golden Triangle, and its excellent transportation and communication links with the trade ports of Hong Kong and Macao. Much of the heroin processed from opium by the Kokang Chinese in the Golden Triangle transits through Yunnan, Guangxi, and Guangdong provinces by road to Hong Kong for overseas distribution.

CULTIVATION CONDITIONS

A number of factors have contributed to the thriving opium economy of the Golden Triangle—and the complex politics surrounding and sustaining it. First, the topographical and climatic conditions are ideal for opium cultivation. The demographic conditions also provide a division of labor conducive to an economic system rooted in drug cultivation, processing, and trafficking. The area under cultivation is largely mountainous, ranging from about 5,000 feet (1,500 m) to more than 9,850 feet (3,000 m), with four major river systems supporting the transportation networks and any ongoing economic-development efforts. The remote harsh terrain has fostered great efforts to topple the central governments and to capitalize on the economic opportunities offered by the opium trade.

Second, the ethnography of the region is complex. The region is inhabited by a multitude of ethnic groups, possessing a diversity that defies simple classification. Burman, Shan, Kachin, Thai, and Yunnanese are broad categories that contain widely varied ethnic subgroups. At least twenty-five mutually unintelligible dialects are spoken among the Kachin people. Moreover, there are numerous other groups who do not belong to the larger ethnic division—such as Ahka, Hmong (Miao), Lisu, Lahu, Karenni, and Wa, to name a few. Most of these groups are nomadic—not geographically localized; therefore, little basis exists for territorial political organization. Yet, national boundaries have paid little heed to this fact and have often cut apart ethnic groups, fueling insurgency as the dominant form of politics in the region.

Cultivating opium in the Golden Triangle has been a way of life since the mid-1800s and has represented an important source of income for impoverished, nomadic hill tribes.

HAIR ANALYSIS AS A TEST FOR DRUG USE Because every drug taken becomes a permanent part of the user's hair, laboratory analysis of hair can reveal the presence of a variety of drugs, including HEROIN, COCAINE, AMPHETAMINES, PHENCYCLIDINE, MARIJUANA, NICOTINE, and BARBITURATES. Hair analysis is widely accepted by courts, parole boards, police departments, and employers around the country for detecting long-term drug use. It's also increasingly used to determine maternal/fetal drug exposure and to validate self-reports of drug use.

Unlike urinalysis, which can only detect drugs ingested within the past three to four days, hair analysis can reveal the ingestion of drugs during the past ninety days (or longer). Since hair grows at a relatively constant rate of ½ inch (1 cm) per month, segmental analysis of hair strands could localize the time of drug exposure to within as little as one particular week. Although various hair treatments—such as tinting and perming—may remove some of the evidence, detectable traces will indelibly remain in the hair.

DRUGS IN HAIR

Hair is nonliving tissue composed primarily of a sulfur-rich protein called keratin. Hair growth occurs at a rate of 0.3 to 0.4 millimeters (0.011 to 0.012 inches) per day from the follicle (a saclike organ in the skin) in cycles of active growth followed by a resting phase. For an adult, approximately 85 percent of scalp hair is in the growing stage at any time. Two sets of glands are associated with the follicle: The sebaceous glands, which excrete sebum (a waxy substance), and the apocrine glands, which excrete an oil that coats the hair. Hair color is determined by genetic programming for varying amounts of melanin, a pigment that is synthesized in hair cells called melanocytes.

The exact mechanism by which drugs enter hair is unknown. They may be deposited from the capillaries, which supply blood to the follicles, or they may be excreted in the sebum, oil, or sweat that coat the hair shafts. Drugs can also be deposited on

Psychemedics Corporation president Raymond Kubacki shows his company's new drug testing pack at a press conference in New York City, July 12, 1995. The kit allows parents to clip a lock of their children's hair and mail it in to test for drug use. (Reuters/Mark Cardwell/Archive Photos)

the hair by environmental exposure (such as marijuana smoke or cocaine powder in the air).

When hair is analyzed for drug use, a sample is taken from either the head or the body. It's washed to remove dirt and any external drug deposits (the wash medium is also tested), then stripped of melanin. The actual analysis is performed by RADIOIMMUNOASSAY that detects not only traces of drugs but their *metabolites*, chemicals that appear only when the body has metabolized (processed) the drug. All positive samples are confirmed by gas chromatography/mass spectrometry (GC/MS). This second test has a cutoff level to eliminate specimens containing drug levels that could come from environmental exposure (inhaling second-hand marijuana smoke or eating food that contains poppy seeds).

SIGNIFICANCE OF HAIR TESTING

Once a drug is embedded in hair it appears to be stable indefinitely, although concentration diminishes somewhat over time. (Cocaine metabolite has, for example, been detected in hair from a pre-Columbian mummy more than 500 years old.) This is an obvious advantage over other methods of DRUG TESTING, such as urinalysis, which can detect drugs ingested only within the past few days. Depending on length, hair analysis can determine drug use from months to years in the past. Hair is also easily collected and stored. If more testing is required, another sample may be easily obtained.

One disadvantage of hair analysis is that it won't reveal drug use during the three to five days before testing, since hair does not grow quickly enough to show this. Hair analysis is also more expensive than urinalysis, and the results take longer to be determined. The two tests can always be used in combination, however, to give a more complete picture of the individual's past and present drug use.

IS IT FAIR?

Some groups have raised concerns that hair testing may be biased against minority subjects because coarser, darker hair tends to trap more environmental drug residue than lighter, thinner hair. Hair testing labs say that their processes, which remove melanin from samples, removes any chance of distinction or discrimination by race or ethnic group. The Society of Forensic Toxicologists disagrees, arguing that even removing the pigment from hair does not eliminate the risk of bias in analysis.

Definitive proof of drug use, however, is based not on environmental exposure to drugs, but on the metabolites incorporated into the hair shaft. These indicators can only appear when the subject's body has metabolized the drug. The results of hair analysis are widely used and accepted by courts, law enforcement bureaus, and government agencies, including Federal Reserve banks and more than 80 state programs and medical research projects.

REVISED BY AMY LOERCH STRYMOLO

HALF-LIFE *See* Dose-Response Relationship

HALFWAY HOUSES Although the term is of recent origin as used in connection with alcohol or drug treatment, the basic idea of the *halfway house* is almost two hundred years old. It designates a residential facility that provides a drug-free environment for individuals recovering from drug or alcohol problems but not yet able to live independently without jeopardizing their progress. By definition, halfway houses are not located in hospitals or PRISONS, but they vary in the extent to which they are integrated with local community life, and in size, sponsorship, sources of financial support, regulatory status (licensed or unlicensed by a state agency), treatment philosophy, and the degree of legal coercion to which residents are subject. Some specialize in alcohol abusers or drug abusers, while some serve both; some focus on specific population groups like offenders, ADOLESCENTS, or WOMEN, while others are inclusive. Some will accept only those with at least a few days of abstinence; others provide DETOXIFICATION services. Some are loosely structured and rely for staff on recovering people; others provide formal treatment and employ a professional staff.

In sum, the term covers a lot of ground and has no stable meaning. Indeed, its meaning in any given state depends on that state's licensing provisions, and whether these make any distinctions among halfway houses, recovery homes, and other similar forms of residential treatment. At a minimum, however, the term implies a group of people with alcohol and/or drug problems living together in a formal, therapeutic arrangement and abiding by the rule of abstinence. In 1987, there were more than 1,300 such programs in North America, many of them members of the National Association of Halfway Houses.

Although there is increasing interest in establishing residential forms that tolerate off-site consumption that does not disrupt facility life, these would not be considered halfway houses in the common use of the term. Further, because the halfway house is a sponsored, therapeutic program, however informally operated, it is everywhere subject to special zoning ordinances that regulate the location of therapeutic agencies. Thus, the halfway house is distinct from what is called "alcohol and drug-free (or sober) housing." The latter is designed to be part of a locality's ordinary housing stock and to be exempt from such regulation.

The Federal Anti-Drug Abuse Act of 1988 (Public Law 100-690) included a provision to encourage the development of ALCOHOL- AND DRUG-FREE HOUSING. Each state that receives federal block grant funds for drug and alcohol programs must establish a 100,000 dollar revolving fund to make start-up loans for such facilities. Although this money can be used to develop halfway houses, as we have defined them, the revolving fund has in practice been used to stimulate less formal approaches to housing recovering people.

JEROME H. JAFFE

HALLUCINATION The word *hallucinate* is derived from the Greek *halyein*, meaning "to wander in mind." Hallucinations are perceptions that occur in the absence of a corresponding external sensory stimulus. They are experienced by the person who has them as immediate, involuntary, vivid, and real. They may involve any sensory system, and hence there are several types of hallucinations: auditory, visual, tactile (e.g., sensations on the skin), olfactory (smell), and gustatory (tastes). Visual hallucinations range from simple (e.g., flashes of light) to elaborate visions. Auditory hallucinations can be noises, a voice, or several voices carrying on a conversation. In command hallucinations, the voices often order the person to do things that at times involve acts of violence.

Hallucinations have been a hallmark of mental illness throughout history. They are an important clinical feature of several psychiatric conditions in which psychosis can occur, such as SCHIZOPHRENIA, manic-depressive illness, major DEPRESSION, and dissociative states. WITHDRAWAL from ALCOHOL can cause visual as well as other sensory hallucinations. In alcoholic hallucinosis, a person dependent on alcohol develops mainly auditory hallucinations that can persist after the person has stopped drinking. Hallucinations may be induced by illicit drugs, such as COCAINE, AMPHETAMINES, and LSD. These hallucinations are usually visual, but they can also be auditory or tactile, as in the sensation of insects crawling up the skin (an example of a haptic hallucination). Occasionally, after repeated ingestion of drugs, some people experience "flashbacks"—that is, spontaneous visual hallucinations during a drug-free state, often months or years later.

The cause of hallucinations is not known, but it is likely to be multifactorial through a combination of physiological, biological, and psychological variables. Numerous hypotheses have been proposed. According to a perceptual release theory, hallucinations develop from the combined presence of intense states of psychological arousal and decreased sensory input from the environment (e.g., sensory deprivation) or a reduced ability to attend to the sensory input (e.g., in delirium). This leads to the emergence of earlier images and sensations that are intepreted as originating in the environment. Other researchers suggest that abnormalities in brain cell excitability or in the information processing system of the central nervous system cause hallucinations. Biochemical theories implicate brain NEUROTRANSMITTERS such as DOPAMINE. Drugs that block brain dopamine activity (ANTIPSYCHOTICS) alleviate hallucinations, whereas drugs that stimulate dopamine release induce hallucinations.

Hallucinations can occur in people who are not mentally ill. In acute bereavement, some people report seeing or hearing the deceased. Sensory, SLEEP, food, and water deprivation can produce hallucinations, as can the transition from sleep to wakefulness and vice versa (called hypnopompic and hypnogogic hallucinations, respectively). These hallucinations can occur as side effects of prescribed medications, such as drugs that treat cardiac conditions, or in various medical disorders (e.g., migraines, Parkinson's Disease, infections). They have been described in persons with hearing loss and blindness; in these instances, it has been hypothesized that they may be due to chronic sensory deprivation.

The treatment of hallucinations is part of the treatment of the entire psychotic syndrome. Antipsychotic medications (e.g., haloperidol, chlorpromazine) are effective in reducing and often eliminating hallucinations. When the hallucinations are part of a medical disorder, it is necessary to correct the underlying condition, or remove the causative agent, in addition to prescribing antipsychotic medication.

KAREN PARKER

HALLUCINOGENIC PLANTS Literally hundreds of hallucinogenic substances are found in

many species of plants. For example, a variety of mushrooms contain indole-type HALLUCINOGENS, the most publicized being the Mexican or "magic" mushroom, *Psilocybe mexicana*, which contains both the hallucinogenic compounds PSILOCYBIN and psilocin, as do some of the other *Psilocybe* and *Conocybe* species. The PEYOTE cactus (*Lophophra williamsii* or *Anhalonium lewinii*), which is found in the southwestern United States and northern Mexico, contains MESCALINE. The seeds of the MORNING GLORY, *Ipomoea*, contain hallucinogenic LYSERGIC ACID derivatives, particularly lysergic acid amide. Many of these plants and plant by-products were and are used during religious ceremonies by Native Americans and other ethnic groups.

Some plant substances may contain prodrugs, that is to say, compounds that are chemically altered in the body to produce PSYCHOACTIVE substances. For example, NUTMEG contains elemicin and myristicin, whose structures have some similarities to the hallucinogen mescaline as well as the psychostimulant AMPHETAMINE. It has been hypothesized that elemicin and myristicin might be metabolized in the body to form amphetamine- and/or mescaline-like compounds, but this has not been proven. The fact that hallucinogenic substances are found in nature does not mean that they are safer or purer than compounds that have been synthesized in the laboratory. Some common edible mushrooms that can be purchased in any supermarket may be sprinkled with LSD or other hallucinogens to be misrepresented as magic mushrooms. In addition, serious problems—even death—may occur when species of hallucinogenic plants are misidentified and people mistakenly ingest highly toxic plants, such as poisonous mushrooms.

R. N. PECHNICK

HALLUCINOGENS The term *hallucinogen* literally means producer of HALLUCINATIONS. A variety of drugs and medicines as well as various disease states can lead to the development of hallucinations. They can occur during a high fever, after acute brain injuries, or as part of a DELIRIUM, accompanied by confusion in judgment, intellect, memory, emotion, and level of consciousness. The patient is said to be "out of it"—not in touch with reality. In fact, many infections affecting the brain, conditions that disrupt the availability of nutrients essential for brain function, or direct brain injury can cause transient or prolonged delirium. Disease states not directly involving the brain also can alter brain function. For example, the overproduction of thyroid or adrenal hormones in endocrine disease can cause psychotic mental symptoms. In addition, poisoning or other toxic reactions can produce hallucinations.

Some drugs used to treat certain illnesses, although not prescribed for their behavioral effects, may be PSYCHOACTIVE and cause auditory and/or visual hallucinations in some but not all patients. High doses of the adrenal hormone, cortisone, which is prescribed to reduce inflammation in arthritis or allergies, can produce elation or depression and mood-related hallucinations. Similarly, the administration of thyroid hormones for the treatment of thyroid grand deficiencies can cause restlessness, nervousness, excitability and irritability, and psychotic mental symptoms. Drugs derived from the belladonna plant, such as atropine and SCOPOLAMINE, have many uses in clinical medicine but in high doses can cause memory lapses and illusions. Delirium also may result from the sudden withdrawal after the chronic administration of certain drugs, especially ethanol (ALCOHOL) and SEDATIVE drugs of the BARBITURATE class. The vivid hallucinations of DELIRIUM TREMENS (DTs) during the WITHDRAWAL from alcohol have been vividly portrayed in the cinema and television.

Many drugs that affect behavior can alter the level of consciousness or the perception of the environment. PHENCYCLIDINE (known as PCP or "angel

dust") can produce a state of altered consciousness in which sensations from the body and relationship to the environment are misinterpreted. The subject may experience numbness in the limbs and feel as though they are removed from their bodies. These distorted perceptions of the real world can lead to confusion, delusions, and hallucinations—and violent behavior can occur with the slightest provocation. There is controversy as to whether these varied reactions are psychotomimetic (imitating mental illness with psychoses), but not about the extent to which, depending on the dose, subjects are out of it. High and/or frequent doses of stimulants such as AMPHETAMINE, METHAMPHETAMINE ("speed" or "ice"), or COCAINE can cause paranoid thought or delusions. Moreover, high doses of MARIJUANA or HASHISH can lead to dreamy illusions or hallucinations. Thus, many drugs under certain conditions can cause hallucinations as part of the production of a complex behavioral syndrome, which may include a general alteration of the level of consciousness and the disruption of the ability of the brain to process information and appreciate the real world.

The term *hallucinogens* has come to mean a group of compounds that reliably, temporarily, and universally alter consciousness without delirium, sedation, excessive stimulation, or any intellectual or memory impairment as prominent effects. Indeed these altered mental effects are the main effects of such drugs. There are a number of synonyms for drugs that produce hallucinations that occur with clear consciousness, but the term *psychedelic* has come into wide use. In the 1960s the term was coined by Humphrey Osmond, a British psychiatrist who came to North America to continue studies of the psychiatric effects of MESCALINE and LSD, and was enthusiastic about their use in enhancing insight in psychotherapy. The term *psychedelic* was invented from greek roots to mean "mind manifesting," from *psyche* (mind, soul) + *deloun* (to show). This refers to the convincing clarity with which a subjective experience is compellingly revealed to the subject who has taken a hallucinogen. What is seen, thought, and felt is vivid—contrasting sharply with the normally ordered perceptions of the world in which we move about and perform our practical tasks. Key to the hallucinogenic experience is that drab everyday reality, while clearly perceived in this drug state, has simply lost its importance in favor of vivid subjective sensations and perceptions and interpretations of them that absorb attention. A door is recognized but not simply for its utility; rather the grain of the wood and its fine detail becomes fascinating, and the grain of the wood seems to move and flow. Thus, during the hallucinogenic experience, it is not the utility of what is seen but rather some aspect of shapes and colors and passing thoughts or memories that take on a life of their own, commanding attentive interest. The color of an object is more important than the object. The subjective impact is that thoughts and sights have some uncanny, undeniable, but inexplicit meaning. The sense of great truth is present, but not an urge to test the truth of these images. Rather, one is a spectator of a "TV show in the head." These events are not only clearly "seen" but remembered without confusion. This has been called "consciousness expanding," implying control over a vast span of experiencing. That is wrong, since judgment is *not* enhanced. Rather, the effect is of enhancing the sense of importance of normally unimportant subjective experiences of sensations and perceptions.

Since with hallucinogens everything—even the most familiar scenes—seems novel and is seen in a new way, the experience is in startling contrast with our normal view of the world. Such effects invite many uses. The intrinsic effects of hallucinogenic drugs not only shift perceptions, making the old new, but evoke a loosening of emotions and thoughts. Hence there were efforts to use hallucinogenic drugs therapeutically—to stimulate and enhance new ways of examining problems. But in spite of the alluring promise, no lasting improvement in learning or problem solving has been found after numerous studies. Similarly, the effects produced by hallucinogens seem so significant and strikingly different from everyday life that they can readily be used to enhance mystical thought and belief. Some Native American groups thus use the hallucinogen PEYOTE in religious ceremonies. The intent is to dispose the celebrants to higher thoughts (to be "in the mind of God"); they are told not to attend to the odd perceptions and rather to relax and contemplate higher thoughts. Because with hallucinogens one is not interested in tracking detail, there is greater suggestibility and dependence on structure, on a leader, on a prior belief, or on the flow of music to guide, interpret, or "carry" one through the experiences.

Whether these drugs produce actual hallucinations or, more commonly, illusions (which the subject usually *feels* are very real but *knows* are not) has sometimes been debated, but not the fact that these perceptions occur. Seeing geometric abstract designs is not unusual. A characteristic effect is the experience of sound triggering color and of the mixing rather than the clear separation of different sensory modalities—called *synesthesia*. For example, sounds may be "seen," or colors "heard." What has just been seen—say, a wall clock—sometimes persists as one focuses on a face. Rather than suppressing a previous perception as we normally do, it may linger. Perceptual boundaries are thus loosened.

The commonly abused hallucinogenic substances can be classified according to their chemical structure. All these hallucinogens are organic compounds, and some are found in nature. Hallucinogenic drugs can be placed in two major groups. The first is known as the indole-type hallucinogens. This family of hallucinogens has in common some structural similarities to the NEUROTRANSMITTER SEROTONIN, suggesting that their mechanism of action could involve the disruption of or some alteration in neurotransmission in NEURONS (nerve cells) that use serotonin as the chemical messenger. The indole-type hallucinogens include lysergic acid derivatives such as LYSERGIC ACID DIETHYLAMIDE (LSD) and other compounds that have structural similarities, such as DIMETHYLTRYPTAMINE (DMT), PSILOCYBIN, and psilocin (see Figure 1).

The second major group of hallucinogens is the substituted phenethylamines (see Figure 2). These are MESCALINE, 2,5-dimethoxy-4-methylamphetamine (DOM or STP), 3,4-methylenedioxyamphetamine, (MDA), and 3,4-methylenedioxymethamphetamine (MDMA or ecstasy). These hallucinogens are structurally related to the phenethylamine-type neurotransmitters, NOREPINEPHRINE, epinephrine, and DOPAMINE. As with the indole-type hallucinogens, the structural similarities of the phenethylamine-type hallucinogens to these natural neurotransmitters may indicate that at least

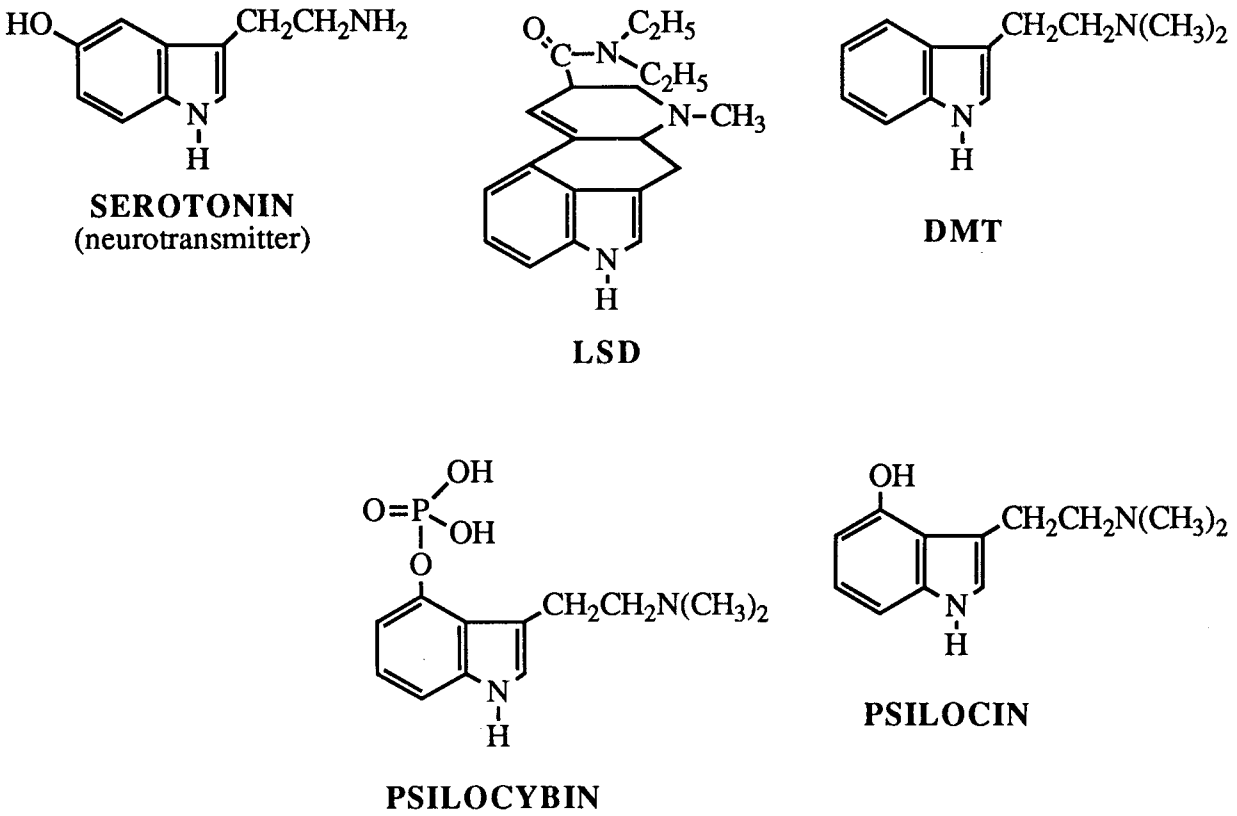

Figure 1
Indole-type Hallucinogens

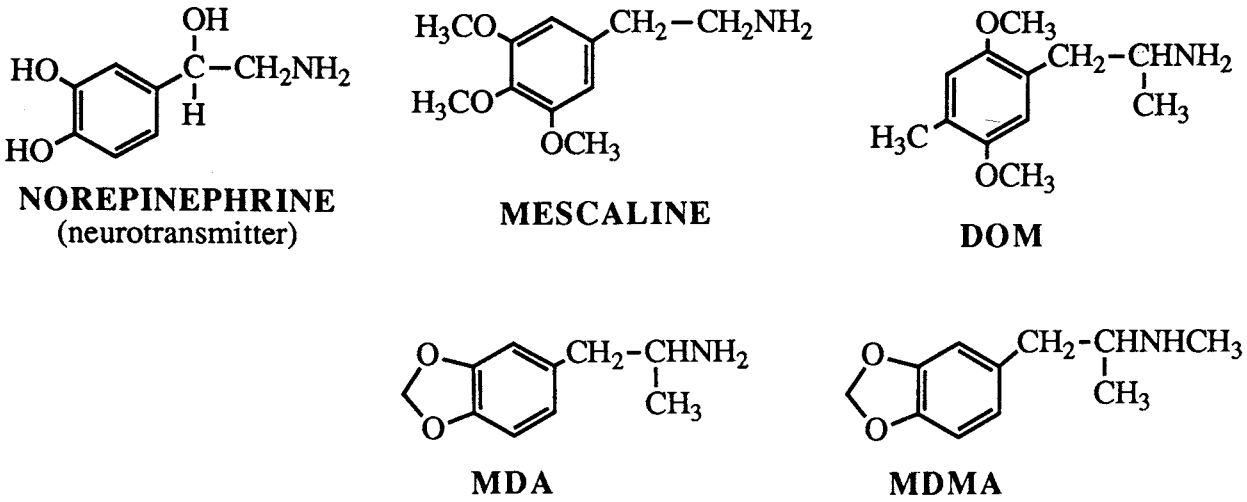

Figure 2
Substituted Phenethylamines

some of their effects involve interactions with systems that use these neurotransmitters. DOM, MDA, and MDMA are synthesized compounds that have structural similarities to the psychostimulant AMPHETAMINE. Thus, they also have some stimulant properties aside from their hallucinogenic activity. They have inaccurately been called psychotomimetic amphetamines, and they are sometimes referred to as stimulant-hallucinogens. It should be pointed out that there are literally hundreds of analogs of the above compounds that have been synthesized and sometimes are found on the street, the so-called DESIGNER DRUGS.

The overall psychological effects of the hallucinogens are quite similar—but the rate of onset, duration of action, and absolute intensity of the effects can differ. As the various hallucinogens differ widely in potency and in the duration of their effects, some of the apparent qualitative differences between hallucinogens may be due, at least in part, to the amount of drug ingested. Aside from their behavioral effects, the hallucinogens also possess significant autonomic activity, meaning that they can affect the sympathetic and parasympathetic nervous systems. The autonomic effects can include marked pupillary dilation and exaggerated reflexes. There may be increases in blood pressure, heart rate, and body temperature. Some of the hallucinogens may initially cause nausea. These autonomic effects of the hallucinogens are variable and may be due, at least in part, to the anxiety state of the user. Acute adverse reactions include panic attacks and self-destructive behavior.

HARRISON NARCOTICS ACT OF 1914

The first international drug-control initiative, the 1909 SHANGHAI OPIUM COMMISSION, brought the international community together in efforts to curb the illicit traffic and consumption of OPIUM, a NARCOTIC drug. The Shanghai Commission encouraged participants to enact national legislation that would address the problem of narcotics in their own countries. Representatives of several countries met at the Hague at conferences in 1911 and 1913.

During this period, the U.S. Congress became aware of public opinion favoring PROHIBITION of all "moral evils," especially alcohol and drugs. New York Representative Francis B. Harrison, encouraged by both the Shanghai Commission's directive to enact national legislation to curb narcotics and the reformists in the Progressive movement in the United States who wanted to eradicate drug use completely, introduced two measures—one to prohibit the importation and nonmedical use of opium and one to regulate the production of opium in the United States. Congress enacted the Harrison Act in December 1914 with minimal debate because public opinion considered its passage necessary to combat the "evils" of drugs.

PROVISIONS OF THE HARRISON ACT

Congress regulated drugs by imposing licensing requirements on manufacturers, distributors, sellers, importers, producers, compounders, and dispensers. The Harrison Act required these parties to register with the director of Internal Revenue, within the Treasury Department, and to pay a gradually increasing occupational tax. Congress wanted to monitor the flow of opium and COCA leaves so that government authorities would have records of any transaction involving these drugs. They would be allowed only for limited medical and scientific purposes. Those individuals found in violation of the act faced a maximum penalty of five years in jail, a 2,000 dollar fine, or both.

TREASURY DEPARTMENT REGULATIONS

Congress intended the Harrison Act to generate revenue by imposing taxes on parties involved in the trade, sale, and distribution of drugs. As a result, Congress entrusted enforcement responsibility to the Treasury Department, in particular the Internal Revenue Service and subsequently the Narcotics Unit of the Bureau of Prohibition. The Treasury Department attempted to limit narcotics to medical and scientific use and prevent their illegal diversion by physicians and druggists. The Harrison Act required pharmacists to review prescriptions to determine whether the quantity was unusually large—that is, a suspicious or coerced prescription.

Sales and transfers of narcotics could only be made pursuant to official order forms obtained from the director of Internal Revenue. District offices of the Internal Revenue Service maintained these records for two years. The act permitted a few notable exceptions to form filings. For example, qualified practitioners (physicians, dentists, and veterinarians) could prescribe or dispense narcotics to patients without completing the order forms but were required to maintain records of all the substances distributed. Druggists could also fill lawful prescriptions without completing order forms.

The Treasury Department interpreted the Harrison Act to prohibit drug addicts from obtaining narcotics. Addicts were prohibited from registering and could receive narcotics only through a licensed physician, dentist, or veterinarian. The Treasury Department regulations also prohibited physicians from maintaining a patient-addict on narcotics, a practice frequently used to help addicts avoid severe WITHDRAWAL pain while they were gradually weaned from narcotic DEPENDENCE. The Treasury Department interpreted possession of narcotics as prima facie evidence of a Harrison Act violation, and the burden of proof shifted to the suspect, who had to document that the narcotics were obtained legally.

The Treasury Department enforced the Harrison Act primarily through warnings. At times, however, the department charged physicians and druggists with conspiracy when authorities arrested an individual who possessed narcotics without a prescription made in good faith, and a connection could be made that the physician or the druggist provided the narcotics.

THE HARRISON ACT AND U.S. DRUG POLICY

Many critics of the Harrison Act argue that the legislation created more problems than it solved. In particular, they charge that the measure failed to eradicate the narcotics problem, primarily because it failed to prohibit the sale and distribution of MARIJUANA. In addition, detractors argue that the act did not resolve the issue of whether drug addicts should be treated as criminals or as patients requiring medical treatment. They also contend that the courts hampered the Treasury Department's enforcement authority. Specifically, courts prohibited the Treasury Department from seizing narcotics, interpreting the Harrison Act to serve as a revenue, rather than as a penal, measure. After passage of the Harrison Act, illicit use of narcotics increased initially as a result of these omissions or ambiguities.

Despite these criticisms, the Harrison Act is significant because it led to a national focus on the dangers of narcotics and drug abuse. Most important, the Harrison Act served as the impetus for further legislation, such as the 1970 Controlled Substances Act, all of which attempt to combat the illegal sale, distribution, and consumption of narcotics and other abusable substances in the United States, while ensuring their availability for medical purposes.

HASHISH Hashish is the Arabic word for a particular form of CANNABIS SATIVA; it came into English at the end of the sixteenth century. Hashish is the resin derived principally from the flowers, bracts, and young leaves of the female hemp plant. The resin contains cannabinoids—the one of major interest being TETRAHYDROCANNABINOL (THC). The THC content will vary depending upon the composition of the hashish, but often it is about 4 percent or more. Usually the resinous portion is sticky enough to allow the material to be compressed into a wafer or brick. Some preparations contain only the resin and are known as hashish oil. Similar preparations of the resinous material and flowering tops of the plant have been given a variety of names in different regions—*charas* in India, *esvar* in Turkey, *anascha* in areas of the former USSR, *kif* in Morocco and parts of the Middle East.

One of the ways in which hashish is prepared is to boil *Cannabis* leaves in water to which butter has been added. THC, being extremely fat-soluble, binds with the butter, which can then be used for making various confections, cookies, and sweets; these are eaten to obtain the effects of the drug. Although hashish is often taken by mouth, it can also be smoked, just as MARIJUANA is.

Hashish was introduced to the West in the middle of the nineteenth century by a French psychiatrist, Moreau de Tours, who experimented with the drug as a means of understanding the phenomenon of mental illnesses. He not only experimented on himself but on a coterie of friends of considerable literary talent. These included Theophile Gautier, Alexander Dumas, and Charles Baudelaire. This group named themselves "Le Club des Haschschins" or "The Club of Hashish-Eaters." The lurid descriptions of the drug effects by these talented writers no doubt helped popularize the drug. Most of their accounts dwelt on beautiful HALLUCINATIONS and a sense of omnipotence.

Doses must have been large, since the effects described are more characteristic of HALLUCINOGENIC DRUGS than effects experienced by present-day users (smokers) of marijuana.

Hashish was introduced into England at about the same time, by an Irish physician, O'Shaughnessy, who had spent some time in India, where he had become familiar with it. The material was soon hailed as a wonder drug, being used for all sorts of complaints: PAIN, muscle spasms, convulsions, migraine headaches, and inflamed tonsils. As most of the preparations were weak and the doses used were small, any beneficial effects might be attributable to a placebo effect.

A preparation, Tilden's Extract of Cannabis Indica, became a popular remedy in the United States in the 1850s. An amateur pharmacologist, Fitz Hugh Ludlow, used this preparation for self-experiments in which he was able to explore its hallucinogenic properties. He may have become somewhat dependent on hashish but finally gave it up. His descriptions of the effects of the drug were similar to what had previously been experienced by Asian users: euphoria and uncontrollable laughter; altered perceptions of space, time, vision, and hearing; synesthesias and depersonalization.

Hashish is currently the most potent of all *Cannabis* preparations: A lot of drug effect is packed into a small parcel. Regulation of the dose is difficult because of its variable potency, and labels for street drugs are notoriously unreliable, however. What may be sold as hashish may often be closer to ordinary marijuana in potency.

HEART DAMAGE *See* Alcohol: Complications; Cocaine; Tobacco: Medical Complications

HEMP In the narrow sense, hemp refers to a fiber derived from certain strains of CANNABIS SATIVA, a bushy herb that originated in ASIA. In the broader sense, it also denotes the other use of the plant, as a source of MARIJUANA. Although *Cannabis sativa* is generally considered to be a single species, two genetic strains show considerable differences. One is used for fiber production and has been so used for centuries to make rope, floor coverings, and cloth. Hemp plants have been grown for this purpose as commercial crops in Asia and even in colonial America; during World War II, they

Figure 1
Hemp Plant

were grown in the midwestern United States when the Asian supply was unavailable.

The other strain of the hemp plant produces a poor fiber but has a relatively high drug content; it is used for its PSYCHOACTIVE effect. Near the end of the nineteenth century, the Indian Hemp Drug Commission (1895) produced one of the first major assessments of *Cannabis* as a drug, finding it not a major health hazard. Consequently, it remains in legal use in India for both medicinal and social purposes, where it is called BHANG.

LEO E. HOLLISTER

HEROIN MORPHINE was first identified as the pain-relieving active ingredient in OPIUM in 1806. But morphine was not free of the habit-forming and toxic effects of opium. By the late nineteenth century, the idea of modifying molecules to change their pharmacological actions was well established. It seemed quite reasonable to use this approach to develop new chemical entities that might be free of the problems seen with morphine. In Germany, in 1898, H. Dresser introduced such a new drug—3,6-diacetylmorphine—into medical use; it was named there by the Bayer Company, which produced and marketed it, named it heroin (presumably from *heroisch*, meaning "heroical"), because it was more potent than morphine.

Although heroin is structurally very similar to morphine, it was hoped that it would relieve PAIN without the tendency to produce ADDICTION. Turn-of-the-century medical writings and advertisements, both in Europe and the United States, claimed that heroin was effective for treating pain and cough. Many suggested that it was less toxic than morphine and was nonaddictive. A few even suggested that heroin could be a nonaddicting cure for the morphine habit. Clearly, this was not the case, and within a year or two of its introduction, most of the medical community knew so. By the 1920s, heroin had become the most widely abused of the OPIATES.

PHARMACOLOGY

Heroin is a white powder that is readily soluble in water. The introduction of just two esters onto the morphine molecule changes the physical properties of the substance such that there is a significant increase in solubility, permitting solutions with increased drug concentrations. A more subtle advantage of heroin is its greater potency compared to morphine. The volume of drug injected may be particularly important when high doses are used. Thus, 1 gram of heroin will produce the effects of 2 to 3 grams of morphine; by converting morphine to heroin, producers increase both the potency and the value of the drug.

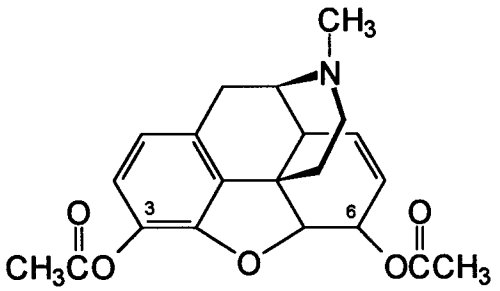

Figure 1
Heroin

Following injection, heroin is very potent, with the ability to cross the blood-brain barrier and enter the brain. This barrier results from a unique arrangement of cells around blood vessels within the brain, which limits the free movement of compounds. Many factors contribute to the barrier—in general, the less polar a drug, the more rapidly it enters the brain. Heroin, however, has a very short half-life in the blood (amount of time that half the drug remains). It is rapidly degraded by esterases, the enzymes that break ester bonds. The acetyl group at the 3-position of the molecule is far more sensitive to these enzymes than the acetyl group at the 6-position. Indeed, the 3-acetyl group is attacked almost immediately after injection and, within several minutes, virtually all the heroin is converted to a metabolite, 6-acetylmorphine. The remaining acetyl group at the 6-position is also lost, but at a slower rate. Loss of both acetyl groups generates morphine. It is believed that a combination of 6-acetylmorphine and morphine is responsible for the actions of heroin.

MEDICINAL USE

The pharmacology of heroin is virtually identical to that of morphine. This probably reflects its rapid conversion to 6-acetylmorphine and morphine. De-

Mexican brown heroin and Southeast Asian heroin. Although pure heroin is a white powder, most heroin that is sold on the street varies in color from white to dark brown, with an average purity of 35 percent. (Drug Enforcement Administration)

tailed studies comparing the actions of heroin and morphine in cancer patients with severe pain have shown very little difference between the two agents, other than simple potency. Heroin may have a slightly more rapid onset of action than morphine and it is certainly two to three times as potent (presumably due to its greater facility in crossing the blood-brain barrier). This difference in potency is lost with oral administration. The pain relief (analgesia) from both agents is comparable when the doses are adjusted appropriately. At equally effective ANALGESIC doses, even the euphoria seen with heroin is virtually identical to that of morphine. From the clinical point of view, there is little difference between one drug and the other. Both are effective analgesics and can be used beneficially in the treatment of severe pain. Heroin is more soluble, which makes it somewhat easier to give large doses by injection, with smaller volumes needed. Many of the similar semisynthetic agents, such as HYDROMORPHONE, however, are many times more potent than heroin and offer even greater advantages.

One widespread use of heroin in the United Kingdom was in the early formulations of Brompton's Cocktail, a mixture of drugs designed to relieve severe pain in terminal cancer patients. The heroin employed in the original formula is now typically replaced with morphine without any loss in effectiveness. For many years, some groups have maintained that heroin is more effective in the relief of cancer pain than morphine is. Careful clinical studies show that this is not true, but the most important issue is using an appropriate dose. Thus, heroin offers no major advantage over morphine from the medical perspective.

STREET HEROIN

Since heroin has no approved medical indications in the United States, it is only available and used illicitly. The marked variability of its purity and the use of a wide variety of other substances and drugs to "cut" street heroin poses a major problem. This inability to know what is included in each drug sale makes the street drug more than doubly dangerous. Typically, heroin is administered intravenously, which provides a rapid "rush," a euphoria, which is thought to be the important component of heroin's addictive properties. It can be injected under the skin (subcutaneously, SC) or deep into the muscle (intramuscularly, IM). Multiple intravenous injections leave marks, called tracks, in a much-used injection site, which often indicate that a person is abusing drugs; but heroin can also be heated and the vapors inhaled through a straw (called "chasing the dragon"). It can also be smoked in a cigarette. While the heat tends to destroy some of the drug, if the preparation is pure enough, a sufficient amount can be inhaled to produce the typical opiate effect.

Heroin use is associated with TOLERANCE AND DEPENDENCE. Chronic use of the drug leads to a decreased sensitivity toward its euphoric and analgesic actions, as well as to dependence. Like morphine, the duration of action of heroin is approximately 4 to 6 hours. Thus, addicts must take the drug several times a day to prevent the appearance of WITHDRAWAL signs. Many believe that the need to continue taking the drug to avoid withdrawal enhances its addictive potential.

Patients taking opiates medicinally can be taken off them gradually, without problems. Lowering the opiate dose by 20 to 25 percent daily for two or

three days will prevent severe withdrawal discomfort and still permit rapid taper off the drug. Abrupt withdrawal of all of the drug is very different—and leads to a well-defined abstinence syndrome that is very similar for both heroin and morphine. It includes eye tearing, yawning, and sweating after about eight to twelve hours past the last dose. As time goes on, people develop restlessness, dilated pupils, irritability, diarrhea, abdominal cramps, and periodic waves of gooseflesh. The term *cold turkey* is now used to describe abrupt withdrawal with the associated gooseflesh. The heroin withdrawal syndrome peaks between two and three days after stopping the drug, and symptoms usually disappear within seven to ten days, although some low-level symptoms may persist for many weeks. Babies of mothers dependent on opiates are born dependent, and special care must be taken to help them withdraw during their first weeks. Medically, although miserable, heroin withdrawal is seldom life threatening—unlike withdrawal from alcohol, which can sometimes be fatal.

OVERDOSE

Overdosing is a common problem among heroin addicts. The reason is not always clear, but wide variation in the purity of the street drug can make it difficult for the addict to judge a dose. Some impurities used to cut the drug may be toxic themselves. With OVERDOSE, a person becomes stuporous and difficult to arouse. Pupils are typically small and the skin may be cold and clammy. Seizures may occur, particularly in children or babies. Breathing becomes slow, and cyanosis—seen as a darkening of the lips to a bluish color—may develop, indicating inadequate levels of oxygen in the blood. With respiratory depression, blood pressure may then fall. These last two signs are serious, since most people who die from overdose, die from respiratory failure. Complicating the problem is the fact that many addicts may have taken other drugs, used alcohol, and so on. Some of them may have been taken on purpose, and some may have been a part of the street drug.

NALOXONE can readily reverse some opiate problems, since it is a potent opiate ANTAGONIST. This drug binds to opiate RECEPTORS and can reverse morphine and heroin actions. The appropriate dose may be a problem, however, since naloxone can also precipitate a severe abstinence syndrome in a dependent person.

HEROIN EPIDEMICS *See* Epidemics of Drug Abuse

HEROIN: THE BRITISH SYSTEM What is sometimes referred to as the British "system" of drug control is not really a system; rather, it is a set of principles and programs that represent one form of societal response to HEROIN use and OPIATE DEPENDENCE. The principles encompass the idea that government ought to offer public-health and medical programs that will help contain Britain's heroin problem, in addition to its response in the form of law enforcement. In BRITAIN, the concept of punishing heroin-dependent individuals for dependence as such is as alien as punishing people for becoming infected with syphilis or needing insulin for diabetes.

A key element in this system is allowing medical practitioners to provide maintenance doses of OPIATES or opioid drugs (sometimes including heroin as well as METHADONE and other opioids) when a diagnosis of heroin dependence can be substantiated. The initial programmatic efforts allowed for the prescribing of such drugs by general medical practitioners; but more recently, responsibility for treatment of opioid-dependent persons has shifted to government-run specialized Drug Dependency Units.

BACKGROUND

Drug control in Britain was established between 1910 and 1930, with a solid grounding in public health and medical practice. This British approach to drug problems as public-health problems seemed especially attractive as an alternative to U.S. drug prohibition policies, even when the heroin problem in the United States was relatively small, back before 1960. Thus, beginning in the late 1940s, some Americans started to advocate the use of the British system in the United States—that is, a nonpunitive, public-health approach to the treatment of drug dependence, especially dependence on heroin.

In 1960, the drug problem was essentially a nonissue in the political life of Britain, although the structures for control in the two countries remained very different. In the United States, a prohibitionist policy continued in place whereby criminal penalties were imposed for heroin possession and use—and sometimes for being addicted to heroin. Physicians rarely treated opiate addicts and could not legally provide a known addict with opiates on a maintenance basis. As a result, from early in the twentieth century, virtually all heroin addicts purchased supplies from illegal heroin sellers. With the exception of a brief time during which maintenance programs were available, relatively few addicts sought drug treatment from doctors, and treatment for heroin dependence often was available only at two federal narcotic hospitals and select public and private facilities. In NEW YORK and CALIFORNIA, in particular, large numbers of heroin abusers were arrested and imprisoned for heroin sales, for possession, or for other crimes sometimes committed to gain funds to purchase illegal heroin (e.g., robbery, burglary).

In contrast, by 1960, Britain had had many years of experience with a "medical" or "public-health" policy for controlling heroin and opiates (originating with the ROLLESTON REPORT of 1926). Fewer than 100 heroin addicts and fewer than 500 abusers of all drugs were known in Britain in 1960. Persons identified by a doctor as being addicted to heroin or other dangerous drugs could be (and usually were) treated by a private practitioner. The physician was required to notify the Home Office of the names of the addicts but was at liberty to prescribe heroin or opiates for them in any amounts for long time periods. Their treatment became funded by the National Health Service after World War II, like any other medical service. No other treatment (at a clinic, hospital, or nonmedical facility) was available. Penalties for the illegal sale of heroin or opiates carried sanctions of less than a year and were rarely imposed. Few British prisoners were heroin addicts.

British drug policy has been and continues to be set primarily by Home Office staff in collaboration with leading physicians and addiction specialists. British law-enforcement and criminal-justice practitioners were largely excluded from policymaking—whereas their counterparts in the United States have a primary role in formulating American drug policy. Following the Rolleston precedent, several special committees issued reports establishing the basic directions of British drug policy. The first Brain Committee (1958) reaffirmed the Rolleston recommendation to provide heroin and allow maintenance doses of opiates; it opposed U.S.-sponsored proposals to prohibit heroin manufacture in Britain.

CHANGING MEDICAL POLICIES ON DRUG CONTROL

The situation changed in the early 1960s, however, and, based on recommendations of the second Brain Committee (1964), clinics for controlling and containing the heroin problem were implemented under the Dangerous Drug Act Regulations in 1968. Responsibility for the treatment of addicts generally was shifted from general practitioners (GPs) to Drug Dependency Units (DDUs). When a heroin abuser seeks treatment from a GP, however, the doctor can refuse treatment, refer the patient to a DDU, or provide declining methadone doses over six months (called long-term detoxification in the United States) or provide regular methadone maintenance (although this is rarely done by a GP).

The DDUs or drug clinics provide a range of services funded by the National Health Service. In 1989, thirty-five DDUs operated in Britain and were directed by consulting psychiatrists who specialized in addiction treatment and prescribing. In smaller towns without clinics, one or two GPs can be licensed by the Home Office to provide treatment for addicts in the area. New applicants are interviewed and their urine tested to verify opiate use. The clinic physician develops a treatment plan with the patient, arranges weekly conferences, and

mails the prescription directly to a local pharmacy; it will be filled for the client on a daily basis. The Home Office also convenes meetings with several DDU directors to discuss common policies and practices, and to recommend approval or removal of licenses, when necessary, for physicians to prescribe dangerous drugs.

When the DDUs opened, most clinics made decisions to shift patients receiving prescriptions for injectable heroin onto injectable methadone. The pharmacist dispensed needles, syringes, and ampoules of methadone.

Over the period 1975 to 1983, many clinic directors shifted most patients from injectable to oral methadone maintenance. In the early 1980s, as illegal supplies of heroin became common in British cities, many clinics shifted away from oral methadone maintenance. Instead, the treatment policy at several clinics was to provide gradual withdrawal (detoxification in the United States); rarely were patients provided with long-term maintenance doses. As AIDS was tied to shared needles and syringes by injecting addicts, prevention became an important subgoal of drug treatment; however, new emphasis was then placed on oral methadone maintenance. In the early 1990s, the DDUs had heroin-abusing clients, many of whom received gradual reduction (detoxification) and others who received maintenance on methadone. Relatively few received prescriptions for injectable methadone or heroin, even though DDU doctors could legally and appropriately provide such services.

A continuing controversy within Britain in the 1990s has been whether the clinic system could stem or contain the heroin problem, and whether the clinic's shift away from prescribing heroin and injectable drugs contributed to the growth of black-market heroin. In discussion groups, some experts argued that many black-market heroin users would seek treatment if the clinics returned to prescribing injectable heroin or methadone. Such a policy also might reduce addict crime and prevent transmission of the AIDS virus. This, however, would change the profile of patients: Clinic directors would have to deal with addicts who have no intention of stopping heroin use.

The British have amended the Dangerous Drug Act several times since 1960, thereby making the illegal sale of heroin, cocaine, and marijuana criminal offenses. Although the vast majority of drug arrestees are only "cautioned," even after repeated instances of offense, many illegal sellers and heroin abusers arrested for robbery, burglary, and theft can be and are imprisoned. Thus, an increasingly larger proportion of British prisoners are heroin addicts. Between 1979 and 1984, seizures of illegal drugs went up tenfold, incarcerated drug offenders went up fourfold, and the consumption of heroin increased by 350 percent—but heroin prices decreased by 20 percent.

Rise of Nonmedical Drug Treatment. The increase in black-market heroin, substantial increases in heroin abusers who avoid the DDUs, apparent increase in penal sanctioning, and a host of complex issues have led to dissatisfaction with the original British System, with its medical model of drug treatment. Influenced by U.S. therapeutic communities and outpatient local programs that promote a drug-free environment, British social service agencies have begun developing similar programs thereby "reaching out" to clients and providing alternative services in a context that is different from the practice settings dominated by the consulting psychiatrists at DDUs.

Other emerging British programs are increasingly built around a philosophy of "harm reduction." This emphasizes informing people of safer ways to take drugs for those who will continue to do so, helping addicts recognize drug-related problems (e.g., infections or diseases), and making sterile injection equipment and/or drug treatment available with minimal restrictions. The program's staff also suggests alternative ways of altering consciousness or seeking pleasure.

AIDS Prevention. Since the years 1984 to 1985, the British have been international leaders in devising innovative programs to reduce the spread of the AIDS virus. Because of the legal provision of opiates by physicians and DDUs, the sale of syringes was never prohibited nor seriously constrained. Addicts using black-market heroin could always purchase sterile needles cheaply as well as receive instructions on safe injection practices although in some areas pharmacists might refuse to sell them to addicts.

Gerry Stimson, a sociologist who had conducted studies of heroin addicts from 1960 through the 1970s, became a leading government consultant in the 1980s in formulating British AIDS prevention policies. Together with other experts, he recommended establishing syringe exchanges to promote safe disposal of used needles (possibly infected with

the AIDS virus) and to reach injecting drug users who avoid the clinics. His subsequent research established the facts that untreated addicts could be attracted to these exchanges but that retention rates were low. Possibly as a result of these efforts, the AIDS infection rate in Britain is much lower than that in many cities of the United States.

Heroin Abuse. After 1960, several major increases in heroin use and abuse occurred in Britain. In the early 1960s, a few British physicians began prescribing large amounts of legal heroin to private patients, some of whom resold it to other people. The number of known heroin abusers grew to 2,240 in 1968 and then increased slowly during the 1970s. In the early 1980s, however, a major increase in illegal importation of heroin to Britain was followed by an epidemic of heroin use in that country—thus, 12,500 heroin abusers were reported to the Home Office in 1984. In the mid-1990s, many heroin abusers avoid clinics and doctors and are not reported to the Home Office. Therefore, the actual number of regular heroin abusers in Britain now is estimated to be between 50,000 to 100,000.

CONCLUSION

Since the 1960s, the British system of drug control has evolved and changed in many important ways. Although the heroin problem expanded dramatically in the 1980s, the major policy decisions of the Rolleston Report have continued to govern the British approach. The British government continues to collaborate closely with medical and public-health experts. Treatment practices have been refined by experience and practical considerations, but not because of imposition by government fiat. Prohibition of heroin did not occur and punishment of drug abusers remains a secondary consideration in British policymaking (but is still a dominant consideration in the United States). Since 1960, the British heroin problem has grown and become complex. Drug-policy and treatment response have become diverse and, therefore, there is less of a clear "system."

In comparison with the situation in the United States, British policymakers and the general public favor public-health considerations over other moral concerns. Some British newspapers do promote "dope fiend" images and demand punitive responses—and the American "drug free" and "just say no" philosophies are often articulated. Nonetheless, British drug policy and funding are primarily directed by medical and public-health specialists. This means that heroin addicts and drug abusers are not as heavily stigmatized as they are in the United States.

The British public accepts the idea of providing heroin and methadone as medicine, has few moral qualms about addicts, and little fear of needles. Lacking the harsh and punitive moral consensus against drugs that prevails in the United States, the British government has considerable latitude to experiment with differing policies, to shift treatment practices to accord with practical experience, and to keep modifying its policy responses to the ever-changing drug scene. Whether the British system could work in the United States, which is much larger and more populous than Great Britain, remains an open question.

HIGH SCHOOL SENIOR SURVEY The use of illegal drugs by large numbers of young people in the United States became an issue of considerable concern during the late 1960s and early 1970s. At that time, there were few accurate data available to assess the extent of use on a national basis. In 1975, Lloyd Johnston and Jerald Bachman of the University of Michigan initiated *Monitoring the Future: An Ongoing Study of the Lifestyles and Values of Youth*, which was intended to address this lack of information.

One of the major purposes of the study was (and is) to develop an accurate picture of the nature and extent of drug use among young people. An accurate assessment of the amount and extent of illicit drug use in this group is a prerequisite for rational policy making. Reliable and valid data on prevalence are necessary to determine an appropriate allocation of resources and to prevent or correct misconceptions. Reliable and valid data on trends allow for early detection of emerging problems and make it possible to assess the impact of external events, including historical events and deliberate policy changes.

In addition, the study was designed to monitor factors that might help explain the observed changes in drug use—that is, it was intended to serve both an epidemiological function (to learn how many young people use drugs) and an etiological function (to study why young people use drugs). The factors measured included attitudes toward drugs, peer norms and behaviors in regard to drugs, beliefs about the dangers of drugs, perceived availability of drugs, religious attitudes, and various life-style factors. The monitoring of these factors has, among other things, provided the country with valuable information. A particular contribution has been to help address a central policy-making question in the nation's war on drugs: The relative importance of supply eduction versus demand reduction in bringing about some of the observed declines in drug use.

STUDY DESIGN

The core feature of the design is an annual survey of each new high school senior class, beginning with the class of 1975. Each year approximately 16,000 seniors are surveyed in approximately 135 public and private high schools that have been scientifically elected to provide an accurate, representative cross section of high school seniors throughout the coterminous United States. Data are collected following standardized procedures via closed-ended questionnaires administered in classrooms by University of Michigan representatives and their assistants.

In 1991, the project was expanded to include nationally representative samples of students from the eighth and tenth grades as well as from the twelfth grade. Approximately 18,000 eighth graders and 16,000 tenth graders are surveyed annually, using procedures similar to those used in the twelfth grade surveys.

One limitation of the design is that it does not include in the target population the young men and women who drop out of high school before graduation, and who make up between 15 and 20 percent of each age group nationally, according to U.S. Census statistics. The omission of high school dropouts does introduce biases in the estimation of certain characteristics of the entire age group, but, because the dropouts are a relatively small proportion of the entire group, the bias due to their omission is small. Because relatively few adolescents drop out before the end of tenth grade, the bias is particularly small for the eighth and tenth graders. It should also be noted that because any bias resulting from exclusion of the dropouts usually remains constant from year to year, their exclusion should introduce little or no bias in estimates of change or trends.

An issue that is relevant to the study of sensitive behaviors, such as drug use, is the extent to which respondents will answer honestly. Considerable inferential evidence suggests that the procedures used in this study produce largely valid data. This evidence includes the following points: Large proportions of respondents report using illegal substances; various drugs exhibit trends in different ways over time; there are very few missing data in response to questions on drug use, even though respondents are instructed not to answer questions they would prefer not to answer; the high correlations with other behaviors such as grades, delinquency, religious attitudes, and truancy indicate a high degree of construct validity; a high degree of consistency can be noted over time in individuals' reports (that is, the responses

are reliable); and other factors that are discussed in detail in other publications (see Johnston, O'Malley, & Bachman, 2000; O'Malley, Bachman, & Johnston, 1983).

MAJOR FINDINGS

One dramatic finding that emerged from the Monitoring the Future surveys was the decrease between about 1980 and 1992 in young Americans involved in the use of illicit drugs.

Illicit Drugs. Annual use of any illicit drug (that is, any use in the past twelve months) peaked among high school seniors in 1979, when more than half (54%) of all high school seniors reported having used such a drug. This peak occurred following a rise in the late 1970s—from 45 percent in 1975, when the first reliable national data were collected. By 1992, the proportion had fallen to 27 percent, half of the peak rate.

The statistics for lifetime prevalence are also dramatic. In the peak year of 1981, 66 percent of the graduating class reported having used an illicit drug at some point in their lifetime. By 1992, that percentage was down by about one third, to 41 percent.

Unfortunately, a second dramatic finding that has emerged from the Monitoring the Future surveys is an increase in the numbers of young Americans involved in the use of illicit drugs during the 1990s. After reaching a low of 27 percent in 1992, annual use among seniors was back up to 42 percent in 1999. Lifetime use was back to 55 percent.

Increases were particularly sharp among the eighth and tenth graders. No data are available before 1991, so longer term trends are not so clear. However, it is clear that there were significant increases in the 1990s. Among eighth graders in 1991, 11 percent had used an illicit drug in the past twelve months; that figure increased to 21 percent by 1999 (and actually peaked in 1996 at 24%). Similarly, among tenth graders, annual use increased from 21 percent in 1991 to 36 percent (and peaked at 39% in 1997).

Among the various illicit drugs, marijuana is the most prevalent. The use of marijuana, as indicated by its annual prevalence, peaked among high school seniors in 1979, when a majority (51%) reported that they had used it in the past twelve months, and it steadily declined after that, reaching a low of 22 percent in 1992. The annual prevalence, thus cut by more than half, declined from one in two seniors in the class of 1979 to less than one in four seniors in the class of 1992. However, by 1999 the figure was back to 38 percent, so that well over one in three seniors had used marijuana in the past twelve months.

A particularly striking trend in marijuana use occurred between 1975 and 1978, when the proportion of seniors who reported using marijuana on a daily or near-daily basis in the past thirty days increased from 6 percent to an unprecedented 10.7 percent. This figure subsequently came down by more than 80 percent and stood at 2 percent in 1992; by 1999 it was back to 6 percent, exactly where it was in 1975.

Among eighth graders, annual marijuana use increased from 6.2 percent in 1991 to 17 percent in 1999 (peaking at 18% in 1996). Among tenth graders, annual marijuana use almost doubled between 1991 and 1999, from 17 percent to 32 percent (peaking at 35% in 1997).

Never as common as marijuana, cocaine became the drug on which the most attention was focused during the mid-1980s, when the national concern about the drug epidemic was at its highest level. The concern with cocaine was well founded because its use, unlike that of marijuana, had not begun to decline in the very early 1980s. As with marijuana, the daily use of cocaine had increased substantially between 1975 and 1979: Annual prevalence doubled from 5.6 percent to 12.0 percent. Several years followed during which there was little change, with annual prevalence reaching a peak of 13 percent in both 1985 and 1986. A period of decline then ensued during which annual use declined to 3.1 percent in 1992; this was the lowest value recorded since reliable data had begun to be collected in 1975. Like marijuana, however, use increased in the 1990s, and by 1999 annual cocaine among seniors had doubled, reaching 6.2 percent.

These data refer to the use of any form of cocaine, including crack cocaine. Crack cocaine first appeared in the early 1980s and became a significant factor among the illicit drugs in the mid-1980s. It was first assessed on a national basis in 1986, and its annual prevalence among high school seniors at that time was recorded at a disturbingly high 4.1 percent. That first reading turned out to be a peak level, and the use of crack cocaine declined thereafter, reaching 1.5 percent

NOTE: See Johnston, O'Malley, & Bachman (2000) for more specific details about measures.
[a]Use of "any illicit drugs" includes any use of marijuana, hallucinogens, cocaine, or heroin, or any non-medical use of other opiates, amphetamines, barbiturates, or tranquilizers.

in 1992. Its lifetime prevalence reached a peak of 5.4 percent among the high school class of 1987 but declined to 2.6 percent by 1992. Use of crack cocaine increased during the 1990s, reaching a lifetime prevalence of 4.6 percent in 1999, and an annual prevalence of 2.7 percent. These figures are still below the peak levels reached in the mid 1980s.

Similar trends were observed among eighth and tenth graders in the 1990s, though at lower absolute levels.

Although not necessarily illicit drugs, inhalants are sometimes used illicitly for the purpose of getting high. This particular behavior is generally more often seen among younger students rather than among high school seniors. In 1999, for exam-

ple, 5.6 percent of twelfth graders reported using inhalants to get high at least once in the past twelve months, compared to 7.2 percent of tenth graders, and 10.3 percent of eighth graders.

The longer term trend in the use of inhalants was slightly upward from its lowest level of 3.0 percent in 1976 (when it was first assessed), to a peak level of 8.0 percent in 1995 (before declining to 5.6% in 1999). Thus, the use of this class of substance, unlike the use of illicit drugs in general, did not show the general decline from 1980 to 1992. Among eighth and tenth graders, annual use levels are not very different between 1991 and 1999: for eighth graders the respective values were 9 percent and 10.3 percent, and for tenth graders they were 7.1 percent and 7.2 percent.

[b]In 1982, the question about amphetamine use was revised; the prevalence rate declined as a result.
[c]In 1993, the question about alcohol use was revised; the prevalence rate declined as a result.

Hallucinogens are the other major class of illicit (or illicitly used) substances that did not evidence declines in the late 1980s and the early 1990s. LSD (lysergic acid diethylamide) in particular is a very significant exception; its use hardly changed among high school seniors, remaining at an annual prevalence of about 5 percent from 1987 to 1991 after a period of some decline. Like marijuana however, there was an increase in the 1990s, reaching 8.8 percent in 1996, the highest value ever recorded. (The lowest recorded value was 4.4 percent in 1985). By 1999, use had declined only slightly, to 8.1 percent.

Very similar patterns of change were evident among eighth and tenth graders in the 1990s, albeit at lower levels.

Substances that generally showed declines during the period from the 1970s to the early 1990s include heroin, opiates other than heroin, amphetamines, barbiturates, and tranquilizers. All of these substances also showed an increase during the mid-1990s.

Thus, five classes of illicitly used drugs had a particularly important impact on appreciable proportions of young Americans: Marijuana, cocaine, amphetamines, LSD, and inhalants. In 1999, they showed annual prevalence rates among high school seniors of 38 percent, 6 percent, 10 percent, 8 percent, and 6 percent, respectively. Among eighth graders, the respective figures were 17 percent, 3 percent, 7 percent, 2 percent, and 10 percent.

In the late 1990s, some "club drugs" appeared on the drug scene. One in particular, MDMA, or

"ecstasy," has shown substantial increases, reaching 5.6 percent annual prevalence among seniors in 1999. The corresponding figures for eighth and tenth graders are 1.7 percent and 4.4 percent.

Alcohol and Tobacco. The history of the use of the major licit drugs—alcohol and tobacco—is rather different than that of the use of most illicit drugs. One significant difference was the extent of the use of alcohol and tobacco. The daily use of cigarettes was far greater than the daily use of any other substance. In 1999, more than one in five (23%) high school seniors had smoked one or more cigarettes per day in the past thirty days. Even among eighth graders, one in twelve was a daily cigarette smoker (8%).

About one in thirty (3.4%) seniors had drunk alcohol daily or almost daily. All other drugs were used on a daily basis by 0.3 percent or less of seniors. Although the daily use of alcohol was relatively infrequent among high school seniors, episodic or periodic drinking was more frequent. In 1999, nearly one third (31%) of seniors reported they had had five or more drinks in a row at least once during the past two weeks. (Drinking five or more drinks "in a row" is likely enough to render the average teenager intoxicated.) This behavior showed some declines in the late 1980s and early 1990s. From 1975 through 1988, the figure for such drinking had been between 35 percent and 41 percent, or consistently more than one in three high school seniors. Between 1988 and 1991, it declined to 30 percent, which represented an encouraging downward trend, although the absolute level remained impressively high; the trend in the 1990s

NOTE: See Johnston, O'Malley, & Bachman (2000) for more specific details about measures.
[a]In 1993, the question about alcohol use was revised slightly.

was not so encouraging, with the level in 1999 slightly higher, at 31 percent.

The trends in the 1990s for eighth and tenth graders are also not encouraging: 1999 levels of heavy drinking are slightly higher than they were in 1991. For example, 23 percent of 1991 tenth graders reported having had five or more drinks in a row in the past two weeks, compared to 26 percent of 1999 tenth graders.

Among seniors, daily use of cigarettes peaked in 1977, when 29 percent of high school seniors smoked daily. By 1992, this had declined to 17 percent, but most of the decline had occurred by 1981, when the figure stood at 20 percent. Between 1992 and 1999, the figure increased substantially, to 23 percent. A measure of heavier smoking, the percent of high school seniors who smoked a half pack or more of cigarettes per day, showed a similar trend; it peaked in 1977 at 19 percent, declined to 14 percent by 1981, was down to 10 percent in 1992, but was back to 13 percent in 1999. Thus, although the 1980s showed some declines in cigarette smoking among young Americans, these declines were far more modest than one might have expected. Given the large increases in antismoking legislation, restrictions as to where smoking is allowed, and the general spread of antismoking attitudes, the declines were surprisingly small, and have eroded some in the 1990s.

The upward trend in cigarette use during the 1990s was strikingly present among eighth and tenth graders. Monthly use increased among both grades by about 50 percent from 1991 to 1996 (from 14 percent to 21 percent among eighth graders, and from 21 percent to 30 percent among tenth graders), before moderating slightly after that.

DEMOGRAPHIC DIFFERENCES

Drug use among several demographic groups is monitored in the surveys, including by gender, four-year college plans, parental education (an indicator of socioeconomic status), geographical region, population density, and racial or ethnic identification.

Gender. By senior year, male adolescents are more likely than female adolescents to use most illicit drugs, and the differences tend to be largest at the higher frequency levels. In 1999, for example, 8 percent of male high school seniors reported that they were using marijuana daily, versus 4 percent of female seniors. For many specific substances, there is little gender difference in use among eighth and tenth graders. Indeed, female eighth graders have slightly higher rates of annual use than males for inhalants, amphetamines, and tranquilizers.

There are large gender differences in the prevalence of occasions of heavy drinking among high school seniors (38 percent for male adolescents versus 24 percent for female adolescents in 1999); thus, as with heavy use of illicit drugs, heavy use of alcohol is more likely among male adolescents than it is among female adolescents. This gender difference is somewhat smaller than the one obtained in 1975, when the figures were 49 percent and 26 percent, respectively. The narrowing of the difference is primarily attributable to the greater decrease in heavy drinking among male adolescents than among female adolescents. The current differences are similar, though smaller, among the younger students. Among 1999 eighth graders, 16 percent of boys reported heaving drinking compared

to 14 percent of girls; the corresponding figures for tenth graders were 30 percent and 22 percent.

In general, there is not much difference between male and female students in cigarette use. As with most drugs, the greater difference is seen among older, heavy smokers, but even so the difference is rather small: In 1999, 15 percent of male seniors reported smoking at the rate of a half pack or more per day, versus 12 percent of female seniors.

College-Bound versus Non-College-Bound. Non-college-bound students are more likely than college-bound students to use any of the licit or illicit drugs. More frequent use of the drug tends to show greater differences. For example, 6 percent of non-college-bound eighth graders report smoking marijuana daily, compared to 1 percent of the college-bound; corresponding figures for tenth and twelfth graders are 10 percent versus 3 percent, and 9 percent versus 5 percent, respectively. Striking differences show up between college-bound and non-college-bound students in cigarette smoking rates. For example, smoking a half pack or more a day is more than six times more prevalent among the non-college-bound 1999 eighth graders than among the college-bound (13% versus 2%). Among seniors, half a pack or more smoking is more than twice as prevalent among the college-bound, 23 percent versus 10 percent. (The greater ratio in the younger students is likely due to the presence of the eventual dropouts in the eighth and tenth grades, because dropouts tend to have higher rates of smoking than nondropouts.) Non-college-bound students are also more likely than their college-bound counterparts to report having had five or more drinks in a row in the past two weeks (39 percent versus 24 percent among tenth graders, for example).

Parental Education. Among high school seniors there is (perhaps surprisingly) rather little association between parental education and use of illicit drugs. There is somewhat more of an association among the lower grades, particularly among eighth graders, with the lowest level or lower two levels having somewhat higher use rates than the others.

Geographical Region. Overall, use of illicit drugs does not vary dramatically by region. As of 1999, the annual use of any illicit drug was (slightly) lowest in the South among tenth and twelfth graders, but in the Northeast among eighth graders.

Both the South and the West tend to exhibit slightly lower rates of alcohol use than the Northeast and the North Central states. For example, in 1999 the prevalence of heavy-drinking occasions (that is, five or more drinks in a row on at least one occasion in the past two weeks) among the seniors was 34 percent and 32 percent in the Northeast and North Central states, respectively, compared with 30 percent and 29 percent in the South and the West. Cigarette smoking tends to be lowest in the West; for example, among 1999 seniors, smoking daily was 23 percent in the Northeast, 26 percent in the North Central, 24 percent in the South, and 17 percent in the West.

Population Density. As of 1999, the differences in high school seniors' use of illicit drugs by population density are quite small. This lack of large differences reflects the fact that illicit-drug use has spread widely throughout the nation. One substance that has shown some significant difference by population density over time is the use of cocaine. The substantial increase in cocaine use in the late 1970s, and the continuing high levels of use until the mid-1980s, was primarily an urban phenomenon. The annual prevalence rates for cocaine were nearly twice as high among high school seniors in the large standard metropolitan statistical areas as they were for seniors in the more sparsely populated areas. Cigarette use varies somewhat by population density. Among eighth graders, daily use in 1999 was at 13 percent in non-metropolitan areas, compared to 5 percent in the largest metropolitan areas, and 7 percent in other metropolitan areas.

Racial or Ethnic Identification. It is difficult to make definitive statements about even the larger minority groups such as African Americans and Hispanics, because of the relatively small numbers who participate in the surveys; it is virtually impossible to make definitive statements about other minority groups. Even Hispanics, who constitute a large segment of the population in many areas, often cannot be accurately represented because there are many important subgroups among the several Hispanic groups (e.g., Mexican, Puerto Rican, Cuban, and Latin American, among others). Nevertheless, certain findings appear to be reliable.

Among high school seniors, African-American students report less use of virtually all substances than do white or Hispanic students. Generally, African-American students in eighth and tenth grades

also report less use of most substances, although marijuana is an exception in the eighth grade, where white students report less use.

By senior year, Hispanic students report higher rates of cocaine and crack cocaine than white or African American students. These differences are stronger among eighth and tenth graders. And, particularly among eighth graders, Hispanic students tend to show the highest rates of use for some substances, including marijuana, tranquilizers, and cigarettes. In other words, in eighth grade, before most dropping out of school occurs, Hispanic students are relatively high in use of substances, while white students tend to have higher rates by twelfth grade. Very likely, the higher rates of dropping out of school observed among Hispanic adolescents (U.S. Dept. of Education, 1992) account for the shift in differences.

Some of these differences could be due to differential reporting biases, but J. M. Wallace and J. G. Bachman (1993) argue that this is unlikely to be an important part of the explanation.

SUMMARY

Between 1975 and 1992, appreciable declines were found in the use of a number of illicit drugs among high school seniors, but not in all drugs. LSD and inhalants were the notable exceptions. Moreover, some relatively slight declines were seen in alcohol use and even smaller declines in cigarette use. This picture of general improvement abruptly changed, with substantial increases seen from 1992 to 1997. The increases were evident not only among seniors, but also among eighth and tenth graders as well, with proportional changes being greater among the younger students. The situation moderated slightly, or changed rather little between 1997 and 1999, at which time drug use remained at high levels among American youth. Some items of interest are:

- As of 1999, about 55 percent of young Americans had tried an illicit drug by the time they had neared the end of their last year of high school; this proportion included about 29 percent who had tried some illicit drug other than marijuana. About 28 percent of young Americans had tried an illicit drug before they finished eighth grade, including 16 percent who had tried some illicit drug other than marijuana.
- Marijuana had been tried by 50 percent of seniors, 41 percent of tenth graders, and 22 percent of eighth graders.
- One in ten (10%) twelfth graders had tried cocaine, and about one in every twenty-two (4.6%) had tried crack cocaine.
- A significant number of high school seniors in 1999 smoked marijuana daily (6%).
- Almost a third (31%) of high school seniors in 1999 had had five or more drinks in a row at least once in the prior two weeks.
- More than a third (35%) of seniors had smoked cigarettes in the month prior to the survey, and 23 percent smoked daily. More than a sixth (18%) of eighth graders had smoked cigarettes in the month prior to the survey, and 8 percent already smoked daily.

In addition to providing basic epidemiologic information on prevalences, trends, and demographic differences, the Monitoring the Future study also contribute information on the reasons for the trends and differences. The study's demonstration that attitudes and beliefs affect drug-use trends (especially in the case of marijuana and cocaine) is particularly important (Bachman, Johnston, & O'Malley, 1998; Johnston, O'Malley, & Bachman, 2000). By virtue of its cohort-sequential design, the study has been able to distinguish among the several possible types of competing changes associated with trends in use-specifically, age, period, and cohort (or birth group) effects (O'Malley, Bachman, & Johnston, 1988). In addition, the study has been able to provide important data with which researchers could evaluate the effects of changes in the laws dealing with marijuana (Johnston, O'Malley, & Bachman, 1981) and alcohol (O'Malley & Wagenaar, 1991). All of these contributions have been vital in the continuing debates about policy regarding the use of licit and illicit drugs.

PATRICK M. O'MALLEY

HISPANICS AND DRUG USE, IN THE UNITED STATES Hispanics in the United States are a large, growing, diverse group. More precisely, 1990 U.S. Census figures put the total at 22 million—of these, 63 percent are Mexican in origin, 11 percent Puerto Rican in origin, and 5 percent Cuban in origin. These three groups are the largest, yet another 14 percent of Hispanics are from the various Central and South American countries; still another 8 percent are classified as "other Hispanic" by the U.S. Bureau of the Census. In this essay the terms *Hispanic* and *Latino* are used interchangeably. *Hispanic* is commonly used in official statistics, and *Latino* is more widely used within the population itself.

The rapid growth of the Latino population within the United States also is noteworthy. It grew by 53 percent between 1980 and 1990. A high birth rate and continuous new immigration fuels this growth.

On average, Hispanics are younger than other minorities and other American population groups. When youthfulness is combined with POVERTY or discriminatory practices, the result sometimes is a disproportionate degree of conflict with law enforcement, especially in connection with drug abuse and drug dealing. The media coverage of these conflicts may lead many into a prejudicial belief about Latinos and drug use.

Although there are many notable exceptions, most Hispanics live in cities in the United States and, lacking other options, they are steadily crowding into the poorest areas of New York, Los Angeles, Chicago, and other large cities. In 1990, 25 percent of Latinos in the United States lived in poverty compared with 31 percent of black families and 13 percent of all other Americans. Poor education, difficulty with the English language, and urban concentration can compound this impoverishment—as it has for the other immigrant minorities in the United States—thereby contributing to the complexity of modern urban problems that they must face daily.

All segments of this highly diverse group are changing rapidly. Documented and undocumented new immigration combined adds about 500,000 arrivals each year, and this flow is increasing. Many of the newcomers crowd into old barrios, and this reduces the quality of life for older residents. Great pressure is therefore exerted on local educational services, health resources, job sources, and job-training services—a pressure that is compounded by problems of acculturation. Many Mexican-American communities predate the Mexican-American War of the 1840s, but other Latino communities have become established in significant numbers only since World War II. Puerto Ricans, for example, settled mostly in the large cities of the Rust Belt in the late 1940s and early 1950s, forming a particularly large concentration in New York City. Like

Mexican Americans (Chicanos), they have been sharply affected by recent shifts in the American economy that relegate poorly educated workers to poorly paid service jobs. Central and South Americans are found in diverse locations, with concentrations in New York, Houston, and Los Angeles, tending to work at the bottom of the labor market. Cubans, who are concentrated primarily in Miami, have been helped both by a vigorous enclave economy (with Cubans owning many of the enterprises and hiring fellow Cubans) and by Miami's emergence as a center for Latin American trade.

HISPANICS AND ILLICIT DRUGS

Latinos often are typecast as drug users (see Helmer, 1975). Such stereotypes persist partly because there is little research information. National statistics about Hispanics mask important variations within the population, not only in ethnicity but in class and culture. Drug problems of the community are treated principally as criminal phenomena, and indeed, in many states a disproportionate number of Latinos are imprisoned for drug-related offenses. The context for drug use is little studied.

What then is really known about drug use by Hispanics? Specifically, 1991 figures from the annual survey of the National Institute on Drug Abuse (NIDA) show that Hispanics are generally less likely to use drugs in their lifetime than either blacks or the white-majority population. However, Hispanics are most likely to have used COCAINE, and next most likely (after blacks) to have used CRACK cocaine. National surveys do not report on HEROIN, an illicit drug that has posed major problems for Latinos, particularly in New York and the Southwest. Heroin use has been studied in several southwestern communities, in particular in the context of peer group and FAMILY in Los Angeles barrios.

The aggregate figures also conceal significant subgroup differences. Puerto Ricans are especially likely to use cocaine, for example, and Cubans are notably less likely to use any drug. (However, clinical data indicate that Cuban drug use is actually higher than survey data show.)

The aggregate figures conceal geographic differences as well. Studies of persons arrested for crimes, for example, show that more than two-thirds of Hispanic arrestees in Chicago, New York, Philadelphia, and San Diego were using drugs but that proportions were far lower in most other cities (U.S. Department of Justice, 1991). Finally, drug-use patterns may change rapidly, even in a high-risk population: for example, 68 percent of San Antonio's Hispanic arrestees were using some drug in 1988, but by 1991 only 47 percent were, according to U.S. Department of Justice figures (1990). Glick (1990) has analyzed the shifting drug-use patterns in Chicago's Puerto Rican community.

Differences in drug use by males and females are sharper for Hispanics than for other ethnic or cultural groups. Mexican American and Puerto Rican boys and girls are socialized very differently to alcohol and drug use—that is, there is more parental and community disapproval for girls and more permissiveness for boys. Yet research on drug use among Hispanic women is scarce. Among the available research, of particular interest is the finding that sedatives and prescription drugs are used differently by women than they are by men (Gonzalez & Page, 1991). There is also research showing that most female heroin addicts usually begin to use heroin with a male friend, spouse, or common-law partner, thus suggesting that the use depends on a relationship. Hispanic women appear to be greatly influenced by traditional ideas about the role of women, even under the pressures of urbanization, acculturation, and poverty (Moore, 1990).

As to adolescents, the most susceptible group, there is little information about how adolescent Hispanic groups differ from other adolescent groups in drug use. National surveys of high school seniors discover only small differences, but the surveys omit dropouts, who are often the adolescents most at risk, and Hispanic adolescents have very high dropout rates. Most studies confirm that the same risk factors that are important for other youth are important for Hispanics: above all, a disruptive family environment; availability of drugs; peer influences; and patterns of unconventional behavior (such as low school achievement, rebelliousness, early sexual activity). These influences (plus the degree of acculturation and individual judgments of the adolescent) seem to be related, in a general way, with beginning drug use and a steady use of drugs (Booth, Castro, & Anglin, 1990). One notable fact is that gender differences are less significant for adolescent Hispanics than they are for adult Hispanics (Gilbert, 1985).

A special factor that affects Latinos is the overriding importance in the culture of the family. This influence has both positive and negative effects. The extended family among Puerto Ricans in New York may limit drug use by protecting and controlling youngsters in both single- and two-parent households (Fitzpatrick, 1990). In Cuban families, by contrast, illicit drug use may occur when the family structure is severely disrupted, often by the trauma of refugee migration, and researchers argue that the very cohesiveness of the Cuban family may be associated with parental overprotectiveness and adolescent rebellion, sometimes accompanied by drug use as a symptom (Rio et al., 1990).

Recent research suggests that Hispanic clients achieve only mixed success in treatment, but that finding needs qualification, because of the limitations of available treatment programs. Because of poverty and residence in blighted areas, a disproportionate number of Latino heroin users, for example, are enrolled in programs that simply administer blocking drugs (e.g., methadone), with virtually no other treatment. Urban drug treatment programs generally face chronic shortages of money and personnel. When drug abusers do get access to broader treatment, failure can often be blamed upon the absence of culturally sensitive therapies (Rio et al., 1990). Fitzpatrick (1990) has suggested that Puerto Ricans in New York City show an "extraordinary" ability to cope with a community saturated with drugs and that efforts should be made to build on this ability.

HISPANICS AND ALCOHOL

Among Hispanic and many other groups, ALCOHOL use has been easier to study than the use of illicit drugs; many of its patterns are similar to and may shed light on drug use. As they do with drugs, Hispanics use less alcohol over their lifetimes than do "Anglos" (i.e., non-Hispanic white U.S. inhabitants in general, not just those of English ancestry), and their usage is only very slightly more than that of blacks. Again as with drugs, there are sharp gender differences in alcohol use, which are especially noteworthy among immigrants. Among Mexican Americans, the gap between male and female drinking narrows but never disappears in succeeding generations, and much recent research focuses on this acculturation effect, so critical in a large new immigrant population (Canino, 1994). Among younger women, the narrowing gap seems to reflect both acculturation and upward social mobility. Even within one city, Mexican-American drinking habits vary greatly by class (Trotter, 1985). But Gilbert found that Mexican Americans in California also speak of family, financial, and job problems as factors in abusive drinking; they tend to recognize alcoholism not as a medical problem but as a failure of will (Gilbert, 1985). Certainly there is no one set of beliefs, behaviors, and norms associated with Latinos and drinking. Lifestyle diversity within Latino subgroups suggests the need for a corresponding diversity of treatment approaches. The failure of such standard treatments as ALCOHOLICS ANONYMOUS among Hispanics in certain areas should be noted.

Finally, as noted before in regard to drugs, there are important differences in drinking behavior between subgroups of Hispanics. Mainland-dwelling Puerto Ricans' use of both alcohol and drugs is comparatively high wherever studied (Gordon, 1985). Pentecostal church groups have had notable success in influencing the drinking behavior of some Puerto Ricans, although some clinicians have expressed the view that Puerto Ricans are reluctant to use treatment services. Cuban drinking patterns are generally moderate: Cultural values of self-control forbid discernible drunkenness for both men and women. With increasing acculturation, there is gradually increasing alcohol usage but reduced reliance on minor TRANQUILIZERS by Cuban women. All the (scanty) information available on the subject stresses the importance of individual ethnic experience.

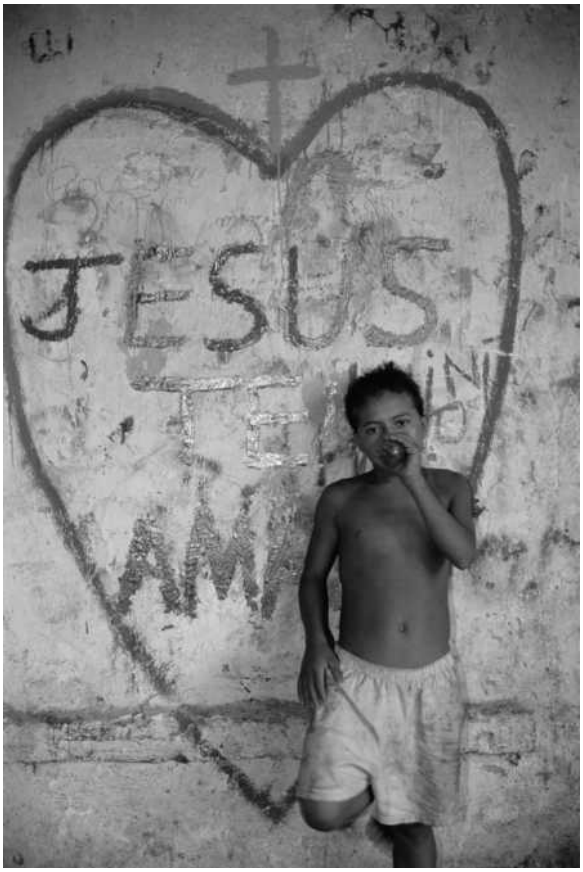
HOMELESSNESS, ALCOHOL, AND OTHER DRUGS, HISTORY OF The word *homeless* has a long and complex use. In its most literal meaning of houseless, it has been employed since the mid-1800s to describe those who have slept outdoors or in various makeshifts, or who resided in temporary accommodations like the police-station lodgings of earlier generations or the emergency shelters of the present day. Another early meaning of the word draws upon the absence of a sense of belonging to a place and with the people who live there. This usage was handed down from the largely rural and small-town society of the nineteenth century, in which the coincidence of family and place provided the basis for community and social order, nurturing traditions of mutual aid and the control of troublesome behavior. To be homeless was to be "unattached," outside this web of support and control; it was to be without critical resources and, equally important, beyond constructive restraint. Many of the young men and women who moved from farm to city, or those who emigrated during the nineteenth and early twentieth centuries, were unattached in this respect. Organizations like the YWCA, and YMCA, and various ethnic mutual-aid societies were invented both to help and superintend them by creating surrogate social ties.

HISTORY

By the 1840s, it was common for Americans to link homelessness with habitual drunkenness. In the popular view, habitual drunkards, usually men, drank up their wages and impoverished their families; they lost their jobs and their houses, and drove off their wives and children by cruel treatment. They became outcasts and drifters and their wives entered poorhouses while their children became inmates of orphanages. By the 1890s, the same logic served to explain the downward, isolated spiral of opiate and cocaine "friends" (as they were called) and the unhappy circumstances of their families.

Until the early years of the Great Depression (which began in 1929), habitual drunkenness, in



A homeless young boy inhales glue in front of graffiti that reads "Jesus loves me." (© Bill Gentile/CORBIS)

particular, often was cited as a principal cause of homelessness. Even so, after the financial collapse of 1893 and an ensuing five-year depression of unprecedented severity, most thoughtful observers did not understand heavy drinking or habitual drug use to cause homelessness in any *direct* manner. Although scholarly studies during the first decades of the 1900s were crude by today's technical standards, their explanations of homelessness were not simple-minded. In fact, they foreshadow today's explanations.

Perhaps most important, pre-Depression students of homelessness noted that the ranks of the dispossessed grew and diminished in close relation to economic conditions. They understood that the profound depressions that haunted the economy long before 1929 caused large numbers of people to lose their grip on security. They noted as well that certain occupations were especially affected by seasonal fluctuations in the demand for labor and by technological change—by the 1920s, agricultural workers, cigar makers, printers, and others had high rates of "structural" unemployment. That is, their jobs had been lost permanently to changes in methods of production and distribution.

These scholars also understood the importance of decisions that employers made about hiring and firing. Workers without families to support and those regarded as the least productive were let go first when the economy soured. Usually, these were single young women assumed able to return to their natal families, married women presumed to be working for "pin money" (people who are today known as secondary wage earners), older men, and in particular, single men known to drink heavily. Minority racial and ethnic status also marked people for layoff. Conversely, in times of high demand for labor, employers relaxed their standards for hiring and job performance. In boom times all but the most seriously disabled, and the most erratic and disruptive heavy drinkers and drug users, could find some kind of work. The ranks of the homeless thus thinned considerably.

Pre-Depression observers also emphasized the impact of working conditions, disability, and the absence of income supports on the creation of homelessness. In an era of dangerous work and widespread chronic disease (especially tuberculosis), large numbers of men, in particular, became substantially disabled, often at a young age. In an era before significant public disability benefits or much in the way of welfare or effective medical treatment, they rapidly became abjectly poor, reduced to begging, soup kitchens, and bedding down in mission shelters or the cheapest, most verminous lodginghouses ("flophouses," as they came to be called).

Some of these men were heavy drinkers, and some were habitual drug users, but it was commonly observed that such problems often developed in the context of POVERTY and rootlessness. The miseries and long stretches of boredom endemic to poverty were understood to promote frequent intoxication—even during the Prohibition years (1920–1933), when illicit ALCOHOL could be had by arrangement, as could illicit drugs. Certain "hobo" occupations that virtually demanded rootlessness, and which brought together large groups of men without families, were regarded as especially corrupting and debilitating. Railroad

gangers, cowboys, farmworkers, lumberjacks, and sailors, among others, pursued risky occupations and lived in ways that provided both motive and opportunity for dissipation. During the Depression it was widely feared that tens of thousands of homeless young people in the United States would be maimed hopping freights and would learn bad habits on the road that would transform them into lifelong tramps.

Finally, and related to their understanding of homelessness as an insalubrious and demoralizing experience, early observers paid a great deal of attention to the milieu of homelessness, which is to say, the urban areas where homeless people congregated and the constellation of institutions with which they were involved. Commonly called "hobohemias" before the Depression and "skid rows" thereafter, such areas were characterized by a particular way of life and a peculiar set of economic and social resources. They were honeycombed with cheap restaurants, residential hotels and lodginghouses, private and eventually public welfare agencies, and formal and informal labor exchanges that offered casual ("day") work. Skid row (and the segregated satellites that developed in minority communities) was also a world dominated by single men. Such areas were saturated with saloons (later bars) and sex workers. Some were the sites of a vigorous drug trade.

By the 1940s, winnowed by wartime labor demand, skid row was both repository and refuge, mainly for impoverished single men disabled by age, injury, and/or chronic illness. They survived on private charity, meager public welfare allowances, modest pensions, and undemanding work. Note, however, that they were housed. In the most literal sense, skid-row denizens were not homeless, and from the 1940s through the 1970s they were more often described as "unattached" or "disaffiliated." They were homeless in the broader, social sense discussed above. Further, and contrary to the enduring stereotype, the residents of skid row were not usually heavy drinkers or habitual drug users. Although perhaps one-third could be so described, and while public intoxication was common and visible, heavy drinking or drug taking was, as today, the exception not the rule.

With the sustained prosperity of the period between 1941 and 1973, and the simultaneous elaboration of the American welfare stale, many observers believed that skid row would wither away. The older men would die off, or—helped by federal Old Age Security, and later by Medicare, state and federal disability benefits, and subsidized housing—would move to better neighborhoods. Or they would remain on a skid row that would be uplifted and transformed by urban renewal projects and effective rehabilitation programs for heavy drinkers and drug users.

In a limited sense, these optimists were correct. The expansion of the welfare state dramatically improved the economic circumstances of the elderly, and they are greatly underrepresented among today's homeless. Aided by federal funds, some cities bulldozed their skid-row areas, thus causing their bricks and mortar, at least, to disappear. But homelessness did not disappear; instead, it underwent an astonishing and tragic transformation. If literal houselessness is used as the definition and measure of the problem, only the Depression produced the prodigious dispossession we see today.

As opposed to the domiciled isolation of skid row, something like today's houseless poverty was beginning to be reported in news magazines and the occasional scholarly publication as early as 1973. But it was not until the early 1980s that a new generation of younger homeless people achieved widespread notice. At first, most observers were struck by the apparently very high rates of mental illness, heavy drinking, and drug use among those new homeless people. Explanations of the problem tended to point toward nationwide changes in policies that governed commitment to and retention in mental hospitals and incarceration for public drunkenness and minor drug offenses. During the 1960s and 1970s many states "deinstitutionalized" both mentally ill people and "alcoholics" and "addicts." That is, state hospital patients were discharged in wholesale fashion, and new commitment laws made initial involuntary commitments difficult; they severely limited the duration of involuntary treatment. Many states also "decriminalized" public drunkenness, referring public inebriates to places where they could sober up rather than housing them in jail for thirty days to six months. Similarly, many minor drug offenders were diverted from jails. During the early 1980s many observers, notably those within the Reagan administration, characterized the resurgence of homelessness as a problem related to mental disorder, excessive drinking, habitual drug use,

and the new policies that kept people with such problems from their customary lodgings in state hospitals and county jails. Homelessness was described mainly as a problem in the rehabilitation and control of troubled and troublesome people who were not only houseless but barred from their traditional institutional shelters and estranged from family and friends who might take them in.

CURRENT VIEWS

Although not discounting this view entirely, most scholars now find it too simple and not supported by the evidence. Although some popular treatments of the subject continue to claim that perhaps 85 percent of homeless people are substance abusers and/or mentally ill, such huge figures are drawn from old studies and that were seriously flawed by two related methodological problems. The first requires little explanation: These studies for their estimates relied on *lifetime* rather than *current* measures of problems. In any group not in treatment or recently discharged, a lifetime measure (a determination of whetehr a person has ever had a sever mental illness or substance-use disorder) will always produce much higher prevalence rates than a measure of current disorder (customarily defined as present within the previous six months or one year).

The second problem is a matter of how homeless respondents were sampled for these studies and concerns the distinction epidemiologists make between "point prevalence" and period prevalence." The first term refers to counts of some condition conducted at a single moment in time (a snapshot), whereas the latter refers to counts taken over some expanse of time (a motion picture). Longitudinal ("period") counts of homeless people will produce much higher numbers than cross-sectional ("point-in-time") enumerations, for many more people are homeless during a year than on a given night. To the extent that people without problems of substance abuse and mental illness move out of homelessness more rapidly than those who suffer from then, they will be overrepresented in snapshot studies because they are more likely to be counted. Recent longitudinal studies demonstrate conclusively that a fairly small group of people with very high rates of disorder (usually single men under forty years old) account for a very large percentage of "shelter nights" in most cities. Since most studies of homeless populations conducted in the 1980s sampled from shelters on a cross-sectional basis, their estimates of substance abuse and mental illness were correspondingly inflated.

With these caveats in mind, it is probably fair to say that among all adults homeless during the previous year, something like half had a substance-use disorder or a major mental illness, alone or in combination. These rates are substantially higher among single men and significantly lower among adults who are homeless in family groups, most often single women.

Even so, sound prevalence estimates do not explain the casual relationship between homelessness and substance abuse and mental illness. Clearly, most people with such problems never become homeless. To explain why some do, current scholarship has returned—often unwittingly—to themes first sounded a century ago: the relationship of homelessness to changes in the economy and the nature and supply of housing; to the availability (or "coverage") and sufficiency of income supports and medical care; and to the tolerance and support capacity of kin. Heavy drinking, habitual drug use, and mental illness are considered in this larger context. Such problems are understood to be among many "risk factors" which make it more likely that some people will become homeless repeatedly or remain so for a long time. Moreover, current scholars are concerned increasingly with how such experience wears people down, introduces or rekindles bad habits or poor health, and makes "exits" from homelessness less likely or short-lived.

Briefly and simply, current scholarship suggests the following relationship between homelessness and heavy drinking and habitual drug use.

The problem of poverty has worsened considerably since the mid-1970s. Changes in the economy have added high-skill, well-paid technical jobs and low-skill, poorly paid service positions, but these changes have simultaneously produced job losses among semiskilled but highly paid workers, primarily in manufacturing. This process of "deindustrialization"—the historic passage from a manufacturing to a service economy—has been especially hard on those younger members of the huge baby-boom birth cohort (boomers are those born between 1946 and 1964), especially Hispanics and African Americans, who have entered a glutted labor market without the advantage of pro-

longed higher education or advanced technical training.

At the same time, the 1980s brought startling inflation in rental housing costs and a steep decline in the inflation-adjusted value of federal and state welfare benefits and unemployment insurance. In consequence, poor people had an increasingly difficult time forming independent households and poor families became increasingly hard put to support dependent adult members. On top of this and simultaneously, the stock of America's most rudimentary housing, the old hotels and lodginghouses of skid row and similar areas, was decimated by urban renewal.

The baby boom's maturation was crucial in another way. Although there is no good evidence that the combined *rate* of persistent and severe mental disorder, heavy drinking, or habitual drug use is significantly higher among boomers, neither is there any evidence that it is substantially lower than in previous birth cohorts. However, if a roughly constant rate (similar percentage) is applied to a much larger population, the resulting prevalence of a problem is of much greater magnitude—the numbers are much larger. Therefore, as huge numbers of boomers reached the age of greatest risk for the development of enduring mental-health, alcohol, and drug problems (roughly eighteen to twenty-five years old), the cohort generated an unprecedented number of such casualties. This situation developed just as conditions of material scarcity were becoming acute and the old policies of institutional containment were being dismantled.

Ironically, the unprecedented, sustained economic growth of the 1990s aggravated the problem of homelessness. As the decade wore on, shelter counts rose all over the country. In some part, this was because the general prosperity of the 1990s had little effect in the lowest reaches of the income distribution from which homeless people come, and cutbacks in federal, state, and local welfare eligibility compounded the problem. Further, rapid ecomonic expansion tends to have a significant inflationary effect on rents. Indeed, for the poorest 20 percent of American households, rents increased faster than incomes between 1995 and 1997. Moreover, the number of units renting renting for $300 per month (in inflation-adjusted dollars) decreased by 13 percent from 1996 to 1998, resulting in the loss of almost one million such units nationwide. At the same time, the number of households assisted by subsidies from the Department of Housing and Urban Development dropped by 65,000 between 1994 and 1998. In sum, the crisis in affordable housing became worse during the great boom.

CONCLUSION

Poor people have been badly squeezed since the early 1970s. As a consequence, perhaps 3 percent of all American adults, about 5.5 million people, experienced at least one spell of homelessness between the beginning of 1985 and the end of 1990. Some, however, experience frequent and prolonged episodes of homelessness, and it is among these people that rates of heavy drinking and habitual drug use are very high. It is not simply the case, however, that their drinking and drugging have caused their homelessness. The health problems and troublesome behavior often associated with such habits may have played an important role in job loss, familial estrangement, or displacement from housing—but this is not a new phenomenon, as we have seen.

Now, though, the absorptive mechanisms of earlier generations have gone awry. Deinstitutionalization has been a factor in this breakdown, mainly because its presumed consequence of community care never has been equal to the unprecedented generational need. Nonetheless, more important factors in the creation of widespread houseless poverty among heavy drinkers and habitual drug users have been the disappearance of casual labor, the erosion of public benefits and the capacities of kinship, and the virtual destruction of the tough but viable refuge of skid-row housing. In 1970, impoverished heavy drinkers and habitual drug users could almost always find some port in the storm, often by moving from one decrepit hotel to another, frequently pooling resources to rent a room by the week. Since the 1980s, they can no longer. Thus they have become a large and highly visible proportion of those who inhabit our public places and persist in our shelters month after month.

HONG KONG AND DRUGS *See* Opioids and Opioid Control: History of

HYDROMORPHONE Hydromorphone is a semisynthetic OPIOID analgesic (painkiller) derived from thebaine, an ALKALOID of the OPIUM poppy (PAPAVER SOMNIFERUM). It is one of the most widely used and effective analgesics for moderate to severe PAIN and is often referred to as Dilaudid, one of the brand names under which it is sold. Its potency is almost eightfold greater than is morphine's. Structurally, it is quite similar to MORPHINE but most like dihydromorphine, differing only in the replacement of the hydroxyl (–0H) group at the 6-position with a ketone (=0). Thus, it is not surprising that hydromorphone has many of the same side effects—including sedation, constipation, and depression of breathing. Chronic use will produce TOLERANCE AND PHYSICAL DEPENDENCE, much like morphine. This drug is reported to have high abuse potential, perhaps due, in part, to its very high potency.

I

IATROGENIC ADDICTION The potential for ADDICTION or ABUSE influences the licit medical use of many drugs, including OPIOIDS, BENZODIAZEPINES, BARBITURATES, and others. This influence can be evaluated from two perspectives—(1) the risk that addiction or abuse will result from medical treatment of patients with no such prior history, and (2) the possibility that overconcern about this risk leads to inappropriate undertreatment of certain medical conditions. Although these issues can be discussed with reference to any of these drug classes, the opioids are most illuminating and are emphasized below.

THE RISK OF ADDICTION OR ABUSE

Like any other potential adverse outcome of drug therapy, the prevalence of iatrogenic addiction (drug addiction or abuse during medical treatment) must be determined so that the risk can be assessed by both the practitioner and the patient. An accurate understanding of prevalence, in turn, requires the application of clinically relevant definitions of these phenomena. Unfortunately, there has been little effort to define the addiction syndrome as it occurs in patients, and there is abundant evidence that clinicians commonly use definitions that are inappropriate.

Definition of Addiction in Medical Patients. Accepted definitions of addiction and abuse (Jaffe, 1985; Rinaldi et al., 1988) have been derived from experience with addict populations. These definitions emphasize that addiction is a psychological and behavioral syndrome characterized by psychological dependence on the drug and aberrant drug-related behaviors. There is loss of control over drug use and evidence of compulsive use. Use of the drug continues, and often escalates, despite overt harm to the user or others. The definitions for abuse project a similar sense and stress the persistence of harmful drug use (Rinaldi et al., 1988) or its deviation from accepted societal or cultural norms (Jaffe, 1985).

The validity of these definitions has not been evaluated in medical populations. Although specific behaviors must be used to establish the diagnoses of addiction or abuse, there have been no studies that assess the predictive value of those behaviors that commonly raise concern in clinicians (Table 1). Some behaviors, such as dose escalation, that strongly support a diagnosis of addiction in an individual who does not have an appropriate medical condition or obtains the drug from nonmedical sources may be more difficult to interpret in patients who acquire the drug from a physician to manage an appropriate problem. Some patients with unrelieved cancer pain, for example, have been said to demonstrate pseudo-addiction—behaviors that suggest addiction but disappear as soon as analgesia (pain relief) improves (Weissman & Haddox, 1989).

In the absence of adequate studies of addiction and abuse in medical patients, the evaluation of drug use in the clinical setting is based on observed

TABLE 1
Behaviors that Raise the Suspicion of Addition or Abuse of Prescription Drugs

Probably More Predictive	*Probably Less Predictive*
Selling prescription drugs	Aggressive complaining about the need for higher doses
Prescription forgery	Drug hoarding during periods of reduced symptoms
Stealing or "borrowing" drug from another patient	Requesting specific drugs
Injecting oral formulations	Acquisition of similar drugs from other medical sources
Obtaining prescription drugs from nonmedical sources	Unsanctioned dose escalation once or twice
Concurrent abuse of related illicit drugs	Unapproved use of the drug to treat another symptom
Multiple dose escalations despite warnings	Reporting psychic effects not intended by the clinician
Multiple episodes of prescription "loss"	

NOTE: There have been no studies to assess the relative predictive value of these behaviors, but separation into the two categories of "more" or "less" predictive is supported by clinical experience.

situations. Although some behaviors may provide compelling evidence (selling prescription drugs), most will require astute and often repeated assessments. Any suggestion of aberrant drug-related behavior should impel a comprehensive assessment by the clinician of all aspects related to the patient's medical disorder and treatment plan (Portenoy & Payne, 1992).

The Problem of Mislabeling. Clinicians often compound the problem of definition by mislabeling patients as addicts without the evidence to support this diagnosis. Such mislabeling increases the perceived prevalence of iatrogenic addiction and unnecessarily stigmatizes the patient.

The most common type of mislabeling confuses PHYSICAL DEPENDENCE with addiction. Physical dependence is a pharmacologic property characterized by the occurrence of an abstinence syndrome following abrupt dose reduction or administration of an ANTAGONIST. Since physical dependence is not apparent unless an abstinence syndrome occurs, and abstinence can be easily prevented, physical dependence is generally regarded as a minor problem in the clinical setting. Although it has been postulated that abstinence symptoms can become conditioning stimuli that contribute to the genesis of addiction (Wikler, 1980), it is evident that physical dependence alone does not produce addiction or abuse. Opioid addicts, for example, may or may not be physically dependent, and cancer patients, who are almost certainly physically dependent after receiving high opioid doses for prolonged periods, almost never develop the aberrant drug-related behaviors consistent with addiction or abuse (Kanner & Foley, 1981).

Studies of Addiction or Abuse in Medical Patients. Thus, the risk of iatrogenic addiction or abuse can only be determined if proper definitions are developed and applied to patient populations. Few studies have met these criteria, but those that have are reassuring, indicating a very low risk of these outcomes during medical treatment with drugs of abuse.

Surveys of opioid use are most illustrative. Although older studies of opioid addicts suggested considerable risk of iatrogenic addiction, these data have been replaced by more recent surveys of pain patients. Addiction and abuse are vanishingly rare outcomes of opioid therapy for acute and chronic cancer pain (Kanner & Foley, 1981; Chapman & Hill, 1989). Most experts have concluded that the risk of addiction during opioid treatment for cancer pain is so remote that this outcome should not even be considered in the decision to use these drugs. Similarly, the Boston Collaborative Drug Surveillance Project could document only four cases of addiction among 11,882 patients with no prior history of substance abuse who were administered an opioid during hospitalization (Porter & Jick, 1980); a national survey of burn units could not identify a single case of addiction among 10,000 patients who had no history of substance abuse and received opioids for burn pain. Finally, surveys of selected patients with chronic nonmalignant pain also suggest that aberrant drug-related behavior is distinctly uncommon among those with no such history who are administered opioids on a long-term basis (Portenoy, 1990).

Other drugs have not been evaluated as extensively as the opioids. Recent analyses of BENZODIAZEPINE use, however, conclude similarly that addiction or abuse as defined here is a rare outcome among patients with ANXIETY disorders

who are administered these drugs by physicians (Woods et al., 1988; Balter & Uhlenhuth, 1991), although many develop physical dependence.

Together, these data indicate that medical patients with no prior history of substance abuse have a very low risk of iatrogenic addiction or abuse when they are medically administered drugs with a potential for these outcomes. This conclusion is consistent with an understanding of addiction as a disorder related to the use of specific drugs, but not inherent in the pharmacology of any. Addiction is presumably determined by an interaction between the reinforcing qualities of some drugs and a constellation of individual factors, including a genetic propensity, psychosocial aspects, and the specifics of drug availability (Jaffe, 1990, 1992; Chapman & Hill, 1989). The evidence suggests that patients who do not demonstrate a proclivity to addiction or abuse by adulthood are extremely unlikely to develop these outcomes during medical treatment thereafter. Furthermore, it is probable that this small risk could be reduced further by strict adherence to guidelines that set parameters of appropriate patient behavior and follow-up assessments. Such guidelines would also facilitate the identification of those occasional patients who develop any addiction problems.

UNDERTREATMENT

Although the conclusion that iatrogenic addiction and abuse are rare, still this appears to be inconsistent with the attitudes held by many healthcare providers and patients. Fear of addiction is commonplace. Consequently, there is evidence that overconcern about addiction adversely influences prescription practices.

The negative effects on patient care produced by an inaccurate estimate of addiction liability are most clearly documented in pain management—inadequate treatment with opioid drugs results in an unnecessarily high prevalence of unrelieved acute pain, especially cancer pain. Concerns about addiction are among the salient factors that contribute to undertreatment (Portenoy, 1995).

CONCLUSION

The data extant indicate that addiction and abuse are rare outcomes during the therapeutic use of opioids and other drugs in populations with no prior history of substance abuse. The intense concern expressed by clinicians and patients alike and the impact of this concern on prescribing practice appear to be disproportionate to the actual risk. To some extent, this may relate to the difficulties encountered in evaluating addiction and abuse in medical populations, or perhaps more likely to the tendency to mislabel outcomes as addiction that do not fulfill criteria for the diagnosis. Although good clinical practice must recognize the potential for addiction and abuse, optimal therapy depends on an accurate understanding of these phenomena and the limited role they play in clinical practice.

IATROGENIC ADDICTION: NONOPIOIDS *See* Prescription Drug Abuse

IBOGAINE The roots of the shrub *Tabernanthe iboga* first aroused pharmacological interest in 1864 when a French naval surgeon brought some back from Gabon, West Africa. The root was eaten by various Gabonese tribes as part of initiation ceremonies of puberty and was said to produce intoxication, visions, and a reduced need for sleep.

An active alkaloid, ibogaine ($C_{20}H_{26}N_2O$), was isolated in 1901 from the roots, bark, and leaves of *Tabernanthe iboga*. In the early 1900s, some medical researchers in France recommended ibogaine for use in treating neurasthenia and asthenia (syndromes that would probably be diagnosed in the 1990s as depression or fatigue syndrome). Although the drug was part of a proprietary medication marketed in Europe in the late 1930s and throughout the 1940s, ibogaine attracted little medical or scientific attention until the emergence of interest in indole alkaloids that accompanied the use of reserpine in the 1950s. During the 1960s, when there was considerable research on the use of LYSERGIC ACID DIETHYLAMIDE (LSD) and other psychedelic agents (HALLUCINOGENS) in psychotherapy, ibogaine was also studied, since it appeared to produce mental effects similar in some ways to other hallucinogens. At about the time of these studies, 1967–1968, the World Health Organization and the U.S. Food and Drug Administration (FDA) classified ibogaine as a hallucinogen, along with LSD, MESCALINE, and PSILOCYBIN.

In 1962, Howard Lotsof, who was at the time addicted to heroin, ingested ibogaine in search of a different drug experience. Lotsof came out of a long psychedelic experience, during which he had not taken any heroin, and found that he had no withdrawal symptoms and did not crave drugs. At the time, he noticed that ibogaine had a similar effect on several other heroin addicts. He subsequently remained drug free, completed law school, eventually obtained a patent on the use of ibogaine for the treatment of addiction (brand name ENDABUSE), and became active in seeking funding to further develop the drug and to obtain FDA approval for its medical use in treatment of addiction.

As a Schedule I drug under the CONTROLLED SUBSTANCES ACT, ibogaine is considered to be highly subject to abuse and without any approved medical use. To be approved by the FDA, an agent must be shown to be safe and effective. Throughout the early 1990s the only reports of the efficacy of ibogaine have been anecdotal ones from individuals in Europe who were addicted to heroin, COCAINE, and TOBACCO. Those who take ibogaine are generally highly motivated since the drug is expensive, costing up to several thousand dollars. While many reported a decrease in drug CRAVING after taking ibogaine, relapse to drug use within a few months was also observed.

As a result of pressure from activists, the U.S. government funded animal studies of ibogaine's actions on opioid and cocaine withdrawal, opioid and cocaine self-administration, and neurotoxicity. Studies in animals have not been entirely consistent. High doses of ibogaine reduced some manifestations of opioid withdrawal in monkeys. Studies in opioid-dependent rodents have shown that ibogaine decreases withdrawal, but other studies have not. Some rodent studies have shown a decrease in drug self-administration. Studies of ibogaine toxicity have also produced mixed results. Some studies in monkeys produced no obvious nervous system toxicity, but a study in rats produced damage to neurons in the cerebellum, the part of the brain known best for its role in control and coordination of movement. Other research studies indicate that ibogaine is not similar to opioids such as MORPHINE and heroin nor to hallucinogens such as LSD in terms of actions at drug RECEPTORS.

Despite these inconclusive research findings, in the early 1990s an FDA advisory committee recommended approval of limited trials in humans aimed at establishing safety and efficacy in treating drug dependence. At least one death has been attributed to the use of ibogaine in the treatment of heroin addiction.

IMAGING TECHNIQUES: VISUALIZING THE LIVING BRAIN Images of the human BRAIN constructed using sophisticated computer systems have proven valuable for studying the effects of abused drugs. Nuclear medicine techniques, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), allow noninvasive studies of brain function in human volunteers by the administration of small amounts of radioisotopes. These procedures allow visualization and quantification of biochemical processes in the living brain. Functional MRI (magnetic resonance imaging) is a recently developed technique that makes it possible to construct functional brain images without radiation.

PET scanning uses radioisotopes that decay by emitting positrons (positively charged particles), which collide with electrons (negatively charged particles that surround atomic nuclei). In each collision, both the electron and positron are annihilated and energy is released in the form of two photons (quanta of light) that move in opposite directions. The detectors of a PET scanner surround the tissue being studied and register the arrival of photons. The associated computer system can calculate the location of each collision and reconstruct an image of the concentration of radioactivity in different parts of the tissue.

The most common applications of PET scanning involve functional measurements of cerebral (brain) metabolism or cerebral blood flow. PET is also used to map and quantify specific RECEPTORS for drugs and NEUROTRANSMITTERS in the brain. Cerebral glucose consumption (metabolism) and cerebral blood flow both reflect the activity of brain cells. Under normal circumstances, the cerebral metabolism and blood flow are tightly coupled. The most active brain cells require the most glucose, a sugar that is the primary energy source of the adult brain. Brain regions that contain the active cells also require high rates of blood flow for the delivery of nutrients and oxygen. In some conditions, however—including those caused by some drugs—cerebral metabolism and blood flow rates may be dissociated.

Rates of consumption of glucose in the whole brain or in specific brain regions have been measured using fluorodeoxyglucose (FDG) labeled with the positron-emitting isotope fluorine-18 (^{18}F). Cerebral blood flow has been measured using oxy-

gen-15 (^{15}O), either inhaled in $C^{15}O_2$ or injected in ^{15}O-labeled water.

In SPECT, radionuclides that emit single photons are used, including iodine-123 (^{123}I) and technetium-99m (^{99m}Tc), and the photons are measured using a rotating gamma camera. The isotopes used in SPECT have longer half-lives (thirteen hours for ^{123}I and six hours for ^{99m}Tc than those used in PET (110 minutes for ^{18}F and 10 minutes for ^{15}O). Therefore, whereas PET generally requires an on-site cyclotron to produce radioisotopes, SPECT radioactive tracers can be made elsewhere and brought in for use. Although SPECT produces useful images, it does not provide either the quantitative precision or the spatial resolution of PET. Currently available PET scanners can resolve differences in the radioactivity of objects only 4 to 5 millimeters (mm) apart, while the resolution of new SPECT scanners is for 6 to 8 mm.

Before the advent of PET and SPECT, blood flow was measured using xenon-133, given by brief inhalation or intracarotid artery injection. Xenon-133 has a gamma emission with a half-life of 5.27 days, and the radioactivity is monitored outside the skull by an array of detectors that each record a beam of particles from a specific location. Unlike PET, the xenon-133 methods do not provide tomographic information—they do not produce images of "slices" of the brain. Therefore, activity in deep brain structures cannot be measured this way.

Recent advances in magnetic resonance imaging (MRI) technology have permitted functional measurement of cerebral blood volume, which is closely related to cerebral blood flow. Functional MRI assessments are based upon the difference between the paramagnetic properties of oxygenated and unoxygenated hemoglobin. Activation of a brain area causes increased blood flow to the region. Oxygen carried to the activated region is delivered in excess of that which is required by the increased activity. Therefore, it accumulates, as does oxyhemoglobin. Functional MRI produces brain images of very spatial and temporal resolution.

Since researchers are interested in the activity of specific brain structures, data are obtained by functional imaging techniques often adjusted (normalized) to remove the effects of differences between individuals in whole brain activity measurements considered irrelevant to the question under study. Normalized data may be expressed numerically as the quotient of the activity in a region of interest divided by the activity in the whole brain or in the slice containing the region. Such data are not always easy to interpret, since changes in the denominator can obscure the direction and magnitude of change in a region.

ACUTE EFFECTS OF DRUGS

Alcohol. Acute administration of ALCOHOL (ethanol)—a depressant—reduces cerebral glucose utilization, as we learned from measurements taken by the FDG technique. Modest decreases of 15 percent or less are seen in the whole brain in response to a dose of 1 gram/kilogram (g/kg) of ethanol (about 2 oz. of 100 proof whiskey for a 150-lb. person). Slightly more dramatic reductions in metabolism have been noted in the brain's cortex, particularly in the frontal and the occipital regions.

In contrast, acute ethanol administration does not reduce cerebral blood flow. Therefore, ethanol appears to dissociate cerebral blood flow from glucose metabolism. Studies with xenon-133 have indicated that ethanol (0.75 g/kg) increases cerebral blood flow by about 20 percent overall. Furthermore, normalized data obtained by PET scanning, using ^{15}O-labeled water, indicate regional effects of ethanol on cerebral blood flow. The largest changes were noted in the cerebellum (decrease), the prefrontal cortex (increase), and the temporal cortex (increase).

Stimulants. Studies with STIMULANTS have indicated that drugs of this class—including COCAINE and AMPHETAMINE—like the DEPRESSANT alcohol, reduce cerebral glucose utilization. Oral AMPHETAMINE at a dose of 0.5 milligrams/kilogram (mg/kg) decreases cerebral glucose metabolism by an average of about 6 percent of values in the unperturbed state, with no variation in the effect of the drug in different brain regions. A euphorigenic intravenous dose of cocaine (40 mg iv) also reduces cerebral glucose metabolism globally, averaging about a 14 percent decrease overall. The largest reductions occur in the left temporal pole and in the left lateral occipital gyrus.

Benzodiazepines. The effects of diazepam (Valium), a benzodiazepine anxiolytic, on cerebral metabolism and blood flow have also been studied, and results indicate that both of these parameters of brain function are reduced. Glucose metabolism is reduced by taking doses as low as 0.07 milli-

grams/kilogram orally (about 5 mg, the dose that might be given for anxiety), and the effect does not show regional specificity. Small reductions in cerebral blood flow, as measured with xenon-133, are also seen in response to intravenous diazepam (0.1 mg/kg). The reductions average about 6 percent overall, with the largest reduction seen in the right frontal cortex.

Opioids. The acute effects of HEROIN on cerebral metabolism or blood flow have not been reported, but a euphorigenic intramuscular dose of MORPHINE (30 mg) reduces cerebral metabolism globally, averaging about a 10 percent decrease overall. The largest reduction is found in the left superior frontal gyrus.

Marijuana. The active ingredient in MARIJUANA, delta-9-TETRAHYDROCANNABINOL (THC), produces variable effects on global cerebral glucose consumption but increases normalized metabolism in the cerebellum, as is consistent with the localization of cannabinoid receptors to this region. The metabolic effect is correlated with self-reported intoxication and with the plasma concentration of THC.

Effects of Abused Drugs. Taken together, these results indicate that all drugs of abuse that have consistent effects on cerebral metabolism produce decreases, but the magnitude of the decrease varies. This discrepancy is due, at least in part, to differences in dose and route of administration. The regional distribution of drug effects also varies, but the regional differences in percent change are not large in any of these studies. It seems that drugs of abuse—whether classified as depressants (alcohol), stimulants (cocaine), tranquilizers (benzodiazepines), or ANALGESICS (OPIOIDS)—reduce cerebral glucose metabolism globally.

Effects of abused drugs on global cerebral blood flow are less consistent, with decreases by the tranquilizer diazepam but increases by the depressant alcohol. Differences in regional effects of drugs on cerebral blood flow are minimal or absent, and the effects are generally global. Drugs of abuse may influence cerebral blood flow by direct effects on the cerebral blood vessels. Such direct vascular effects do not reflect changes in blood flow to meet the energy demand of the brain—in contrast, measurements of glucose metabolic rates are less sensitive to vascular responses that are seen as alterations in cerebral blood flow. In this respect, glucose metabolism can be a better measure of brain function than cerebral blood flow.

CHRONIC EFFECTS OF ABUSED DRUGS

Long-term drinking (chronic ethanol abuse) has toxic effects on the brain, and imaging techniques have added to the understanding of these effects. Brain glucose metabolism is decreased in recovering alcoholics (abstinent at least seven days), even if they do not show brain damage severe enough to be diagnosed as organic brain syndrome. The largest differences from controls were found in frontal lobe structures. Cerebral blood flow, measured using xenon-133, is also decreased in chronic alcoholics, with the largest differences in frontal and temporal lobe structures. To some extent, the changes are reversible with abstinence. Low cerebral blood flow is related to heavy drinking history, with the lowest flow rates in patients with brain damage (organic brain syndrome) due to alcohol.

Chronic use of cocaine has also been associated with persistent effects on functional markers in the brain. Whether measured by PET or SECT, cerebral blood flow in recovering cocaine addicts (abstinent four to fourteen days) shows focal abnormalities and lower flow rates than controls, particularly in frontal cortex. The etiology of abnormalities in cerebral blood flow in those with histories of cocaine abuse is not clear. In some cases, focal decrements may be related to the use of alcohol or other drugs of abuse or to the dysphoria related to the withdrawal of cocaine. Heroin addicts showed perfusion abnormalities as measured by SPECT during withdrawal (one week of abstinence), but cerebral blood flow had improved by three weeks of abstinence.

Taken together, studies using imaging techniques suggest that chronic use of alcohol and cocaine may damage certain structures in the frontal lobe of the brain. The frontal lobe is thought to be involved in decision making, planning, and other executive functions necessary for self-control. Thus chronic abuse of these drugs may injure the very brain structures that are required for a person to terminate drug use.

Current imaging techniques offer the promise of delineating the anatomical substrates of the acute and chronic effects of drugs of abuse. Such information may contribute to a further understanding

of the causes and the consequences of substance abuse and, ultimately, may lead to more effective prevention and treatment strategies.

REVISED BY MARY CARVLIN

IMMUNOASSAY Immunology is a laboratory science that studies the body's immunity to disease. The basic mechanism of immunity is the binding of drugs or other chemical compounds to antibodies (large proteins produced by the body's immune system). An assay is a general term for an analytical laboratory procedure designed to detect the presence of and/or the quantity of a drug in a biological fluid such as urine or serum (the fluid component of the blood obtained after removal of the blood cells and fibrin clot). An immunoassay, therefore, is an analytical procedure which has as its basis the principles of immunology—specifically the binding of drugs to antibodies.

Several different types of immunoassay are routinely performed in the laboratory. Although they differ in the types of reagents and instrumentation used, they are all based on the same scientific principle (the binding of drugs to antibodies). The three types of immunoassay that are commonly used for drug testing are the radioimmunoassay (RIA), enzyme multiplied immunoassay (EMIT), and fluorescence polarization immunoassay (FPIA).

It may facilitate the reader's understanding of immunoassay to envision the reactions that occur in the body following a vaccination (e.g., polio). The vaccine contains a weak or a killed solution of (polio) virus. When the vaccine is injected into the body, the immune system recognizes the presence of a foreigner (the polio virus), and it generates antibodies to that virus. These antibodies circulate in the blood, and they constitute the body's protection; if at some later date a live (polio) virus invades the body, the antibodies recognize it by its unique size and shape (similar to the fit of a lock and key); they spontaneously bind to the virus, leading to its inactivation and removal from the body.

This binding of antibodies to drugs forms the basis for immunoassay. In the development of an immunoassay, the first step is to inject an animal (host) with the drug that we ultimately wish to analyze. The host immune system, recognizing the drug as a "foreigner," generates antibodies to this drug, and these antibodies can then be harvested from the serum of the animal. In the test-tube environment of the laboratory (*in vitro*), these antibodies can be recombined with the appropriate drug. Just as it did inside the body (*in vivo*), the antibody will recognize the drug based on the lock-and-key fit and will spontaneously bind to it.

The second step in the development of an immunoassay is to synthesize a "labeled" drug. This involves the chemical addition of a "marker" to the drug. This marker can be small, such as an atom of radioactive iodine, or it can be large, such as an enzyme, which is a fairly large protein. Irrespective of its size, this marker is added in such a way that it does not interfere with the lock-and-key recognition between the antibody and the drug.

Commercially available immunoassay kits contain the antibody (which the company has prepared as described above) and the labeled drug (which has been chemically synthesized) necessary to perform the assay. In the laboratory, a fixed amount of antibody and a fixed amount of labeled

drug are placed into a reaction vessel (test tube). If these were the only two ingredients, all the binding sites on the antibody would react with (bind to) the labeled drug. A third ingredient added to the assay is, however, the unlabeled drug (i.e., the urine, saliva, or serum specimen containing the drug that is being measured). Because the label on the labeled drug is placed in a position that does not interfere with binding to the antibody (i.e., it is "hidden"), the antibody cannot distinguish between the labeled and unlabeled drug.

Immunoassays are always designed so that there are fewer antibody-binding sites present in the reaction mixture than there are molecules of (labeled plus unlabeled) drug. Because the labeled and unlabeled drug appear the same to the antibody, they will compete equally for the limited number of available binding sites on the antibody. By measuring the amount of labeled drug bound to the antibody, the analyst can calculate the amount of unlabeled drug in the biological specimen.

All immunoassays work in the same basic fashion. They differ in the types of labels that are added to the labeled drug and in the analytical methods by which the amount of binding of labeled drug to the antibody is measured.

RADIOIMMUNOASSAY

Radioimmunoassay (known as RIA) was the earliest of the immunoassay techniques. It was developed during the 1950s by a pair of research immunologists in New York City, Dr. Solomon A. Berson and Dr. Rosalyn S. Yalow. Their initial RIA was designed to detect very low blood levels of insulin and they published their findings in 1959. Their development of this technique was considered of such importance to science that Dr. Yalow was awarded a Nobel prize in 1977 for their work (since Dr. Berson died in 1972 and Nobels are not awarded posthumously, Berson's contribution was remembered in Yalow's acceptance speech).

In RIA, the marker is an isotope of a radioactive element, hence the name *radio*immunoassay. In most RIAs performed in the laboratory today, the radioactive isotope used as the marker is iodine 125, although tritium (hydrogen 2), carbon 14, and cobalt 57 are used in some assays. RIAs can be used in two different fashions to give information about the drug in a sample: (1) they can be used qualitatively—to determine whether a drug is present or absent (e.g., in urine drug testing); (2) they can be used quantitatively—to determine how much of a drug is present (e.g., to measure serum levels of drugs such as digoxin, a heart medication, or theophylline, an asthma medication).

RIA is an extremely powerful tool. One of its main advantages is the sensitivity that can be achieved. Drug levels in serum and urine that are as low as 10 to 100 parts per billion are routinely measured. Two of the most sensitive of the radioimmunoassays are the urine LSD assay and the serum digoxin assay, both of which can detect less than one part per billion. RIA is also an extremely versatile tool. It is used to measure a wide range of drugs of abuse in blood, serum, saliva, and urine, as well as therapeutic (physician administered) drugs in blood or serum. It is also used as a diagnostic tool to detect and quantify numerous naturally occurring chemicals in human serum and urine. Another characteristic that makes RIA such a powerful tool is the specificity of the assay. The antibodies are highly specific for the drugs analyzed and they rarely make a mistake in recognizing the lock-and-key fit between antibody and drug.

One of the major limitations of the radioimmunoassay is that it generates radioactive waste. To avoid spreading the radioactive compounds and contaminating the environment, the laboratory must conform to very strict regulations, including very elaborate procedures for waste disposal—and undergo frequent inspections. Because of a short half-life for some isotopes, another limitation is that the reagents with a radioactive label have a short shelf life. For instance, the majority are RIAs labeled with iodine 125; they have a shelf life of only approximately sixty days.

Some very sophisticated automated equipment is available for performing RIA or, if need be, the assays can be performed manually. All RIAs require the use of an instrument called a gamma counter, which measures the amount of gamma radiation given off by the radioactive drug bound to the antibody. In the 1990s, gamma counters can be purchased for as little as a few thousand dollars; but the reagents are moderately expensive (costing from less than fifty cents/test to two to three dollars/test, depending on the specific assay and the volume of reagents purchased).

ENZYME MULTIPLIED IMMUNOASSAY

The enzyme multiplied immunoassay technique, also known as EMIT™, is a variation of the general immunoassay technique, in which the marker used to prepare the labeled drug is an enzyme, rather than a radioactive isotope. EMIT is a two-stage assay. As in the other immunoassays, the sample, which contains some amount of the drug being measured, is combined with the antibody plus a fixed amount of the enzyme-labeled drug. In the first reaction, the labeled and the unlabeled drug compete for the available binding sites on the antibody (standard immunoassay reaction). A secondary reaction is then performed, which involves only the enzyme portion of the labeled drug. The results of this secondary reaction are used to calculate the amount of enzyme-labeled drug that is bound to the antibody and thus how much (unlabeled) drug there was in the original urine or serum specimen.

As with other forms of immunoassay, the EMIT can be used either qualitatively or quantitatively. In urine specimens, it is used to detect the presence of drugs, such as THC (MARIJUANA), COCAINE, PCP, OPIATES (HEROIN), AMPHETAMINES, and BARBITURATES. In serum specimens, EMIT is used to determine the amount present of drugs used for therapeutic (medical) purposes. Such drugs include acetaminophen (Tylenol), salicylate (aspirin), theophylline (widely used to treat asthma), several drugs used to treat epilepsy, and several drugs used to treat heart abnormalities.

Advantages that the EMIT technology has over the RIA are (1) that no radioactivity is involved, so the waste is more readily disposable; (2) the reagents are relatively stable, which may be particularly attractive to a small laboratory, which runs only a few specimens. The EMIT reagents are also less costly than the RIA reagents. The basic instrumentation requires less capital outlay than does the RIA, however the expense grows as more sophisticated automation is acquired.

Some limitations of the EMIT technique are (1) that it is somewhat less sensitive than the RIA (in particular, the LSD assay requires detection of such minute levels of the drug in urine that it can only be done by RIA); (2) also, EMIT is less specific than RIA and is subject to some interferences that do not affect the RIA—for example, the EMIT assay for amphetamines in urine gives a positive response with several other drugs that are similar in structure to amphetamines.

FLUORESCENCE POLARIZATION IMMUNOASSAY

Fluorescence polarization immunoassay (known as FPIA) is a technique that was developed by Abbott laboratories and marketed under the trade name TD_X. As the name FPIA implies, the marker for the labeled drug is a molecule of a naturally fluorescent compound called fluorescein. The amount of labeled drug that binds to the antibody is measured by a sophisticated instrument called a spectrofluorometer. As with the other immunoassays, this measurement is used to calculate the amount of labeled drug bound to the antibody and thus the amount of drug in the original urine or serum specimen.

The instrumentation necessary to perform the FPIA is only made by Abbott. It is expensive to purchase (upwards of $50,000) but can be leased from the manufacturer. The reagents are more expensive than EMIT reagents, being roughly comparable in cost to RIA reagents. They come in a liquid form and have a more limited shelf life than those for EMIT, but they tend to be more stable than RIA reagents.

The attractiveness of FPIA is in the speed and ease of operation of the instrument. The reagents come in a kit that is bar coded and is placed right into the instrument. All the operator has to do is fill the sample cups with serum or urine, place the reagent pack inside the instrument, and push a button marked "run." The instrument reads the bar code, enters the necessary programs into its memory, performs the assay, and prints out the results. For the routine hospital lab or small drug-testing lab, it is as fast or faster than EMIT or RIA and a lot easier; however, the instrument can only run twenty specimens at a time. For the large drug-testing laboratory, more rapid results can be achieved with the automated instrumentation available for the EMIT or RIA techniques.

FPIA is nearly as sensitive as RIA; digoxin can be run by FPIA, although LSD is still not available. The specificity of FPIA is also comparable to that of RIA.

JEFFREY A. GERE

IMPAIRED PHYSICIANS AND MEDICAL WORKERS Concern about impairment from alcohol and drugs in health-care professionals in the United States and in other countries has waxed and waned during the twentieth century. Until the 1960s, ALCOHOL, the OPIATES, and other PRESCRIPTION DRUGS were the primary concerns. More recently, the concern was extended to MARIJUANA and COCAINE.

Although there are many estimates of addiction rates among physicians, the prevalence of alcohol and other drug problems within the entire health-care profession is unknown. Brewster (1986) reviewed published estimates of U.S. addiction rates among physicians and found that available reports were not adequate to support firm conclusions about the prevalence rates. Adding to the difficulty is the physician's ability of self-medication, and the fact that much of the detection of abuse to begin rehabilitation can come only after a voluntary confession.

Physicians (since we do have data on them) are as likely as their age and gender peers to have experimented with drugs—both licit and illicit. They are, however, less likely to be current users of illicit substances (Hughes et al., 1992). Self-medication by physicians has changed little since the 1960s, whereas the use of cocaine and marijuana has greatly increased (McAuliffe et al., 1986).

Figure 1 shows the results of three surveys of drug use among U.S. medical students. Substantial numbers of medical students come to medical training having had some experience with illicit drugs.

Disciplinary or diversion actions by health professionals' licensing boards and studies of health professionals who receive treatment for alcohol or drug dependency are additional sources of information about the kinds of problems caused by drugs and alcohol and their relative frequency.

It is widely believed that health-care professionals are especially vulnerable to problems of alcohol and drug abuse because of familiarity with and ready access to drugs, the high STRESS associated with patient-care responsibilities, and their

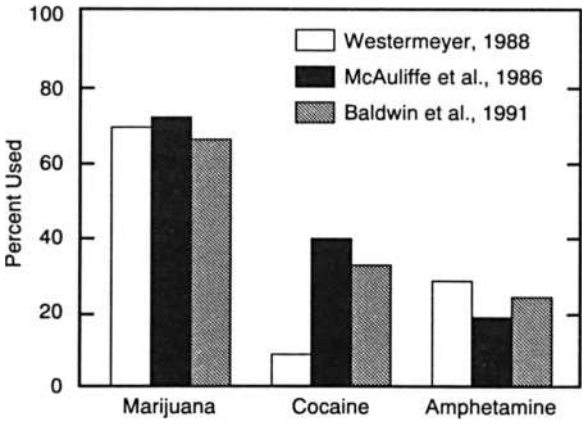

Figure 1

Lifetime Drug Use by Medical Students. Westermeyer (1988) surveyed first-year medical students (n = 195) at the University of Minnesota. During 1984–1985, McAuliffe et al. (1986) mailed anonymous questionnaires to a random sample of medical students in New England (n = 381). In 1987, Baldwin et al. (1991) mailed questionnaires to senior medical students at 23 schools located throughout the country (n = 2,046).

NOTE: n is the number of medical students who returned questionnaires.

own family problems may also contribute. Many physicians self-prescribe medications for relief of PAIN and ANXIETY. A 1989/90 survey of U.S. physicians found that 11.4 percent had used BENZODIAZEPINES and 17.5 percent had used minor opiates during the preceding year without medical supervision (Hughes et al., 1992a).

While the problem of drug addiction among health-care professionals is now widely acknowledged, such awareness has not always been the case. Impaired physicians and other health-care workers have been fearful of seeking help because they have not known how patients and colleagues might respond, which has become even more complicated since courts in numerous states have determined that physicians are not obligated to reveal their drug and alcohol practices to patients. Doctors also do not reveal their difficulties because they fear loss of practice privileges and licenses. Like many other professionals, physicians often feel uncomfortable about confronting drug or alcohol abuse in a colleague. They want to believe that a colleague in trouble will know when to seek help and will voluntarily seek it. The reluctance of physicians to report colleagues has been called a conspiracy of silence.

In 1972, the American Medical Association (AMA) Board of Trustees accepted the report of its Council on Mental Health and officially ended the conspiracy of silence by making physicians ethically responsible to recognize colleagues' inability to adequately practice medicine—an inadequacy that includes difficulties caused by drug or alcohol abuse. The council recommended a series of steps that should be taken if the impaired physician does not curtail practice: referral of the problem to the medical staff of hospitals in which the physician practices; referral to the state or county medical association; or, if other steps fail, referral to the licensing agency. In 1974, the AMA drafted model legislation allowing states' licensing agencies to require treatment and rehabilitation of impaired physicians as a condition of maintaining licensure. Before that time, the only possible response of the licensing agency was to discipline the physician. Since then, many state medical societies and licensing bodies have established programs for health professionals with alcohol or drug addiction.

In response to increasing malpractice, the U.S. Department of Health and Human Services established the National Practitioner Data Bank to collect information about malpractice and state-board licensing actions, hospital restrictions, revocation or denial of privileges, or denial of membership by a professional society. The purpose of the data bank is to prevent physicians from moving from state to state and continuing to practice without disclosing previous adverse actions against them. Hospitals must request information from the data bank when a physician applies for clinical privileges. The data bank prevents physicians with untreated alcohol or drug dependencies who have been disciplined in one state from practicing without restrictions in another state.

As a means of detecting drug and alcohol abuse, random urine testing is sometimes proposed for physicians and other health-care professionals. The AMA opposes routine urine testing because it intrudes on personal privacy and because a positive test does not establish impairment. Furthermore, drug- and alcohol-induced impairments are complex psychosocial and neurobehavioral problems that require a comprehensive clinical assessment, and neurobehavioral testing may better reflect the degree of impairment. Urine testing is useful for other purposes, though It is, for example, one of the best ways to document abstinence, which is an indicator of treatment progress.

DIFFERENCES IN PREVALENCE BY SPECIALTY

The choice of a particular drug and route of administration is influenced by accessibility and familiarity. Among anesthesiologists, for example, injectable fentanyl and its analogs are the most frequently abused opioids (see Table 1).

Although opioid addiction—and addiction treatment—among anesthesiologists has received frequent notice, the addiction rate among anesthesiologists may not be higher than among other physicians. Opiate abuse among anesthesiologists may be discovered more frequently because of the hospital environment in which they must practice. Interpersonal stress and the isolation of an office practice are believed to make psychiatrists particularly vulnerable to alcohol and drug abuse. The privacy of a solo office practice also makes detection difficult.

TABLE 1
Drugs of Abuse by Anesthesiologists

Drug of Abuse	*California Diversion Program* n = *42* *(percent)*	*Resident Anesthesiologists* n = *132* *(percent)*
fentanyl/sufentanyl	40	80
meperidine (Demerol) and other opiates	29	17
alcohol	17	11
cocaine	10	3
diazepam (Valium)	2	12
inhalation anesthetics (e.g., nitrous oxide)	0	8
ketamine	0	6
other	2	6

Data from the Diversion Program of the Medical Board of California shows the *primary* drug of abuse of anesthesiologists who were participating in the program during 1989 (Ikeda & Pelton, 1990). The data on resident anesthesiologists show their drug or drugs of abuse (Menk et al., 1990). Some residents abused more than one drug.

DETECTION OF ADDICTION

In hospitals, drug use by health-care professionals is often uncovered during inventory audits of medications, and the concealment efforts of impaired health-care professionals are often reflected in their treatment of or attitude toward patients. Some physicians who abuse prescription medications routinely overprescribe opiates or other drugs to patients in an effort to hide their self-prescription; others may prescribe unusually conservatively to avoid drawing attention to themselves.

TREATMENT

Many health professionals are pessimistic about the treatability of substance abuse, and if they develop an alcohol or drug problem, they may discount the value of treatment for themselves. Those who train or work in public-sector hospitals or clinics often observe that the treatment of their patients is rarely successful. Their perception is unduly pessimistic, however, because such clinics often treat recalcitrant, end-stage substance abusers. Furthermore, recent observation has seen medical care givers surpass all other professions as the most successful with intervention programs. This is possibly attributable to the ability of doctors to notice the difficulties in colleagues and the consequential early response.

The resistance to seeking treatment on their own often necessitates some form of coercion to force health professionals into treatment. One method of breaking down denial and forcing a person to seek treatment is called an *intervention*. The process consists of a group confrontation of the drug-abusing professional by concerned friends, family, and colleagues. A peer professional experienced in conducting interventions often assists in setting up the confrontation. The interventionist rehearses those who will be involved. When the stage is set, participants each tell the abuser what they have observed concerning the drug abuse and how it has adversely affected them. The confrontation, which may include threats to notify the abuser's employer, hospital, or state licensing board, may motivate an abuser to go for treatment. Such motivation is often fleeting, so it is important for the addict to go immediately into a treatment setting.

TREATMENT MODALITIES

Most treatment for impaired health professionals is drug-free and recovery-oriented, emphasizing follow-up participation in ALCOHOLICS ANONYMOUS (AA), COCAINE ANONYMOUS (CA), or

other peer-led groups. Recovering physicians rate participation in AA, for example, as an important factor in their recovery. In most respects, treatment of addiction for health professionals differs little from that used for other middle- and upper-class patients. Health-care professionals who abuse prescription drugs often see themselves as being different from street-drug users. Some programs deal with this form of resistance by insisting on a uniform treatment for all patients. There are, however, special problems that must be addressed. For example, addicted physicians, unlike street addicts, often underreport their degree of PHYSICAL DEPENDENCE on a substance in an effort to project a false sense of being in control. A period of inpatient treatment is often required.

METHADONE MAINTENANCE, which has been employed successfully for some HEROIN (and other OPIOID) addicts, is generally not an option for practicing health professionals, since most licensing boards will not allow them to practice while taking methadone. NALTREXONE has been particularly successful with health-care professionals and is the only medication for treatment of opioid dependency acceptable to most licensing boards. The ingestion of naltrexone reassures licensing boards and hospitals that the recovering health professional is not impaired from abuse of opioids. Its lack of mood-altering effect also fits well with the drug-free treatment philosophy.

WORK REENTRY

Work reentry can be difficult for recovering health professionals. Those who have abused prescription medication face reexposure to their drugs of abuse, which could lead to relapse. Hospital and other professional privileges are not easily regained. Licensing boards often opt to revoke or restrict the impaired health professional's license to practice, and insurance companies often refuse malpractice coverage to recovering addicts.

Some of these obstacles can be overcome with planning and peer support. For example, a nurse may find employment in a blood bank or other setting in which there is no access to drugs. Also, a physician may make arrangements to have a colleague see all the patients that require a NARCOTIC, thus avoiding having to write narcotic-containing prescriptions. Reentry may involve redirecting the health-care practitioner's professional activities to a different location or area of treatment, restricting the recovering health professional's scope of practice, or removing him or her from the previous practice environment altogether. For many health professionals, return to full practice after a period of monitored abstinence and compliance with treatment is possible.

One matter that remains unnegotiable, however, is the safety of the public. Medical boards do find it is their responsibility to aid the physician in reentering the workforce, but not at the expense of the health of patints.

RESPONSE TO TREATMENT

Prognosis for physicians treated for ALCOHOLISM or drug dependency is generally favorable. A study comparing physicians with other middle-class patients similarly treated in an inpatient program showed that physicians did better. The California Physicians' Diversion Program reported a 69 percent success rate for anesthesiologists and an overall success rate of 73 percent. This success is attributed to regular attendance at group meetings, regular testing for sobriety, and immediate corrective action whenever a slip or relapse occurs.

Such high rates of success are not uniformly attained. In a survey of training programs for anesthesiologists, it was found that of the seventy-nine anesthesiology residents who returned to their specialty following treatment, only twenty-seven (34%) did not relapse—and of the fifty-two who relapsed, thirteen (25%) died of drug overdose (Menk et al., 1990).

Some medical specialties are more stringent than others in allowing recovering trainees to return. Minor slips that are often dealt with by additional treatment in some specialties are usually not acceptable in anesthesiology training programs. Therefore, comparison of recovery rates between treatment programs and different subgroups of physicians is difficult to impossible.

INDIA, DRUG USE IN *See* Asia, Drug Use in; Bhang

INDUSTRY AND WORKPLACE, DRUG USE IN The 1991 NATIONAL HOUSEHOLD SURVEY ON DRUG ABUSE (NHSDA) indicated that roughly ten million employed Americans were "current users" of illegal drugs. Drug use by employees and workers has become an important issue for American business. In the 1990s, employers of all types (large and small businesses, nonprofit organizations, government) are attempting to contain the negative impact of illegal drug use on job performance, PRODUCTIVITY, safety, and health (Walsh & Gust, 1989).

Drug use "in the workplace" is perhaps a misnomer in that today's employer policies focus on drug use by the "worker," whether that use is at the work site or off the job. In the United States, drug abuse in the workplace was recognized as a serious problem in the early 1980s, and in the next decade a slow but progressive response by both labor and management yielded model programs and policies to deal with the issue. Typically, by 1993 most

organizations had comprehensive programs that included the following basic components: a written policy; supervisory training; employee education; employee assistance resource; and DRUG TESTING.

With such a comprehensive approach, the workplace has proven to be one of the most effective venues for drug prevention, treatment, and rehabilitation efforts (Gust & Walsh, 1989; Gust et al., 1991). Figure 1 shows the NHSDA data for "current users" (those reporting use of an illegal drug within thirty days prior to the survey), with figures broken down by employment status. Many observers believe that comprehensive workplace-based programs that reach out not only to the workers but also to their spouses and their student children can have an impact on at least 80 percent of all current users.

These endeavors have not been undertaken without controversy, especially with regard to the use of employee "drug testing," but the controversy is perhaps the most interesting part of the story. The development, current status, and future of these policies and programs will be discussed in detail later in this article. The evolution of workplace-based antidrug programs provide insights into the way unique social problems create a need for and the eventual development of innovative public policy (for additional information, see Walsh & Yohay, 1987).

Workplace "antidrug" policies date back to the 1960s, particularly in the transportation and other safety-sensitive industries. These policies were not then very effective because detection methods were poor and the signs and symptoms of drug use are often subtle and difficult to identify. Not until 1980, when new technology became available that provided reliable, inexpensive detection methods for MARIJUANA and other commonly abused drugs, did workplace detection efforts begin to be effective. Interestingly, the "workplace" that triggered the birth of these antidrug initiatives was the U.S. military.

In 1971, President Richard M. Nixon, as commander in chief, changed the Uniform Code of Military Justice so that testing positive for an illicit drug was no longer a court-martial offense. He ordered the military to start a program of urine testing among U.S. troops in VIETNAM and to offer treatment to those who tested positive for drug use. This urine-testing program was then expanded to service personnel worldwide. In the mid-1970s, the

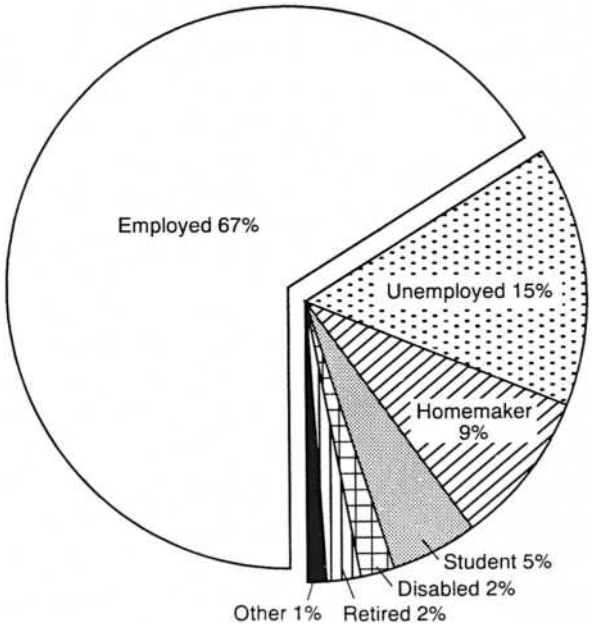

Figure 1
Employment Status of Illegal Drug Users

program was discontinued as a result of court challenges. At the time, the only drugs that could easily be tested for were OPIOIDS and some STIMULANTS.

The remarketing and reintroduction of drug-testing technology in 1981 occurred at roughly the same time as the Department of Defense (Burt & Biegel, 1980) and the Congress (House Select Committee on Narcotics, 1981) independently reported the survey results of drug use by MILITARY personnel. The results of these two surveys indicated high rates of drug use by military personnel and brought about considerable congressional scrutiny. The accident on the aircraft carrier U.S.S. *Nimitz* in May 1981, in which drug use was discovered by the postmortems of the crew members, increased political pressure on the military to do something about the drug-abuse problem. The juxtaposition of these events—the availability of drug-testing technology and congressional demands for the Defense Department to address drug taking in the military—was pivotal in justifying the widespread application of drug testing and the formulation of strict policies forbidding the illegal use of drugs on or off the job.

The development of such policies in the military received wide media coverage and generated much discussion in 1981. Shortly thereafter (1982–1983), similar policies began to be adopted in the transportation and utility industries for employees

in safety-sensitive positions. The National Transportation Safety Board documentation of drug involvement in railroad and airline accidents more than justified the increasing concerns about workplace drug abuse.

Early military and private-sector policies were punitive in nature; employees found to be using drugs were summarily dismissed. This created a dilemma for many major corporations that recognized they had a drug problem but didn't feel comfortable firing employees, especially when there was no safety or security nexus. The rationale for workplace drug policies and the use of drug testing has evolved considerably since 1981. The philosophy of why to test and what to do with the results changed dramatically during the 1980s and early 1990s. At the outset, the primary purpose of a drug policy was to identify users and to fire them without evaluating the circumstances of the drug use. Subsequently a more positive, helping-hand philosophy evolved.

The basic purpose of today's model corporate drug policy is twofold:

1. to minimize the risk of hiring drug users by denying employment to applicants who use illegal drugs (as manifested by a positive preemployment drug test); and
2. to provide active programs to get the substance-abusing employee into treatment, to afford the opportunity to get help, and to get the individual back on the job.

This philosophical change to a more politically acceptable, socially responsible policy in dealing with drug abuse evoked about 1986 and allowed major corporations and professional organizations to involve themselves in antidrug workplace initiatives.

The federal government facilitated, encouraged, and in some instances required the development of private- and public-sector workplace antidrug programs. The Federal Railroad Administration began hearings on drug rules for the railroad industry in 1984 and issued regulations requiring written policies and the testing of employees; after a number of legal delays, the regulations went into effect in 1986. In September 1986, President Ronald W. Reagan issued an executive order (EO 12564) that required all federal agencies to develop drug-free workplace programs to ensure that the more than 2 million federal employees were not illegally using drugs on or off the job. In 1988 the Department of Transportation issued regulations for the airline, maritime, trucking, railroad, pipeline, mass transit, and other transportation industries, requiring (1) written policies prohibiting the illegal use of drugs on or off the job and (2) preemployment, reasonable-suspicion, postaccident, and "random" drug testing without cause for employees in specified safety-sensitive occupations. By 1992 the regulations were extended to cover intrastate as well as interstate transportation, a move that increased the number of transportation workers affected by the regulations to ten million, or nearly 10 percent of the total U.S. workforce. The Nuclear Regulatory Commission also issued regulations requiring written policies and extensive testing of personnel at nuclear sites.

Congress got on the bandwagon and passed the Drug-Free Workplace Act of 1988, which requires all federal grant recipients and federal contractors (whose contracts exceed $25,000) to certify that they will provide a drug-free workplace. The final rules describing the requirements for such grantees and contractors were published in the *Federal Register* on May 25, 1990. In general, the law requires covered employers to:

1. Develop and publish a written policy and ensure that employees read and consent to the policy as a condition of employment;
2. Initiate an awareness program to educate employees about:
   the dangers of drug abuse
   the company's drug-free workplace policy
   any available drug counseling, rehabilitation, and employee-assistance programs
   the penalties that may be imposed on employees for drug-abuse violations;
3. Require that all employees notify the employer or contractor of any conviction for a drug offense in the workplace;
4. Make an ongoing effort to maintain a drug-free workplace.

In 1988, the Bureau of Labor Statistics (BLS) surveyed business establishments throughout the United States about their policies on drug abuse (BLS, 1989). The survey found that half the nation's nonagricultural workforce was employed by organizations with a formal policy on drugs, and that 20 percent of payroll workers were employed in establishments with some type of drug-testing

program. More than 90 percent of the establishments surveyed had an EMPLOYEE-ASSISTANCE PROGRAM available to employees. In the years since the BLS survey, the number of corporate and other employers and the employees covered by these policies continued to grow exponentially. The American Management Association (Greenberg, 1993) has surveyed its membership about their workplace drug policies annually since 1987. The 1993 survey indicated that 84 percent of respondents believe that drug testing is an effective way to deal with workplace drug abuse, compared with 50 percent in 1987. The share of surveyed firms that test for drugs rose to 85 percent in 1993. Since 1987, drug testing has increased nearly 300 percent. From the drug-treatment perspective, more than half of all companies (54%) have indicated that employees who test positive are referred for counseling and treatment.

As indicated above, progress in using the work site to intervene in individual substance abuse has not happened without controversy. Generally, employees and workers have no problem with supervisory training or employee education. However, the utilization of drug testing to make employment decisions and the involvement of employee-assistance programs (EAPs) in what many feel is a policing action generates an emotional, gut-level response from both labor and management. The drug testing and EAP components are so critical to any workplace effort that a detailed discussion of the issues is required.

DRUG TESTING

When drug testing is considered, it is important to be familiar with the basic issues with which management and labor have been struggling (a full range of issues are discussed in Walsh & Trumble, 1991). The question of whether to utilize drug-testing technology evokes a complex array of moral, social, ethical, medical, scientific, and legal issues for many Americans. Although most citizens do not condone drug abuse, their concerns about the erosion of civil liberties generate feelings of uncertainty as to whether the end justifies the means. "Where will it stop? Where do you draw the line?" are questions raised by unions, civil libertarians, and others who worry that employee AIDS testing and pregnancy testing will be the next battlegrounds.

Many Americans view the drug-testing process (i.e., collection of urine) as degrading and dehumanizing. Government employees, unions, and civil libertarians argue strongly that drug testing is an invasion of privacy, that it constitutes an illegal search and seizure (i.e., of body fluids) and therefore violates individual rights guaranteed by the Constitution. In general, the constitutional protections apply only to testing conducted by the government (federal, state, and local). Therefore, test-

TABLE 1
Some Recent Attempts to Define Alcoholism and/or Drug Dependence

Drug dependence. A state, psychic and sometimes also physical, resulting from the interaction between a living organism and a drug, characterized by behavioural and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid the discomfort of its absence. Tolerance may or may not be present. A person may be dependent on more than one drug. (*World Health Organization Technical Report Series*, 1969, no. 407, p. 6.) This definition was reaffirmed in the WHO Expert Committee on Drug Dependence Nineteenth Report, *World Health Organization Technical Report Series*, 1973, no. 526, p. 16.

Alcoholism is a chronic, progressive, and potentially fatal disease. It is characterized by tolerance and physical dependency or pathologic organ changes or both, all of which the direct or indirect consequences of the alcohol ingested. (National Council on Alcoholism/American Medical Society on Alcoholism, 1976.) (See Flavin & Morse, 1991.)

The 1976 definition was revised and broadened in 1991 to include the concept of *denial:*

Alcoholism is a primary, chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. The disease is often progressive and fatal. It is characterized by continuous or periodic impaired control over drinking, preoccupation with the drug alcohol, use of alcohol despite adverse consequences, and distortions in thinking, most notably denial. (National Council on Alcoholism and Drug Dependence/American Medical Society on Alcoholism, 1976) (See Flavin & Morse, 1991.)

TABLE 2
A Comparison of ICD-10 and DSM-IV Criteria for Dependence

ICD-10 Dependence Syndrome	*DSM-IV Substance Dependence*
A cluster of physiological, behavioural, and cognitive phenomena in which the use of a substance or a class of substances takes a higher priority for an individual than other behaviours that once had greater value. A central characteristic of the syndrome is the desire (often strong, sometimes overpowering) to take psychoactive drugs (medically prescribed or not), alcohol, or tobacco. There may be evidence that return to substance use after a period of abstinence leads to a more rapid reappearance of other features of the syndrome than occurs with nondependent individuals. *Diagnostic guidelines* A definite diagnosis of dependence should usually be made only if three or more of the following have been experienced or exhibited during the previous year: (a) a strong desire or sense of compulsion to take the substance; (b) difficulties in controlling substance-taking behaviour in terms of its onset, termination, or levels of use; (c) a physiological withdrawal state . . . when substance use has ceased or been reduced, as evidenced by: the characteristic withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms; (d) evidence of tolerance, such that increased doses of the substance are required to achieve effects originally produced by lower doses (examples are alcohol- and opiate-dependent individuals who may take doses sufficient to incapacitate or kill nontolerant users); (e) progressive neglect of alternative pleasures or interests because of psychoactive substance use, increased amount of time necessary to obtain or take the substance or to recover from its effects; (f) persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; determination should be made of the user's actual or expected awareness of the nature and extent of the harm. Narrowing of the personal repertoire of patterns of psychoactive substance use has also been described as a characteristic feature (e.g. a tendency to drink alcoholic drinks in the same way on weekdays and weekends, regardless of social constraints that determine appropriate drinking behaviour).	A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three or more of the following occurring at any time in the same twelve-month period: (1) tolerance, as defined by either of the following: (a) need for markedly increased amounts of the substance to achieve intoxication or desired effect (b) markedly diminished effect with continued use of the same amount of the substance (2) withdrawal, as manifested by either of the following: (a) the characteristic withdrawal syndrome for the substance . . . (b) the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms (3) the substance is often taken in larger amounts or over a longer period than was intended (4) a persistent desire or unsuccessful efforts to cut down or control substance use (5) a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects. (6) important social, occupational, or recreational activities given up or reduced because of substance use (7) continued substance use despite knowledge of having had a persistent or recurrent physical or psychological problem that was likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption) Specify if: *with physiological dependence:* Evidence of tolerance or withdrawal (i.e., either item [1] or [2] is present): *without physiological dependence:* No evidence of tolerance or withdrawal (i.e., neither item [1] nor [2] is present).

ing conducted by private employers is not covered by the constitutional safeguards. However, government-mandated drug testing of private-sector employees—for example, in the federally regulated transportation and nuclear-power industries—must also pass constitutional muster. Although several of these constitutional questions have been brought before the Supreme Court and have generally been upheld, many specific issues may not be resolved by the current cases and will likely continue to be the subject of litigation for some time. This legal uncertainty— whether testing will be upheld and programs go forward or will be found unconstitutional and therefore be restricted—has created confusion for policymakers as well as for employees and unions.

Medical and scientific questions about the accuracy and reliability of drug testing were and are continually raised by those who oppose testing. Concerns have been voiced that many laboratories offering drug-testing services do not have the expertise or capability to perform the assays required. In addition, many employers may be using inappropriate technology and falsely accusing employees of drug use. Congressional support for these concerns has been manifested by the passage of legislation (P.L. 100-71, sec. 503, July 11, 1987) that requires stringent technical and scientific procedures for federal workplace drug-testing programs, as well as standards for the certification of laboratories engaged in drug testing for federal agencies. Similar legislation has been introduced in both the U.S. Senate and House of Representatives that would require such standards and lab certification for the private sector.

In response to concerns about the accuracy and reliability of drug testing, the U.S. Department of Health and Human Services (HHS) issued *Technical and Scientific Guidelines for Federal Drug Testing Programs* (Walsh, 1988). These guidelines are mandatory for federal programs and have rapidly become the gold standard for private-sector programs as well. By 1993, the rigor of the federal standards virtually eliminated concerns regarding accuracy and reliability. The issue of the quality of laboratories has also been addressed by HHS through the establishment of a national laboratory certification program. The College of American Pathologists has also established a forensic urine drug-testing certification program making certified labs available in virtually every state. The use of a certified lab has become the standard by which drug-testing programs are measured. A consensus report from HHS on the scientific issues of drug testing provides detailed information (Finkle et al., 1990).

A discussion of the pros and cons of drug testing provides no clear answers (Walsh & Trumble, 1991). The American Civil Liberties Union (ACLU) has been among the most vocal organizations actively lobbying against drug testing. In addition to constitutional issues, a major concern has been the potential for abuse by managers and supervisors to discriminate against and harass employees. The focus of the ACLU argument is that a positive urinalysis does not prove intoxication or impairment of performance; therefore it cannot be used to draw a nexus between drug use and job performance.

For their part, employers have wrestled with competing objectives and values to develop substance-abuse policies that fulfill multifaceted obligations. On the one hand, many employers feel a moral obligation to do all they can to achieve a drug-free workplace. They have corporate responsibilities to provide a healthy and safe workplace for all employees and to protect shareholders from losses resulting from drug abuse. On the other hand, employers have obligations to their workers—to respect the individual rights and civil liberties of loyal and trustworthy employees (who for the most part are not involved with drugs).

This is an exceedingly difficult balancing act, and, as workplace policies are designed, the balance will shift depending on the individual work site and the nature of the particular job.

EMPLOYEE-ASSISTANCE PROGRAMS

EAPs have become the key component of model workplace policies (Masi, 1984). Although drug testing has provided the major turning point in the evolution of workplace antidrug programs, the EAPs have expanded, grown more sophisticated, and become a vital part of the antidrug initiative. EAP programs were developed in the 1970s to focus on ALCOHOL abuse and to assist employees in dealing with the stresses of employment and personal life. Typically EAP programs provide short-term counseling and serve as a referral source for those employees who need treatment or long-term counseling. So-called broad-brush EAP programs provide a variety of services, in addition to crisis

intervention, including management training and health workshops and seminars (e.g., SMOKING CESSATION, weight reduction).

As managers began to develop antidrug policies, the question was raised: What will we do if we find an employee using drugs? Generally, corporate lawyers and security officers would suggest termination, while corporate medical and EAP staff would recommend treatment. The issue proved difficult to resolve for many corporations when the cost of treatment and the uncertainty of success weighed heavily on the minds of financial officers responsible for making a profit in a bad economy. Fortunately, most corporations have EAP resources to implement the "helping-hand" approach that management sought.

The involvement of the EAP program in the antidrug effort was also not without problems. Initially some EAP providers had difficulty expanding their programs to deal with illegal drug users, a different type of client from ones with whom they had previously worked. The illegal aspect of drug behavior was troublesome in a field where confidentiality is the cornerstone of the therapeutic relationship. Also the advent of drug testing created an ethical dilemma for the EAP provider who was accustomed to being an ombudsman between management and labor. A good percentage of EAP referrals were coming from the drug-testing program in a last-chance situation in which the pressure was on the EAP to "cure" the problem—or management would fire the employee. In the past, many employees using EAP services had sought assistance on their own, and management was never aware of the employee's initiative.

Despite these problems, the EAP field has expanded its efforts to treat substance abuse and has proven to be integral to the entire program. Employers have recognized that EAP programs not only help employees but are cost-effective. New materials, training programs in substance abuse, and certification programs have developed that have made the EAP provider more skilled in dealing with the drug-using employee.

SUMMARY

Although drug abuse in the workplace is still a significant concern of American employers, substantial progress has been made since the early 1980s. Companies with comprehensive programs report significant reductions in accidents, absenteeism, and positive drug tests. There continues to be progressive growth in small and mid-size businesses, as resources for EAP, testing, management training, and legal services are being made available through local business consortia. The business community has developed a consensus that the workplace is an appropriate site for confronting drug abuse and has sent a clear message to the workforce and to the community that drug use will not be tolerated.

For the future, we are likely to see continued growth and expansion of workplace programs. As the country has gained confidence in the accuracy and reliability of drug testing, lower thresholds will be permitted that will make it much more difficult for the casual user to escape detection. We will probably see federal legislation setting additional standards for workplace programs, including standards for testing and for protection of employees.

Educating high school and college students that they must be drug-free to get and hold a job will in the long run contribute significantly to the reduction of drug abuse in the student population. And finally, because the workplace efforts are the most organized drug education, prevention, and treatment initiatives in the country today, they represent the best prospect for turning around the drug problem in America.

INHALANTS Inhalants are solvents or volatile anesthetics that are subject to abuse by inhalation. Most are central nervous system (CNS) depressants, but some are convulsants. As a class they are characterized by high vapor pressure and significant solubility in fat at room temperature. Vapors and gases have been inhaled since ancient times for religious or other purposes, as at the oracle at Delphi. Experimentation with inhalants did not occur to any significant extent until after the discovery of nitrous oxide and the search for volatile anesthetics commenced in earnest. Arguably the most toxic of abused substances, inhalants can produce a wide range of injuries, depending on the chemical constituents of what is inhaled. Many are very complex mixtures formulated for a specific purpose, or are used because they are the least expensive alternative, or both. Thus their purity and safety are in no way comparable with those achieved by pharmaceutical companies manufacturing medications for human consumption.

Inhalants are typically abused by achieving a high airborne concentration of a substance and deliberately inhaling it. With solvents, this typically involves putting the solvent in a closed container, or saturating a piece of cloth and inhaling through it. Compressed gases are sometimes released into balloons and inhaled; directly releasing these substances into the mouth may freeze the larynx, causing laryngospasm and death by asphyxiation. Once the chemical is inhaled, its uptake and duration of action are determined by its solubility in blood and brain, and by the respiratory rate and cardiac output.

The mechanism of action of this class of agents is less well understood than those of other drugs and medications. As CNS depressants, they have been thought to exert their actions by dissolving in membranes and altering their function in a nonspecific way; the potency of these compounds is frequently related to their solubility in membranes. Many consider this relationship to better predict the access of the agent to the site of action, and to be unrelated to the mechanism by which the solvents exert their effects. Solvents impair conduction in isolated nerves, and affect nerves with smaller diameters first. This suggests that parts of the nervous system such as the cortex would be affected before systems consisting of large fibers. There is significant interest in the GABA receptor complex as the site of action of many of these compounds. There is not yet evidence for specific interactions with a receptor, in the sense of a "lock and key" mechanism. However, these agents may "lubricate" or "obstruct" such mechanisms.

Although inhalant abuse has been implicated in a variety of organic diseases, its effects on the nervous system have been of the greatest concern. Such injuries range from paralysis and loss of bowel and bladder control, to permanent impairment of the higher cognitive functions and fine motor control. Those who become involved in inhalant abuse vary across culture and, as in many

Inhalants are typically "huffed" from a rag soaked in the substance and placed in a plastic bag so the vapors can concentrate. (Drug Enforcement Administration)

other types of drug abuse, the vulnerability to becoming dependent on these substances may depend on present economic well-being and perceptions of the possibility of future well-being. Their ability to act as a reward has been demonstrated in laboratory animals, so there is no doubt that they exert powerful actions on the nervous system. Preventive actions are of two types: education about the adverse effects of solvents on bodily function, and the possible formulation of consumer products with less intrinsic toxicity. Some manufacturers have attempted to minimize the abuse of their products by adulterating them with irritants. Intervention strategies for those habitually using inhalants are not different from those employed for other CNS depressant dependence disorders. Frank withdrawal symptoms are rarely seen with organic solvents. They do, however, accumulate under some conditions of use, and can be associated with prolonged delirium and behavioral disturbances.

ALKANES

Alkanes are hydrocarbons of the general formula $C_nH_{2n}+2;$. The potency of this family of straight-chain chemicals increases with the number of carbons. The smaller molecules (methane, ethane, butane, propane) are gases at room temperature; their deliberate inhalation produces cardiac arrhythmias and sudden death. Pentane, hexane, and longer alkanes are liquids that become progressively less volatile. Hexane produces a devastating neurotoxicity. Alkanes are paraffins; cycloparaffins are rings without alternating double bonds; and alkylcycloparaffins have a short substituent on the ring. Alkylcycloparaffins such as methylcyclopentane and methylcyclohexane (hexahydrotoluene) are convulsants.

AMYL NITRITE

Amyl nitrite is a volatile, oily liquid with a sweet, banana-like odor. It is sold by prescription in glass ampules for the treatment of angina pectoris, chest pain caused by the narrowing of vessels in the heart. When the glass ampules are broken, they "pop"; hence they are sometimes called "poppers." Amyl nitrite relaxes the vessels of the heart by relaxing the muscles of the veins as well as all other smooth muscles in the body. When the veins throughout the body dilate, blood pressure falls. Because a minimum blood pressure is required to maintain blood supply to vital organs such as the brain, a reflex protects the brain by increasing heart rate and blood flow. This produces a "rush" as the heart pounds, and there is a throbbing sensation in the head. Users also experience a warm flush as the blood accumulates near the skin because of the dilation of veins. Vision also may "redden" as the retinal vessels dilate. The user may faint if the heart cannot maintain blood flow to the brain. If this occurs, the user falls to the floor, and blood flows to the brain, restoring consciousness. Use in a situation where it is impossible to become horizontal may result in brain damage.

The duration of action of the drug is very brief, and as the effect wears off, the user may experience headache, nausea, vomiting, and a chill. The drop in body temperature occurs because of the loss of heat when the veins dilate and the skin flushes. Use of the drug for prolonged periods, or swallowing the liquid, may produce fatal methemoglobinemia, a "chocolate" blood condition in which the blood is brown and cannot carry oxygen to the brain. The drug produces a thick, crusty brown rash if it is spilled on the skin, and is irritat-

ing to the lungs. It is flammable and explosive. Volatile nitrites are converted to nitrosamines in the body, and most nitrosamines are very potent cancer-causing chemicals. There is an association of the use of volatile nitrites with Kaposi's sarcoma, an AIDS-related skin cancer. Volatile nitrites impair the function of the immune system. The physiology of sexual intercourse involves smooth muscle; the nitrites relax those muscles as well and so will affect sexual function.

The prescription requirement for amyl nitrite was eliminated in 1960, and its use became popular; in 1964 prescription requirements were reestablished. "Designer" nitrites, such as butyl and isobutyl nitrites, were then bottled and sold as "room deodorizers" with such names as RUSH, Locker Room, and Aroma of Men, so named because it smelled like a locker room. Since these products were not controlled substances or sold as medicines, they were once legal products.

ANESTHETICS

Anesthetics are used in medicine to permit surgical procedures without pain or consciousness. They are of two types: local and general. A local anesthetic is usually injected near nerves to prevent pain in a limited area, such as a Novocaine injection to anesthetize a tooth. General anesthetics are administered to the whole body and depress the CNS to such an extent that major surgery can be performed without killing the patient from the shock resulting from procedures that otherwise would be unendurable. General anesthetics were developed in the mid-nineteenth century by doctors experimenting, usually on themselves, with the organic solvents available at the time. These experiments were sometimes done by groups of people who inhaled the vapors and described the effects, or passed out. Later, careful experimental work identified volatile chemicals that are used to save lives by permitting surgery that would otherwise be impossible to perform, and that are safe to use and have relatively low toxicity.

Some anesthetics can be given by injection. Short-acting anesthetics are used for brief procedures in medicine and dentistry where inhalation anesthesia is inappropriate or difficult, or for starting anesthesia before longer-acting agents are given to the patient. Drugs used for this purpose include barbiturates such as sodium methohexital and sodium thiopental, and benzodiazepines such as midazolam. Fentanyl and related compounds are used for a longer duration of action. A dissociative anesthetic, ketamine, is used for treating burn patients and small children. These agents affect the brain in a more selective way than other anesthetics, so that there is more muscle tone and better circulation in the head and neck. A related veterinary drug, phencyclidine (PCP), has a longer duration of action; when given to humans, however, it has produced terrifying hallucinations upon recovery. It is subject to abuse.

VOLATILE ANESTHETICS

Volatile anesthetics induce unconsciousness and loss of reflexes for surgical procedures. This CNS depression can be induced by a wide variety of different chemicals; those used in clinical medicine are selected for reasons that include low toxicity, ease of maintaining and adjusting a given depth of anesthesia, and freedom from adverse effects upon recovery. Many compounds were examined in the search for modern anesthetic agents.

The depth of anesthesia depends on how much of the medication is present in the CNS. This in turn depends on how much is in the air, to what extent the anesthetic passes between air and blood, and how much passes from blood to brain (or fat, since the brain is largely fat). An agent that is highly insoluble in blood achieves a plateau, or saturation, concentration very rapidly; an example is nitrous oxide. More soluble agents take a longer time to come to plateau, and take a longer time to be exhaled as well, so recovery from them takes longer. Nitrous oxide and cyclopropane have the same solubility in blood, and take the same amount of time to come to a steady concentration in blood; cyclopropane is more soluble in brain and fat, however, so it takes a much lower concentration to achieve the same effect. (Cycloproane is explosive, and therefore is not used in the operating room.) The way an anesthetic functions in a given individual depends on a number of variables, including the amount of fat in the individual's body, the volume of air inspired per minute, the amount of blood pumped through the lungs per minute, and various preexisting medical conditions.

AROMATIC HYDROCARBON SOLVENTS

Aromatic hydrocarbon solvents have a structure that includes a benzene ring. The simplest form is benzene, a six-membered ring with double bonds and six hydrogen atoms. All other aromatic hydrocarbons have alkyl substituents around the ring; for example, toluene has one methyl group and xylene has two methyl groups.

BENZENE

Benzene is a volatile aromatic hydrocarbon (see above). Its presence in consumer products and in the workplace has been reduced because it causes a form of leukemia. Its chemical formula is C_6H_6; it is a six-membered ring with alternating double bonds and a hydrogen on each carbon. The ring opens when metabolized, causing the formation of reactive and toxic chemicals. Benzine, a name applied to automotive fuel in Europe, is a solvent mixture.

BLACK JACK

This is a trade name for several inhalant products that contain either volatile nitrites or ethyl chloride.

CHLORINATED HYDROCARBONS

These substances comprise a large class of industrial chemicals. Those which are highly volatile are sometimes subject to abuse. Chlorinated hydrocarbons undergo significant metabolism in the body, and these changes in chemical structure usually result in an increase of the solvent's toxicity. Because many of these metabolic products are reactive chemicals, they can produce injuries to the kidneys, the liver, and the blood-forming organs. Chlorinated hydrocarbon inhalation is also associated with lethal disorders of heart rhythm, ventricular arrhythmias.

CHLOROFLUOROCARBON PROPELLANTS

Halogenated hydrocarbons are relatively nonreactive chemicals with very high vapor pressure that have been used to blow products out of containers through a tiny hole. Their widespread use in the early 1960s was followed by an epidemic of aerosol sniffing that led to cardiac arrhythmias and death among young people. The halogens—chlorine, fluorine, and bromine—are used to make various chemicals for purposes ranging from propellants and refrigerants to fire extinguishers. Their use has been severely limited since the recognition that their release into the atmosphere depletes the upper layers of ozone, exposing the earth to excessive amounts of ultraviolet radiation. Freon is a brand name for a family of commercial products.

CHLOROFORM

Chloroform, $CHCl_3$, was one of the earliest solvents put to use as an anesthetic agent. It has been replaced with agents that are much less toxic. Its use in cough and cold medications is obsolete. Chloroform was widely abused in the nineteenth century.

ETHYL CHLORIDE

This is a local anesthetic, CNS depressant, and refrigerant that has been subject to abuse by inhalation. Ethyl chloride has a very high vapor pressure, and spraying it directly into the mouth may freeze the tissues of the throat and cause fatal laryngospasm (contraction of the muscles of the throat and larynx), and the shutoff of air to the lungs. Ethyl chloride has been sold in canisters and spray cans (e.g., Black Jack). A related chemical, methyl chloride, has similar effects and was used in refrigerators until it was recognized as highly poisonous in closed spaces.

ETHYL ETHER

A volatile anesthetic agent subject to abuse by inhalation, ethyl ether was used as an inhalation anesthetic for many years. It has been supplanted by other agents with fewer recovery side effects, such as headache, nausea, and vomiting. It is explosive. Ethyl ether was drunk during the Whiskey Rebellion of the eighteenth century, when heavy taxes were imposed on whiskey. Consumed by this route, ether "tanned" (hardened dramatically) the soft palate. When swallowed, profound intoxication follows, but recovery is faster than from alcohol. Alcohol is metabolized at a fixed number of grams per hour, except under extreme conditions; ethyl ether is eliminated by exhalation.

FREON

Freon is a brand name applied to a class of aerosol propellants. See Chlorofluorocarbon Propellants, above.

GASOLINE

Gasoline, a fuel that powers internal combustion engines, is a complex petroleum product that is subject to abuse by inhalation. The toxicity produced from gasoline exposure depends on the constituents of the mixture and the route of administration. Oral ingestion of gasoline is usually followed by vomiting; subsequent aspiration of gasoline liquid into the lungs is followed by a frequently fatal chemical pneumonia. Deliberate inhalation of leaded gasoline fumes can lead to brain injury related to absorption of tetraethyl lead, a very toxic chemical.

GLUE

Glues are made by dissolving a sticky or adhesive material in a solvent. When the solvent evaporates, the adhesive material remains attached to the surfaces to which it is applied, sticking them together. Glues are complex mixtures formulated for specific purposes. They are not designed for human consumption. When inhaled, they may produce severe injury or death. Most of the solvents used in glues are flammable, and fires have resulted from their inappropriate use. The solvent mixtures in glues and glue thinners are designed to dissolve the solid glue material and to evaporate evenly at a rate appropriate for the product. Solvents of relatively low industrial purity are used in these products; they are usually complex mixtures whose formulation changes with market price. Their toxicity can be great when concentrated and inhaled. Some manufacturers label their products or add irritants in an attempt to dissuade youths from deliberately inhaling these products.

HEXANE

Hexane is a volatile solvent that contains six carbons in a straight chain and has the chemical formula C_6H_{14}. It can cause severe damage to the peripheral nervous system, producing death of the long myelinated nerves (distal axonopathy). This condition results in an inability to walk, loss of muscle mass in all limbs, and sometimes loss of bowel and bladder control. This injury occurs because hexane is metabolized to a gamma-diketone. Another solvent subject to abuse that undergoes the same change in the body is methylbutylketone.

NITROUS OXIDE

Nitrous oxide is a volatile analgesic and anesthetic agent. It was discovered at the beginning of the nineteenth century by Sir Humphry Davy, who was looking for gases and vapors that might have some therapeutic use. Nitrous oxide quickly produces an inebriation that many found pleasurable, and it rapidly became the subject of much experimentation and merrymaking. Nitrous oxide parties became very fashionable, but could not long be limited to the upper classes. Popular demonstrations were conducted, and at one such demonstration Horace Wells noticed that a participant had injured his leg, yet seemed oblivious to the pain. Although Davy had noted that nitrous oxide deadened the pain of his toothaches, it was Wells who underwent the first tooth extraction using nitrous oxide for pain relief. The first widespread use of nitrous oxide for clinically significant pain relief was its use in childbirth by S. Klikovich. Nitrous oxide inhalation is about as effective as 30 mg of morphine for pain relief.

Nitrous oxide is not very soluble in either blood or brain tissue, and consequently it has a short duration of action and requires very high levels to produce effects, on the order of 15 to 30 percent by volume. Because the use of gases at this high a concentration might result in asphyxiation, special equipment is used to guard against this possibility in medical settings. Because it displaces oxygen, nitrous oxide frequently kills those who inhale it for pleasure in closed rooms or automobiles.

Nitrous oxide was long thought to be a relatively innocuous anesthetic, almost as safe as inert gases. Recent work has demonstrated, however, that its inhalation irreversibly inactivates methionine synthetase, and this enzyme inhibition produces a vitamin deficiency that can injure the peripheral nervous system. This was first observed in dentists and others with access to nitrous oxide and who inhaled it habitually. This nervous system injury is associated with numbness and clumsiness of the hands, and with Lhermitte's sign, a lightning-like shooting

sensation that occurs when the patient bends the neck.

Nitrous oxide is used in dentistry because it has both analgesic and anxiety-relieving properties. It is used as a carrier gas and inducing agent in major surgery, facilitating induction of anesthesia maintained by other agents. Because it is not very soluble in blood, oxygen must be provided to patients at the end of the surgery, because the nitrous oxide can displace oxygen as it rushes out of the patient's body (diffusion hypoxia).

PERCHLOROETHYLENE

This chlorinated hydrocarbon solvent, used in the dry-cleaning industry, is also known as PERC (see Chlorinated Hydrocarbons, above).

TOLUENE

Toluene (methyl benzene, toluol) is an aromatic hydrocarbon solvent widely used in industrial processes, fuels, and consumer products. It is among the least irritating of the aromatic hydrocarbon solvents. When inhaled, it can produce CNS depression, like alcohol and other solvents. Its pharmacologic effects resemble those of other CNS depressant drugs, displaying actions like those of medications used for the treatment of epilepsy or for the clinical management of anxiety.

Toluene is removed from the body by exhalation and by metabolism. It is metabolized to methylhippuric acid, and is excreted by the kidneys. Overexposure to toluene can produce distal tubular acidosis of the kidney, an injury attributable to excess acidity that is reversible upon termination of exposure. Toluene has been demonstrated to produce loss of high-frequency hearing in laboratory animals following repeated high exposure, such as occurs during solvent abuse. Toluene also has been implicated in severe injuries to the nervous system in a large number of patients who deliberately inhaled toluene-containing solvents. These injuries are characterized by injury and loss of brain tissue. Patients display flattened emotional responses, impaired cognitive abilities, and a wide, shuffling gait associated with injury to the cerebellum. Animal studies have not yet conclusively demonstrated that toluene alone is responsible for this severe brain injury syndrome; nonetheless, solvent abusers who inhale toluene-containing mixtures run a very high risk of irreversible brain injury.

1,1,1 TRICHLOROETHANE (TCE)

This is a chlorinated hydrocarbon solvent with very high vapor pressure. It is useful in products that need to dry quickly, such as liquid paper products used to cover errors. The deliberate inhalation of these products has been associated with sudden death from ventricular arrhythmias (see Chlorinated Hydrocarbons, above).

TRICHLOROETHYLENE

A chlorinated hydrocarbon solvent used as a degreaser and dry-cleaning agent, it is subject to abuse by inhalation. When alcohol is consumed after exposure to trichloroethylene, profound blushing of the face occurs, the "degreaser's flush." One of the metabolites of trichloroethylene is chloral hydrate, an anesthetic agent used in "Mickey Finns," drinks used criminally to anesthetize robbery victims.

WHIPPETS

Whippets are small canisters of nitrous oxide used at soda fountains to make whipped cream. They have been incorporated into various products, such as balloon inflators, "carburetor pipes," and other drug paraphernalia (see Nitrous Oxide, above).

(SEE ALSO: *Complications; Ethnicity and Drugs; High School Senior Survey; Inhalants: Extent of Use and Complications*)

RONALD W. WOOD

INHALANTS: EXTENT OF USE AND COMPLICATIONS About 12 1/2 million ADOLESCENTS in this country say that they have sniffed INHALANTS—usually volatile solvents such as spray paint, glue, or cigarette lighter fluid—at least once in their lives, according to the National Institute on Drug Abuse (NIDA) in its 1997 MONITORING THE FUTURE study, a national survey of 8th-, 10th-, and 12th-grade students (also called the HIGH SCHOOL SENIOR SURVEY). In fact, results from a number of surveys suggest that among children under 18, the

level of use of inhalants is comparable to that of stimulants and is exceeded only by the level of use of MARIJUANA, ALCOHOL, and CIGARETTES.

The abuse of inhalants, which include a broad array of cheap and easily obtainable household products, is frequently viewed by the public as a relatively harmless habit and not in the same high-risk category as drugs such as alcohol, COCAINE, and HEROIN. Some people tend to view inhalant "sniffing," "snorting," "bagging" (when fumes are inhaled from a plastic bag), or "huffing" (when an inhalant-soaked rag is stuffed in the mouth) as a kind of childish fad to be equated with youthful experiments with cigarettes. But inhalant abuse is deadly serious. Sniffing volatile solvents, which include most inhalants, can cause severe damage to the brain and nervous system. By starving the body of oxygen or forcing the heart to beat more rapidly and erratically, inhalants have killed sniffers, most of whom are adolescents.

The difficulty people face in recognizing the scope and magnitude of the problem lies in the dearth of documenting information. Survey data on the prevalence of inhalant abuse are difficult to obtain for a number of reasons—and what information does exist may underemphasize the severity of the situation. No one knows how many adolescents and young people die each year from inhalant abuse, in part because medical examiners often attribute deaths from inhalant abuse to heart problems, suffocation, SUICIDE, or ACCIDENTS. What is more, no national system exists for gathering data on the extent of inhalant-related injuries, although medical journals have described the situation as serious. As serious as the situation may be, some researchers warn that doctors and emergency medical personnel are not adequately trained to recognize and report symptoms of inhalant abuse.

SCOPE OF THE PROBLEM

Inhalant abuse came to public attention in the 1950s when the news media reported that young people who were seeking a cheap "high" were sniffing glue. The term *glue sniffing* is still widely used, often to include inhalation of a broad range of common products besides glue.

With so many substances lumped together as inhalants, research data describing frequency and trends of inhalant abuse are uneven and sometimes contradictory. However, evidence indicates that inhalant abuse is far more common among all socioeconomic levels of U.S. youth than is typically recognized by parents and the public. For example, the National Institute on Drug Abuse's (NIDA's) Monitoring the Future survey shows that in 1997, 21.0 percent of 8th graders had used an inhalant in his or her lifetime.

Inhalants were used by equally high percentages of 10th and 12th graders, according to the NIDA survey. Lifetime inhalant use among 12th graders, which had increased steadily for most of the 1980s, leveled off somewhat at 16.1 percent in 1997; 10th graders also reported a lifetime inhalant use of 18.3 percent.

Inhalants are most commonly used by adolescents in their early teens, with usage dropping off as students grow older, unlike the case for other drugs. For example, while 5.6 percent of 8th graders reported using inhalants within the past 30 days, known as "current" use, only 2.5 percent of seniors reported current use of inhalants.

One major roadblock to recognizing the size of the inhalant problem is the ready availability of products that are inhaled. Inhalants are cheap, or even free, and can be purchased legally in retail stores in a variety of seemingly harmless products. As a result, adolescents who sniff inhalants to get high do not face the drug procurement obstacles that confront abusers of other drugs. Youthful inhalant abusers can easily buy airplane glue, hair spray, spray paint, cigarette lighter fluid, nail polish remover, or typing correction fluid.

DANGERS OF INHALANT ABUSE

Despite the dangers associated with inhalant abuse, no central system exists in the United States for reporting deaths and injuries from abusing inhalants. A study by Dr. James C. Garriott, the chief toxicologist in San Antonio and Bexar County, Texas, examined all deaths in the county between 1982 and 1988 that were attributed to inhalant abuse. Most of the thirty-nine inhalant-related deaths involved teenagers, with twenty-one deaths occurring among people less than twenty years old. Deaths of males outnumbered those of females thirty-four to five. Many of the abusers met with a violent death possibly related to but not directly caused by the use of volatile solvents. Eleven deaths were caused by suicide (ten by hanging), nine by

homicide, and ten by accident, including falls, auto accidents, and overdoses.

Most of those people who died in Bexar County had used toluene-containing products, such as spray paints and lacquers, Dr. Garriott reported. The next most frequent cause of death in the Texas study was the use of a combination of chemicals found in typewriter correction fluids and other solvents. Other abused substances that resulted in death included gasoline, nitrous oxide, and refrigerants, such as fluorocarbons (Freon). Freon now has been replaced with butane or propane products in most aerosols.

As reported in the Texas study, the solvent toluene is identified frequently in inhalant-abuse deaths and injuries because it is a common component of many paints, lacquers, glues, inks, and cleaning fluids. A 1986 study of twenty chronic abusers of toluene-containing spray paints found that after one month of abstinence from sniffing the paint, 65 percent of the abusers had damage to the nervous system. Such damage can lead to impaired perception, reasoning, and memory, as well as defective muscular coordination and, eventually, dementia.

In England, where national statistics on inhalant deaths are recorded, the largest number of deaths in 1991 resulted from exposure to butane and propane, which are used as fuels or propellants. Many researchers believe that abuse of butane, which is readily available in cigarette lighters, is on the increase in the United States.

A recent report of this particular inhalant problem in the Cincinnati region indicates that butane gas is the cause of enough deaths to foster national concern about the abuse of fuel gases, whether or not it is a passing form of inhalant abuse. Sniffers seem to go out of their way to get their favorite product; in certain parts of the country, Texas 'shoeshine'—a shoe-shining spray containing toluene—and silver or gold spray paints are local or current favorites.

Since the banishing of fluorocarbons, the most common sniffing death hazards among U.S. students probably are due to butane and propane. Doctors and emergency room staffs need to be aware that the profile of the teenager who inhales volatile solvents is not limited to ethnic lower socioeconomic classes. Many sources lead us to believe that abuse of these readily available inhalants has reached epidemic proportions, indicating an urgent need for preventive efforts.

WHO ABUSES INHALANTS?

One possible reason for the increased use of volatile solvents is that more girls are joining boys in sniffing solvents. Studies in New York State and Texas report that males are using solvents at only slightly higher rates than females. Among Native Americans, whose solvent-abuse rates are the highest of any ethnic group, lifetime prevalence rates for males and females were nearly identical, according to 1991 NIDA data.

There is a public perception that inhalant abuse is more common among HISPANIC youth than among other ethnic groups. However, surveys have not found high rates of abuse by Hispanics in all geographic areas. Rates for Hispanics may be related to socioeconomic conditions. Hispanic youths in poor environments may use solvents heavily, but the usage rates in less stressful environments are lower.

In fact, inhalant abuse shows an episodic pattern, with short-term abuse outbreaks developing in a particular school or region as a specific inhalant practice or product becomes popular in a fashion typical of teenage fads. This episodic pattern can be reflected in survey results and can overstate the magnitude of a continually fluctuating level of abuse.

Inhalant abusers typically use other drugs as well. Children as young as fourth graders who use volatile solvents will also start experimenting with other drugs—usually alcohol and marijuana. Adolescent solvent abusers are POLYDRUG users prone to use whatever is available, although they show a preference for solvents. Solvent abuse is held in low regard by older adolescents, who consider it unsophisticated, a childish habit.

It is not just juveniles who are abusing inhalants. Reports in the mid-1990s indicate that college-age and older adults are the primary abusers of butane and nitrous oxide.

REVISED BY DONNA GRAFT

INJECTING DRUG USERS AND HIV

One of the major risk behaviors for infection by the HUMAN IMMUNODEFICIENCY VIRUS (HIV) is injecting drug use; the others are unprotected male homosexual sex (Centers for Disease Control, 1991a) and unprotected heterosexual sex with an HIV-infected partner. The NATIONAL INSTITUTE ON DRUG ABUSE (NIDA) estimated that there were between 1.1 and 1.3 million injecting drug users (IDUs) in the United States in the late 1980s (Centers for Disease Control, 1987). Although the number of IDUs increased between 1990 and 1997, participation in needle exchange programs also increased, as did participation in HIV testing and counseling (Des Jarlais et al., 2000).

In 1990, 30 percent of ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) cases were heterosexual injecting drug users; in addition, 30 to 50 percent of new cases identified were related to IDU (Iguchi et al., 1990). Injecting drug use was also related to most instances of heterosexual transmission of the virus (Centers for Disease Control, 1992). Also, whether directly or indirectly, injecting drug use accounted for 70 percent of AIDS cases among women and children (Centers for Disease Control, 1989). In these cases, either the woman or her sex partner was an IDU (Gayle, Selic, & Chu, 1990). Since 1995 Belarus, Moldova, Kazakhstan, Russia, and Ukraine have seen rapid HIV increases, with at least 50 percent among IDUs (Henderson, 2000a).

The transmission of HIV among IDUs occurs directly through blood transmission of the virus, as when drug users share used, nonsterilized hypodermic needles and syringes, cotton, cookers, rags, and water that has been contaminated with the infected blood of other users. It is also transmitted when bodily fluids (e.g., semen, saliva, blood) are exchanged during sexual acts. The virus can also be transmitted to a fetus by a pregnant, HIV-positive woman. However, the risk of transmission to the fetus can be sharply reduced if the HIV-positive woman takes the antiviral drug AZT during pregnancy. Various studies have found that prior to the HIV epidemic, between 70 and 100 percent of IDUs shared injection paraphernalia (Lange et al., 1988; Des Jarlais et al., 1988). These percentages have been decreasing, since the connection with AIDS has been widely publicized since the 1980s. Still, dirty syringes cause 80,000 to 160,000 HIV infections worldwide annually (Henderson, 2000b).

Historically the most commonly injected drug has been HEROIN; however, the increased availability of COCAINE has resulted in an increased use by IDUs since the late 1980s. Injecting cocaine has elevated the risk of HIV spread because the shorter duration of a cocaine "high" leads to more frequent injecting (Gottlieb & Hutman, 1990). It has also been reported that cocaine injectors, when the number of injections was statistically controlled, were at higher risk than other drug-injecting populations for HIV because cocaine use is associated with increased unprotected sexual activity (Chaisson et al., 1989).

BACKGROUND

The prevalence of HIV/AIDS among injectors varies widely from region to region in the United States. The highest rates of IDU and HIV are found along the east coast and west coast, in the southwest, Florida, Puerto Rico, and in major metropolitan areas. Overall, of the 48,269 new cases of HIV reported in 1998, more than 50 percent were IDU-associated (Centers for Disease Control and Prevention, 1999). The prevalence of HIV infection is also related to the social context of needle sharing. In areas where injectors go to "shooting galleries"—where anyone using a previously used needle may not know who else used the needle—there are generally high rates of HIV infection. Conversely, in areas where the IDU social network is well known and only a limited number share works with one another, the infection rate is lower (Leukefeld et al., 1991).

While IDUs with HIV infection are predominantly males of color (Hispanics and African-Americans) in their late twenties and early thirties,

variations and exceptions are noted and reflect dynamics in individual metropolitan areas. In 1989, the highest prevalence of IDUs in drug treatment centers who tested positive for HIV were in the Middle Atlantic states (New York, New Jersey, and Pennsylvania), where the overall rate for HIV-positive intravenous drug using men and women in treatment was 44 percent (Centers for Disease Control, 1990b).

REDUCING RISK-TAKING BEHAVIOR

Drug-abuse treatment and prevention can be effective in controlling the spread of AIDS among IDUs and for reducing the risk of exposure to the HIV virus. The goals of drug treatment and prevention are different. The goal of treatment is to eliminate injecting drug use as a risk factor in the spread of HIV. The goal of prevention is to reduce and eliminate harmful behaviors, like sharing needles, that place the IDU at risk for either becoming infected or infecting others with HIV. Prevention does not necessarily focus on changing drug-seeking and needle-using behavior. Four areas are considered to be of prime importance: (1) increasing the number of drug abusers in treatment, (2) enhancing the effect of treatment, (3) developing outreach and counseling strategies, and (4) developing prevention strategies for reducing the risk-taking behavior among IDUs.

Drug Treatment. Several organizations and groups have suggested that drug-abuse treatment is important in helping to decrease and prevent the spread of AIDS. These ogranizations include the World Health Organization (WHO), the American Medical Association (AMA), the National Academy of Sciences/Institute of Medicine and the Presidential Commission on the HIV Epidemic.

Drug-abuse treatment can play an important role in preventing HIV transmission. Treatment reduces the number of people engaging in risky behavior. In addition to reducing the number of active drug addicts, treatment can also reduce the number of people out recruiting new drug addicts (Brown, 1991). Barriers to treatment now exist for IDUs with HIV. IDUs themselves avoid people they suspect have HIV or AIDS, and some treatment programs will not allow HIV-infected people to participate in their programs (Brown, 1991). But the most serious barrier to drug-abuse treatment is the lack of treatment availability and programs. More specifically, some IDUs, including those known to be HIV infected, are not admitted into drug treatment for as long as six months due to a lack of available openings in treatment programs (Gotlieb & Hutman, 1990). In some community-outreach programs designed specifically to target IDUs to prevent HIV transmission, the majority of IDUs contacted have never been in treatment (Schrager et al., 1991). There is evidence that drug-abuse treatment reduces needle sharing by eliminating or reducing needle using behaviors.

Drug-abuse treatment incorporates several modalities (approaches), which include: (1) drug-free outpatient services, (2) METHADONE MAINTENANCE PROGRAMS, and (3) therapeutic communities (Leukefeld, 1988), as well as a number of programs that do not fit into these categories. Ideally, HIV and drug treatment should be integrated to increase social supports, which should increase adherence to medication schedules and resistance to drugs (Stein et al., 2000).

Outreach and Counseling. One way to increase the number of IDUs in treatment is to increase the number of outreach and counseling programs. The National AIDS Drug Abuse Research Demonstration Program is an example of outreach and counseling (National Institute on Drug Abuse, 1988). This demonstration program, initiated in 1987, provided an opportunity to assess the characteristics and risk-taking behaviors of injecting drug abusers not in treatment. Additional purposes included focusing on sexual partners of IDUs at high risk for AIDS, determining and monitoring HIV seroprevalence (rate a given population tests positive) across cities, and evaluating prevention strategies. The overall goal was to reduce the spread of HIV infection by reducing and eliminating drug-use practices and certain high-risk sexual practices. Counseling and outreach approaches were applied, tested, and evaluated at each community site. Projects were targeted on three levels: (1) high-risk individuals, (2) family and social networks of IDUs, and (3) the larger community. Although intervention components varied across sites, the focus and objectives were similar (Chitwood et al., 1991; Leukefeld, 1988). These projects provided information about protective behaviors, and IDUs were encouraged to enroll in drug-abuse treatment programs. Trained indigenous outreach workers distributed and discussed materials using informal groups or through one-on-

one interactions. Sixty-three communities were involved in this demonstration project (McCoy & Khoury, 1990; Leukefeld, 1988).

Strategies for community outreach differ between the IDU, their sex partners, and prostitutes. Reaching the IDU means that outreach workers go to places where IDUs hang out and buy their drugs, as well as going into criminal-justice settings (jails, PRISONS, courts), drug-treatment centers, and the health-care system. Although there is inherent danger in many of these settings, recovering drug users—savvy men and women of the same backgrounds as IDUs—have achieved success in contacting IDUs in these settings (Serrano, 1990; Brown, 1990).

Many male IDUs hang out on the street or can be found in places where other IDUs hang out. However, female sex partners of IDUs frequently stay close to home with children and they frequently work (Margolis, 1991). While women may purchase drugs for their partners, they do not generally hang out at those locations. Thus, targeting female partners of IDUs requires different strategies than those used for contacting the IDU. The YES project of San Francisco is an example of a program targeted toward female sex partners of IDUs. It began by supporting high-risk women in meeting their basic needs by helping them get general assistance, food, clothing, and health care. A second strategy was to rent a hotel room, called "A Room of Her Own" in which education, counseling, and service could be provided to the female partner of the IDU. Another project (serving Bridgeport, Connecticut, San Juan, Puerto Rico, and Juarez, Mexico) contacted the female sex partners of male IDUs; it examined an approach that attracted women to a safe setting established by the program—a clothing boutique where women could pick up new clothes and then stay for an AIDS information video. Another strategy as part of this project was to have outreach staff available in the afternoons and evenings, hours when the women were available (Moini, 1991). In another project in Long Beach, California, a drop-in center was established for youth and women (Yankovich, Archuleta, & Simental, 1991).

Prostitutes, another high risk group, require strategies appropriate to their setting. Contacting prostitutes can be difficult, since their pimps can severely restrict contact with social-service workers. In one study, contact was made when the pimp was not around and through the Salvation Army mobile canteen that served coffee to prostitutes in the late night/early morning hours (Moini, 1991). Another study reported that prostitutes are aware of AIDS, know how it is transmitted, and are aware that their drug use and unsafe sexual behavior are putting them at risk (Shedlin, 1990). However, barriers to behavioral changes in prostitutes include low self-esteem and low levels of education, along with POVERTY, addiction, hopelessness, lack of knowledge, and lack of support services.

Prevention Strategies. Prevention is of central importance in controlling the spread of HIV among IDUs. Abstinence from drug use and needle use is the overall approach for preventing the spread of HIV. Preventing infection is a self-preservation issue (protecting self), while preventing the spread of HIV is an altruistic issue (protecting others) (Moini, 1991). It has been reported that among IDUs there is greater resistance to changing sexual behaviors (using condoms) than drug-use behaviors (sharing needles) (Sorenson, 1990). Thus, it is important to target not only IDUs but also their sex partners and prostitutes who engage in unsafe sex practices. These people may also be exchanging drugs for sex and may be IDUs themselves (Centers for Disease Control, 1991b). Three prevention strategies have been developed: education, NEEDLE-EXCHANGE PROGRAMS, and community-based interventions.

Education. In addition to the community-outreach programs, three overarching prevention-education strategies have been developed: (1) prevention education for HIV-antibody-negative individuals, (2) AIDS pre- and post-test counseling, and (3) prevention and support for HIV-antibody-positive individuals (Schensul & Weeks, 1991). AIDS prevention education involves delivery of information related to HIV spread, risk behaviors, and preventing the spread of the virus. Educational activities have been targeted on the general public, school-aged populations, and populations at risk, like IDUs. The U.S. Centers for Disease Control (CDC) National Public Information Campaign has produced numerous educational materials for the radio, television, and print media. Education targeted to individuals at risk for HIV infection has included counseling, testing, the teaching of behavioral responses to risky behaviors, and providing support for low or no-risk behaviors (Roper, 1991).

Prevention education for IDUs includes several informational components. Of primary importance to active drug users are issues related to needle sharing as a risk behavior for HIV transmission. Also of critical importance to needle-sharing IDUs in preventing HIV transmission are describing ways to effectively sterilize shared paraphernalia. Of importance to IDUs, the sex partners of IDUs, and prostitutes are safe-sex issues and knowledge of HIV transmission through unsafe sex. Of importance to potential partners—both men and women who have relationships with IDUs and who may be IDUs—is knowledge about the transmission of the virus from mother to fetus (Strawn, 1991). Early to mid-1990s research indicates that the use of AZT (an anti-HIV drug) by pregnant women who are HIV-positive sharply reduces the probability that the baby will be infected with the virus.

Pre- and post-test AIDS counseling is another strategy for HIV prevention. In the early 1980s, at the beginning of the AIDS epidemic, testing was controversial because of the fear of discrimination, concern about the accuracy of tests, the usefulness of the results, and the psychological distress associated with a positive result. However, with more effective treatment for symptomatic AIDS and early treatment for HIV-infected individuals, the resistance is diminishing (Strawn, 1991).

Generally, individuals seek HIV testing for one of two reasons: (1) an agency or person, (like a plasma center, a penal institution, or a medical professional) requests it, or (2) the individual seeks to be tested because of identified high-risk behaviors (Roggenburg et al., 1991). HIV testing can represent a crisis in the life of an individual being tested. Receiving the results can be difficult due to the anxiety of the situation, even if the results are negative. Pre- and posttest counseling is necessary to assess the psychological well-being of the individual being tested. Some people believe that being informed of a positive test result can make some people suicidal (Strawn, 1991).

A controversial prevention approach in the United States for preventing HIV infection is the provision of clean needles to IDUs. In needle-exchange programs, a clean needle and sometimes injection equipment (works) are exchanged for used ones. Proponents of these programs argue that needle exchanges help prevent HIV transmission and offer opportunities for education and referral to drug-treatment programs. It has been reported that in areas where needle-exchange programs have been in operation, the incidence of sharing used needles has diminished (Karpen, 1990). Some needle-exchange programs are conducted illegally by AIDS activists (Karpen, 1990). Occasionally, in the United States, needle exchanges are managed legally by health departments. To conduct a needle-exchange program legally, in many regions the PARAPHERNALIA LAWS related to drug-use equipment would need to be modified (Wood, 1990).

Opponents of needle-exchange programs point out that needles and syringes are only two of the many drug-use implements that can be contaminated with blood and transmit HIV. For example, cotton, cookers, and the water used to rinse out syringes can transmit HIV if they have been contaminated with infected blood. In addition, some injecting rituals can transmit HIV even if a clean needle and syringe are used. Sharing an injection can be part of a ritual between addicts. For example, in a "rinse" or a "geezer" one addict injects another person and then injects him- or herself with the remnant in the syringe (Primm, 1990). Few rigorous U.S. studies have examined needle-exchange programs and their effects on HIV transmission. One group of researchers interviewed IDUs participating in needle-exchange programs to help determine needs for prevention programs (Des Jarlais, 1999). Although some areas showed low rates of HIV, others showed no marked decrease in cases. The researchers believed that more complete reporting of risk behavior was necessary.

As above, one component of the National AIDS Demonstration Project has been to compare the CDC basic outreach and counseling intervention with an enhanced intervention. The CDC basic intervention includes factual information about AIDS transmission, prevention, and self-assessed risk. Enhanced community-based educational-intervention programs have involved several strategies: counseling individuals, couples, and groups; developing behavioral skills; and using applied ethnography with outreach workers to disseminate information (Chitwood et al., 1991). Using these strategies helped the rate of sharing between IDUs to decrease by up to 59 percent in a five-city study. In the same study, IDU condom use increased by up to 16 percent (Iguchi et al., 1990).

CONCLUSION

Preventing the spread of AIDS for IDUs and their sex partners requires a multidisciplinary, multiple-strategy approach. Community-intervention strategies have proven to be partially effective in reducing IDU risk behaviors (Leukefeld, Battjes, & Amsel, 1990). Much remains to be accomplished, however. Targeting HIV-prevention approaches and interventions will receive additional emphasis as the epidemic progresses (Leukefeld & Battjes, 1991). Research needs to continue to examine methods to reduce HIV in IDUs, to reinforce IDU behavior changes, to increase the effectiveness of drug-abuse treatment, and to provide psychosocial and other supports focused on HIV-infected IDUs.

INSTITUTE ON BLACK CHEMICAL ABUSE (IBCA) *See* Treatment Programs/Centers/Organizations: An Historical Perspective

INTERNATIONAL CLASSIFICATION OF DISEASES (ICD) This is the official classification system of the World Health Organization (WHO). As a general system for the classification of diseases, injuries, causes of death, and related health problems, the ICD is used throughout the world as a common frame of reference for statistical reporting, clinical practice, and education. The ICD is a system of categories to which specific disease entities can be assigned consistently in different parts of the world. Recognizing the growing importance of alcohol and drug misuse, the ninth revision of ICD was published in 1975 (ICD-9), and it introduced the terms *dependence* and *abuse* into the international nomenclature. *Drug dependence* was defined as "a state, psychic and sometimes also physical, resulting from taking a drug, and characterized by behavioural and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid the discomfort of its absence" (WHO, 1977, 198). *Alcohol dependence* was defined in a similar way. The category Non-Dependent Abuse of Drugs was designed for cases where a person "has come under medical care because of the maladaptive effect of a drug on which he is not dependent and that he has taken on his own initiative to the detriment of his health or social functioning" (WHO, 1978, 43–44).

In 1993, the tenth revision, ICD-10, was introduced—replacing ICD-9 as the official classification system for international use (WHO, 1992a). Chapter 5, which describes mental and behavioral conditions (WHO, 1992b), includes a section for the classification of disorders based on ten kinds of PSYCHOACTIVE substances: ALCOHOL, SEDATIVE-HYPNOTICS, CANNABIS (MARIJUANA), COCAINE, other STIMULANTS, OPIOIDS, HALLUCINOGENS, TOBACCO, VOLATILE SOLVENTS, and multiple drugs. The major disorders associated with these substances are acute intoxication, harmful use, dependence syndrome, withdrawal state, amnesic syndrome, and psychotic disorders (WHO, 1992b). The identification of the substance used may be made on the basis of an interview with the patient, laboratory analysis of blood or urine specimens, or other evidence (such as clinical signs and symptoms or reports from third parties).

Acute intoxication is a transient condition following the ingestion of alcohol or other psychoactive substances. It results in disturbances in consciousness, cognition, perception, mood, or behavior. According to ICD-10, psychoactive substances are capable of producing different types of effect at different dose levels. For example, alcohol may have stimulant effects at low doses, lead to agitation and aggression with increasing dose levels, and produce clear sedation at very high levels. The term *pathological intoxication* in ICD-10 refers to the sudden onset of violent behavior that is not typical of the individual when sober. This occurs very soon after amounts of alcohol are drunk that would not produce intoxication in most people.

A central feature of the ICD-10 approach to substance-use disorders is the concept of a dependence syndrome, which is distinguished from disabilities caused by harmful substance use (Edwards, Arif, & Hodgson, 1981). The *dependence syndrome* is defined as "a cluster of physiological, behavioural, and cognitive phenomena in which the use of a substance or a class of substances takes on a much higher priority for a given individual than other behaviours that once had greater value" (WHO, 1992b, 75). A central characteristic of the dependence syndrome is the strong and persistent desire to take psychoactive drugs, alcohol, or tobacco. Another feature is the rapid reappearance of the syndrome soon after alcohol or drug use is resumed after a period of abstinence. A definite diagnosis of dependence is made only if three or more of the following have been experienced during the previous year: (1) a strong desire or sense of compulsion to take the substance; (2) difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use; (3) a physiological withdrawal state; (4) evidence of tolerance; (5) progressive neglect of alternative pleasures or interests because of substance use; and (6) persisting with substance use despite clear evidence of overtly harmful consequences.

Harmful use, a new term introduced in ICD-10, is a pattern of using one or more psychoactive substances that causes damage to health. The damage may be: (1) physical (physiological), such as fatty liver, injuries associated with alcohol intoxication, or hepatitis from needle-injected drugs; or

(2) mental (psychological), such as depression related to heavy drinking or drug use. Adverse social consequences often accompany substance use, but they are not in themselves sufficient to result in a diagnosis of harmful use.

Chapter 5 of ICD-10 is available in several different versions. The *Clinical Descriptions and Diagnostic Guidelines* is intended for general clinical, educational, and service use. *Diagnostic Criteria for Research* is designed for use in scientific investigations and epidemiological studies. A shorter and simpler version of the classification is available for use by primary health-care workers.

INTERNATIONAL DRUG CONTROL *See* Anslinger, Harry J., and U.S. Drug Policy; Psychotropic Substances Convention of 1971; Single Convention on Narcotic Drugs

INTERNATIONAL DRUG SUPPLY SYSTEMS The majority of illicit drugs consumed in the United States are of foreign origin—including all the COCAINE and HEROIN and significant amounts of MARIJUANA. In the early 1990s, the U.S. National Narcotics Intelligence Consumer Committee (NNICC) report estimates that Latin American countries supplied approximately 25 to 30 percent of the heroin, perhaps 60 to 80 percent of the marijuana, and all the cocaine. Southeast Asian and Middle Eastern countries supplied the remaining 70 to 75 percent of the heroin.

Drug use and drug abuse have been a part of many cultures for centuries. Although once considered a problem only for countries with massive demand and consequent loss of labor and life, drugs are now recognized as a policy concern for all countries involved—the producing, TRANSIT, and consuming countries alike. No country is insulated from the destabilizing forces of illicit drugs. For SOURCE (producing) countries, drug trafficking appears to provide short-term economic benefits, but mainly for those involved in the business. Eventually, long-term negative economic consequences ensue, with foreign investment, tourism, and domestic production diminished—and with off-shore money laundering and the concentration of wealth in the hands of a few. The drug trade does not stimulate regional economies through jobs, capital appreciation, and investment.

Since 1971, when modern international drug-control efforts began, a number of major shifts have occurred in the drug-producing capabilities of various countries. For example, in the early 1970s, after the so-called French Connection was broken (Turkish OPIUM was processed into heroin in France), MEXICO replaced Turkey as a major source of U.S. heroin; Pakistan then supplanted Mexico after 1979, when the Islamic political revolution in Iran created a population of refugees. At about the same time, the Soviet Union occupied Afghanistan, and the resistance movements there increased their income-generating opium cultivation practices.

In the 1980s, cocaine production in the Andean countries of Peru, BOLIVIA, and COLOMBIA expanded significantly into nontraditional growing zones (the Bolivian Chapare region and Peruvian Upper Huallaga Valley, or UHV), augmenting the more traditional licit production areas of the Bolivian Yungas and Peruvian Cuzco regions. In the early 1980s, U.S. demand for Mexican marijuana decreased dramatically, because of consumer con-

TABLE 1
Cocaine Production Estimates

U.S. MEASURE

Source Country		*Net Coca Cultivation (acres)*	*Estimated Coca Leaf Yield (tons)*	*Potential Cocaine HCl Capacity (tons)*
Peru	1990	299,611	216,590	627–671
	1991	298,376	244,970	710–759
Bolivia	1990	124,241	84,480	270–457
	1991	118,313	86,240	275–462
Colombia	1990	99,047	33,310	72
	1991	92,625	33,000	66

Potential
Cocaine HCl Production
1990 = 969–1,199 tons 1991 = 1,051–1,287

METRIC MEASURE

Source Country		*Net Coca Cultivation (hectares)*	*Estimated Coca Leaf Yield (metric tons)*	*Potential Cocaine HCl Capacity (metric tons)*
Peru	1990	121,300	196,900	570–610
	1991	120,800	222,700	645–690
Bolivia	1990	50,300	76,800	245–415
	1991	47,900	78,400	250–430
Colombia	1990	40,100	32,100	65
	1991	37,500	30,000	60

Potential
Cocaine HCl Production
1990 = 880–1,090 metric tons 1991 = 955–1,170 metric tons

NOTE: The figures reflected here are consistent with the *International Narcotics Control Strategy Report (INCSR) 1992.* The INCSR states cultivation in hectares and yields in metric tons. All figures have been converted to acres or short tons, as appropriate, in the chart on the left. A new procedure introduced in the 1991 INCSR is used for calculating coca leaf production. Previous methods did not deduct immature, non-producing fields from net cultivation before calculating production. Multiple harvests of coca do not begin until plants are at least two years old. Here, only mature cultivation was used to calculate production. Estimates included here for 1990 have been revised to reflect the use of the mature cultivation methodology cited. These figures do appear in the NNICC Report 1990 charts in parenthesis.
According to past UHV Reduction Agency (CORAH) and U.S. Agency for International Development (USAID) reports, the dry leaf yield of mature coca in the UHV ranges between 2.0 and 2.7 metric tons per hectare. A mean yield factor of 2.3 metric tons was used for this area. Other areas of Peru have lower yields similar to the Yungas in Bolivia. Last year's reported yield of 1.14 metric tons was for areas of Peru outside the UHV. According to the Bolivia's Coca Eradication Directorate (DIRECO), mature coca leaf yield averages 2.7 metric tons in the Chapare and 1.0 metric tons in the Yungas. The conversion rate for calculating potential cocaine production from dry leaf is 322–345:1 in Peru and 195–330:1 in Bolivia. Production in Colombia is determined by multiplying a yield factor of .8 metric tons per hectare by net cultivation. All Colombian cultivation was assumed to be mature. The conversion rate for Colombia is 500:1.

cern about Mexico's drug-elimination program, where marijuana was sprayed with the herbicide paraquat, some of which is reported to have killed U.S. users. Consequently, Colombia replaced Mexico as the preferred source of high quality marijuana. Colombia and Guatemala also began to cultivate substantial amounts of opium in the early 1990s.

Traffickers have also adjusted their smuggling routes in response to government law-enforcement pressures. For example, in the mid-to-late 1980s, Colombian drug traffickers began to shift their routes away from the Florida peninsula and toward Central America and Mexico. By the early 1990s, the U.S. government estimated that up to 50 percent of the Colombian cocaine consumed in the United States entered via Mexico. Wide variations in source-country response to these shifts in production have also been chronicled, ranging from government complicity and corruption to modest attempts to reduce crop production and trafficking to intensified organized efforts to eliminate or hamper seriously the drug trade.

PRINCIPAL DRUG-PRODUCING COUNTRIES

Coca/Cocaine. As of the early 1990s, all the cocaine, about 30 percent of the heroin, and a significant amount of marijuana entering the United States is produced in the Western Hemisphere—in Mexico, Central, and South America. They are smuggled in through the southern borders of the United States. All of the cocaine consumed in

	1991	627	570**
Pakistan	1990	182	165
	1991	198	180
Lebanon	1990	35	32
	1991	37	34
Iran	1990	330	300
	1991	330	300
Total:	1990 = 4,202 tons (3,819 metric tons)		
	1991 = 3,908 tons (3,552 metric tons)		

NOTE: Opium generally converts to heroin hydrochloride at ratio of 10:1. Point estimates cited above reflect a mathematical mean point estimate and are not intended to imply a degree of accuracy or certitude which cannot be obtained due to the nature of illicit drug cultivation and production.

*The U.S. Drug Enforcement Agency believes that multi-cropping and the use of fertilizers in Afghanistan renders the 1990 estimate of 457 tons (415 metric tons) to the lower end of a potentially higher production range in Afghanistan.

**The U.S. Drug Enforcement Agency believes that higher yields may exist in Afghanistan and that production could potentially be above 990 tons (900 metric tons.)

SOURCE: *International Narcotics Control Strategy Report 1992.*

the world is grown and processed in the Andean countries of Peru, Bolivia, Ecuador, and Colombia. Some 60 percent of COCA PLANTS (*Eryroxylon coca*) are cultivated in Peru, about 15 percent in Colombia, and about 25 percent in Bolivia.

Peru. Traditional legal cultivation of coca is licensed for cultivation in Cuzco, Peru, but the majority of Peru's illicit crop comes from the Upper Huallaga Valley (UHV), which includes portions of Huanuco, San Martin, and Ucayali departments. Other illicit cultivation occurs in La Convencion and Lares valleys in Cuzco and in the Ayachucho department. Much of the coca leaf is processed into COCA PASTE and cocaine base in crude maceration (steeping) pits positioned near cultivation sites. Clandestine labs then process the paste into base. Normally the base is then shipped to hydrochloride (HCl) laboratories in Colombia, although cocaine HCl production in Peru is rising. Reportedly, traffickers have been moving their laboratories from isolated jungle sites nearer to towns, where corrupt officials can offer protection. The chemicals (kerosene, lime, ether, acetone, hydrochloride acid) needed to process coca leaves into paste, base, and hydrochloride are diverted from legitimate chemical shipments that reach Peru by sea.

Although the Colombian traffickers control most of the cultivation and the processing of coca into

paste and base in Peru, some 20 Peruvian trafficking organizations have also been identified. By early 1991, self-limiting by coca growers increased the price for coca derivatives in the UHV; this was largely because of *Sendero Luminoso* (SL—Shining Path), Maoist political insurgents, who demanded a greater share of the cocaine-base profits. The SL extended their area of influence; charged a tax on coca leaf, paste, and base; and attempted to set prices among the Colombian traffickers, growers, and lab operators—therefore, the prices for coca products varied widely in 1990, showing an average 100 percent increase.

The majority of cocaine base is moved from UHV staging areas by air and by river to Colombia for conversion to cocaine HCl. Drug-control efforts in Peru have been ineffective; violence, political factions, rivalry between the Peruvian police and military, and widespread corruption in a severely depressed economy have contributed to Peru's lack of effectiveness.

Bolivia. By the early 1990s, almost 75 percent of illicit coca was grown in the Chapare, Carrasco, and Arani provinces, in Cochabamba department, Bolivia. Legal cultivation of some 35,000 acres (14,000 ha) occurs only in the Yungas. Small farmers and unemployed migrants cultivate the coca in the Chapare on plots that average one to two acres (less than 1 hectare). When the market price drops below their cost of production, farmers choose not to sell the leaf. Most leaf that is sold to middlemen (*intermediarios*) is processed in the Chapare and then refined into base or cocaine HCl in the Beni, Cochabamba, or Santa Cruz departments. Due to increased enforcement in the early 1990s, some traffickers moved their base of operations to less accessible locations, and more paste is refined into cocaine base or HCl by about 35 Bolivian trafficking organizations.

Colombian and Bolivian traffickers have integrated some operations vertically, from wholesale paste purchase through cocaine base and HCl refining and export. The U.S. government estimates that as much as 35 percent of Bolivian coca paste may be processed in Bolivia prior to export. Chemicals arrive by truck, train, and aircraft from Brazil, Chile, Argentina, and Paraguay. The base is smuggled to Colombia in private aircraft from the Beni. Increasing its law-enforcement efforts, the Bolivian government eradicated about 10 percent of the cultivation, dismantled a number of laboratories, and disrupted several major trafficking organizations (e.g., Meco Dominquez, Mario Ariaz-Morales, Martin Morales-Daczer).

Colombia. Proximity to a large cash-based U.S. marketplace, powerful criminal organizations, indigenous entrepreneurial spirit, vast tracts of uncontrollable land, and a long tradition of smuggling have made Colombia an ideal source for cocaine. The U.S. government estimated that in 1991 92,000 acres (about 37,500 ha) of the world's 526,500 acres (213,000 ha) of coca were cultivated in Colombia—mainly in the Llanos (plains) region, which encompasses almost 50 percent of eastern Colombia. There is also coca cultivation in Caqueta, Guaviare, Putumayo, and Vaupes departments, with crop expansion into Bolivar department and into south and southwest Colombia. Colombia's drug cartels are the world's leading producers of both cocaine HCL (which is sniffed or snorted) and CRACK (which is smoked).

Colombian cocaine-trafficking organizations are sophisticated and well-organized industries, which derive their strength from control of cocaine laboratories and the smuggling routes to North America. After financing the cultivation of coca plants in Bolivia and Peru, Colombian traffickers often oversee the processing of the leaves into coca paste and sometimes base, which may then be shipped to laboratories in Colombia where the traffickers refine the coca paste—first into coca base and then into cocaine HCl by the ton. Recently, Peru and Bolivia have stopped shipping some of their coca products to Colombia and have begun to refine them into cocaine HCl in laboratories near their own fields, but as of the early 1990s Colombia operates the greatest number of base and HCl labs.

Cocaine is a major threat to weakening Colombia's democratic institutions and directly or indirectly affecting everyone in the country. Colombians increasingly recognize that the violence and corruption that accompany drug trafficking are harming their economy and society. By the early 1990s, under President Cesar Gaviria, the Colombian government security forces began enforcement procedures against cocaine traffickers. The Colombian police have also eradicated virtually all marijuana cultivation in the traditional growing areas along the North Coast and Guajira peninsula. The government of Colombia consequently damaged the leadership structure of the Medellin cartel by jailing its leader, Pablo Escobar. Some feared

	1991	NA	3,815–4,615	

Summary	*1990*	*1991*
Gross Marijuana Available	33,660–34,760 (tons)	19,889–20,989 (tons)
Less U.S. Seizures,** Seizures in Transit, and Losses	3,850–4,950 (tons)	3,850–4,950 (tons)
Net Marijuana Available	28,710–30,910 (tons)	14,939–17,139 (tons)

Summary	*1990*	*1991*
Total Marijuana Available	30,600–31,600 (metric tons)	18,080–19,080 (metric tons)
Less U.S. Seizures,** Seizures in Transit, and Losses	3,500–4,500 (metric tons)	3,500–4,500 (metric tons)
Net Marijuana Available	26,100–28,100 (metric tons)	13,580–15,580 (metric tons)

*Percentages were rounded off and reflect midpoints of the quantity ranges in this table. For purposes of calculation and comparison, all the marijuana produced overseas was assumed to be potentially available for import to the United States.

**U.S. seizures included coastal, border and internal (not domestic eradicated sites). Seizures in transit included those on the high seas, in transit countries, from aircraft, etc. The loss factor included marijuana lost because of abandoned shipments, undistributed stockpiles and inefficient handling and transport, etc.

SOURCE: *International Narcotics Control Strategy Report 1992* and the U.S. Drug Enforcement Agency.

that jailing Escobar would not curtail his cocaine trafficking, but it did have a symbolic effect on the Medellin cocaine business. (Escobar was later killed after escaping from jail.)

A signatory of the 1961, 1971, and 1988 United Nations International Narcotics Control Conventions, Colombia demonstrates its political will and commitment to investigate and immobilize major cocaine traffickers and to eradicate marijuana and opium. Colombia has also created public-order courts and begun to share evidence, reform its judiciary, and track the substantial money flows into the country—requiring the banking institutions to keep records on cash transactions over $10,000.

In the realm of CROP CONTROL, despite widespread testing of various coca herbicides, the government has not begun a major coca-eradication effort; this is largely because it is not a focus of antidrug efforts—given the location of the fields in terrorist controlled land, it is dangerous for ground forces and almost impossible for air attack. Fearing a new and burgeoning heroin business, in 1992 the Colombian government agreed to spray the common garden herbicide glyphosate (Roundup) to kill the source—the opium poppy fields—after a widespread manual eradication effort in 1991. Since the mid-1980s, marijuana production continues to be minimal because of an effective herbicidal campaign.

The Colombian national police, the military, and the security forces have conducted major operations against the Medellin and Cali cocaine cartels with the assistance of U.S. technical and information support. Colombia's government has, however, paid a heavy price for its action, suffering almost 500 deaths by assassination or during enforcement operations. Colombia has also threatened to use, or has used, the tool of extradition to incarcerate or immobilize major traffickers. In late 1990, President Cesar Gaviria's offer of amnesty (a plea-bargaining opportunity for major traffickers) resulted in decreased violence throughout the country and the surrender and imprisonment of five traffickers and one terrorist, including Pablo Escobar and the three Ochoa brothers (Jorge Luis, Juan David, and Fabio).

Opium/Heroin. The opium poppy (*PAPAVER SOMNIFERUM*) is the source of heroin. It is grown in three principal geographic regions: Southeast ASIA, Southwest Asia, and Latin America. The Southeast Asian GOLDEN TRIANGLE countries of Myanmar (Burma until 1989), Laos, and Thailand in 1991 cultivated approximately 81 percent of the world's total, 488,000 acres (195,000 ha), yielding 2,500 metric tons of opium, which would yield 250 metric

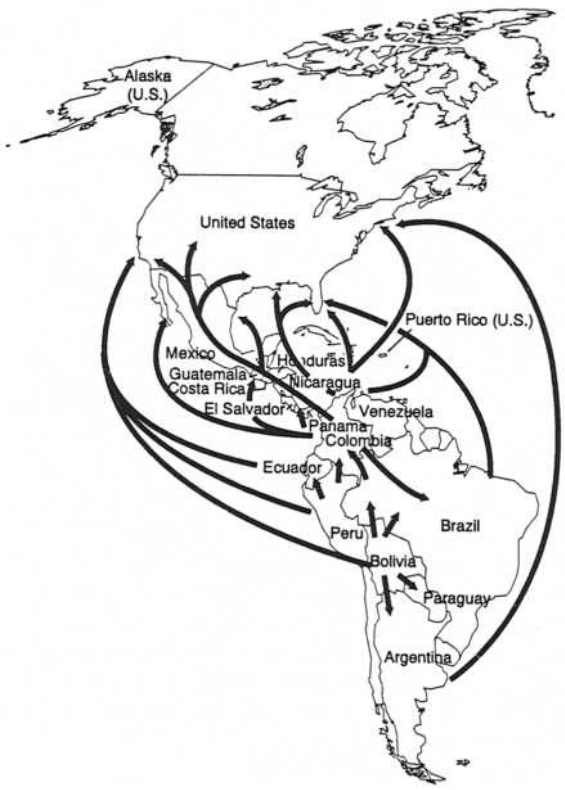

Figure 1
Cocaine Distribution

tons of heroin. The Golden Crescent countries of Afghanistan, Iran, and Pakistan cultivated approximately 11 percent, and the Latin American countries of Mexico, Guatemala, and Colombia (plus the Middle Eastern country of Lebanon) produced approximately 8 percent. India is the world's largest cultivator of licit opium, producing about 35,000 acres (14,000 ha) annually for the international medicinal market.

Southeast Asia's Golden Triangle: Myanmar. The largest supply of illicit opium—56 percent of U.S. availability—comes from the Golden Triangle of Southeast Asia. Fields of opium poppy are planted on hillsides that have been prepared by ancient slash-and-burn agricultural methods. Nearly 90 percent of Southeast Asian opium comes from the Union of Myanmar (Burma), where cultivation areas are largely controlled by antigovernment insurgents in the Shan state. Heavy cultivation exists east of the Salween river and in the eastern and southern parts of the Shan state, at an average elevation of 3,300 feet (1,000 m). Fields are small, averaging about an acre (0.5 ha). The climate is ideal for growing poppy. The growers depend on opium for survival, receiving subsistence prices for and selling entire stocks to the political insurgents, who use the proceeds for food, arms, and ammunition. The opium is also consumed locally by large numbers of addicts.

Most processing of opium and heroin in Southeast Asia occurs in Myanmar, with only small amounts in Thailand and Laos. The Shan United Army and the Wa insurgent groups control refineries along the Thai/Myanmar border; the Kokang, Wa and Kachin ethnic groups also operate large heroin refineries along the China/Myanmar border. Increasing amounts of heroin are smuggled via southern China to Hong Kong, south through Malaysia and Singapore, and west through India and Bangladesh.

With the overthrow of the long-standing government of Burma by a military junta in 1988—and ongoing political strife in the new Union of Myanmar—suspension of aerial opium eradication and diminished enforcement contributed to increases in opium cultivation, heroin refining, and drug trafficking. A signatory to the 1961 SINGLE CONVENTION ON NARCOTIC DRUGS, but not to the 1972 Protocol to the Convention or the 1971 PSYCHOTROPIC SUBSTANCES CONVENTION, MYANMAR had acceded to the 1988 UN Convention but now disputes the validity of extradition and submission of disputes to the International Court of Justice.

Thailand. Only a small amount of land is used to grow opium in Thailand, but it remains a net importer of opium, consuming far more than it produces. Developed transportation systems make Thailand the primary transit route to the opium/heroin world markets, shipping by air, sea, and overland. Since the mid 1800s, opium has been grown in the northern highlands by nomadic hill tribes, who are not tied to Thailand culturally, religiously or politically. Opium cultivation in Thailand is illegal, so the government has sponsored both eradication and crop-substitution efforts in the north.

Thailand is a party to the 1961 Single Convention on Narcotic Drugs and the 1972 Protocol to the Single Convention. In 1991, Thailand passed conspiracy and asset-forfeiture laws and a new extradition treaty with the United States; both are working on a mutual legal-assistance treaty.

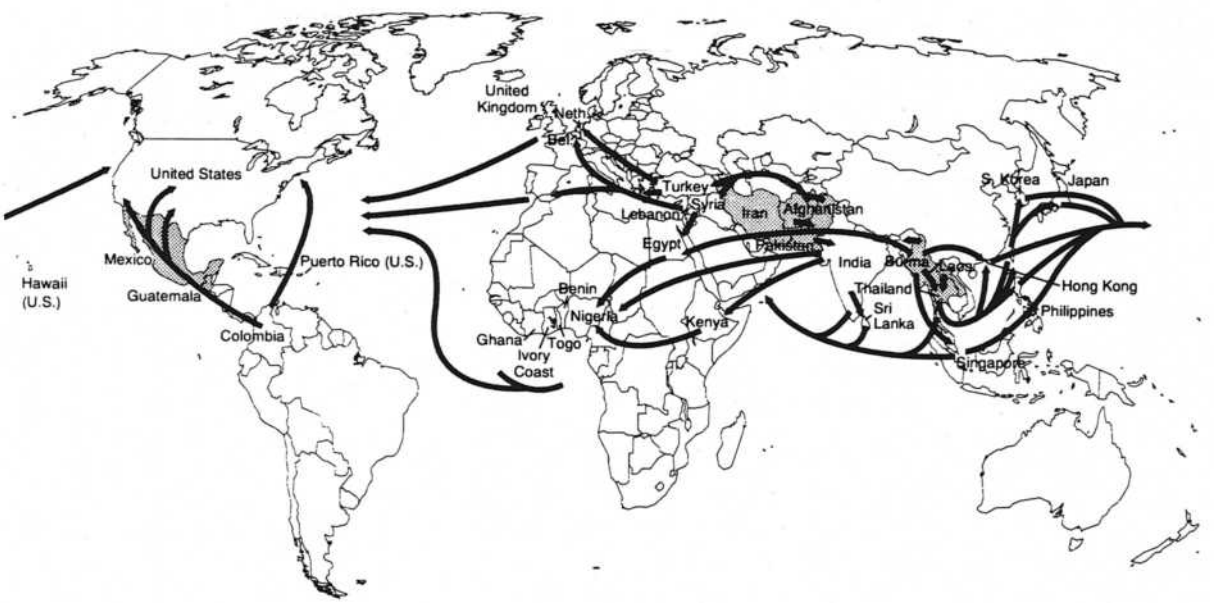

Figure 2
Opium/Heroin Distribution.

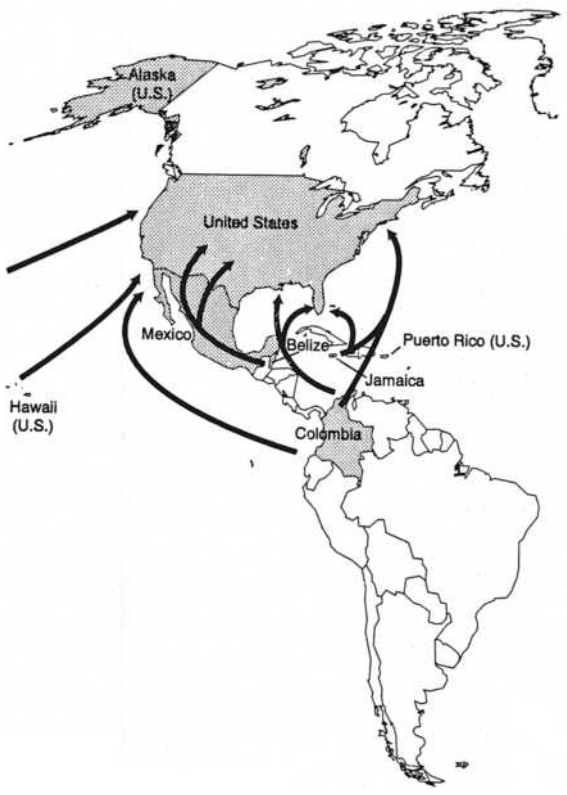

Figure 3
Marijuana Distribution.

Laos. Recent changes in the world's political order have resulted in cooperation by the Laotian government to reduce opium cultivation. Widespread reports of Lao military corruption and involvement with the traffickers, however, have limited the success. A landlocked country, Laos has been isolated and ignored by the West since 1975 when the Communist Pathet Lao seized power; opium poppies have been grown in its nine northern provinces, yielding in the early 1990s about 20 percent of Burmese production. Three crop-substitution projects have had limited success—one in Houaphanh province, one in Vientiane province, and one in Xiang Khouang province.

The Lao government does not have a mutual legal-assistance treaty or an extradition treaty with the United States, but it does have a formal memorandum of understanding and informal agreements with U.S. agencies to cooperate more fully in drug-control efforts.

China and the Golden Triangle. In its 1992 International Narcotics Control Strategy Report, the U.S. government stated that opium cultivation may be emerging as a major problem in the People's Republic of China. China has become a major narcotics transit point with its open border to Myanmar, its location adjacent to the Golden Triangle, and its excellent transportation and commu-

nication links with the trade ports of Hong Kong and Macao. Much of the heroin processed by the Kokang Chinese in the Golden Triangle travels by road through China's Yunnan, Guangxi, and Guangdong provinces to Hong Kong for overseas distribution. In 1991, Chinese law enforcement seized more drugs and investigated more cases than at any time since the Communist takeover. A spreading domestic opium consumption appears to be accompanying the increased heroin flow.

The Golden Crescent: Pakistan, Afghanistan, and Iran. The Golden Crescent supplied about 21 percent of the heroin consumed in the United States in the early 1990s. In area under cultivation, the Golden Crescent countries produce almost 11 percent of the world's opium.

Pakistan. This is a producer and an important transit country for opiates and HASHISH. The Islamic government of Pakistan maintains a poppy ban in areas under its control and manages to maintain about the same production level from year to year, but cultivation has increased slightly in areas where government control is ineffective or only nominal. Cultivation is both rain fed and irrigated in the northwest and the tribal areas of Kyber, Mohmand, and Bajaur. Once the poppy is harvested, it is processed into opium and heroin in more than a 100 clandestine mobile laboratories in the Northwest Frontier Province (NWFP) bordering Afghanistan, which is controlled by armed tribes who maintain traditional cross-border connections.

Pakistan is party to the 1961 UN Single Convention on Narcotic Drugs, the 1971 UN Convention on Psychotropic Substances, and the 1988 UN Convention Against Illicit Traffic of Narcotic Drugs and Psychotropic Substances. Yet, with widespread corruption and government inaction, Pakistan failed to enforce its counternarcotics laws in the tribal areas, raising questions about its compliance with the 1961 Convention. Pakistan's government does however cooperate with U.S. law-enforcement agencies and has responded positively to extradition requests.

Afghanistan. After Myanmar, Afghanistan is the world's second largest producer of illicit opium. Considered an effective cash crop, opium has been grown for generations in Afghanistan, in the Helmand valley and Nangahar province, and used for medicinal and culinary purposes. The opium is processed into heroin and smuggled across the borders of Iran through Turkey. Afghanistan's government exerts little control over production or trafficking. Drug revenues continue to finance political resistance operations against the Communist government and provide a livelihood for farmers who depend on the opium crops. Unless the government is willing and able to control opium production in the countryside, both production and domestic consumption will continue to rise. The end of Soviet occupation (1979–1989) has not brought the refugees home, but their return will affect Afghanistan's overall economy and may cause an increase in drug trafficking.

Afghanistan is a party to the 1961 Single Convention but not to the 1972 Protocol amending the Convention. It is a signatory to the 1971 Convention on Psychotropic Substances but not to the 1988 Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances.

Iran. Limited data exist on drug cultivation and trafficking since the Islamic Republic of Iran was established in 1979 under the Ayatallah Khomeini. Iran outlawed opium cultivation in 1980 but growth reportedly occurs in remote areas near the Pakistan and Afghanistan borders. Allegedly, laboratories process heroin from opium in the Kurdish areas of the northwest and the Baluch region in the southeast, with significant Irani and local addict populations consuming the product. The U.S. government estimated that Iran produces about 50 percent of the amount of heroin produced in Afghanistan.

Drug trafficking is increasing along the Afghan-Iran and Afghan-Pakistan borders. Baluch and Pashtun tribesmen from all three Golden Crescent countries smuggle drugs in addition to traditional contraband. Pakistanis and Iranis could increase poppy cultivation to help rebuild their livelihoods that were interrupted by almost twelve years of war.

Mexico. In the 1970s, Mexico began to smuggle significant amounts of heroin into the United States, replacing Turkey as the principal heroin supplier for U.S. addicts. Opium is grown and harvested twice a year—winter and spring—in Mexico's states of Sinaloa, Chihuahua, and Durango. In the 1990s, harvesting has become year round, and cultivation has expanded to include Mexico's west coast from Sinaloa to the Mexican-Guatemalan border. Supplying an estimated 23 percent of the heroin consumed in the United States, Mexican

traffickers produce both traditional brown and black-tar heroin, although the predominant type smuggled into the United States is the black-tar type. Conversion from the popular "Mexican brown" in the 1970s to the black-tar variety is a result of traffickers using more cost-effective mobile laboratories. The mobile labs are much harder to detect and can move with the harvesters, as they go from field to field collecting the opium gum and producing the purer black tar preferred by U.S. addicts. Although the mobile labs are found near the fields, Mexican law-enforcement personnel are also finding them near towns and cities, where chemicals and security can be acquired more easily. The administration of President Carlos Salinas (1988–1994) instituted effective law enforcement, including strong measures to combat official corruption, a 40 percent increase in opium eradication, and increased cocaine interdiction.

Mexico is a signatory to the 1988 UN Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances and entered into a Mutual Legal Assistance Treaty (MLAT) with the United States in 1991.

Guatemala and Colombia. These two countries have both begun to cultivate substantial amounts of opium in the late 1980s. By 1991, in Guatemala's western provinces of San Marcos and Huehuetenango, farmers harvested approximately 4,300 acres (1,700 ha) of opium poppy, which had been cultivated in steep mountain valleys on small plots. Mexican traffickers provide the financial, technical, and agricultural support for local growers to harvest three crops per year; the opium, however, is sent to Mexico for processing into heroin. The Guatemalan government has conducted aerial herbicidal eradication with some success, destroying almost a third of the total cultivated, but farmers are relocating their fields to more remote areas. In Colombia, in 1991, over 6,000 acres (2,500 ha) of opium poppy were located in 12 of the 32 states—planted for the most part in the Cauca and Huila departments and financed and controlled by the Cali cartel. Colombia has agreed to begin herbicidal spraying from crop-duster aircraft, as it did during its mid-1980s marijuana-eradication program.

Cannabis. A by-product of the HEMP plant *CANNABIS SATIVA* is marijuana, which is the most commonly used illicit drug in the United States. Both the plant and its PSYCHOACTIVE ingredient TETRAHYDRO-CANNABINOL (THC) are classified as CONTROLLED SUBSTANCES by the U.S. government, which estimates that Mexico supplies the majority of U.S.-consumed marijuana—perhaps as much as 63 percent. The U.S. supply accounts for another 18 percent, Colombia for 5 percent, Jamaica for 3 percent, and the remaining 11 percent comes from Belize, Laos, the Philippines, Thailand, Lebanon, Pakistan, and Afghanistan. Brazil and Paraguay also cultivate cannabis but the majority is consumed locally or exported to neighboring South American countries.

Mexico. Although *Cannabis* grows throughout the country, major concentrations have been located historically in the western states of Chihuahua, Jalisco, San Luis Potosi, Sinaloa, Sonora, and Zacatecas; it is also found in Mexico's eastern state of Veracruz and, recently, in the southern states of Chiapas, Guerrero, Michoacan, and Oaxaca. Farmers grew two crops per year, traditionally, but in many areas it is grown and harvested year round. *Cannabis* is cultivated by subsistence farmers who often intermingle the crop with corn and beans. Traffickers have introduced irrigation and technological advances to help the farmer (*campesino*) avoid eradication attempts and survive cyclical droughts. The traffickers control the processing and transport of the product into the United States, smuggling the vast majority by road.

Colombia. Once the primary source for marijuana consumed in the United States, in the 1990s Colombia cultivates about 5,000 acres (2,000 ha) in the traditional growing areas of Sierra Nevada de Santa Marta and Serrania de Perija of northeastern Colombia. Since the dramatic success of the Colombian government's 1980s aerial-eradication program, only small amounts of low-quality cannabis have been cultivated in Colombia.

Southeast Asia. This region produces a high-grade marijuana that became popular in the late 1980s; it is cultivated in Thailand and Laos, then shipped to staging points along Thailand's southern coast, to western Cambodia, and to the coast of Vietnam. Moved by ten-wheel trucks, the product is then loaded onto trawlers and taken to motherships in the Gulf of Thailand. Oceangoing vessels, yachts, and sailing boats have all been used to smuggle the product to the United States, with trans-Pacific shipments occurring in the spring and summer. U.S. traffickers usually control the commerce of marijuana into the United States, off-loading

their cargo to smaller faster vessels off the U.S. coast.

Two crops a year are generally harvested in Southeast Asia, in December–January and April–May. Cultivators normally press the harvested marijuana into kilogram blocks, using a hydraulic press, and then package the blocks into aluminum foil or plastic bags that are vacuum-packed. They are hermetically sealed with heat and wrapped with nylon-reinforced plastic tape, then stored in tin canisters, burlap sacks, nylon or canvas gym bags, or boxes—all designed to maintain the product's composition, eliminate odor, and prevent mildew.

The THC content of Southeast Asian marijuana can be as high as 9 percent, whereas the average THC content for Mexican or U.S. marijuana is only 2 to 3 percent.

Jamaica. The successful eradication campaigns mounted since 1987 have decreased significantly Jamaica's importance as a supplier of *Cannabis* in the form of ganja. Cultivation has shifted from the accessible wetlands of west-central Jamaica to remote sites in the highlands, often in plots smaller than an acre. In the early 1990s, of 4,500 acres (1,800 ha) cultivated, almost 50 percent were reportedly eradicated. The rest was smuggled into the United States in concealed storage areas of pleasure craft, as well as in commercial fishing vessels, cargo ships, and container ships.

POLITICAL AND ECONOMIC SIGNIFICANCE

Although drug cultivators, transportation workers, processors, laboratory workers, middlemen, and smugglers receive their wages, the majority of the money made in the drug business remains in the consuming country or is invested in off-shore banking havens. Drug-producing countries do not normally offer attractive long-term investment opportunities. Countries such as Peru, Bolivia, Myanmar, and Afghanistan have troubled economies, which do not attract traffickers' investment portfolios; rather, traffickers spend money on luxury items, such as foreign real estate and automobiles, race horses, gambling houses, yachts, clothes, and jewels.

In the Golden Triangle and the Golden Crescent, drug production and trafficking offer a primary cash crop for food and the support of political (antigovernment) operations. Resistance groups in Afghanistan and Pakistan and insurgent tribes in the Golden Triangle use the profits from the sale of opium to buy rice and the arms to fight the central governments. Politically speaking, illicit-drug production and trafficking offer a viable means of acquiring wealth, which can be instrumental in buying power and influence. In some countries, the traffickers and insurgent groups may be identical (such as the Wa or the Shan United Army of Burma); in others, insurgency and trafficker goals may be diametrically opposed (such as the Cali cartel and the FARC in Colombia). Most trafficker organizations work to coopt the government and maintain the status quo, buy power and protection, and keep a low profile; insurgent groups, however, seek to be highly visible and wish to change the existing power structure. Despite the opposing objectives of both, traffickers and insurgents often function symbiotically; that is, both need hard currency, security, protection, and armed support to evade detection and apprehension.

HISTORICAL SUPPLY SHIFTS

The 1960s and 1970s. Drug production and trafficking have undergone major shifts since the 1960s. After the so-called French Connection was broken between 1968 and 1972, Mexico began to supply the United States with a low-quality heroin to fill the market demand. As Mexican eradication became more successful in the mid to late 1970s

and the Iranian Islamic revolution erupted in 1979, significant amounts of Southwest Asian heroin from Afghanistan and Pakistan were smuggled, often by Iranians, through Western Europe into the United States. Throughout the 1970s, heroin from Mexico, Southeast Asia, and the Middle East was high on the U.S. drug-control policy agenda. No one denied that cocaine and marijuana abuse might be dangerous; indeed, initial attempts were made to initiate bilateral programs with the Andean cocaine source countries in their traditional growing areas, but because policymakers believed that the negative health consequences of heroin consumption were far worse, the U.S. law-enforcement emphasis was placed on cocaine and marijuana.

The 1980s. In the 1980s, targeting heroin gave way to focusing on the reduction of cocaine and marijuana use in the United States, since greater numbers of Americans were using and abusing them, creating large drugged populations. Nongovernmental institutions became very active in spreading the Just Say No message of the Reagan Administration (1981–1989). Moreover, until the early 1980s, when research had documented the negative health consequences of cocaine, the drug enjoyed a glamour and allure that heroin had never possessed. In some circles, the ability to afford cocaine was a sign that one had succeeded. Most believed that cocaine was not addictive and it became the recreational drug preferred by Hollywood, sports figures, and musicians. The 1980s was the Coke Decade—with cocaine used both by the affluent consumption-oriented yuppie "me generation," as well as the poor disenfranchised underclass who tried to emulate their heros and "make it" in their own world. Both the powder and the rock-crystal crack forms found eager markets and ready money in the so-called affluent Reagan years. The stock market crashes of 1987 and 1989 ended the boom in the national and the drug economies.

When Colombia replaced Mexico in the early 1980s as the primary source of U.S. cocaine and marijuana, smuggling vast quantities through the South Florida peninsula, the Reagan Administration turned its focus to cocaine and marijuana control in the Western Hemisphere. In the late 1980s, the Bush Administration (1989–1993) continued the same cocaine policy but decreased federal attention on marijuana supply reduction. Bolivia and Peru quickly expanded their production of illicit coca in nontraditional growing areas of the Chapare and the Upper Huallaga Valley, two areas that remain the major source for the world's illicit coca. Surrounding and potential transit countries also became more involved in the cocaine smuggling enterprise. The Caribbean nations functioned as attractive transit points for both cocaine and marijuana from South America. As the United States placed more enforcement pressure on the Caribbean, the traffickers shifted their routes through Central America and Mexico. In the mid-to-late 1980s, Mexico became a principal transit and smuggling route for an estimated 50 percent of the cocaine entering the United States. In response to smuggler shifts, both Mexico and the United States have increased interdiction efforts along the joint southwest border and the U.S. 1992 Drug Control Strategy focuses its attention in Mexico predominately on improving cocaine interdiction.

The 1990s. U.S. policymakers are faced with a number of new challenges—namely, increased heroin production and trafficking in Central Asia (China), in Central and South America (Guatemala and Colombia), and in Myanmar and Afghanistan. Another challenge is the growing cocaine business in Bolivia and Peru, where increased processing of coca into cocaine products occurs. Finally, policymakers need to consider the potentially devastating impact of increased cocaine and heroin demand and consumption in the new democracies of Eastern Europe and the new republics of the former Soviet Union.

Beginning in 1991, the U.S. government expressed its concern over an increase in worldwide heroin production, trafficking, and abuse. Record seizures have been made in China's Yunnan province—signaling major changes in trafficking routes out of the Golden Triangle through China, Hong Kong, and Taiwan to the West. Heroin traffickers have begun to use the immense container-shipping industry to smuggle large amounts of heroin from Asia into the United States. In June 1991, the single largest heroin seizure in the world was made in San Francisco, hidden in containerized freight from Taiwan. Colombia also became a significant cultivator of opium for the first time, in the 1990s—planting an estimated 6,000 acres (2,500 ha) of opium in 1991. Although opium cultivation has decreased in Mexico and the Golden Crescent, increasing demand in the United States may be met by Colombia and Myanmar.

The cocaine epidemic of the 1980s, as measured by prevalence and incidence indicators, appears to have peaked and is declining for certain cohort populations, but concern continues over the chronic intensive use of the crack form among the predominantly minority underclass; those least able to cope—the uneducated, unemployed, and disenfranchised—are the victims. With processing facilities now closer to source countries least able to implement effective drug-control programs politically and economically, these two problems present daunting challenges for U.S. public policymakers.

Finally, the massive political, economic, and social changes that occurred since 1989—the democratization and political upheaval in the Eastern bloc and the Soviet Union—may result in increased drug demand, driving up drug production, trafficking, and serious negative health consequences. Unfortunately, accompanying the economic difficulties and growing political pains in the fledgling democracies are increases in crime, violence, and drug abuse.

ITALY, DRUG USE IN In Italy, the impact of illicit drug use was first felt on a broad scale during the mid-1960s. The patterns in Italy were similar to those seen in other European countries. They seemed to be associated with the contestation by young people of existing political and social situations. As in the United States at the same time, this phase was influenced by the cultures of the East—especially those of the Indian subcontinent, Southeast Asia, and the Middle East—in all of which some amount of drug use was not illegal. *Cannabis sativa*, the HEMP plant that produced MARIJUANA, GANJA, HASHISH, and other variants, was particularly unhampered by legislation there and was enjoyed by locals and outsiders, some of whom found ways to smuggle it into the West, where in many instances it was illegal.

In addition, the OPIOIDS (especially HEROIN) began to be used illicitly, and by the 1970s serious consequences ensued. By then, the countercultural movement and its abuse of illicit drugs had lost most of its original idealistic principles. Abusers were simply in search of ever more and ever stronger psychotropic effects. Moreover, criminal organizations took charge of the illicit drug trade, not only to increase their profits but also to control and direct the political and social development of the youth of Italy. For the most part, users became abusers who were physically dependent on their drug, so their behavior could be controlled by the suppliers.

In the 1980s, the drug scene changed, with various control measures and less heroin available. In addition, with less heroin being sold, longer intervals occurred between drug doses for many users. Such modified habits led to decreased tolerance and increased overdosing, with ensuing deaths. For these reasons, the number of heroin addicts in Italy decreased—then, in the mid-1980s, COCAINE emerged as the new illicit drug problem. The CRACK and FREEBASE forms were especially harmful among young ADOLESCENTS. More detailed data are contained in the annual reports of the National

LEGISLATION

At the beginning of the drug-abuse phenomenon of the 1960s, the legislation in force had been passed in 1954. It proved to be insufficient for coping with emerging conditions; it did not take into consideration the political-cultural trends, the scientific knowledge of the day, or the increasingly important role of public health.

New legislation in 1975 was characterized by such innovative elements as the nonpunishment of

*average dose, heroin = 0.015–0.025 gr
mean dose, cocaine = 0.040–0.060 gr

the addict found to be in possession of a moderate quantity of illicit drugs. The quantity was to be examined and quantified, and it was to be considered in relationship to the physical and psychological needs of the addict. Unfortunately, this individualistic approach was poorly applied, which made the law useless.

The regulations approved in 1990 improved the state's power of both repressive action and intervention, and it defined a daily mean dose to separate administrative offenses from crimes. The objective was to recover and rehabilitate drug addicts. A 1993 referendum, however, repealed the prohibition on personal drug use and canceled references in the regulations to the daily mean dose.

TREATMENT FACILITIES

In accordance with national policy guidelines, a network of facilities was set up and various links were established with rehabilitation, law enforcement, and judicial structures. This process was worked out with public support; the aim has been to sustain every initiative to reduce the availability and demand for drugs.

Of the addicts served by the facilities, almost all are heroin abusers, some not yet dependent. Starting by weaning them from heroin with METHADONE, the facilities provide integrated and custom-designed programs founded mainly on nonpharmacological support.

A wide range of resources are available; 576 public facilities and 276 residential communities and sociorehabilitative structures (public, private, and voluntary—most of them situated in northern Italy). Voluntary services continue to increase in importance both in number and in regional distribution. The effectiveness of the facilities has been proved, since trained personnel and good records provide such statistics on trends (see Table 1).

SEIZURES OF ILLICIT DRUGS

Various trends can be seen by studying the records of seized drugs. Some decreasing trends have been recorded for MORPHINE in 1982, for heroin in 1981 and 1985, and for cocaine in 1984. Irregular trends emerged for *Cannabis* products: a 128-percent increase in 1981, a decreasing trend until 1985, and two huge increases in 1986 and in 1989 (see Table 2). The decision to standardize descriptions of drug seizures by reference to the percent of the primary drug instead of the raw weight of the primary drug seized should improve the accuracy of record keeping (see Table 3).

DRUG ABUSE-RELATED DEATHS

Drug abuse-related deaths also show irregular trends. Most deaths could be attributed to heroin overdoses or to accidents while injecting it. After 1980, two large increases in the death rate occurred, first in 1982 and then in 1984, followed by a steady rise into 1986. From 1986 to 1988, the "empiric" mortality rate nearly doubled; it subsequently remained steady until 1991 and then dropped until 1994 (see Table 4), except among the elderly, for whom the rate increased.

ALCOHOL ABUSE

ALCOHOL use in Italy strongly differs from drug use for historical, traditional, behavioral, and cultural reasons; supply and distribution are also different, since alcohol is free from legal restrictions. Wine is the most frequently used alcoholic beverage. Although a gradual displacement in wine consumption occurred during the 1980s, with substitution of other liquors and beers, still the total amount of alcohol (percent of ethanol) consumed remained almost constant.

ALCOHOLISM is mainly a problem of chronic abuse by adults over the age of 40. It is mainly a problem in northern Italy. Since the 1980s, however, increasing numbers of young people are abusing liquors and beer. Alcoholism has also become complicated by the combining of alcohol with psychotropics (e.g., tranquilizers), especially by women over 40.

Driving-license regulations have, since 1988, included a test that measures the breath concentration of alcohol. The alcohol level must not be over 8 grams per liter (g/l), approximately that of other countries of the European Economic Community.

JELLINEK MEMORIAL FUND In 1955 the Jellinek Memorial Fund was established to commemorate Dr. E. M. Jellinek's great contribution to the field of ALCOHOL studies. A capital fund was developed and the interest from this fund has been used to provide an annual cash award to a scientist who has made an outstanding contribution to the advancement of knowledge in the alcohol/alcoholism field. The first award was presented in 1968.

Each year the board of directors of the Jellinek Memorial Fund designates the specific area of research for which the award will be made and appoints an Expert Selection Committee to review candidates and recommend an appropriate awardee. The awardee may be selected from any country, the sole criterion being the scientific contribution that the person has made within the selected category. The award is traditionally presented at a major international conference and, if necessary, travel and accommodation expenses are provided to permit the winner to attend the conference for the presentation. The following general criteria have been accepted by the board and by previous selection committees as guidelines:

1. The award is to be given to the person deemed to have made, during the preceding years, the greatest scholarly contribution to human knowledge of problems relating to alcohol, in the designated research area.
2. The person selected for the award should be someone who would provide an example and serve as a model for others who might be attracted to work in the field.
3. Only living scientists should be considered for the award.
4. Advanced age or impending retirement would not disqualify someone from candidacy. However, if two or more scientists were considered approximately equal, the one more likely to continue longer in the field would be favored.
5. If the outstanding contribution of a candidate was made more than ten years ago, consideration for the award would require evidence of the candidate's continuing interest and active participation in alcohol research.
6. Other factors being equal, the person would be favored whose primary identification continued to be in the field.
7. If a member of the Expert Selection Committee is deemed eligible for the Jellinek Award, the chair of the selection committee should consult with the president and request the resignation of the committee member.

8. If a previous award winner becomes a candidate and appears equal to or above all other candidates on the basis of unique new achievements, he or she should not be ruled ineligible. The chair of the selection committee should consult with the president to ensure that the award is for new achievement and determine if he or she is eligible.
9. The award will normally be made to an individual researcher most highly recommended by the selection committee. In special circumstances, if the selection committee recommends two persons of equal and outstanding merit, a joint award may be made to the two.

In 1999, the award was given in the category of epidemiology and population studies jointly to Kaye Middleton Fillmore and Alexander Wagenaar. Fillmore, a School of Nursing adjunct professor in the Department of Social & Behaviorial Sciences and the Center for Health & Community, received the award for her contribution to the basic understanding of the life course of drinking and of alcohol problems in a multinational context. Wagenaar, Professor of Epidemiology and Director of the Alcohol Epidemiology Program at the School of Public Health, University of Minnesota, received the award for lifetime achievement in community intervention and policy evaluation research on alcohol.

REVISED BY DONNA CRAFT

JEWS, DRUGS, AND ALCOHOL

Who hath woe?
Who hath sorrow?
Who hath contentions?
Who hath babbling?
Who hath wounds without cause?
Who hath redness of eyes?
They that tarry long at the wine;
they that go to seek mixed wine.
Look not thou upon the wine when it is red,
when it giveth his color in the cup,
when it moveth itself aright.
At the last it biteth like a serpent,
and stingeth like an adder.
Thine eyes shall behold strange women,
and thine heart shall utter perverse things.
Yea, thou shalt be as he that lieth
down in the midst of the sea,
or as he that lieth upon the top of a mast.
They have stricken me, shalt thou say,
and I was not sick;
they have beaten me, and I felt it not:
when shall I awake?
I will seek it yet again.

—Proverbs 23:29–35

As illustrated by this biblical description of intoxication, alcoholic blackouts, alcohol-related physical and social problems, alcoholic hallucinations, loss of control of drinking, and alcohol dependence was not unknown to the ancient ancestors of today's Jewish population. The Hebrew Bible (called by Christians the Old Testament) includes several illustrations of alcohol-related problems, such as the drunkenness of Noah, which led to family strife, and the incest between Lot and his daughters.

Modern literature about the role of ALCOHOL in the Jewish community displays two very different trends. On the one hand, Jews are regarded as a population with few alcohol problems; and a variety of cultural, spiritual, or physiological explanations are suggested to explain the relatively low rate of ALCOHOLISM among Jews. On the other hand, studies of alcoholism among Jews point out that many cases often go unrecognized, because of the myth of Jewish immunity to alcohol abuse.

Surveys of U.S. drinking practices conducted in the 1960s found that most males who considered themselves Jewish reported drinking to some extent, but few reported alcohol problems. However, the number of Jewish subjects in these studies was small. A more recent study of U.S. male college students and university employees reported that although Jewish and Christian subjects had generally similar drinking patterns, Jews were less likely to drink more than six drinks on any one occasion and less likely to report alcohol problems.

Israel reports a lower per-capita alcohol consumption than countries in Western Europe or the Americas and a lower death rate from cirrhosis of the LIVER. (Cirrhosis mortality is thought to correlate with rates of alcoholism.) A single study of a sample of 266 adult Jews in the general public in

New Haven, Connecticut, found a lifetime prevalence of alcohol abuse of 1.7 percent, significantly lower than the rate reported for Protestants, Catholics, or those without religious affiliation. The prevalence of alcohol dependence was not reported and the actual rates of alcohol dependence among Jews, either in the United States or in other parts of the world are unknown.

Explanations of Jewish sobriety go back at least as far as the German philosopher Immanuel Kant, who in 1798 theorized that Jews (like women and ministers) avoided drunkenness because their special position in European Christian society was based on the perception that they adhered to a religious law that dictated a higher code of conduct. Intoxication for a Jew would therefore be sinful as well as scandalous. Others have suggested that the traditional use of wine for religious ritual in Jewish life, rather than for hedonistic or social purposes, protects Jews from alcoholism.

In the 1950s, C. R. Snyder studied the drinking patterns of seventy-three Jewish men living in New Haven, Connecticut, and also analyzed data from Jewish and non-Jewish male college students. He concluded that SOBRIETY was a positive factor in Jewish identity, as opposed to drunkenness, which was associated with non-Jews. He also concluded that the greater the adherence to Jewish religion and its "ceremonial orthodoxy," the lower the alcohol problem risk. This finding has led many to theorize that those Jews who do develop alcohol problems are those who have rejected or left Jewish religious practices, abandoning their Jewish identity.

The finding that genetic factors may predispose to alcoholism has led to speculation that there may also be some hereditary protection for Jews. Dr. Y. D. Neumark and his colleagues in Israel studied sixty-eight Jewish families of male heroin addicts, 75 percent of whom also drank to excess. Using statistical methods they found evidence for a combination of genetic and environmental factors influencing the levels of alcohol use in family members. They also found that the presence of a specific gene (the ADH2*2 allele, a variant of the gene for an alcohol-metabolizing enzyme) was associated with lower alcohol intake in a comparison of fifty-three of the heroin-dependent heavy drinkers with a group of ninety-two Jewish male light drinkers. A 1991 study by Monteiro and colleagues found suggestive evidence that young adult Jewish males were more sensitive to the subjective effects of low levels of blood alcohol than were a control group of Christians. Although this finding awaits replication, the authors theorize that heightened sensitivity in Jews might either deter heavy drinking or help facilitate internal mechanisms for the control of alcohol consumption. Nearly all studies of Jewish sobriety concentrate on male subjects, leaving the applicability of these theories to women unknown.

In 1980, Dr. Sheila B. Blume and colleagues published a study of 100 Jewish members of ALCOHOLICS ANONYMOUS from the New York city area (58 men and 42 women). The subjects had been abstinent for an average of 4 years. The belief among clinicians that Jewish alcoholics would have a high rate of preexisting psychiatric illness (because they would have to be mentally ill to be so deviant from their cultural group) was found not to be accurate. The Jewish subject group generally resembled their fellow non-Jewish alcoholics in treatment and at Alcoholics Anonymous, with similar family histories of alcoholism, drinking histories, and rates of additional psychiatric diagnoses. They did differ in having an unusually high rate of dependence on prescribed psychoactive medications, a combined result of their attempts to obtain professional help and the frequent failure of their physicians to reach an accurate diagnosis. Although there was evidence of less adherence to orthodox Judaism later in life in these Jewish alcoholics, their subjective feelings of Jewish identity were strong and remained so throughout their alcoholism and recovery.

Many subjects reported that their families, their friends, their physicians and they themselves had dismissed the possibility that they might be suffering from alcoholism, because "Jews can't be alcoholics." They experienced great relief when they finally met another recovering person who was Jewish.

It is an interesting footnote to history that the great psychiatrist Sigmund Freud seemed to have accepted the idea of Jews' immunity to alcoholism. He once reassured a Jewish patient who expressed concern about his drinking by saying that alcohol would neither help nor harm him; alcohol was for the gentiles.

During the late 1970s and 1980s interest in helping Jewish alcoholics grew, both in the United States and in Israel. The Federation of Jewish Philanthropies, based in New York City, organized a

task force on alcoholism, which later extended its purview to all addictive diseases, including compulsive GAMBLING. In 1980, the Jewish Alcoholics, Chemically Dependent Persons and Significant Others Foundation, Inc. (JACS) was organized to serve as a forum for the sharing of recovery by Jewish addicts and their families. Both groups continue to educate the Jewish community and to encourage prevention, treatment, and the opening of synagogues and Jewish community centers to twelve-step groups such as Alcoholics Anonymous, NARCOTICS ANONYMOUS, Gamblers Anonymous, AL-ANON, Nar-Anon and Gam-Anon. In addition, JACS has sponsored the most extensive study of chemically dependent Jews and their significant others in the literature.

The literature on drug addictions other than alcoholism in the Jewish community has been less divided, because of an absence of long-standing belief concerning Jewish immunity to drug dependence. The New Haven study mentioned above found a lifetime prevalence of drug abuse of 1.3 percent in the Jewish adults, which did not differ significantly from the rates for the other religions or those reporting no religious preference. Nevertheless, denial of drug problems in many Jewish households and communities is an ongoing problem.

The JACS study collected information from 538 recovering Jewish alcholics, addicts, and significant others (i.e., those affected by the addiction of a family member or close friend). One hundred thirty seven of the subjects considered themselves both chemically dependent and significant others, 242 of the subjects were chemically dependent but not significant others, and the remaining 159 were significant others and were not addicted. Susan L. Vex and Blume reported that 71 percent of the chemically dependent subjects were dependent on more than one substance. Alcohol was the most prevalent drug of dependence. Alcohol was the primary drug of choice for 54.7 percent of the addicts and a secondary drug for 24.5 percent. The JACS data did not support the idea that alcoholism in Jews was a result of lack of education, poor income, alienation or loss of religious identity, as had been hypothesized earlier. As in the 1980 Blume et al. study, the male to female ratio was much lower than usually found in studies of alcoholism and addiction in the general United States population, but the significance of finding equal numbers of male and female alcoholics is not clear. Like the Jewish alcoholics studied twenty years earlier, the JACS subjects also reported that in their search for recovery they had found little help within the Jewish community, and felt that education of rabbis and Jewish leaders about addiction was of utmost importance.

Efforts to promote education, PREVENTION, and TREATMENT of other drug problems among Jews have gone hand-in-hand with the efforts to fight alcoholism—and have employed the same methods. Self-help fellowships based on the twelve steps of Alcoholics Anonymous can be helpful to alcoholics and to other addicts of the Jewish faith, even though the spiritual base of the twelve steps was originally adapted from the philosophy of a Protestant Christian movement. Several authors have published guides to the twelve steps as related to Judaism.

JEWISH ALCOHOLICS, CHEMICALLY DEPENDENT PERSONS AND SIGNIFICANT OTHERS FOUNDATION, INC. (JACS) *See* Treatment Programs/Centers/Organizations: An Historical Perspective

JIMSONWEED A tall, coarse, poisonous plant that flowers, produces seed, and dies in one year. It belongs to the nightshade family (Solanaceae), and has foul-smelling leaves and large white or violet trumpet-shaped flowers. It produces round, prickly fruits. Jimsonweed (Datura stramonium) grows in several parts of the world. A strong intoxicant made from this plant was used by the woodland tribes of eastern North America. The plant was also used as an ingredient of wysoccan, an intoxicant employed in the puberty rites of Native Americans in what is now Virginia. Indeed, the name Jimson is another form of Jamestown, the English colony founded in Virginia in 1607.

Smoke from burning jimsonweed was breathed to relieve symptoms of asthma in India, and cigarettes containing jimsonweed have also been used for the same purpose.

As in other members of the Solanaceae family, the mind-altering substances are tropane ALKALOIDS, and the seeds and leaves contain up to 0.4 percent of these compounds. The principal alkaloid found in jimsonweed (also found in belladonna) is atropine. Atropine widens the pupils of the eyes, helps stop muscular spasms, lessens pain, and reduces bodily secretions. Large to toxic doses of atropine result in restlessness, irritability, disorientation, hallucinations, and delirium.

K

KAVA A drink prepared from the root of the Australasian pepper shrub *Piper methysticum*. The word *kava*, which is Polynesian for bitter, pungent, is given to the drink because of its strong peppery taste. Several variations of this drink were once used widely as social intoxicants in the islands of the South Pacific, particularly Fiji. The quality of the drink improves with the age of the root, and the roots are generally at least four years old before they are used. After the root is cut and crushed or grated, the active components are extracted by soaking the preparation in water.

Common effects of kava include general muscular relaxation, euphoria, and loss of fatigue. Visual and auditory effects are also common. In large quantities kava can induce muscular incoordination and ultimately stupor.

While no ALKALOIDS or glycosides have been found in kava, several aromatically substituted α-pyrones, including kawain, dihydrokawain, methysticin, and yangonin, have been isolated from the extracted root. Other as-yet-unidentified components of kava may also be important in the effects of the drink.

ROBERT ZACZEK

KHAT This is a shrub or small tree that grows wild and is largely cultivated in the uplands of Yemen and East Africa. The plant is known under many names; it is called *qat* in Yemen, *tschad* in Ethiopia, and *miraa* in Kenya. The botanical name is *Catha edulis*. Khat is a habituating stimulant containing ALKALOIDS released by chewing the leaves, buds, and sprouts. The leaves are about two to three inches long, with a serrated edge (see Figure 1), are brownish-green, somewhat leathery, and have a glossy upper surface. Since these plants lack more specific botanical features, a chromatographic test for their identification has been developed.

Use. Khat leaves can be made into a tea, but generally they are chewed for their stimulating effect. They are thoroughly masticated one by one; the juice is swallowed while their residue is stored in the cheek and later ejected. Young leaves are the most tender and potent; the leaves must be fresh to be effective. A portion is about 100 to 200 grams of leaves; they are predominantly consumed in a social setting. In Yemen, the habit is part of the cultural tradition and of great importance to social life; many houses have a room specifically arranged for the khat session, for which men meet almost every day. During the session, the group may also smoke from a water-pipe, and there is a supply of beverages. Khat use by women is less formal and much less frequent. In East Africa, khat use is more recreational in nature, with the leaves being consumed at times together with ALCOHOL or other

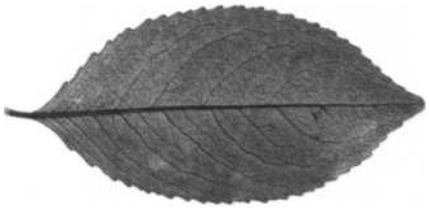

Figure 1
Full-grown Khat leaf (at about two-thirds natural size)

drugs. There is also a tradition of khat use by farmers and craftspeople, who chew it to enhance work performance and to stay alert.

Khat consumption has increased significantly during recent decades; it has been estimated that at present about 5 million portions per day are consumed. Although use is limited to the region where it grows, khat is now also exported by air to Europe and North America, where it is sold mainly to immigrants from Yemen and East Africa.

Effects. The pharmacology of khat has been reviewed and its effects are characterized by a moderate degree of central nervous system (CNS) stimulation, resulting in a state of mild euphoria and excitement, often accompanied by talkativeness to excess. High doses may induce restlessness and sometimes manic behavior. Excessive consumption may lead to toxic psychosis. Khat produces ANOREXIA (loss of appetite) and constipation; it has sympathomimetic effects on the cardiovascular system. Dilation of the pupil and staring are indicative of the acute effect of khat. Habitual chewing is usually revealed by a brownish staining of the teeth.

The effects are very similar to those of AMPHETAMINE, and the difference between the two drugs is quantitative rather than qualitative. Accordingly, habitual khat use may give rise to psychic dependence, which usually is moderate but often persistent. The withdrawal symptoms after prolonged use are slight trembling, lethargy, mild depression, and recurrent bad dreams. Khat use by the habitué is often compulsive, with the necessary supplies obtained at least once a day, even at the expense of vital needs; in the countries where khat use is widespread, the socioeconomic consequences of the habit are considerable.

Constituents. Khat contains the alkaloids norephedrine, cathine, and cathinone (see Figure 2). Norephedrine and cathine do not contribute significantly to the psychostimulant action, however, they are probably of importance for the sympathomimetic effects (on the autonomic nervous system). The constituent that is mainly responsible for the stimulant qualities and the dependence-producing effects of khat is cathinone. This ALKALOID must be considered a natural amphetamine, since the two substances have the same mechanism of action. However, cathinone has a half-life of only 1.5 hours, whereas that of amphetamine is much

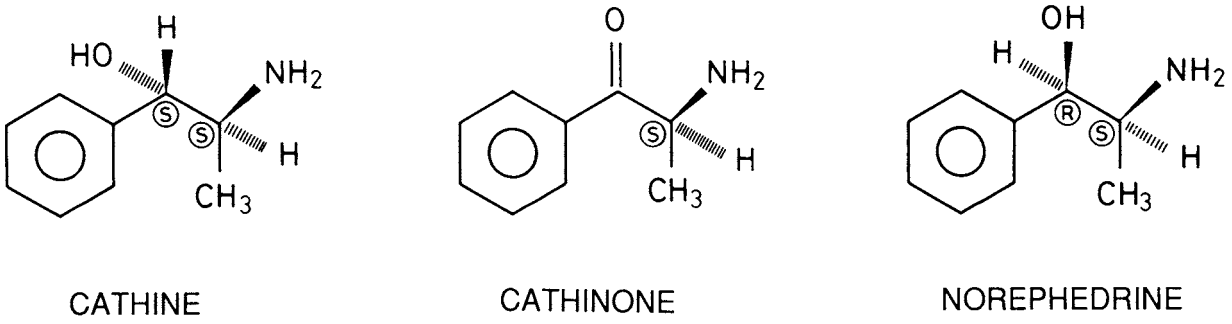

Figure 2
Structure of the Khatamines.
Cathine (S,S(+)phenylpropanolamine or (+)norpseudoephedrine, cathinone (S(−)alphaaminopropiophenone) and norephedrine (R,S(−)phenylpropanolamine). In an analysis of twenty-two khat samples of different origin, the average concentration of these alkaloids in 100 grams of fresh khat were found to be 120 milligrams, 36 milligrams, and 8 milligrams, respectively (Geisshüsler & Brenneisen, 1987).

longer. Since cathinone is absorbed gradually from the leaves during chewing and is inactivated in the body rather rapidly, the pharmacological effects of khat are usually limited.

L

L-ALPHA-ACETYLMETHADOL (LAAM) Acetylmethadol (also referred to as *l*-alpha-acetylmethadol, methadyl acetate, LAAM or L-AAM) is structurally related to METHADONE. LAAM is a potent OPIOID agonist with properties similar to methadone, except for its prolonged half-life. This slow elimination can be useful clinically, since 50–80 milligram doses of LAAM given three times a week are equivalent to daily doses of 50–100 milligrams of methadone in preventing the symptoms of opioid WITHDRAWAL. Thus, addicts on maintenance treatment would need to come to a clinic only three times a week for LAAM instead of daily for methadone. Since the early 1970s, methadone has been the only agent approved for use in maintenance-treatment programs for HEROIN addicts, but research has shown that LAAM can be a useful alternative. In 1993, the U.S. Food and Drug Administration (FDA) initiated the legal changes needed to make LAAM available for clinical use.

LATIN AMERICA AS DRUG SOURCE *See* Bolivia; Colombia as Drug Source; International Drug Supply Systems; Mexico as Drug Source

LAUDANUM Laudanum refers to a tincture of OPIUM—an alcoholic extract (about 20%) of opium, which contains approximately 10 milligrams per milliliter of morphine. If used at all currently, it would be as an antidiarrheal. The solution is more concentrated than PAREGORIC, and smaller

Laudanum, Cistus ladanifer, *in flower.* (© Eric and David Hosking/CORBIS)

volumes are given; however, their actions are almost identical. At standard doses, they rapidly and effectively treat diarrhea without producing euphoria or analgesia. The solution does contain MORPHINE and other opioid alkaloids and, at higher doses, it can be abused—as it was during the late-nineteenth and early twentieth centuries, when it was sold widely as a tonic and cure-all, in shops, by mail order, and by traveling medicine shows. Laudanum use and abuse are often mentioned in novels and plays of and about the period.

LD50 In preclinical studies, the LD50 is the median lethal dose—the dose of a drug that produces death in 50 percent of the experimental animals tested. The LD50 can be estimated from a dose-effect curve, where the concentration of the drug is plotted against the percentage of animals that die. The ratio of the LD50 to the ED50 (the median effective dose) indicates the therapeutic index of a drug for that effect and suggests how selective the drug is in producing its desired effects. In clinical studies, the concentration of the drug required to produce toxic effects can be compared to the concentration required for therapeutic effects in the population to esimate the clinical therapeutic index.

LEGALIZATION OF DRUGS *See* Policy Alternatives

LEGAL REGULATION OF DRUGS AND ALCOHOL Legal regulation can be used in four general ways to influence the incidence, prevalence, patterns, and circumstances of consumption of potentially harmful substances—including ALCOHOL, TOBACCO, and other DRUGS. The most direct mode of legal intervention is *to establish the conditions under which a potentially harmful substance is available.* In doing so, the law can employ either

(1) a "prohibitory" scheme that prohibits the production or distribution of the substance for nonmedical or self-defined uses, or
(2) a "regulatory" regime, which permits the substance to be lawfully available for nonmedical or self-defined uses but that may regulate the product, its price, and the conditions under which it is accessible.

A completely successful prohibition would prevent any nonmedical consumption of the proscribed substance; however, the more likely consequence of a prohibitory scheme is that an illicit distribution

system will arise to respond to whatever demand exists for the substance. In that case, the manner in which the prohibition is enforced can also influence the product, its price, and the conditions under which it is available.

A second mode of legal regulation is to *regulate the flow of information and messages regarding use of the particular substance.* The government may initiate its own informational efforts to influence attitudes, beliefs, and behavior. Government may also attempt to influence private communications, either by proscribing certain messages altogether or by regulating or restricting their content. Such restrictions have generally taken two forms—mandatory warnings and proscriptions of certain types of messages.

A third mode of legal control is the *direct regulation of consumption*, either by proscribing and imposing sanctions for undesired behavior or by withholding benefits or privileges to which the individual would otherwise be entitled. Thus, the law may proscribe use of a substance altogether, or it may prohibit such behavior in certain specified circumstances. Examples of total bans include unauthorized possession and consumption of controlled substances and consumption of alcohol by persons under the minimum age. Situational prohibitions include laws against consuming alcohol or smoking tobacco in public areas. Laws that require drug testing of workers and that permit job termination or discipline as a consequence of a positive test illustrate less coercive measures of deterrence.

A fourth use of the law emphasizes its declarative aspects. Whether or not a legal control has a direct impact on the marketplace or on the prevalence of the disapproved behavior, it may *symbolize and express the official government view of the behavior and may generate derivative effects on behavioral patterns by influencing attitudes and beliefs.* To the extent that citizens customarily defer to and respect the law or are influenced by messages of official approval or disapproval, a declaration of illegality may serve an educative, or didactic, role. Specification of a minimum drinking age, regulation of the availability of drug PARAPHERNALIA, and sanctions for possession of illicit drugs may all generate these symbolic effects, even if the direct effects tend to be modest.

AVAILABILITY

The National Commission on Marihuana and Drug Abuse identified four models of availability for psychoactive substances: The first involves no special controls at all; the substance is treated in the same way as other [unregulated] market commodities. Under the second approach, the substance is subject to special controls but remains lawfully available for self-defined [or nonmedical] purposes. The third model limits availability to specific purposes, generally to medical and research uses only. Under the fourth approach, the substance is not legally available at all except perhaps for narrowly circumscribed use in research. The first two models can be characterized as regulatory approaches (because the substance is legitimately available for nonmedical or self-defined purposes) and the second two as "prohibitory" approaches (because the substance is not available for self-defined or nonmedical purposes). Tobacco and alcohol are lawfully available for nonmedical uses, but they are subject to variable regulatory controls designed to affect the product, place, and conditions of consumption. (Only the solvents and INHALANTS—glue, lacquer, thinner, ether, gasoline, nitrous oxide—are essentially uncontrolled.) However, most psychoactive substances (legally denominated controlled substances) are subject to prohibitory controls; with the one minor exception of PEYOTE, which has been available to members of the Native American Church for sacramental uses—this means their availability is limited by law to medical and research uses.

Alcohol. The availability of alcohol is governed by alcoholic beverage controls (ABC) that vary from state to state. ABC agencies view their primary responsibilities as providing an orderly market for the distribution of alcoholic beverages, controlling criminal involvement in the market, and generating tax revenues. Since the 1960s, the trend has been to liberalize restrictions on access to, and availability of, alcohol in order to facilitate private choice, to protect commercial interests, and to raise revenue. Only since the late 1980s have some ABC agencies shown any inclination to use their regulatory authority to influence the prevalence pattern, and circumstances of consumption. Relevant aspects of ABC regulation include pricing and/or taxation policies, zoning, and rules regarding hours and days of sale.

Direct regulation, under the authority of ABC boards, is not the only method by which the law can influence the conditions under which alcohol is available. For example, one way to discourage retail sellers of alcohol from selling the substance to a person already intoxicated is to hold them legally liable for injuries subsequently caused by the intoxicated consumer, even after leaving the premises. Although the legal theory has changed over the years, the risk of liability for commercial suppliers under so-called DRAM SHOP LIABILITY LAWS is relatively well established. Moreover, the courts of several states have extended liability to the hosts of social events who served alcohol to "obviously intoxicated" guests who then cause injuries in their intoxicated condition.

Tobacco. For the most part, the public health dimensions of tobacco regulation have been reflected only in product, package, and advertising requirements designed to facilitate informed consumer choice. Only since the late 1980s has the federal government moved toward a policy that unequivocally establishes reduced consumption as its goal. Although a national prohibition is unlikely in the foreseeable future, several regulatory initiatives are being undertaken at all levels of government. For example, states will not receive federal money for mental health and substance-abuse services, unless they implement a plan for enforcing bans against the distribution of tobacco products to minors. Many localities have banned vending machines. In addition, several states have raised cigarette excise taxes with the aim of reducing consumption, and the federal excise tax has been increased by a substantial amount, with the dual aims of reducing smoking and raising revenue.

In 1996, the federal Food and Drug Administration (FDA) asserted jurisdiction over traditional tobacco products under the Food, Drug and Cosmetic Act, on the theory that tobacco products are intentionally marketed to satisfy consumers' addiction to nicotine. Based on this interpretation of the Act, the FDA adopted regulations prohibiting the distribution of tobacco products to minors and, as discussed below, restricting the marketing of tobacco products to youths. Although the U.S. Supreme Court ruled in 2000 that the FDA did not have jurisdiction over traditional tobacco products under existing law, it is only a matter of time before Congress confers such authority.

In addition, smokers or their survivors have sued tobacco companies, with mixed success, seeking damages for smoking-induced disease or death. In 1998 the major tobacco companies entered into a Master Settlement Agreement with the state attorney general, agreeing to pay $246 billion to the states over the duration of 25 years to settle lawsuits seeking to recover the states' costs of treating smoking-related diseases. Obviously, imposing liability on manufacturers for the adverse health consequences of smoking can have a major impact on the economics of the industry. In this instance, the indirect regulation of tobacco by the tort system has exerted a more potent influence on industry behavior than many direct regulatory alternatives, such as pricing policies, outlet limitations, or tar and nicotine limitations.

Controlled Substances. The manufacture and distribution of OPIATES, COCAINE, CANNABIS (MARIJUANA) stimulants, depressants, and hallucinogenic substances outside medical and scientific channels are unlawful under both federal and state "controlled substance" laws. The production and distribution of these substances within medical and scientific channels are subject to varied levels of restrictions based on their "potential for abuse" and their level of accepted medical use under the CONTROLLED SUBSTANCES ACT of 1970. The wisdom of these prohibitions, especially in relation to cannabis, has been questioned by some on the grounds that the suppression of nonmedical use is not a legitimate governmental objective, and if it is, that the costs of the prohibitions exceed the benefits of the reduced consumption they achieve.

A particularly controversial aspect of cannabis regulation has been its classification as a Schedule I drug under the Federal Controlled Substances Act and its state counterparts. Schedule I is the most restrictive classification, reserved for drugs without any accepted medical use. Critics of the law have argued that marijuana is medically useful to treat glaucoma, AIDS wasting syndromes, and other conditions, and several states have adopted laws that aim to legitimize bonafide medical uses under state law. These laws have created the unusual situation in which any effort to make marijuana available for medical uses could be prosecuted as a violation of federal law. The Institute of Medicine of the National Academy of Sciences has identified promising avenues of therapeutic use for the active

constituents of cannabis and has recommended further research.

INFORMATION REGULATION

A government aiming to discourage what it perceives as unhealthy or unsafe behavior is not likely to be satisfied with the influence of its own messages and may seek to regulate communication by others within the bounds of the First Amendment, which protects freedom of speech. This can be done in two ways. First, the government may require individuals or organizations to convey the government's desired message. Laws requiring product manufacturers to include information on or with their products have become a standard feature of health and safety regulation. In recent years, mandatory package warnings have been utilized as a means of informing consumers about the dangers of tobacco and, more recently, of alcohol use. Second, government may ban communication of messages that it regards as undesirable. For example, laws banning false or misleading advertising are common, but government may choose to go a step further—to suppress a message because it is thought to encourage unhealthy or socially disapproved drug, alcohol, or tobacco-using behaviors. Examples include the federal ban on broadcast advertising of cigarettes and state laws that ban alcohol advertising. Public-health advocates have urged the federal government to prohibit all forms of tobacco advertising. Whether such prohibitions actually affect the level of consumption (as opposed to product choice) remains controversial. The FDA's 1996 Tobacco Rule, which was invalidated by the Supreme Court in 2000, would have restricted the advertising of tobacco products to a text-only format, and would also have banned other forms of promotional activity that are thought to make use of tobacco products attractive to children and adolescents. The tobacco companies agreed to abide by some of these marketing restrictions in the Master Settlement Agreement executed in connection with the suit brought by the attorney generals of these states.

Proposals have also been made to move beyond advertising into the area of entertainment programming, eliminating messages that portray smoking and drinking in an attractive way. Clearly, such initiatives would raise serious constitutional questions concerning free speech.

Governments have also occasionally attempted to purge the environment of messages that are thought to encourage illicit drug use. For example, one provision of the Model Drug Paraphernalia Act (drafted by the federal drug enforcement agency as a model for states to enact) specifically bans paraphernalia advertising. In 1973, the Federal Communications Commission (FCC) threatened to revoke the licenses of radio stations whose lyrics were thought to encourage illicit drug use.

DIRECT REGULATION OF CONSUMER BEHAVIOR

A decision to discourage nonmedical drug use—and to proscribe transactions outside medical channels in order to restrict availability for such use—does not necessarily entail a decision to proscribe and punish unauthorized consumption. Values of individual freedom weigh very differently in the two contexts.

From the perspective of libertarian philosophy, it has been argued that the criminalization of private use (and possession for such use) of drugs is categorically illegitimate, and the criminal prohibition should be limited to behavior that endangers others. This, also leads to a discussion of the ways in which drugs might affect others. Even if criminalization is not categorically objectionable, the costs of it may exceed the benefits. The National Commission on Marihuana and Drug Abuse relied on such a cost-benefit assessment in 1972 when it recommended the decriminalization of possession of marijuana for personal use. A few states have decriminalized the possession of marijuana, although they have usually substituted a civil fine. Some of the states that took this action subsequently recriminalized the possession. Aside from marijuana, possession of all other controlled substances is a criminal offense in all states as well as under federal law. In addition, the possession of alcohol by underage consumers is an offense in most states. Even if the possession or use of a substance is not categorically proscribed, prohibitions can be utilized to deter and punish socially harmful behavior or to provide leverage to coerce individuals into treatment. Public smoking laws and laws prohibiting driving while intoxicated (or while having a certain level of blood alcohol content) provide the prime examples.

DECLARATION ASPECTS OF LEGAL REGULATION

Government sends messages by its actions as well as its words. By declaring conduct illegal or by using any of the other instruments of legal intervention described above, the government expresses and formalizes social norms. However, knowledge of the official preferences may actually encourage the disapproved behavior among disaffected, outsider groups. Measuring such symbolic effects is difficult because of the need to isolate these hypothesized effects from other influences on attitudes and beliefs.

Arguments drawing on the declarative aspects of legal regulation are routinely employed by proponents of restrictive controls over the availability and consumption of alcohol, tobacco, and other drugs. Criminal sanctions against the simple possession of controlled substances are frequently regarded as indispensable symbols of social disapproval. Such arguments have been prominent in debates concerning the decriminalization of possession of marijuana. Moreover, graded or stratified penalty schemes, which punish the possession of "more harmful" drugs more severely than that of "less harmful" drugs, may be favored because they denote the relative seriousness of these transgressions. Public SMOKING bans and antiparaphernalia laws seem to be particularly designed to reinforce attitudes unfavorable to smoking and recreational drug use.

Statements of legal rules can serve an educational role even if they do not penalize the undesired behavior. Minimum-drinking-age laws (which prohibit the distribution of alcohol to youth) provide a good example because they denote the norm even if the youthful drinker is not punished. Similarly, bans on alcohol or tobacco advertising might be enacted to erase a possible symbol of social approval even if the proponents did not believe that such bans would directly reduce consumption.

LE PATRIARCHE Le Patriarche is both the name of an organization treating addicts and the nickname (the "patriarch") of its founder, Lucien J. Engelmajer. The program was begun in Toulouse, France, in 1972, and by 1989 it had spread to Spain, Belgium, Italy, Germany, Portugal, and Ireland.

Le Patriarche focused its work in residential treatment centers, located primarily in rural areas on large farming estates. In addition, the organization operated small intake and community-interaction units in urban centers throughout Mediterranean Europe. During the 1990s, it also opened several centers in large cities in the United States, but most of these closed after several years.

The program's philosophy is vague: remain drug-free and work hard in a semi-Utopian setting. It offers little in the form of organized therapies with measurable outcomes.

Almost from the start, Le Patriarche was embroiled in controversy. Addicts were made to work

on projects owned by Engelmajer without salary. Some individuals were relocated from one European country to another while their passports were withheld. Use of force was not uncommon. The organization used illegal immigrant labor for commercial activities.

After a finding of fraud by the French government, Le Patriarche tried to reorganize to gain credibility. However, the organization in Italy with which it began to associate—San Patrigiano—was surrounded by similar controversy. Eventually, Engelmajer was removed from visible leadership, and members of his family now direct the program, renamed Dianova. The headquarters are located in Switzerland, where the finances for all locations are controlled.

Dianova continues the practice of not paying wages for what in essence is forced labor, thereby perpetuating Le Patriarche's structure of creating dependence among the addicts who seek help there.

In the early 1990s, worldwide membership was about 10,000. There is no reliable information about the current number of participants in Dianova.

LIMBIC SYSTEM The limbic system is a group of BRAIN STRUCTURES organized into a functional unit that is important in the expression of emotion and mood states. The term *limbic lobe* and associated terminology can be traced to the French neuroanatomist Paul Broca (1824–1880), who used it first to describe the forebrain structures that encircle the brain stem. The *limbic system* is a broader classification, composed of brain structures that form an integrated circuit surrounding the thalamus—an important relay station between higher brain centers and the hind brain and spinal cord.

The limbic system is thought to be important in emotional behaviors. This was hypothesized on the basis of neuropathological investigations of the brains of individuals displaying bizarre emotional disturbances. These initial clinical observations were followed by animal studies, in which the loss of these structures produced significant changes in emotional responsiveness. As research techniques and methodologies were refined, it became clear that limbic structures had an important and complex role in the expression of behavior. It is now believed that these structures are involved in a number of significant behavioral processes. In particular, the limbic system and related structures are thought to be important in the expression of emotion related to euphoria and feelings of well-being. For these reasons, the limbic system may have an important role in drug abuse.

LIMBIC SYSTEM COMPONENTS

The limbic system that surrounds the thalamus provides an interface between the midbrain and higher cortical structures. The general structure and components of the limbic system are shown in Figure 1. These include the AMYGDALA, the NUCLEUS ACCUMBENS, the olfactory tubercle, the septal nuclei, the hippocampus, the hypothalamus, the cingulate cortex, and the frontal cortex. As can be seen in the figure, these structures are positioned between the brain's major relay station—the thalamus—and higher cortical structures. The separate components of the limbic system are interconnected such that activity initiated in one structure affects other components. One of the hypotheses about the basis of emotion speculated that reverberating neuronal activity in this system was responsible for affective behaviors. Initial animal studies using either direct electrical stimulation or lesions (loss) of various components of the limbic system substantiated the important role of this system in behavior.

THE ROLE OF THE LIMBIC SYSTEM IN BEHAVIOR

Electrical stimulation or the destruction (lesions) of components of the limbic system alter behavioral processes. Lesions of the hippocampus disrupt memory processes, whereas lesions or stimulation of the amygdala affect emotional behavior and feeding in a manner similar to manipulations of the medial and lateral hypothalamus. Stimulation of the lateral hypothalamus produces aggres-

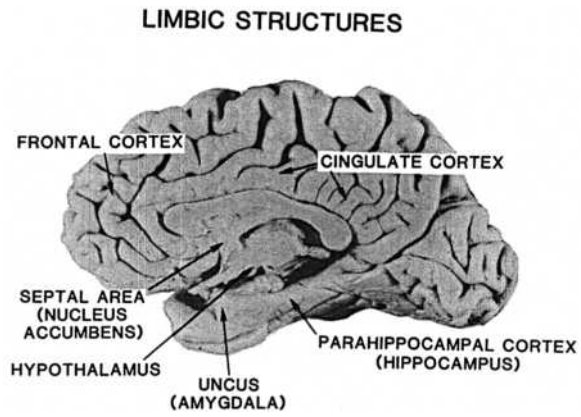

Figure 1
The Limbic System—composed of structures generally located between the brain stem and higher cortical structures. Some of these components are labeled in this sagittal section of the brain. The structures in parentheses lie behind the structures listed above them. The hypothalamus, hippocampus, septal nuclei, nucleus accumbens, amygdala, cingulate cortex, and frontal cortex are components of the limbic system that may have an important role in drug abuse.

sive responses, whereas lesions of this area produce a placid behavioral profile. In contrast, lesions of the medial hypothalamus produce a highly excitable and aggressive pattern of behavior, whereas lesions of the amygdala result in placid and nonaggressive behavior. Early studies found that lesions of the lateral hypothalamus can decrease feeding, whereas lesions of the ventromedial region produce excessive levels of feeding resulting in obesity. Recent experimental studies have demonstrated the complex nature of the involvement of hypothalamic cells in feeding and drinking; however, like most complex behaviors, the mechanisms that control hunger and satiety are not simply located in a single brain center.

Some structures of the limbic system are important in REINFORCEMENT processes. The term *reinforcement* applies to processes perceived as rewarding or good, which therefore are repeated, such as electrical self-stimulation. For example, animals will repeatedly emit a response that leads to the delivery of brief electrical stimulation of small electrodes that are implanted in selected brain structures. Humans will also choose to stimulate many of these same brain regions and report positive feelings of well-being and euphoria. The limbic system sites that produce these effects in animals include the lateral hypothalamus, nucleus accumbens, frontal cortex, cingulate cortex, and the brain-stem nuclei believed to be part of the limbic system—these include the substantia nigra and ventral tegmental area, which both contain DOPAMINE neurons that send inputs to many limbic-system components. Measures of brain-glucose metabolism, which directly reflect brain-cell activity, have been used to determine the involvement of specific brain regions in animals electrically self-stimulating three of these brain regions. The stimulation of each of these regions produced significant activation of several limbic-system structures that included the nucleus accumbens, amygdala, hippocampus, and the frontal and cingulate cortices. This area of investigation has led neuroscientists to propose that there are brain circuits dedicated to the behavioral processes related to reinforcement. Drugs of abuse likely produce their positive effects through the activation of these brain circuits.

THE ROLE OF THE LIMBIC SYSTEM IN DRUG ABUSE

A large number of experiments have focused on identifying the brain circuits that mediate the reinforcing effects of abused drugs, because the reinforcing effects are responsible for drug abuse. These experiments have included the use of drug self-administration techniques and sophisticated neurochemical procedures to measure the involvement of specific NEUROTRANSMITTER systems. As of the early 1990s, evidence indicates that limbic structures and brain cells that project to limbic structures play an important role in these processes. It is clear that dopamine-containing neurons that project from the ventral tegmental area to the nucleus accumbens have a critical role in the reinforcing actions of COCAINE and AMPHETAMINE. Removal of these inputs with toxic agents that selectively destroy dopamine-releasing brain cells disrupts intravenous self-administration of these drugs. Additional evidence of the importance of this region in drug abuse comes from glucose-utilization studies. The levels of glucose metabolism are significantly elevated in a number of limbic structures in animals self-administering co-

caine intravenously. Other experiments have directly shown dopamine levels in the nucleus accumbens to be increased in animals intravenously self-administering cocaine. Collectively, these data imply an important role for the limbic system in general and specifically for dopamine neurons in the limbic system tied to the brain processes involved in stimulant abuse.

The brain circuits involved in OPIATE reinforcement appear to be very similar to those mediating cocaine self-administration. Limbic structures are clearly implicated in opiate reinforcement, but a central role for dopamine is less obvious. Significant changes in the utilization of some chemicals (neurotransmitters) involved in transmission between brain cells have been shown in the nucleus accumbens, amygdala, and the frontal and cingulate cortices of animals intravenously self-administering morphine. However, loss of dopaminergic inputs to the nucleus accumbens does not affect drug intake, whereas a similar loss of serotonergic inputs does. Similarly, nucleus-accumbens dopamine does not appear to be elevated in animals self-administering heroin as it is in animals self-administering cocaine. However, evidence does indicate an important role for limbic structures and chemicals used to communicate between cells of the limbic system in opiate reinforcement.

Limbic structures also appear to be important for ethanol (drinking ALCOHOL) reinforcement. The levels of dopamine appear to be elevated in the nucleus accumbens of rats orally self-administering alcohol. Injections of drugs that antagonize dopamine directly into the nucleus accumbens decrease alcohol self-administration, whereas drugs that enhance dopamine action increase alcohol intake. In addition, animals will self-administer alcohol directly into the ventral tegmental area—an area that contains the cell bodies for the dopamine cells that send inputs to the nucleus accumbens. These data collectively indicate that the nucleus accumbens and dopamine-releasing inputs to the nucleus accumbens are important to alcohol reinforcement.

CONCLUSION

The limbic system plays an important role in behavior. These brain structures appear to be central to the processes that mediate the reinforcing effects of electrical-brain stimulation and of several highly abused drugs. The nucleus accumbens appears to be a structure central to the reinforcing properties of cocaine and amphetamine, but it appears less important to opiate and alcohol reinforcement. A more exact definition of specific neurochemicals and brain-cell pathways in the limbic system that are involved in drug abuse will become clearer as new methodologies are developed.

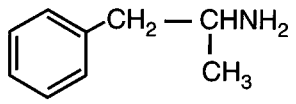
LYSERGIC ACID DIETHYLAMIDE (LSD) AND PSYCHEDELICS LSD is the abbreviation for lysergic acid diethylamide. It is the most potent member of a group of hallucinogenic substances called the indole-type HALLUCINOGENS. These drugs have structural similarities to another indole, the neurotransmitter SEROTONIN.

HISTORY

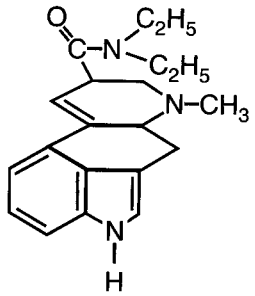
LSD was originally synthesized at the Sandoz Pharmaceutical Company, in Switzerland, as part of a long project begun in the 1930s. The aim was to develop useful medications that were derived from ergot, a fungus (*Claviceps purpurea*) that infects such grasses as rye. Some of these compounds were found to be useful in medicine—such as methysergide, for the treatment of migraine headaches, and ergotamine, which is widely used in obstetrics to induce contractions of the uterus and stop bleeding after the delivery of a baby. These medications do not have hallucinogenic properties.

The chemist in charge of this drug development project was Albert Hofmann. In 1943, he synthesized a compound he called LSD-25, since it was the twenty-fifth compound made in this series of ergot derivatives. He accidentally ingested some of it and within forty minutes had the first LSD "trip." He told his colleagues he was not feeling quite right and got on his bicycle to go home. Later, he carefully described the vividly clear flood of perceptions that are characteristic of the "mind manifesting" or psychedelic drug. This, then, was a complete surprise. Thereafter, the drug and various substitutions of different atoms on the basic molecule were extensively tested for medical uses in the late 1940s and in the 1950s. No specific medical use of LSD or its psychedelic variants has been found.

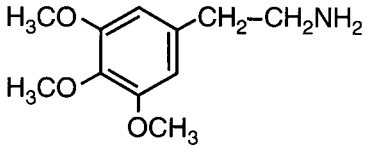
Because of its potency and the extensive reports of laboratory studies in animals and in the clinic, LSD has become the prototypical hallucinogen, or psychedelic drug. It also became the emblem of a social movement—which, in fact, was a confluence of various movements that had begun in the early 1960s; they peaked in the late 1960s. By 1973, the "acid culture" had subsided into a small but still active subculture of various psychedelic drug devotees seeking meaning and profound insights. The feeling of a "great discovery" about such drugs and the human mind had occurred as early as the nineteenth century; artists and writers, such as Baudelaire and Rimbaud in Paris, had discovered HASHISH and the altered, somewhat dreamy, states of consciousness and euphoria produced by this potent form of MARIJUANA—the active ingredient of which is TETRAHYDROCANNABINOL (THC). For a period, they became absorbed with hashish and wrote about its alluring effects. The drug scene



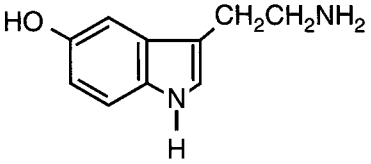
AMPHETAMINE
(psychostimulant)



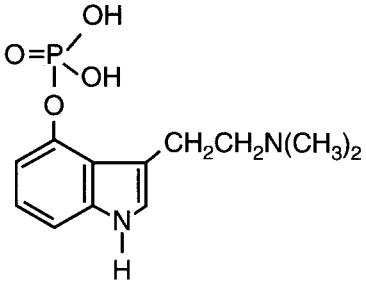
LSD



MESCALINE



SEROTONIN
(neurotransmitter)



PSILOCYBIN

evoked the promise that the human mind must contain remarkable powers. Toward the beginning of the twentieth century, MESCALINE, the active hallucinogenic compound in the PEYOTE cactus, similarly was tried by a few explorers in medicine and in the arts. In New York City, during the early part of World War I, many influential people and intellectuals took either peyote "buttons" (the dried tops of the peyote cactus) or mescaline (the synthesized active ingredient of the buttons) and called it a "dry drunk." Similarly, after World War II, LSD caused a flurry of excitement among some professionals, and its medical value was tested in psychiatric patients. Writers such as Aldous Huxley wrote exciting books about the effects of mescaline and, later, LSD—yet there was still no widely popular movement until 1960.

Then Timothy Leary, a young psychology instructor at Harvard, explored the Mexican or "magic" mushroom, *Psilocybe mexicana*, and its active ingredient, PSILOCYBIN—and later LSD—claiming criminals became loving and peaceful and others more creative. He popularized this on campus and, when he was not reappointed to the faculty, proclaimed himself to be a martyr to his cause. Between 1960 and 1966, the media repeatedly "discovered" LSD—in effect, advertising it. As publicity increased, subcultures experimenting with mushrooms and LSD grew up in the East and West Coast cities. Musicians, rock music, the hippie lifestyle, "flower children," and many in the various protest movements against the Establishment and the VIETNAM War were loosely joined to Leary's attempt to lead affluent and middle-class youth. Well-publicized festivals celebrated LSD and marijuana, such as the Summer of Love in the Haight-Ashbury section of San Francisco. Leary's challenge was for youth to "turn on, tune in and drop out" with acid. As more and more youth were curious to try experiences their parents had never dreamed of, rebellion led not only to acid experiments but to extensive POLYDRUG ABUSE—the extensive use of marijuana and various street substances. Either LSD or some variant and even heroin were tried. In addition, the search for new drugs with different and improved characteristics (more or less euphoria, hallucinogenic activity, or stimulant properties), literally hundreds of so-called DESIGNER DRUGS were synthesized (DOM, MDMA, DMT, etc.). Because any drug can have bad effects, the unsupervised use of all of these compounds led to frequent "bad trips" (which fundamentally were panic reactions) that brought people to emergency rooms. This generated widespread concern that all American youth (and, later, those in Europe) would become dreamy and "way-out acid heads." In 1966, the Sandoz Laboratories ceased distribution of the drug because of the often-exaggerated bad reactions and the public concern. As the claims for enduring LSD insights proved transient, research with LSD in humans essentially stopped.

Thus, one of the ways people use the effects of drugs that seem to enhance the clarity of mentation (mental activity) and perception (while not producing confusion, dreamy-euphoria, or oversedation) is to become absorbed in periods of intense exploration with a few others "in the know." Those with such inside information form a kind of cult and then advertise, but they eventually see some bad effects (the wrong people taking the drug in the wrong circumstance with unfortunate consequences) and sooner or later see little real use for the drugs. The minor or major epidemics then die down, only to recur as later generations rediscover the compounds.

EFFECTS

LSD is one of the most potent hallucinogens known; one-billionth of a gram of LSD per gram of brain produces profound mental changes. Although subjective effects occur in some individuals after doses as low as 50 micrograms, typical street doses range from 10 to 300 micrograms—street dosages vary widely. Misrepresentation also frequently occurs; someone will try to purchase synthetic TETRAHYDROCANNABINOL (THC), the active ingredient of marijuana, and receive LSD. Thus, the intake of LSD can be accidental as well as intentional, and the lack of quality control in illicit supplies is a hazard. Because of its high potency, LSD can be applied to paper blotters or the backs of postage stamps from which it is dissolved for consumption. Unsubstantiated reports of LSD added to stick-on tattoos for young children have caused alarm, even though absorption through skin would be far too slow to deliver enough drug to the brain to produce and sustain a trip.

The absorption of LSD from the gastrointestinal tract and other mucous membranes occurs rapidly, with drug diffusion to all tissues, including brain.

The onset of psychological and behavioral effects occurs approximately 30 minutes after oral administration, peaks in the next 2 to 4 hours, depending on the dose, with gradual return to normal by 10 to 12 hours. The first 4 hours after a 200-microgram dose are called a trip. In the next 4 to 8 hours, when over half the drug has left the brain, the "TV show in the head" has stopped. At this point subjects think the drug is no longer active, but later they recognize that they, in fact, had paranoid thoughts and "ideas of reference" in the last 4 to 8 hours of the trip. This simply means that there is the feeling of being at the center of things, being hyperalert, and having a conviction that everything going on refers to oneself. This is a regular but little publicized aftereffect, which finally dissipates 10 to 12 hours after the dose.

From 12 to 24 hours after the trip, there may be some slight letdown or feeling of fatigue—as if one had been on a long, steep roller coaster ride. After these intense and even frightening moments, the ordinary world might for a time seem drab. There is no craving to take more LSD to relieve this boredom; one trip usually produces satiation for a time, although some may want to repeat the experience. Memory for the events during the trip is quite clear. Those who revisit the experience sooner or later decide they have learned what they can and go on with the practical, daily affairs of living. In one experiment on CREATIVITY, subjects received either LSD or the stimulant amphetamine during a period of pleasant surroundings and music. The only difference between the two groups six months later was a slight tendency for those who had received LSD to buy more recordings! So the promise of lasting insight or creativity was not kept.

Drugs that make one feel different—alcohol being typical—can signal a "holiday from daily reality." The way the effects of such drugs are interpreted is critical. BEER at the Super Bowl means "loudly letting go" and champagne at the White House means a time for graceful speech and feelings. Thus personal and social expectations (called *set*—or how one is set to go) and the surroundings (called *setting*) have much to do with the ultimate effects of drugs. This is distinctively and especially the case with psychedelics. Thus when the chemist Albert Hofmann first ingested the active ingredient of the Mexican mushroom, psilocybin, the perceptions capturing his attention were related to Aztec symbols and art! For some, therefore, the trip may simply be funny and odd—for others it will have special meanings. Set and setting partially determine the character of such trips.

Fundamentally, LSD produces a heightened clarity and awareness of sensory signals—of sights, sounds, touch, lights, and colors. Similarly there is special significance given to thoughts, memories, or verbal interchanges. For example, gestures or inflections of speech or many cues that are normally in the background are felt to be more important than what is being said or usually meant—and in looking at a picture, the central figures may take on a life of their own, the small background details that are normally ignored emerging, capturing attention.

While awareness is strikingly increased, control over what is being attended to is weakened. For all these reasons, unstable surroundings or confused motives at the time of drug ingestion may lead to a less-controlled trip or even a panic-generating trip. Many are aware that the trip is not quite real and fundamentally feel as if they are "spectators" of what they are so intensely experiencing. Many rely on guides, a group, or the rhythm of music to carry them through this period of altered perceptions in which control is diminished. Thus, personal intent and reliable surroundings are major factors affecting the different kinds of experiences that people will have.

While every trip has an individual characteristic, there are regularities in the trips. This has been called a "march of effects" following drug ingestion. Thus, observers note, the first sign of feeling different is like "butterflies in the stomach" or a slight nausea and feeling of "whoops, here we go" as if on a roller coaster. Parts of the body simultaneously feel strange or different. At about the same time (30–40 minutes after drug ingestion), the cheeks are slightly flushed and pupil size begins to increase, maximizing within an hour or two. These changes are due to the effects of LSD on the sympathetic and parasympathetic nervous systems. The pupils react normally but are enlarged. After 4 hours they slowly begin to return to normal size, which finally is achieved at 10 to 12 hours after taking LSD. At the beginning of the trip, all soon note that what is at the periphery of their vision suddenly seems as clear as what is normally at the center of vision. Over the next 90 minutes, there is a feeling that tension is welling up. Laughing or crying will relieve the tension. Often subjects say they

Dr. Timothy Leary (center) in the custody of U.S. customs officials in New York City, October 11, 1966. Leary had been arrested under a section of federal law prohibiting users of narcotics or convicted narcotics violators from leaving or re-entering the U.S. without permission. (© Bettmann/CORBIS)

are laughing because of what they see or crying because of their feelings. But this is simply based on a need to relieve the fluctuating rise of tension. The trip moves on into the second and third hours when perceptual fluctuations and intensities are mainly noted. People also report perceiving several feelings simultaneously. A common observation is, "I don't know if I'm anxious, thrilled, or terrified." Just as perceptions are in flux, so are feelings, and these feelings and emotions may capture center stage in the second and third hours. Throughout the trip, people feel as if they are on the brink of an exhilarating but also dangerous experience. This intensity dies down about 4 hours after the usual dosage. If very large doses of LSD (500–1,000 micrograms) are taken, there is less capacity to be a spectator and far more intense self-absorption and fear. Some call this "dying of the ego" and relate the experience to mystical versions of death and rebirth.

Since the familiar seems novel and is seen in a different way, specialists in perception have been interested in what is called the "breakdown of constancies" that occurs with the drug. Normally we correct for what the retina sees by putting the world into order. We usually suppress the nonessential and focus on what we need to do to get about during the day. Just as with a camera, the retina sees the hand placed 6 to 8 inches in front of the eye as large. But the brain corrects for it and keeps size constant. Under LSD, corrections for constancy do not seem to happen. Many sensations that are normally dampened can thus have free play under the drug and the world will seem far less regular than it does in daily life.

One of the aftereffects in some—clearly not all—people is called "flashbacks." Days, months, or years after tripping, with no particular trigger or with an intense sensation, there may be a sudden few minutes in which subjects feel like they are back under the drug. They also may see flashing lights and other optical illusions. These flashbacks may be very disturbing. Flashbacks can occur after only a single drug experience and unpredictably. There has been no explanation as to why or how flashbacks occur. Scientists cannot predict (by observing a trip) if flashbacks will later occur or who is vulnerable. While these aftereffects are upsetting to some, most people do not experience them or those that do are not bothered. Others simply observe that their dreams may be more intense for a time after the drug experiences. One scientist noted that riding on a train to work, he was distracted from focusing on his newspaper for several months by the telephone poles whizzing by. These were normally at the periphery of his attention as he was reading, but after LSD, he could no longer suppress this irrelevant detail. There were more reports of such phenomena after publicity about them; given the millions of trips with LSD, these aftereffects are certainly infrequent but not rare.

Perhaps the most alarming bad effects of the drug have been the panic states occurring during a trip. Native Americans note that if one is in conflict, the effects of mescaline during religious ceremonies are unpleasant and can evoke terror. They then pray with the panicked person and "talk him down." One cannot predict whether a panic experience will occur. "One good trip does not predict a second one" is the general wisdom concerning this risk. Higher doses lead to less control and more intense effects, but panic states can occur at doses as low as 75 to 100 micrograms. For those who might be at risk for other mental disorders, hallucinogenic experiences may often destabilize them and precipitate some form of mental illness. For others, the experience may lead to a subsequent absorption with the unreal ("dropping out"), rather than coping with the challenges that the

tasks of the ordinary world present. Occasional suicides or rare impulsive acting out of odd ideas arising during a trip have led some to loss of control and tragedy.

For most, the experiences have few negative or positive aftereffects. Although it has often been suspected, no permanent change to the cells of the brain (brain damage) has ever been scientifically established. There is no generally accepted evidence that the drug produces chromosomal abnormalities or damage to a developing fetus (although no nonprescription drugs during pregnancy is the only safe rule to follow). The bad effects of a period of diminished control are unpredictable, and in that fact lies the real risk. Thus, it is the intensity of the experience and how well or poorly it can be managed, the unpredictable flashbacks, and how this "TV show in the head" or this "waking dream" gets woven into one's subsequent life that are at issue when hazards are considered.

TOLERANCE

One striking feature of LSD, mescaline, and related psychedelic drugs is tolerance, which is a loss of typical drug effects after repeated doses. In brief, with daily doses the duration and intensity of effects rapidly diminish to the point where no subjective effects are perceived. After 200 micrograms per day of LSD, there is simply no detectable drug effect on the third or fourth day. After three or four days without LSD, the full initial effects can be triggered by the same dose that has been "tolerated." Thus tolerance develops and dissipates rapidly. When subjects are tolerant to LSD, the usual dose of mescaline required for a trip is also no longer effective. This is called cross-tolerance. It is readily seen with similar dosage schedules of psilocybin, LSD, and mescaline. There is no cross-tolerance with the nonhallucinogenic stimulant drug amphetamine. Thus, there must be some common mechanism of action among the psychedelic drugs beyond their structure and similar array of mental effects.

Tolerance is seen both in humans and laboratory animals. The lack of pupil enlargement is a common sign of tolerance. In animals, some drug effects show tolerance and some do not. For example, a heightened sensitivity of rats to mild electric shock persists after daily doses and does not show tolerance. Such persisting drug effects during periods of tolerance have not been studied in humans. How and why a psychedelic drug loses and regains its potency in this fashion is not yet understood, but there is no withdrawal discomfort after stopping a psychedelic drug when it has been taken over several days. This differs from the classic effects described for opioid drugs, where an uncomfortable withdrawal with drug cessation requires more drug for relief. Such physical drug withdrawal phenomena are not found with psychedelics.

LSD AND SEROTONIN

LSD is known to affect many places in the brain where the body's neurotransmitter serotonin naturally has actions and effects, and the biochemical effects of LSD in the brain are mostly linked to those sites related to serotonin. LSD acts as a kind of impostor at receptors that recognize serotonin. LSD is like serotonin but different. Thus with LSD, the receptor signals other parts of the brain that there is too much serotonin, and these parts of the brain respond by tuning down cells that make serotonin. Yet, in fact, the chief effect of LSD is to cause *less* serotonin to be released in the neighborhood of the receptor—rather than too much, there is too little. This is one example of how LSD miscues the systems governing the flow of information between various brain neurons. In fact, overloading the brain with serotonin can reduce the LSD effect, and diminishing brain supplies of serotonin will increase LSD effects. Yet serotonin itself does not cause the scrambled perceptions that LSD does. How this miscue by LSD leads to the vivid effects is still unknown.

LSD, other indole-type psychedelics, and many hallucinogens related to mescaline (but surprisingly not mescaline itself) are known to act especially at a subtype of the serotonin receptor called the $5HT_2$ receptor. In laboratory animals, daily doses of LSD or psilocybin lead to fewer of these receptors, an effect that would be expected to produce tolerance; however, with 3 or 4 days off the drug, the number of $5HT_2$ receptors returns to normal. Both LSD and mescaline act at certain brain neurons, such as the locus coeruleus, and make it more responsive to inputs from the environment—such as a pinch. Researchers speak of such effects as lowering the gates to sensory input. We know the ways by which LSD affects certain

brain systems but still far less than we need to know to explain the full panoply of effects.

Although many of the psychedelic drugs are known to interact with serotonergic $5HT_2$ receptors, and this interaction appears to be of critical importance in producing their hallucinogenic effects, the hallucinogenic drugs can bind to a subtype of serotonin receptors that is located on serotonin nerve-cell bodies and on their terminals (which release serotonin that goes to the adjacent nerves with $5HT_2$ receptors). Interactions with these various receptors can lead to changes in the firing rate of such cells. The designer drugs MDMA and MDA cause the release of both dopamine and serotonin, effects that might contribute to their psychostimulant properties. The differential interactions of the various hallucinogens with multiple sites and systems may underlie the qualitative differences in the experience they produce.

MANDATORY SENTENCING Mandatory sentencing laws provide that people convicted of particular crimes receive particular sentences. Examples include laws specifying that people convicted of selling HEROIN or COCAINE within 1,000 yards of a school receive at least a three-year prison term, or that people convicted of selling more than four ounces of heroin or cocaine receive at least a five-year prison term. The latter are referred to as mandatory minimum sentences. Some mandatory sentencing laws require life sentences. A Michigan law, for example, which the U.S. Supreme Court upheld against a claim that mandatory life sentences constitute "cruel and unusual punishment" in violation of the Eighth Amendment to the U.S. Constitution, required life sentences without possibility of parole for people convicted of possessing more than 650 grams of cocaine (*Harmelin v. Michigan*, 49 Cr.L. 2350 [6/27/91]). An Alabama law required life sentences for people who, having previously been twice convicted of felonies, are convicted of a third felony. Laws like Alabama's are sometimes called "habitual offender" or "predicate felony" laws.

ENACTMENT OF MANDATORY SENTENCING LAWS

A historically unprecedented number of mandatory sentencing laws were enacted during the 1970s and 1980s. Most involve drugs, firearms, or both. Between 1978 and 1981, forty-nine states enacted mandatory sentencing laws. Every state and the federal government enacted mandatory sentencing laws during the 1980s. In 2000, over a hundred separate mandatory minimum penalty provisions were contained in federal criminal statutes.

Apart from specific offenses that carry mandatory sentences, state and federal sentencing guidelines mandate that judges impose minimum sentences based on the crime committed, aggravating factors, and the criminal history of the defendant. These guidelines increased punishment for criminal offenses and limited judicial discretion in sentencing by identifying the punishment required upon conviction for a particular offense. Many of these statutes eliminated or greatly restricted parole for prison inmates. Congress passed the Sentencing Reform Act of 1984 (SRA). The SRA eliminated parole for federal prisoners and reduced the amount of time off granted for good behavior. The SRA also established the U.S. Sentencing Guidelines Commission and directed it to create a new

sentencing system. In 1987, the commission's guidelines became effective.

The popularity of sentencing guidelines in the United States marked a rejection of *indeterminate sentencing*. Under indeterminate sentencing, judges set maximum lengths of prison sentences, and sometime minimums, but parole boards decide when a prisoner will be released. In contrast, the Federal Sentencing Guidelines shift the focus in sentencing from the offender to the offense. The guidelines categorize offenses and identify the sentence required upon conviction. Judges are allowed to increase or decrease sentences, which are called departures, only if they have good reasons and cite these reasons into the trial record. Upward departures are easy to achieve, as judges are allowed to consider all relevant conduct. This conduct can include the circumstances surrounding the crime, offenses that were committed at the same time as the charged offense but were not charged, prior convictions, and acts for which the defendant was previously tried but acquitted. Federal judges have a more difficult time decreasing a sentence. A downward departure is acceptable if the defendant accepts responsibility for the crime, or committed the crime to avoid a more serious offense. Prosecutors often successfully challenge decreases sentences on appeal.

Mandatory sentencing laws have long been controversial. The American Law Institute, an association of lawyers, judges, and law professors that created the *Model Penal Code*, a model law on which the criminal laws of nearly half the states are patterned, opposes enactment of mandatory sentencing laws. So does the American Bar Association. In 1991, a survey of U.S. federal judges showed that 62 percent favored repeal of federal laws calling for mandatory sentences in drug cases. Federal and state judges have continued to chafe under these statutory mandates.

OBJECTIONS TO MANDATORY SENTENCING LAWS

Opponents of mandatory sentencing laws oppose them for a variety of reasons. Many judges and lawyers believe that mandatory sentencing laws are arbitrary and sometimes require judges to impose sentences that are unduly harsh. They think that justice requires that sentences be individualized to fit the circumstances of the offender and of the crime. They also think that sentences should vary depending on considerations such as whether the offender was a ringleader or a follower; whether the offender played a major role or a minor one; whether he or she was motivated by greed or poverty; whether a seller of drugs was an addict raising money to support a drug habit or a professional drug dealer; and whether the quantity involved was large or small. A law requiring that anyone convicted of selling more than a small amount of heroin receive a five-year prison sentence ignores all such distinctions.

Opponents also complain that mandatory sentencing laws adversely affect court operations. Because prosecuting attorneys decide what charges to file in each case, mandatory sentencing laws shift power from the judge to the prosecutor. Most crimes are not covered by mandatory sentencing laws. Typically, for example, trafficking in drugs is subject to mandatory penalties, but possession of drugs is not. Since nearly every drug trafficker also possesses drugs, prosecutors can decide which charge to file; a trafficking charge ties the judge's hands; a possession charge gives the judge discretion.

Another objection is that mandatory penalties remove much of the defendant's incentive to plead guilty and thus increase the frequency of trials and lengthen the time required to resolve cases. In most courts, 85 to 95 percent of convictions result from guilty pleas. Many result from plea bargains, in which the prosecutor agrees either to dismiss some charges or to approve a particular sentence if the defendant pleads guilty. If mandatory penalties remove incentives from plea bargains, then trials, backlogs, and delays increase.

Yet another objection is that mandatory sentencing laws sometimes result in deceptive practices on the part of judges. To avoid imposing sentences that they believe are too severe, judges sometimes ignore the mandatory sentence law and impose some other sentence, or acquit defendants of crimes that bear mandatory penalties.

In the context of drug laws, the controversy over disparate mandatory minimum sentences for dealers of crack and powder cocaine has raged since the late 1980s. Under a 1986 federal law, one gram of crack is equivalent to one hundred grams of powder cocaine. The U.S. Sentencing Guideline Commission adopted this ratio when it revised its guidelines that year. However, in 1988 Congress

amended the law to establish mandatory minimum sentences for cocaine dealing. Thus, selling five grams of crack cocaine is punishable by a mandatory minimum sentence of five years. To receive the same sentence for trafficking in powder cocaine, a defendant would have to sell five hundred grams. This has resulted in longer prison sentences for small-time crack dealers than for cocaine wholesalers. The federal law and similar state laws have been challenged as violations of equal protection, as African Americans have been charged with more crack cocaine offenses than whites. Similarly, whites have been charged with selling powder cocaine more often than African Americans. These legal arguments have met with little success. By the mid-1990s, the U.S. Sentencing Guideline Commission sought to reduce the disparity in sentencing. As of late 2000, however, it had been unsuccessful in its efforts.

ARGUMENTS FOR MANDATORY SENTENCING LAWS

Supporters of mandatory sentences are not troubled by the harshness of the laws or the fact that they shift power from the judge to the prosecutor. One of the goals of such laws is to assure that the mandated sentence will be imposed whether the judge agrees with the sentence or not. Supporters are troubled by deceptive efforts of judges (and sometimes of prosecutors) to avoid applying them. They argue that judges are wrong to try to circumvent mandatories, that if legislatures pass laws, judges should enforce them whether or not they agree with them. Finally, supporters say they are sorry if mandatory sentencing affects guilty pleas, trial rates, and court delays, but they regard those problems as a price worth paying.

Proponents of mandatory sentencing laws make four arguments. First, that the laws allow legislators to assure citizens their concerns are being taken seriously. Second, that harsh mandatory sentencing laws deter offenders from committing crimes. Third, that certain crimes are so serious that people who commit them should be severely punished and that legislators should insist judges impose severe penalties in such cases. Fourth, that mandatory sentencing laws are a device for assuring that offenders who commit the same crime will receive the same penalty.

RESEARCH ON MANDATORY SENTENCING LAWS

Evaluations of mandatory sentencing laws offer greater support to their opponents than to their supporters. The Panel on Sentencing Research of the National Research Council, the research wing of the National Academy of Sciences, examined all research on mandatory penalties through 1983. Studies on the deterrent effect of mandatory sentencing laws conclude either that passage of such laws has no deterrent effect or that they have a modest deterrent effect that soon disappears. Research on how mandatory sentencing laws affect court operations shows that such laws do shift power from judges to prosecutors, do sometimes result in lower guilty plea rates and higher trial rates, often cause case processing delays, and frequently result in imposition of sentences that the judges and lawyers involved believe are harsher than the defendant deserves. All of these conclusions were reached by the evaluators of the ROCKEFELLER DRUG LAWS in New York State in the mid-1970s.

The conclusions of earlier research were confirmed by the most ambitious and sophisticated study of mandatory penalties ever completed—a report on mandatory penalties in the U.S. federal courts by the U.S. Sentencing Commission. That study concluded that people convicted of crimes subject to mandatory penalties were two and one-half times more likely to be convicted after trials (30% of convictions) than are other federal defendants (12.5%). The study found that "mandatory minimums transfer sentencing power from the court to the prosecutor," that "honesty and truth in sentencing" are compromised by prosecutors' and judges' efforts to work around mandatory sentences, and that "lack of uniform application [of mandatories] creates unwarranted disparity in sentencing."

Thus, on the major empirical issues about which opponents and supporters of mandatory penalties disagree, the great weight of the evidence supports opponents' views. Empirical evidence, however, cannot refute supporters' normative claims that mandatory penalties should be enacted to assure citizens that their concerns about crime are taken seriously or that certain crimes deserve severe punishment and that mandatory sentencing laws should be enacted to increase the likelihood

that such punishments will be imposed. Opponents of mandatory penalties do not necessarily disagree that lawmakers should try to respond to citizens' concerns, or that some crimes deserve harsh penalties; they do believe that mandatory penalties are an ineffective way to achieve those goals.

MARIHUANA COMMISSION: RECOMMENDATIONS ON DECRIMINALIZATION

Before 1960, use of MARIJUANA in the United States was generally confined to drug-using subcultures in the inner cities or in rural areas. Sale and use of the drug were prohibited both by federal law and by the laws of every state. Because marijuana was classified in 1937 as a "narcotic drug," along with COCAINE and OPIATES, penalties were severe; simple possession for personal use was a felony in most states. During the 1960s, marijuana smoking suddenly became prevalent on college campuses—for the first time among white middle-class youth of the baby-boom generation. Marijuana use also became associated, as a protest behavior, with dissenters (both adults and youth) against the war in VIETNAM, and by the U.S. MILITARY serving in Vietnam, especially from 1963 to 1973. As use of the drug increased, so did the number of arrests and so did the surrounding controversy. Questions were raised about the actual effects of marijuana on the health and behavior of those who used it and about the wisdom of prevailing social policy.

In response to swirling controversy, many proposals were introduced in Congress for a commission to undertake an authoritative study of the marijuana issue. Eventually, in the Comprehensive Drug Abuse Prevention and Control Act of 1970, Congress established the NATIONAL COMMISSION ON MARIHUANA AND DRUG ABUSE to undertake a two-year study—the first year on marijuana and the second year on the causes of drug abuse in general.

The commission had thirteen members—four from Congress (two each from the House and the Senate) and nine appointed by the president. President Richard M. Nixon appointed Raymond P. Shafer, formerly governor of Pennsylvania, as chairman of the commission, and he appointed Dana L. Farnsworth, M.D., director of Student Health Services at Harvard University, to be vice-chairman. The executive director was Michael R. Sonnenreich, formerly the deputy chief counsel of the Bureau of Narcotics and Dangerous Drugs of the Justice Department.

The commission assimilated the available literature on marijuana use and its effects and also sponsored its own research, including a national survey of use patterns and public attitudes, and a study of enforcement of the marijuana laws in six jurisdictions. In March 1972, the commission issued its first report, *Marihuana: A Signal of Misunderstanding*.

PRINCIPAL FINDINGS

The commission estimated that although 24 million Americans had used marijuana at least once, about 50 percent had simply experimented with the drug out of curiosity and given it up. Among the 50 percent who had continued to use marijuana, most used it only occasionally, once a week or less, for recreational purposes. A small percentage of the more frequent users (about 2% of the total ever-using population—or 4% of the continuing users) used the drug more than once daily. Marijuana use was clearly age-related: about half of the ever-users were 16 to 25 years of age, and 44 percent of those who were currently in college or graduate school had used marijuana at least once.

The commission concluded that there was "little proven danger of physical or psychological harm from the experimental or intermittent use" of marijuana. "The risk of harm," it continued, "lies instead in the heavy, long-term use of the drug, particularly of its more potent preparations." Even this risk was of uncertain dimensions, the commission noted, because the psychological consequences of long-term heavy use were unknown. In light of the fact that 90 percent of marijuana users used the drug only experimentally or intermittently, the commission judged that "its use at the present level does not constitute a major threat to public health." The commission also specifically found that marijuana did not induce physical dependence; did not lead, by virtue of its pharmacology, to use of other drugs; and did not cause criminal behavior.

POLICY RECOMMENDATIONS

The commission's principal policy recommendation was that possession of one ounce or less of marijuana for personal use be "decriminalized." At the same time, the commission rejected outright legalization of the drug and recommended perpetuation of prohibitions against cultivation and distribution for commercial purposes. The commission stipulated that social policy should aim to discourage use of the drug, but it emphasized that the costs of a criminal prohibition against possession far exceeded its benefits in suppressing use.

Although President Nixon disavowed the commission's principal recommendation on marijuana, it won widespread support. In 1973, the National Conference of Commissioners on Uniform State Laws promulgated amendments to the Uniform Controlled Substances Act that codified the commission's recommendation. Some form of decriminalization was endorsed the same year by a variety of national organizations, including the American Bar Association and numerous state and local bar associations, the National Education Association, the Consumers' Union, the National Council of Churches, the American Public Health Association, and the governing board of the American Medical Association.

In 1973, Oregon became the first state to decriminalize possession of small amounts of marijuana. Within the next five years, ten additional states eliminated incarceration as a penalty for simple possession, usually substituting a $100.00 fine. Five of these states made possession a "civil offense"; in others, it remained a criminal offense although the law typically contained a provision for expunction of criminal records after a specified period of time. Decriminalization of marijuana use was endorsed by President Jimmy Carter in 1977.

Political and legislative support for decriminalization began to wane, however, even during the Carter Administration. The more permissive stance on marijuana use implicit in decriminalization efforts led to mounting public resistance. Some of the strongest opposition came from groups of parents who organized to lobby for more focus on PREVENTION efforts. Although these parent groups were generally conservative politically, they gained a receptive ear in the Carter White House. Their arguments against decriminalization were bolstered by findings from the National High School Senior Survey showing that, starting in 1975, daily marijuana use had been increasing progressively among high school students. During the Reagan and Bush administrations the parents' movement and their concerns about marijuana use came to have a major influence on national drug policy. In the early 1990s, possession of the drug remained a criminal offense in most states, as well as under federal law.

RICHARD J. BONNIE

MARIJUANA In the United States, this is the most common term for the HEMP plant Cannabis sativa and its mind-altering (PSYCHOACTIVE) products. The term derives from the Mexican Spanish *mariguana/marihuana* (sometimes explained as Mary's leaf or Mary's plant, or from María y Juan, that is, Mary and John, the source of the English slang Mary Jane or maryjane.) It came into recorded English about 1890 and has become the mainstream term in American publications, law, and general usage. The term cannabis is sometimes used in medical literature and by the British; it means *hemp* in Latin and is derived from the Greek, *kannabis*, itself borrowed into Greek from an unknown source. In ASIA, where the plant originated, it is grown legally and commercially both for its fiber content (it is used to make strong rope) and for its drug content; there it is called BHANG (from Sanskrit bhang) or bang, GANJA or churganja, and HASHISH.

BOTANY

Hemp grows easily throughout the tropics, subtropics, and temperate regions, varying from a few feet to 15 feet (4.6 m) in height. Once established, it reseeds itself and spreads to neighboring areas; when birds eat the seeds, the defecated seeds may be scattered over considerable distances and produce new plants.

Two genetic strains of hemp are recognized: one produces plants excellent for fiber with very little drug material; the other produces plants with weak fibers but much drug content (TETRAHYDROCANNABINOL, THC). To harvest the drug-laden plant, it is simply cut down and usually chopped into small pieces with all parts included. These clippings resemble lawn cuttings, so one of the slang terms is "grass." The major use of this form in the United States is for illegal marijuana cigarettes, often called reefers.

Since the early 1900s, marijuana has been considered the one drug that might introduce the susceptible to hard drugs, drug abuse, and drug dealing. In the United States until 1937, Cannabis had been used in medical practice for a number of conditions but marijuana use for its euphoric effect was relatively uncommon. By 1937, forty-six of the then forty-eight states had laws against the use of marijuana, and its use had already been made a criminal offense under federal law. Until the 1960s, it was smoked largely by African Americans and Hispanics in the United States but was generally shunned by the white majority. During the social and political protests of the 1960s, a change in attitudes allowed widespread but illegal marijuana use into all levels of society, along with an increase in the use of several other illegal drugs and a boom in the drug trade that continued into the 1990s.

HISTORY

Various historical allusions to medicinal plants suggest that Cannabis was known and used for several thousand years. The earliest references to the plant are in ancient Chinese and Indian writings. From India, the use of Cannabis spread to Persia, Assyria, and the rest of the Near East. The Arabs adopted and spread it through North Africa as they conquered those lands for Islam from the seventh to the fifteenth centuries. Islam forbids the use of ALCOHOL, but not explicitly Cannabis (since it was adopted after the laws established by the Prophet Muhammad, who lived from about 570 to about 632 A.D.). In Arabic, it is called HASHISH, meaning grass. After the Arabs crossed the Strait of Gibraltar into the Iberian peninsula in 711, they ruled there until 1492. Portugal and Spain did not generally adopt its use. The Spanish conquistadors, however, introduced Cannabis into the New World, where it was readily adopted by African slaves, who were already familiar with it because of Arab trade and the spread of Islam into their continent.

CHEMISTRY

Like most plants, Cannabis contains many substances, perhaps two hundred or more. Those that relate most to the drug effects are a group of chemically similar compounds called cannabinoids. Of these, the most important and plentiful are cannabidiol (CBD), tetrahydrocannabinol (THC), and cannabinol (CBN). The biosynthetic pathway in the plant (that is, the step-by-step sequence in which the plant produces substances) goes from CBD to THC to CBN. Thus it is possible to identify the maturity of the plant by the relative content of these three cannabinoids. Immature plants show a preponderance of CBD; old plants may contain solely CBN; plants that are at their peak contain all cannabinoids, but mostly THC, which is the agent that produces the mind-altering effect. Some strains of plants contain variants on the THC structure, which usually have somewhat less drug effect than those with THC. Although some users contend that marijuana has different effects from those of isolated THC, most evidence indicates that virtually all of the mind-altering effects of marijuana are attributable to the THC content.

The THC content may vary greatly, depending on the genetic strain of the plant, the part of the plant involved (for example, the leaves or the flowers), and the maturity of the plant. The THC content of plants used for hemp production, such as those that grow wild in the U.S. Midwest, may be negligible to zero; marijuana produced from plants known for high drug content, such as sensemilla, may contain 2 to 3 percent THC. Manicured plants, from which the leaves are carefully separated and only the new leaves used for drug effect, may contain 3 to 4 percent THC. Hashish, which represents the ultimate in manicuring, generally contains 4 to 8 percent THC.

THC is sensitive to exposure to air and light. Thus, marijuana that is not protected from such exposure undergoes gradual degradation until the drug content is gone. When protected from air and light, marijuana may retain its activity for many months.

EPIDEMIOLOGY

Marijuana may rank behind only CAFFEINE, alcohol, and NICOTINE as the most widely used drug in the world. It is estimated that between 200 and 300 million people use this material in one way or another. In the United States alone, probably some 20 to 30 million people have used the drug, although the number of regular users is probably far less, but still a few million.

A tobacco-like substance produced by drying the leaves and flowering tops of the cannabis plant, marijuana varies significantly in its potency, depending on the source and selection of plant materials used. (Drug Enforcement Administration)

In the United States, marijuana is a drug preferred by young people; the rate of marijuana use is therefore followed among schoolchildren to estimate changing trends. Survey responses of highschool students, concerning marijuana, show very wide variations. Overall, 3 to 17 percent (median 12%) reported at least a single use of marijuana during the preceding thirty days. Such use is relatively low compared with that of smoking at least one cigarette, 9 to 37 percent (median 31%), or having at least one drink of alcohol, 28 to 64 percent (median 54%). Thus, it would appear that marijuana is not nearly as widely used as two of our three national drugs. Although this data indicates a trend toward decreased use of and greater concern about marijuana compared with nicotine and alco-

hol, this pattern has not held long enough to establish a true trend; it may be simply a minor blip.

A number of factors seem to contribute to use of marijuana among young people. Being male, using cigarettes and alcohol, and becoming delinquent are predisposing factors. Coming from a broken home and performing poorly in school are also predictive factors. Among adolescents in Australia and New Zealand, use of stimulants, HALLUCINOGENS, NARCOTICS, and SEDATIVES was virtually limited to those young people who used marijuana. Overall, it appears that school factors are less predictive of Cannabis use than are other social factors.

PSYCHOPHARMACOLOGY

Marijuana has a wide range of pharmacologic effects that suggest actions like those of stimulants such as the AMPHETAMINES, hallucinogens such as LSD, and depressants such as alcohol, SEDATIVES, atropine, or MORPHINE. Thus, marijuana does not fit any single traditional pharmacologic classification, and, hence, must be considered as a separate class.

The experienced smoker of marijuana is usually aware of a drug effect after two or three inhalations. As smoking continues, the effects increase, reaching a maximum about twenty minutes after the smoke has been finished. Most effects of the drug have usually vanished after three hours, by which time tests show that concentrations of THC in the body's plasma are low. Peak effects after eating marijuana may be delayed for three to four hours, but may then last for six to eight hours.

The early stage is one of being high, characterized by euphoria, uncontrollable laughter, alteration of one's sense of time, depersonalization, and sharpened vision. Later, the user becomes relaxed and experiences introspective and dreamlike states, if not actual sleep. Thinking or concentrating becomes difficult, although by force of will the person can concentrate to some extent.

Two characteristic signs of Cannabis intoxication are increased pulse rate and reddening of the conjunctiva (the whites of the eyes). The latter correlates well with the presence of detectable concentrations of THC in the plasma. Pupil size is not changed. The blood pressure may fall, especially in the upright position (orthostatic hypotension). An antiemetic (decrease in sense of nausea) effect may be present, and muscle weakness, tremors, unsteadiness, and increased deep-tendon reflexes (such as the knee jerk) may also be noted.

Virtually any performance test shows impairment if the doses are large enough and the test is difficult enough, although no distinctive biochemical changes have been found in human beings.

TOLERANCE to Cannabis has been demonstrated in virtually every animal species that has been tested. It is apparent in human beings only among heavy long-term users. Different degrees of tolerance develop for different effects of the drug, with tolerance for the tachycardiac effect (increased pulse rate) developing fairly rapidly. A mild WITHDRAWAL syndrome has been noted following very high doses.

HEALTH CONSEQUENCES

The ambiguity surrounding the health hazards of Cannabis may be attributed to a number of factors besides those that ordinarily prevail. First, from animal studies, it has been difficult to prove or disprove health hazards in human beings. Second, Cannabis is still used mainly by young persons in the best of health. Third, Cannabis is often used in combination with tobacco and alcohol, among licit drugs, as well as with a variety of other illicit drugs. Finally, the whole issue of Cannabis use is so laden with emotion that serious investigations of the health hazards of the drug have been colored by the prejudices of the experimenter, either for or against the drug as a potential hazard or benefit to health.

Psychiatric Consequences. Cannabis may directly produce an acute panic reaction, a toxic delirium, an acute paranoid state, or acute mania. Whether it can directly evoke depressive or schizophrenic states, or whether it can lead to sociopathy or even to the so-called AMOTIVATIONAL SYNDROME is much less certain.

That Cannabis use may make schizophrenia already present even worse is beyond any question. Such worsening followed acutely after use of Cannabis by schizophrenics, despite continued maintenance of antipsychotic drugs, and other adverse reactions were encountered among seventy patients in Sweden—anxiety reactions, flashbacks, dysphoric reactions, and abstinence syndromes.

Whether chronic use of Cannabis changes the basic personality of users so that they become less impelled to work and to strive for success has been

a vexing question. As with other questions concerning Cannabis use, it is difficult to separate consequences from possible causes.

Automobile Driving. If marijuana were to become an accepted social drug, it would be important to know its effects on driving ability. Fully 50 percent of the fatal auto accidents in the United States are associated with alcohol, another social drug. Neither experimental nor epidemiological approaches to the marijuana question have yet provided definitive answers.

Cardiovascular Problems. For persons with heart disease caused by hardening of the coronary arteries or by congestive heart failure, the effects of Cannabis smoking would be harmful: tachycardia, orthostatic hypotension, and increased concentrations of carbon monoxide in the blood.

Clearly, smoking of any kind is bad for patients with angina, but the greater effect of Cannabis as compared with tobacco in increasing heart rate makes this drug especially bad for such patients. Fortunately, thus far, few angina patients have been devotees of Cannabis.

Lung Problems. Virtually all users of Cannabis in North America take the drug by smoking. As inhaling any foreign material into the lung may have adverse consequences, well proven in the case of tobacco, this mode of administration of Cannabis might also be suspect. A formal study has shown that very heavy marijuana smoking for six to eight weeks caused mild but significant airway obstruction.

The issue of damage to lungs from Cannabis is somewhat unclear because many Cannabis users also use tobacco. As yet, it is far easier to find pulmonary cripples from the abuse of tobacco than it is to find any evidence of clinically important weakness of the lungs caused by smoking Cannabis.

Endocrine and Metabolic Effects. A review of literature on this subject concluded that sperm production was decreased, but without evidence of infertility. Ovulation was inhibited as luteinizing hormone, which stimulates ovulation, was decreased.

Immunity. A number of test-tube studies, using both human and animal material, suggest that cell-mediated immunity (the capacity of white blood cells to fight invading bacteria, viruses, or cancer cells) may be decreased after exposure to Cannabis. Clinically, one might assume that sustained impairment of cell-mediated immunity might lead to increased opportunistic infections or to increased prevalence of cancer, as seen in the current epidemic of ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS). No such clinical evidence has been discovered.

THERAPEUTIC USES

For many centuries, Cannabis was used as a treatment, but only during the nineteenth century did a particularly lively interest develop for exploiting its healing powers. Cannabis was then reported to be effective in treating tetanus, convulsive disorders, neuralgia, migraine, menstrual problems, psychoses following childbirth, insomnia in the aged, depression, and gonorrhea, as well as in helping cure addiction to opium or to chloral hydrate. In addition, it was used to stimulate appetite and to relieve the pain and anxiety of patients terminally ill with cancer. Few of these claims have even been properly tested in clinical studies.

Antiemetic for Patients in Cancer Chemotherapy. An antiemetic is a substance that suppresses vomiting. CANCER chemotherapy, especially with the agent cisplatin, produces severe nausea and vomiting, which is extremely difficult to treat with ordinary antiemetic drugs, such as prochlorperazine. This complication is so severe that many patients forgo effective cancer chemotherapy. The antiemetic effects of Cannabis had been suggested as early as 1972. In that year, a synthetic drug similar to THC, nabilone, was developed. It has been tested extensively for antiemetic activity. A crossover study comparing nabilone with prochlorperazine revealed significantly better results (that is, less nausea and vomiting) following nabilone therapy, although side effects from nabilone were also common.

The potential role of THC as an antiemetic may have become irrelevant because of recent developments. Metoclopramide, a newly developed antiemetic unrelated to the cannabinoids, has been found to be effective when given in high intravenous doses. Lorazepam, dexamethasone, and ondansetron are also useful as antiemetic agents when given by injection. These drugs are often used in various combinations, which meet most requirements. Thus, THC may be superseded even before it has had widespread clinical trial.

Glaucoma. The disease glaucoma causes pressure in the eyeball to increase greatly. If untreated, it can lead to blindness. Discovery of the ability of Cannabis to lower intraocular (inside the eyeball) pressure was more or less a matter of chance. This pressure was measured as part of a multifaceted study of the effects of chronic smoking of large amounts of Cannabis: it decreased as much as 45 percent in nine of eleven subjects, thirty minutes after smoking.

This exploitation of cannabinoids for treatment of glaucoma will require much further developmental work to ascertain which cannabinoid will be lastingly effective and well tolerated topically.

Miscellaneous Uses. Cannabinoids have been found to have analgesic (pain-relieving) activity, and efforts are being made to synthesize new compounds that separate this action from the others. They have also been used for relaxing muscles, for treating bronchial asthma, and for stopping convulsions. Thus far, none of these additional potential therapeutic uses has been fully established.

TREATMENT OF MARIJUANA USE

In general, marijuana users, even those whose use is heavy, do not feel compelled to seek treatment unless such use is complicated by other drugs, such as COCAINE or alcohol. In this case, treatment efforts are usually directed toward the complicating drug. Thus, treatment programs directed specifically at marijuana use are rare. A TWELVE-STEP approach, similar to that for alcohol, has been proposed, but its feasibility and its efficacy have not been tested.

GATEWAY EFFECT

Since about 1950 (but not much prior to that time) in the United States, smoking of marijuana has been linked statistically to the use of other illegal drugs, such as heroin and cocaine. Most observers have concluded that the link is sociological rather than biological, and that the use of marijuana is a marker for individuals who are more prone to seek new experiences even when these violate social norms and local laws. Further, the process of obtaining illegal marijuana increases the likelihood of contact with dealers and other individuals who have access to drugs such as HEROIN. Consequently, marijuana has been referred to as a "gateway" drug, one whose use often leads to the use of other illegal drugs. Some programs are aimed at preventing even experimentation with marijuana—not only for whatever inherent benefits this approach may have, but also in the hope that in doing so the movement to other more potentially lethal drugs will be prevented.

LEGAL STATUS

Despite its widespread use, marijuana has not yet been admitted to the company of accepted social drugs such as alcohol and nicotine. Laws remain that prescribe penalties for its possession, use, and sale. In some jurisdictions, possession and use of small amounts of the drug is a civil crime punishable only by a small fine. Despite the liberalization of the law in these areas, they have not been overrun with eager marijuana users. Perhaps the reason is that in most other jurisdictions, laws against its use are rarely enforced. Enforcement can be capricious, however, when employed in situations in which more serious crimes cannot be adequately documented.

A new drug application was approved for THC (Marinol) to be used therapeutically for control of the nausea and vomiting associated with cancer chemotherapy. Thus, THC was moved from Schedule 1 of controlled substances (no medical use) to Schedule 2 (medical use despite potential for abuse). Nabilone, the synthetic drug similar to THC, used for the same purpose, also has this status.

Thus far, no attempt has been made to establish legal limits on the amounts of THC in the blood that might be construed as impairing automobile driving. No doubt the issue has not yet appeared to be of enough gravity, since marijuana contributes little to the danger of driving as compared with alcohol.

MDMA This drug is popularly known as "ecstasy," XTC, and ADAM. It is a synthesized compound and a member of the family of HALLUCINOGENS known as the substituted phenethylamines, which also includes methylenedioxyamphetamine (MDA) and 2,5-dimethoxy-4-methylamphetamine (DOM) (see Figure 1). These hallucinogens are structurally related to the phenethylamine-type NEUROTRANSMITTERS dopamine, norepinephrine, and epinephrine. Many analogs of these compounds have been synthesized and are sometimes found on the street—the so-called DESIGNER DRUGS.

Controversy exists as to whether MDMA and MDA should be classified with the other hallucinogens. Both MDMA and MDA have structural similarities to the PSYCHOSTIMULANT AMPHETAMINE, and they have amphetamine-like psychostimulant properties. Yet, these designer drugs also have properties in common with LYSERGIC ACID DIETHYLAMIDE (LSD) and MESCALINE; with lower doses, however, they produce fewer perceptual phenomena and less emotional liability, or "keyed-up" feelings and disturbances of thought, than other hallucinogens, and there tends to be a tranquil state with a feeling that tender emotions are meaningful. As doses are increased, the illusions and other LSD-like phenomena are seen. Because of their mixed effects, MDMA and MDA are sometimes referred to as STIMULANT-hallucinogens.

Unlike LSD, users of MDMA have reported nausea, jaw clenching and teeth grinding, increased muscle tension, and blurred vision, as well as panic attacks. MDMA also causes amphetamine-like stimulation of the autonomic nervous system, producing increases in blood pressure, heart rate, and body temperature. A type of hangover the day after taking MDMA has been described, involving headache, insomnia, fatigue, drowsiness, sore jaw muscles, and loss of balance.

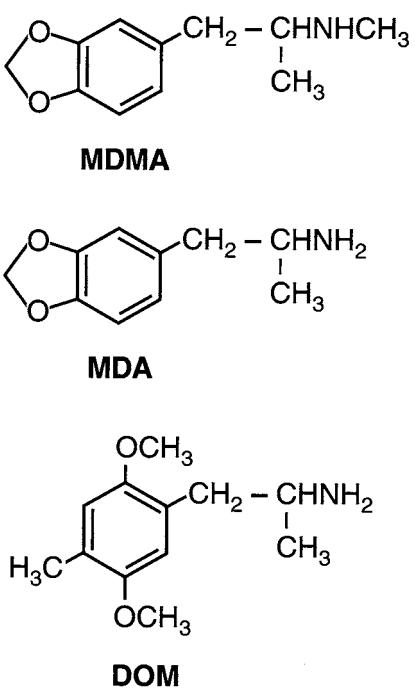

Figure 1
Phenethylamine Hallucinogens

Like the other hallucinogens, the exact mechanisms of action of MDMA are not known. MDMA, like the indole- and phenethylamine-type hallucinogens, binds to receptors for the neurotransmitter serotonin. Thus, many effects might be due to interactions with brain serotonergic systems. MDMA, however, also causes the release of both dopamine and serotonin, so some effects may be related to their stimulant properties.

By the early 1990s, some evidence indicated that MDMA might damage nerve cells. In laboratory experiments, MDMA can produce long-lasting changes in the function of neurons that use serotonin as the neurotransmitter, sometimes causing the death of these cells. Even though LSD also interacts with serotonergic nerve cells, the administration of massive doses of LSD does not damage these cells. In contrast, in experimental animals, a single dose

MDMA (Ecstasy) packaged for bulk distribution. (Drug Enforcement Administration)

of MDMA approximately three times higher than the typical street dose has been shown to affect brain serotonergic systems for several weeks. In some studies, neurochemical markers did not return to normal until one year after drug administration. Moreover, it is not clear whether there was actual regeneration of neurons or only compensatory changes in the remaining undamaged neurons. In these experiments, the neurotoxic effects of MDMA appear to depend on total exposure. Both the dose taken and the number of times the drug is consumed may be related to brain-cell changes. The exact mechanism of MDMA-induced neurotoxicity is unknown at this time and may be due to MDMA itself, or it could involve the formation of a neurotoxic metabolite.

Although there is controversy whether studies utilizing laboratory animals can be extrapolated to human MDMA users, some evidence suggests that brain function can be altered in humans exposed to MDMA. Although the consequences to behavior and thinking caused by damage to the serotonergic nerve cells in young users are unknown, some effects of MDMA-induced toxicity may become apparent as the users age. Cells die as part of the aging process, and if exposure to MDMA kills or weakens a certain proportion of cells, the effects of normal cell loss due to aging might be exacerbated. Serotonergic systems have been implicated in the control of sleep, food intake, sexual behavior, anxiety, and mood. Thus, serotonergic cell loss could have major consequences.

MEMORY AND DRUGS: STATE DEPENDENT LEARNING The term *state dependent learning* (SDL) refers to the fact that memories acquired while a person is drugged may be forgotten when the drug wears off and not remembered until the person again takes the drug. Conversely, material learned in the undrugged state may be forgotten when a drug is taken; and material learned under one drug may be forgotten when another drug is used. SDL is sometimes called drug

dissociation of learning, referring to the fact that material learned while drugged is dissociated from normal consciousness and not able to be retrieved.

Throughout the nineteenth century, there was a high level of public interest in multiple personality, fugue states, and other types of episodic amnesia; SDL was first reported in 1835 by George Combe, an English phrenologist, who viewed it as an analogous phenomenon, perhaps based on similar properties of the brain. SDL became an accepted property of mind during the latter half of the nineteenth century, and was a central theme in the plot of *The Moonstone*, (1868), a well-known mystery novel written by Wilkie Collins. Then, at the beginning of the twentieth century, interest in these dissociative phenomena waned and was replaced by an interest in the amnesias caused by repression, which Freud described. SDL was essentially forgotten.

SDL was rediscovered in the 1960s, this time in experiments using animals, and since then has been a popular topic of research and clinical speculation. Two types of mechanisms are postulated as possibly producing SDL. According to one theory, drugs produce sensory stimuli, subjective sensations—and one's ability to retrieve memories is aided by reinstatement of the stimuli that were present when learning occurred. A second theory suggests that some other property of brain results in memories being most easily retrieved when the conditions of brain excitability that were present during learning are reestablished. Sensory stimuli are not involved in producing SDL, according to this second theory. Thus far it has not been possible to confirm either of these proposed mechanisms experimentally, although the sensory model is more widely accepted.

SDL is produced only by drugs that act on the brain. There are marked differences in the strength of the SDL effects produced by the different centrally acting drugs. For example, BARBITURATES and ALCOHOL produce strong SDL effects, whereas chlorpromazine (Thorazine) produces almost no such effects. SDL is more likely to occur with high doses of drugs, and research on SDL has been severely hampered by the fact that these doses also produce other effects on memorization and retrieval that are difficult to distinguish from SDL effects. Some research suggests that the relative ability of different drugs to produce SDL may differ depending on the type of task that is employed, but this conclusion is not yet well substantiated.

Many consider SDL to be closely related to drug discriminations, believing that the discriminative control exercised by drug conditions is produced by the same drug effects that produce SDL amnesias at higher doses.

After SDL was rediscovered in the 1960s, clinicians feared that the lessons of psychotherapy carried out while a patient was drugged might be forgotten when drug treatment was discontinued. Subsequent studies showed that strong SDL effects typically did not occur except at doses higher than those normally employed during chronic treatment with psychotropic drugs. Some evidence, however, suggests that the stimulant drugs used to treat hyperactive children may produce SDL in those children. There is increasing evidence that some types of learning may take place under general anesthesia, although patients report they remember nothing after the anesthesia wears off. A considerable amount of research is currently focused on the possibility that SDL may block explicit recall of learning under general anesthesia, even though such learning occurs.

Many centrally acting drugs alter moods. A currently active area of research deals with the possibility that emotions act as memory cues and that memories learned in one emotional state may be recalled best when that emotion reoccurs; they may be recalled less easily at other times. Finally, there has been a dramatic increase in the number of reported cases of multiple personality disorder during the past decade. One of the theories used to explain this disorder holds that the process underlying it is similar, at a mechanistic level, to that which produces drug-induced SDL.

MEMORY, EFFECTS OF DRUGS ON

Research investigating the effects on memory of ALCOHOL (ethanol) and drugs of abuse is disproportionally small in relation to the widespread use of these substances worldwide. The available evidence clearly indicates that ethanol and abused drugs significantly affect memory processes. Much of current knowledge of the effects of such commonly used substances on memory is based on experiments using laboratory animals. In typical experiments, the animals are trained in a learning task and given a memory retention test after a delay of one day or longer. In experiments on commonly used learning tasks, the animals are trained to acquire responses that provide escape from, or avoidance of, aversive (negative) stimulation. Appetitive motivation (food or water reward) is also used to train animals in mazes and other types of spatial learning.

When investigating acute (single treatment) influences on learning and memory, drugs can be administered before the training, shortly after the training, or before the memory test. When drugs are administered before training, it is difficult to distinguish effects on memory from other influences on sensory, motivational, and motor processes. When administered within a few minutes after training, but not after a delay of several hours, drugs of many classes can enhance or impair memory. Such findings are interpreted as indicating that the drugs can modulate memory-consolidation processes occurring after a training session. The drug effects are typically dose-dependent. For example, drugs that enhance memory when administered in low doses may impair memory when administered in higher doses. Experiments examining the effects of a drug administered prior to memory testing are difficult to interpret, since drugs can affect many processes affecting behavior other than memory. For the same reasons, the alterations in memory performance that are produced by the chronic (long-term) administration of drugs are also difficult to interpret.

ALCOHOL (ETHANOL)

In rats and mice, an acute (a large) dose of alcohol prior to learning usually impairs memory of the training. The effect is heightened by the drug clonazepam, a BENZODIAZEPINE RECEPTOR AGONIST; it is lessened by bicuculline and picrotoxin, drugs that block receptors for the inhibitory NEUROTRANSMITTER GABA (GABA-A receptors). Such findings suggest that ethanol-induced amnesia is mediated by the benzodiazepine/GABA-A receptor complex. These findings are consistent with extensive evidence that benzodiazepines (see section below) induce amnesia in humans as well as in laboratory animals. Memory impairment induced by a large dose of alcohol is also lessened by physostigmine, the acetylcholinesterase inhibitor, suggesting that ethanol influences on memory involve cholinergic mechanisms.

Chronic administration of a high dose of ethanol to rats or mice over time induces memory impairment, accompanied by a decreased function of cholinergic systems in specific brain regions, including the hippocampus and neocortex. The syndrome can be reversed by an implant, into either BRAIN STRUCTURE, of fetal brain tissue that has high numbers of cholinergic cells or by giving oxotremorine, the cholinergic muscarinic agonist, prior to memory testing. Such findings suggest that the memory impairment resulting from chronic ethanol ingestion is associated with a deficit of brain cholinergic function.

Acute or chronic ethanol ingestion produces memory problems in humans. Large amounts of ethanol taken over a short period (hours or days) may cause a severe amnesia—a "blackout" for events occurring during and/or shortly before the period of intoxication. Some alcoholic blackouts may be caused partially by state-dependency—that is, during a later intoxication, individuals may sometimes remember experiences that occurred during a previous blackout. This phenomenon was illustrated in Charles Chaplin's 1931 film *City Lights*, in which the hard-drinking millionaire remembered Charlie only when under the influence of alcohol.

Paradoxically, experiments with human subjects indicate that low doses of ethanol administered

immediately after learning enhance retention. Similar results have been obtained in studies using laboratory animals; however, it is not clear that effects seen in animals are due primarily to ethanol effects on brain processes underlying memory. They may reflect, at least in part, the aversive aftereffects of ethanol.

Clinical research shows that chronic ingestion of alcohol can produce three general categories of brain impairment that are associated with memory deficits: the Wernicke-Korsakoff syndrome, alcoholic dementia, and "nonamnesiac" or "non-Korsakoff" disorders. Wernicke-Korsakoff syndrome, the best known, is due to Vitamin B_1 (thiamine) deficiency, resulting from poor food intake during sustained periods of alcohol consumption. It involves an acute phase, with mental confusion and difficulty with eye movements and walking. Most people who recover from this acute phase after treatment with thiamine will have Korsakoff's syndrome, in which impairment of the ability to learn and remember new information (anterograde amnesia) as well as retention of recently acquired information (retrograde amnesia) occur, although apparently normal intellectual function and the ability to acquire and retain skill-based information, such as purely visual/motor tasks, appear to be relatively unaffected. Some improvement in the memory deficits may occur with prolonged abstinence from alcohol.

Alcoholic dementia differs from Korsakoff's syndrome in that it is characterized by severe memory impairment as well as major intellectual deterioration that can be difficult to distinguish from Alzheimer's Disease by clinical examination. Improvements are, however, often seen if patients abstain from alcohol.

It is not known whether the deficits seen in early alcoholic dementia and in Korsakoff's syndrome are accompanied by alterations in GABAergic or cholinergic functioning. The changes seen in late alcoholic dementia, like those of Alzheimer's Disease, involve multiple focal brain lesions, primarily in the temporal lobe but also in other brain regions, and involve deficits in glutaminergic, GABAergic, and cholinergic systems.

The third type of memory problem linked to alcohol ingestion has been variously referred to as "neurologically intact" or "neurologically asymptomatic" and is characterized by subtle impairments in dealing with abstractions, problem solving, and memory. Significant recovery with abstinence is typical.

BENZODIAZEPINES

BENZODIAZEPINES, which are used clinically in the treatment of ANXIETY and the induction of sleep, are among the most widely used (and abused) drugs. It has been known for several decades that benzodiazepines, including diazepam (Valium), triazolam (Halcion), and CHLORDIAZEPOXIDE (Librium) induce anterograde amnesia in humans. Studies using laboratory animals indicate that benzodiazepines impair memory when administered before training, but they generally do not impair memory when administered posttraining. The lack of posttraining effects may be due, at least in part, to the fact that benzodiazepines are absorbed slowly and are slow to reach peak concentrations in the brain following peripheral injections. The anterograde amnesia induced by benzodiazepines is not due either to alterations in sensory or motivational processes affecting learning or to state-dependency.

Benzodiazepines are known to act by modulating GABA-A neurotransmitter receptors on the benzodiazepine/GABA receptor complex. Their effects on memory appear to be mediated primarily by the brain structures designated as the amygdaloid complex and hippocampus. When administered acutely, either systemically or directly into specific brain regions, including the amygdaloid complex and the hippocampus immediately posttraining, retention is enhanced by flumazenil, the benzodiazepine-receptor antagonist, and by the GABA-A-receptor antagonists bicuculline and picrotoxin. Findings indicating that the amnesia induced by peripherally administered benzodiazepines is blocked by GABAergic antagonists administered directly into the amygdaloid complex, as well as by lesions of the amygdaloid complex, provide additional evidence that this brain region is involved in benzodiazepine effects on memory. Although benzodiazepine-like substances are found in the brain, it is not yet known whether they are synthesized in brain cells or derived from food. Evidence that training experiences release these naturally occurring brain substances from synaptic vesicles in neurons suggests that they may play a role in modulating memory-storage processes.

MARIJUANA

In laboratory animals, both acute and chronic administration of marijuana extracts or of their active principles, the TETRAHYDROCANNABINOLS (THC), have been reported to impair the acquisition and retention of a very wide variety of tasks. It is not known whether these effects are due to influences on memory or simply to the sedative influences of the drug. There is some evidence suggesting that acute or chronic use of MARIJUANA impairs human memory. It is not known, however, whether such effects are due specifically to influences on brain processes underlying memory or to other influences on behavior. Cessation of marijuana use typically results in rapid recovery from the drug effects. Little is known about brain influences mediating marijuana effects on learning and memory.

OPIATES AND OPIOID PEPTIDES

The OPIATE drugs MORPHINE and HEROIN, administered posttraining, impair retention in laboratory animals. The memory impairment is not state-dependent: Administration of opiates prior to retention testing does not decrease the impairment. Opiate-receptor ANTAGONISTS, including NALOXONE and NALTREXONE, enhance memory and block the memory impairment produced by opiates. Endogenous opioid peptides (brain peptides that mimic the effect of morphine, heroin, and other opiates) also affect memory. The opioid beta-endorphin is released in the brain when animals are exposed to novel training situations. Memory impairment is induced by posttraining injections of beta-ENDORPHIN as well as by injections into several brain regions, including the amygdaloid complex and medial septum. Opiate antagonists administered into these brain regions enhance memory. Unlike the effects of opiate drugs, the memory impairment induced by beta-endorphin may be due, at least in part, to the induction of state-dependency: Under some conditions beta-endorphin administered (or endogenously released) prior to memory testing may lessen the memory impairment induced by a posttraining injection of the peptide.

Despite the widespread and long-standing use of opiate drugs by humans, there have been no systematic studies on the effect of morphine, heroin, or other opiates on human memory. Chronic opiate users do show memory deficits, but these may result from general deterioration rather than from any specific effect of the opiates. Acute administration of opiates (as in preanesthetic medication, for example) may induce a temporary amnesia. The failure of patients to remember experiences immediately prior to surgery may be due, at least in part, to an amnestic effect of the opiates used for ANALGESIA (PAIN suppression). The effect of opiate antagonists has been explored clinically in the treatment of dementias, but with limited success.

AMPHETAMINE

In laboratory animals, chronic administration of AMPHETAMINE prior to training impairs performance in many types of learning tasks. Such effects are typically obtained in experiments using high doses of amphetamine and complex learning tasks. In contrast, extensive evidence, from studies using a variety of types of training tasks, indicates that acute posttraining injections of amphetamine produce dose-dependent enhancement of memory. Retention is also enhanced by direct administration of amphetamine into several brain regions, including the amygdaloid complex, hippocampus, and caudate nucleus. Amphetamine is known to act by releasing the catecholamines epinephrine, norepinephrine, and dopamine from cells and block their reuptake. Amphetamine effects on memory appear to result primarily from influences on brain dopaminergic systems as well as influences on the release of peripheral catecholamines.

Amphetamine users often report that their "learning capacity" is enhanced by single doses of the substance. Since there are few systematic and well-controlled studies of the effects of amphetamine on memory in humans, however, it is not known whether such reports reflect subjective changes in perception and mood or effects on memory. Chronic amphetamine use is usually accompanied by a deterioration of memory function, an effect that subsides with cessation of use.

COCAINE

Despite the extensive use and abuse of COCAINE, little is known about cocaine effects on memory. Results of studies using rats and mice indicate that acute posttraining administration induces dose-de-

pendent effects comparable to those of amphetamine: Memory is enhanced by low doses and impaired by higher doses. The brain processes mediating cocaine influences on memory have not been extensively investigated. The effects appear to be mediated by influences on adrenergic and dopaminergic systems. Also, as with amphetamine, users of cocaine report that memory is enhanced by acute doses and impaired by chronic use. Systematic, well-controlled studies of the effect of cocaine on human memory are lacking. The effects on memory and intellectual functioning of other drugs—such as PHENCYCLIDINE (PCP), BARBITURATES, NICOTINE, and INHALANTS—are considered in connection with these agents and in separate articles.

MEPERIDINE Meperidine is a totally synthetic OPIOID analgesic (painkiller) with a structure quite distinct from MORPHINE, a natural OPIATE. Unlike morphine's rigid fused ring structures, the structure of meperidine is flexible; it is a phenylpiperidine and bends so that the key portions of the molecule can assume positions similar to those of morphine. A number of other compounds with similar structures are widely used in medicine, including loperamide (used primarily for treating diarrhea) and the extraordinarily potent ANALGESIC agents fentanyl, sufentanil, lofentanil, and alfentanil (for treating PAIN).

Meperidine is a compound with strong analgesic effects similar to morphine's, although greater amounts are needed to produce the same level of analgesia. It is one of the more commonly prescribed opioid analgesics and is better known under one of its brand names, Demerol. Given by injection, 100 milligrams of meperidine equals 10 milligrams of morphine. Meperidine can be administered orally as well as by injection but its potency it not as great following oral administration, so the dose must be increased proportionally. Like morphine, continued use of meperidine is associated with decreased analgesia—TOLERANCE—as well as PHYSICAL DEPENDENCE. As with the other opioids, ADDICTION (defined as a drug-seeking behavior) is not commonly observed with this drug when used for medicinal purposes, but meperidine is highly

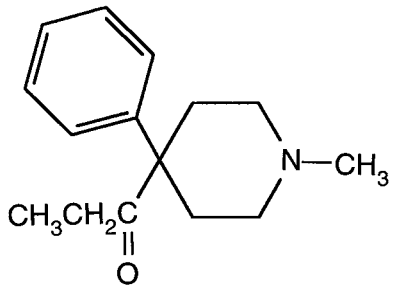

Figure 1
Meperidine

valued on the street and is widely abused, particularly in its injectable forms.

Medically, meperidine is a significant problem in patients with kidney conditions, where drug-removal from the body is impaired. Metabolized to normeperidine, a closely related compound, it is eliminated by the kidneys. In patients with kidney problems, this metabolite can accumulate to high levels, which can cloud mental processes and even produce convulsions. Since ELDERLY patients often have impaired kidney function, special care must be taken when using meperidine with them.

MEPROBAMATE This is a SEDATIVE-HYPNOTIC drug that is now typically used to treat muscle spasms. Meprobamate is prescribed and sold as Deprol, Equagesic, Equanil, Meprospan, and Miltown. Because of its abuse potential, it is included in Schedule IV of the CONTROLLED SUBSTANCES ACT. It was first introduced into clinical medicine in 1955 for the treatment of ANXIETY. At the time it was thought to have specific antianxiety effects and to be quite different from other sedative-hypnotics. Also introduced at about the same time were chlorpromazine (Thorazine), which had remarkable ANTIPSYCHOTIC effects, and reserpine, which had tranquilizing as well as blood pressure-lowering effects. These three agents were considered the harbingers of the new era of PSYCHOPHARMACOLOGY and helped popularize the new term *tranquilizer*.

Within a year or two after its introduction, meprobamate had become one of the most widely prescribed drugs in the United States. It was not long however, before its distinction from other sedative-hypnotic agents was reassessed, and within a decade it was recognized that meprobamate shared many of the properties of other central nervous

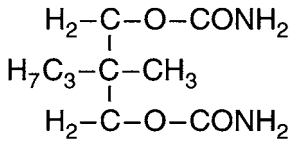

Figure 1
Meprobamate

system depressants, such as the BARBITURATES. By the early 1960s, its use for the treatment of anxiety was eclipsed by the BENZODIAZEPINES. Although it is prescribed as a muscle relaxant, the only use currently approved in the United States by the Food and Drug Administration is as a sedative-hypnotic.

Meprobamate has a number of side effects, including tremors, nausea, depression, and various allergic reactions. Continued use of high doses can result in TOLERANCE AND PHYSICAL DEPENDENCE. Convulsions and other signs of withdrawal are reported upon termination of high-dose treatment or inappropriate use.

MESCALINE This is a naturally occurring HALLUCINOGEN, one of the oldest PSYCHEDELIC substances known. It was first obtained from the PEYOTE cactus (*Lophophra williamsii* or *Anhalonium lewinii*), which grows in the southwestern United States and northern Mexico. Peyote buttons, the dried tops of the peyote cactus, were originally used by pre-Columbian Native Americans in those regions as an antispasmodic as well as for highly structured religious rituals; the button was eaten or

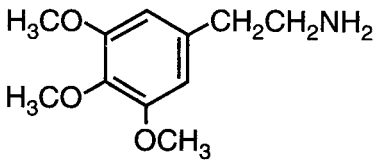

Figure 1
Mescaline

was steeped to make a drink. It continues to be used in ritual by the Native American Church.

Mescaline is a member of the phenethylamine-type family of hallucinogens, which includes DOM, MDA, and MDMA. The overall behavior effects of mescaline are very similar to those produced by LYSERGIC ACID DIETHYLAMIDE (LSD); however, it is approximately 100 to 1,000 times less potent than LSD, although the effects of mescaline last from 10 to 12 hours.

METHADONE Methadone (Dolophine) is a synthesized molecule with pharmacological actions very similar to those of the OPIOD drug, MORPHINE. Methadone serves an important place in the history of opioid ANALGESICS, since it is one of the first synthesized agents (1939). The ability to synthesize opioid analgesics from simple chemicals diminishes our reliance on natural products (such as morphine, CODEINE, and thebaine) to provide the base for many of the currently used opioid analgesics. Structurally, the drug does not look like morphine. Unlike the rigid fused ring structures of morphine, the structure of methadone is extremely flexible. It bends so that the key portions of the molecule can assume positions similar to those of morphine. The structure of methadone is very similar to that of propoxyphene (Darvon), a weaker opiate widely used to treat mild to moderate pain. It has two stereoisomers, but the (−)isomer is far more active than the (+)isomer.

Methadone can be administered orally, intramuscularly, or intravenously. It is well absorbed from the gastrointestinal track making it very useful orally. Its oral/parenteral ratio of potency is approximately two. Methadone is threefold more potent than morphine orally, but about equipotent when given by injection. It is metabolized by the liver to a variety of inactive compounds, which then are eliminated by the kidneys.

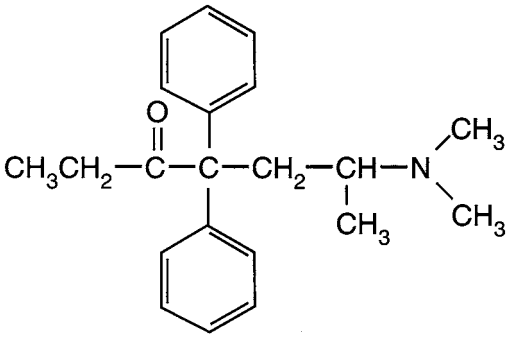

Figure 1
Methadone

Pharmacologically, methadone is used in the form of its hydrochloride salt. It has actions quite similar to morphine and works predominantly through *mu* opiate RECEPTORS. As an analgesic, methadone is similar in actions and in potency to morphine. It produces analgesia, as well as many of the side effects associated with morphine use, including respiratory depression and constipation. A major difference between methadone and morphine is methadone's long duration of action. Typically, the drug is given to patients every six to eight hours. This long duration of action can be very advantageous, particularly in patients who require the drug for long periods of time, such as cancer patients. However, there are some disadvantages. With a half-life ranging from twenty to thirty hours, it may take many days of continued dosing to reach constant (or steady-state) levels of the drug in the body. Thus, the full effect of a change in drug dose may not be seen for three or four days. This may make it difficult to adjust the dose for an individual patient. Increasing the dose too rapidly may even lead to delayed increases in its concentration in the body, far beyond those anticipated and, in some situations, may actually lead to an overdose. Continued administration of methadone will produce TOLERANCE AND PHYSICAL DEPENDENCE. The actions of methadone, like those of morphine, are readily reversed by ANTAGONISTS such as NALOXONE or NALTREXONE; however, these antagonists will also produce an immediate WITHDRAWAL syndrome in physically dependent people.

Despite its clear utility in the control of PAIN, the major use of methadone in the United States is in the treatment of HEROIN addicts. Although metha-

done must be administered approximately every six to eight hours to maintain analgesia, its slow rate of elimination prevents the appearance of withdrawal symptoms for over twenty-four hours. This slow appearance of withdrawal signs has made this agent very useful in maintenance programs, since it permits once-a-day dosing. With chronic administration of high doses of methadone, addicts become very tolerant, markedly limiting the euphoria an addict might obtain from illicit use of other opiates such as heroin. Thus, methadone minimizes occasional opiate use, is readily tolerated by the addicts, and can be administered once a day, which makes it easily dispensed. Methadone has been used clinically in maintenance programs and is one of the most effective treatment modalities available for opiate addicts.

METHADONE MAINTENANCE PROGRAMS The history of methadone treatment offers a striking example of the benefits and limits of research findings on public attitudes and policies for methadone maintenance treatment. To understand methadone maintenance treatment, it is necessary to appreciate the profound stigma attached to both patients and treatment providers. This establishes the context for understanding how a modality with the most extensive research base in the addiction treatment field nonetheless can engender passionate dispute.

Methadone maintenance as a treatment modality was developed in the mid-1960s by Vincent Dole and Marie Nyswander in response to prevailing concerns about epidemic levels of heroin addiction and related health problems, mortality (especially among young people 15 to 35 years old) and high relapse rates. Methadone itself had been synthesized in Germany in World War II as a synthetic analgesic and was studied at the U.S. Public Health Service Hospital in Lexington, Kentucky, after the war. It was approved by the U.S. Food & Drug Administration in August 1947 for use in the treatment of pain. Its initial use in the treatment of addiction was to ease withdrawal in addicts being treated for heroin addiction; it was subsequently determined to be well suited to long-term maintenance treatment. As a treatment tool, methadone provides a safe and effective way to eliminate drug craving, withdrawal, and drug-seeking behavior, and free patients to lead productive lives. In conjunction with educational, medical, and counseling services, it has been thoroughly documented as enabling patients to discontinue or reduce illicit drug use and associated criminal activity, improve physical and mental well being, become responsible family members, further their education, obtain and maintain stable employment, and resume or establish a productive lifestyle. Despite three decades of research confirming its value, methadone maintenance treatment remains a source of contention among treatment providers, the public in general, and officials and policymakers in particular. Unlike controversies based on a difference of opinion between informed parties, debate about methadone usually involves several common misunderstandings about the drug and its uses.

COMMON MISUNDERSTANDINGS

Much of the uneasiness about methadone stems from the idea that it is "just substituting one addicting drug for another." Indeed, this is technically correct; methadone treatment is drug-replacement therapy in which a long-acting, orally administered preparation is substituted for a short-acting opioid that is used intravenously. The long-acting (24 to 36 hours) effect of preventing withdrawal allows most patients to receive a dose and function in a stable manner, without the four-hour cycles of euphoria and withdrawal that characterize heroin use. The objection that methadone is "addicting" reflects the recognition that the medication is dependence-producing. Addiction treat-

ment professionals increasingly distinguish between physical dependence and addiction, the latter being characterized by behavior that is compulsive, out of control, and persists despite adverse consequences. Chronic-pain patients will develop physical dependence though their overall functioning is improved. Appropriate prescribing of benzodiazepines for patients with anxiety disorders is another example of another dependence-producing drug used beneficially for thousands of patients. Although physical dependence is a factor to be considered, addiction specialists increasingly assess the extent to which the person's functioning and quality of life are improved or impaired in order to determine whether physical dependence is an acceptable consequence of medication use.

Another point of discord is the belief that "methadone keeps you high," a notion that reflects misunderstanding about the effects of a properly adjusted dose. Once stabilized, most patients experience little or no subjective effects; heroin addicts will readily state that they seek methadone to avoid becoming sick (prevent withdrawal effects), not to get high. When the patient's dose is being stabilized, he or she may experience some subjective effects, but the wide therapeutic window allows for dose adjustment between the points of craving and somnolence. Dose adjustment may take some weeks and may be disrupted by a variety of medical and lifestyle factors, but once achieved the patient should function normally. There is ample scientific evidence that the long-term administration of methadone results in no physical or psychological impairment of any kind that can be perceived by the patient, observed by a physician, or detected by a scientist. More specifically, there is no impairment of balance, coordination, mental abilities, eyehand coordination, depth perception, or psychomotor functioning. Recently, advocacy efforts have been successful on behalf of patients identified through workplace drug testing and threatened with negative consequences. It is anticipated that the Americans with Disabilities Act will further protect patients against such forms of discrimination.

A third point of resistance, objection to long-term or even life-long maintenance, is better addressed following the presentation of some basic information about opioid addiction and the nature of treatment.

HOW DOES METHADONE TREATMENT WORK?

Most addiction specialists agree that addictive disorders are complex phenomena involving the interaction of biologic, psychosocial, and cultural variables, all of which need to be considered to make treatment effective. Dole and Nyswander, who pioneered the use of methadone, held the view that there was something unique about opioid addiction that made it difficult for patients to remain drug-free. Although originally intended as a long-term treatment for a metabolic defect, many initially hoped that methadone could be used to transition heroin addicts to a drug-free lifestyle and then be discontinued. Research in the subsequent 30 years indicates that less than 20 percent will be able to discontinue methadone and remain drug-free. As his thinking evolved, Dole (1988) postulated that a receptor system dysfunction resulting from chronic use leads to permanent alterations which we do not currently know how to reverse. New brain imaging technology holds the promise of better understanding and, eventually, improved intervention, but in the interim it appears that methadone is corrective although not curative for the severely addicted person. Two important questions for future research are whether a preexisting condition enhances the vulnerability of some patients more than others, and whether long-term addicts can ever recover normal functioning without maintenance therapy.

For now, studies indicate that methadone is a benign drug which exhibits stability of receptor occupation and thus permits interacting systems to function normally. One example of this is the normalization of hormone cycles and the return of regular menstrual cycles in women. This distinguishes it from heroin, a short-acting narcotic producing rapid changes that make a stable state of adaptation impossible. Although tolerance develops to most effects, it is fortunate that even long-term use (30 years or more) does not produce tolerance to the reduced craving, or to the narcotic withdrawal prevention effect.

The desired response to methadone depends on maintenance of a stable blood level at all times. Appropriate doses usually keep the patient in the therapeutic range of 150 to 600 ng per mL in the blood and produce the stable state so important for rehabilitation. What is referred to as a "rush" or

"high" is the result of rapidly changing blood levels; thus, once therapeutic levels are achieved and maintained, the patient experiences little subjective effect.

Unfortunately, negative attitudes toward methadone have historically played a significant role in dosing practices, manifested in dose ceilings imposed by state or local regulations without regard to medical criteria. Such policies placed value on giving as little of the drug as possible (versus the therapeutic level needed to accomplish the goal), influenced in part by the belief (unsubstantiated) that lower doses would make it easier to discontinue methadone. It was common to have dose ceilings of 40 mg per day. It is now well established that this is inadequate to maintain the necessary plasma concentrations to be effective; the effective range is between 60 and 120 mg per day for most patients, with some needing less than 60 and others considerably more than 120 mg. The higher and more adequate doses are strikingly well correlated with reductions in illicit drug use and improved retention in treatment (GAO, 1990; Caplehorn & Bell, 1991). How painfully ironic to recall that patients on low doses who complained that "my dose isn't holding me" were often dismissed with the assertion that they were "merely engaging in drug-seeking behavior." And when the distressed patient then supplemented the methadone dose with heroin, it was concluded either that the patient was poorly motivated, or the treatment was ineffective. Studies by D'Aunno and Vaughan (1992) show that more than 50 percent of patients nationwide receive doses that are inadequate to prevent continued illicit narcotic use, indicating both poor physician training and inappropriate involvement by regulatory agencies and legislative policies.

Initial hopes to use methadone as a drug to transition patients to a medication-free life style have proven unrealistic. Studies indicate that although short-term abstinence is common, relapse is the norm for 80 percent or more (McLellan et al. 1983; Ball & Ross, 1991). Clinicians who have worked with this population over the long term believe that although lifestyle changes are essential to successfully discontinuing methadone, such changes in conjunction with high motivation will still be insufficient for most; neurobiological factors remain a deciding factor. Because the current treatment system, overburdened by regulations and inappropriate expectations, is dehumanizing for many, programs usually make efforts to assist the patient who wishes to taper off methadone. However, many of these programs attempt to create an environment in which the patient is encouraged to succeed, but also to resume methadone treatment promptly once relapse or the likelihood of it occurs.

METHADONE AND OTHER DRUG USE

Methadone patients may engage in alcohol, cocaine, and other drug use prevalent in their communities. It is important to remember that methadone is opioid-specific and does not in itself increase or prevent other kinds of drug use. It does, however, offer the enormous advantage of making the patient accessible to other kinds of intervention. Rules governing take-home medication are intended to reduce the diversion of methadone onto the illicit market. At minimum, they mandate that the patient come to the clinic at least once weekly and, in most cases, even more frequently. Thus, the patient can be exposed to educational presentations and materials, and to counseling interventions as indicated by an individualized treatment plan, which is required as part of the treatment effort. Cocaine use has received particular attention, as it has been identified as increasing dropout, slowing progress, and undermining the gains of previously stable patients. Research and training efforts have been brought to bear on this problem. Alcohol use

remains a problem, particularly since many patients define their difficulty in terms of illicit drug use and are resistant to the notion of giving up drinking. With the blending of the "cultures" of alcohol and drug treatment providers, counselors are increasingly sophisticated about addressing problem drinking, although it is uncommon for programs to define goals for everyone in terms of abstinence from all intoxicants, as other parts of the treatment system do. Nonetheless, there is increasing sophistication in interventions, and programs have the added advantage of being able to dispense disulfiram with methadone when appropriate.

TREATING OPIOID-ADDICTED PREGNANT WOMEN

Methadone maintenance has been viewed as an effective treatment for opioid addiction in pregnant women since the early 1970s. In addition to the benefits of psychosocial interventions provided by the program, methadone maintenance treatment prevents erratic maternal opioid drug levels, thus protecting the fetus from repeated episodes of withdrawal. Programs either provide prenatal care onsite, or monitor the patient to see that prenatal care is obtained elsewhere, thus reducing the incidence of obstetrical and fetal complications, in utero growth retardation, and neonatal morbidity and mortality (Finnegan, 1991). Exposure to HIV infection through ongoing needle use is also reduced. Programs typically provide interventions around nutrition, parenting skills, exercise, and other related topics.

Methadone-maintained mothers produce offspring more similar to drug-free controls, in contrast to the poorer health status of offspring born to women using street drugs. It is clear that the most damaging consequences of opioid use during pregnancy occur with repeated episodes of intoxication and withdrawal (Jarvis & Schnoll, 1994). Although expectant mothers can be stabilized on methadone, body changes specific to pregnancy cause them to frequently develop increasing signs and symptoms of withdrawal as the pregnancy progresses, and they may need dose increases in order to maintain therapeutic plasma level and remain comfortable. Splitting the dose so that it can be ingested twice daily often produces better results, both reducing fetal stress and increasing the comfort of the pregnant woman, but local regulatory obstacles, not allowing patients to take half their daily dose out side the clinic, make this impractical for many programs.

There is inconsistent evidence to support the commonly held belief that the severity of the neonatal abstinence syndrome is proportional to the methadone dose, but many programs urge the expectant mothers to reduce their dose so the "baby won't be born addicted." In fact, the management of neonatal abstinence syndrome is relatively straightforward; fetal discomfort can usually be eliminated within hours and withdrawal can be accomplished within 14 to 28 days. No lasting impairment from these experiences has been demonstrated.

ADDRESSING PSYCHOSOCIAL ISSUES

Many existing methadone programs fall far short of the resources needed to do an effective job, but extensive research over a long period of time has clarified many of the treatment tasks. The stigma against heroin addicts in general and methadone patients in particular has created a treatment climate in which both patients and treatment providers may become demoralized about the value of the treatment endeavor. Often isolated from the mainstream, providers may not be able to obtain access to resources for patients on methadone. For example, methadone patients are often excluded from housing support or residential treatment. Nonetheless, there exists growing documentation that minimal intervention using methadone does reduce illicit drug use and hence needle sharing, and enhanced treatment accomplishes a great deal more (McLellan et al., 1993).

Historically, drug counseling has been provided in clinics by counselors who often have no credentials but are provided some training onsite. This counseling focuses on managing the patient's personal problems: problems specific to drug use, physical health, interpersonal relationships, family interactions, and vocational and educational goals. The counselor also performs the role of the case manager and is a liaison between physicians and medical institutions, courts and social services. Counselors also help the patient to develop coping strategies for current problems, perform initial screening for medication and other program services, and attend to issues concerning program

rules, privileges, and policies. The regulations governing methadone treatment are more complex, detailed, and restrictive than others in medicine or psychology, and maintaining a therapeutic alliance while meeting these obligations is a daunting task for clinical staff.

Studies of the drug-dependent population indicate that over 50 percent have a comorbid psychiatric disorder (Regier et al., 1990), and among the opioid-dependent population, depression is particularly common. Treatment outcome is improved by adding supplemental psychotherapy with professionally trained staff (Woody et al., 1983) for patients who meet the criteria for high psychiatric severity. It is important that such staff be well integrated into the treatment team. Medication may also be given concurrent with methadone, and methadone patient's use of antidepressants is increasingly common. Possible interaction effects are manageable with consistent monitoring and good staff teamwork. Psychotic conditions are relatively less frequent, but clinics are likely to have some highly disturbed individuals as part of their population and hence should be able to recognize and manage these patients appropriately. The patients benefit from the structure of frequent clinic attendance combined with the low psychological intrusiveness possible within the program.

It is also desirable for vocational interventions to be integrated into the program's mission, although the economic conditions in many urban areas also necessitate the development of alternatives to bring structure to daily life. Parenting classes that provide information and skill training and the opportunity to explore related issues are often well received by parents who feel the absence of good role models and skills.

Since twelve step programs actively promote abstinence from all potentially addictive drugs, this has been a barrier to methadone patients participating in them. Coupled with this are negative attitudes toward methadone and its users. Medication interventions such as methadone were not compatible with twelve step program participation in the minds of the Alcoholic's Anonymous' founders (Zweben, 1991), but meeting participants nonetheless may not always be open to methadone patients. In recent years, this climate has begun to change and methadone patients have started to increasingly attend twelve step meetings. Methadone maintenance programs are developing their own special meetings onsite, which in turn encourage patients' utilization of twelve step meetings in the larger community.

HIV/AIDS AND HEPATITIS C

A positive reexamination of methadone treatment has been greatly stimulated by documentation of its role in reducing the spread of HIV. Seroprevalence is much lower among those who have been on long-term maintenance, particularly those who entered treatment prior to the onset of the rapid spread of HIV in the local population (Hartel et al., 1988; Batki, 1988). Clinics provide accessibility to large numbers of intravenous drug users, making them an excellent site for prevention and education, screening, testing, and counseling. Because methadone patients have a continuing forum to discuss their life issues, counselors may be able to facilitate behavior change around the issues of safer sex practices and other high-risk behaviors. Further gains accrue as the patient progresses in treatment, as an abstinent person is in a better position to exercise good judgment than an intoxicated one. Currently, efforts are being made to integrate HIV/AIDS-related activities as fully as possible into methadone treatment programs.

The hepatitis C virus (HCV) has emerged as a problem of major significance, with many clinics reporting a prevalence upwards of 80 percent. Among those with HIV, coinfection with HCV is high. Inasmuch as 50 to 80 percent of new injectors become infected with HCV within 6 to 12 months, methadone maintenance will not reduce its spread as effectively as has occured with HIV. However, it does provide a structured system in which the patient can be monitored for good medical care, informed of emerging treatments, and educated about health practices to reduce the burden on the liver while more promising treatments are being developed.

WHAT THE FUTURE HOLDS

Methadone maintenance has demonstrated its effectiveness in reducing illicit drug use and facilitating the transition to a productive lifestyle. In the mid to late 1990s, two major scientific bodies reviewed the evidence on methadone maintenance and concluded it was an effective modality whose usefulness was greatly reduced by stigma and over

regulation (National Consensus Development Panel on Effective Medical Treatment of Opiate Addiction, 1998; Rettig & Yarmolinsky, 1995). The documents produced by these groups have been instrumental in efforts around the country to reduce barriers and make the delivery system more flexible and responsive to patient needs.

Research including long-term followup indicates that stabilized and socially responsible methadone patients can be safely given a month of take-home medication by physicians in an office-based practice (Novick & Joseph, 1991; Novick et al., 1994). The federal government is in the process of formulating guidelines and regulations to permit treatment to occur in the office of a physician affiliated with a methadone clinic. For the patient, this represents a significant opportunity to shift from the traditional treatment system, segregated from the rest of medical practice since the 1960s, to the mainstream medical system. Although these changes are likely to be implemented most easily with stabilized methadone patients, pilot programs are underway to admit new patients (such as those in rural areas) to an office-based practice. Concurrently, the development of an accreditation mechanism is intended to simplify regulations and emphasize clinical practice guidelines that are more easily modified in response to emerging research findings. These activities will likely reduce barriers to treatment and allow for the development of less restrictive treatment settings.

Other maintenance pharmacotherapies, particularly LAAM and buprenorphine, have been developed and will broaden the options and possibilities for effective intervention. Federally sponsored training efforts have improved the quality of care and will continue to be essential to disseminating current information and providing opportunities for skill development. Slowly, patients have emerged as visible examples of success and to serve as role models for others. Barriers to participation in residential treatment are beginning to be removed. It is hoped that developments will engender future gains and allow this modality to gain the acceptance it so greatly deserves.

METHAMPHETAMINE Methamphetamine (also called METHEDRINE) is a potent PSYCHOMOTOR STIMULANT with a chemical structure similar to AMPHETAMINE. Methamphetamine's stimulant effects on the central nervous system are more pronounced than those of amphetamine, while its peripheral effects (e.g., cardiovascular and gastrointestinal) are less marked. Like amphetamine, it causes increased activity, increased talkativeness, more energy and less fatigue, decreased food intake, and a general sense of well-being. Injecting the drug intravenously results in the production of a "rush," described by some as the best part of the drug effect. Methamphetamine is more soluble than DEXTROAMPHETAMINE, and, when available, of this group is generally the illicit user's drug of choice for intravenous injection—although dextroamphetamine dissolves sufficiently to permit intravenous use.

Japan was the first nation to experience a major epidemic of methamphetamine use. Immediately following World War II, large quantities of methamphetamine, which had been produced to keep combat troops alert, were released for sale to the Japanese public. Within a short time there was widespread use and abuse of the drug, much of it

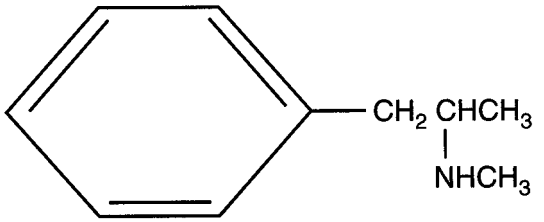

Figure 1
Methamphetamine

intravenously. At the peak of the epidemic, more than a million users were involved. Despite the experience of the Japanese, the belief persisted in the United States that amphetamines did not lead to serious compulsive use, and these drugs were not subject to any special regulatory controls like the ones governing the availability of the opioid drugs until 1964.

The first methamphetamine ("speed") epidemic in the United States began in the 1960s in the San Francisco area. A number of physicians there were prescribing the drug to HEROIN abusers for self-injection—to treat their heroin dependence by substituting methamphetamine. The drug achieved widespread popularity, with increasing numbers of people claiming heroin abuse and requesting prescriptions for methamphetamine. When the sale of intravenous methamphetamine to retail pharmacies was curtailed in the mid-1960s, illicitly synthesized methamphetamine began to appear. By the late 1960s a substantial number of users throughout the United States were injecting high doses of this illicit methamphetamine in cyclical use patterns—resulting in toxic syndromes that included the development of a paranoid psychosis (i.e., amphetamine psychosis).

Although illicit methamphetamine never completely disappeared from street use, its availability was considerably reduced by the 1970s. This trend began to reverse during the 1980s, with pockets of methamphetamine abuse occurring in the United States. Hawaii was the first area of the United States to experience the most recent methamphetamine outbreak, mostly in the form of smokable methamphetamine. Initial reports of smoking methamphetamine occurred in late 1986, with increases occurring about a year later, and a more sustained increase occurring in 1988 and 1989. Called "ice" or "crystal," this is the same sub-

stance as "speed," which was abused several decades earlier.

Methamphetamine, sold as "ice," is a large, usually clear crystal of high purity (greater than 90%) that is generally smoked using a glass pipe with two openings, much like a CRACK-cocaine pipe. Because it is a large crystal, it is difficult to adulterate with inert substances, a property that makes it extremely desirable to purchasers of illicit products. The smoke is odorless and, unlike crack, the residue of the drug stays in the pipe and can be resmoked. The effect is long-lasting, reported by users to be as long as twelve hours, although it is likely that this prolonged effect is due to the use of several doses.

Like COCAINE, methamphetamine abuse occurs in binges, with users taking the drug repeatedly for several hours to several days. During this time the user generally neither eats nor sleeps. Ending a methamphetamine binge is accompanied by fatigue, depression, and other "crash"-related effects. One of the most profound of the toxic effects of repeated methamphetamine use is the development of a paranoid psychosis, often indistinguishable from schizophrenia. With time off the drug, this psychosis generally resolves, although it can reappear if the user returns to methamphetamine abuse. Some Japanese psychiatrists have reported that methamphetamine psychosis may persist for many months.

METHANOL Methanol is the simplest alcohol, containing only one carbon atom, four hydrogen atoms, and one oxygen atom (CH_3OH). It is also called methyl alcohol, WOOD ALCOHOL, carbinol, wood naphtha, wood spirit, pyroxylic spirit, and pyroligneous alcohol or spirit. It is a flammable, potentially toxic, mobile liquid, used as an industrial solvent, in antifreeze, and in chemical manufacture. Ingestion may result in severe acidosis, visual impairment, and other effects on the central nervous system. Methanol does not produce significant inebriation unless a very large amount is consumed.

Methanol itself is not toxic, but it is metabolized by enzymes in the body to create formaldehyde and formic acid—both of which are very toxic substances. The formic acid can cause blindness. Ethanol (ethyl alcohol—drinking alcohol) can be used as an antidote for methanol poisoning, because it competes with the methanol for the enzyme. As a result, there is a delay of formaldehyde and formic acid production, and these toxic substances do not rise to such high levels. Although methanol is frequently added to ethanol-based cleaning solutions, its addition denatures the solution and makes it unsafe to drink. Only desperate alcoholics will drink methanol, but it is sometimes drunk by accident by people experimenting with various alcohol substitutes.

METHAQUALONE This is a nonbarbiturate, short-acting SEDATIVE-HYPNOTIC drug that has been used to treat insomnia. It was originally introduced in 1951 as a treatment for malaria. In the 1960s and 1970s, it became a popular drug of abuse among college students. Frequently called Quaaludes or "Ludes," the drug, like the short-

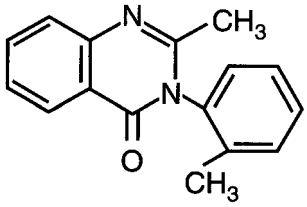

Figure 1
Methaqualone

acting BARBITURATES, produced euphoric effects; some users claimed it had APHRODISIAC effects.

It is usually taken in pill form, and depending on the dose, the effects last a few hours. The body eliminates about half of the ingested dose in about ten to forty hours, so that even forty-eight hours after ingestion, some drug may still be present. Prolonged use of methaqualone in high doses can lead to TOLERANCE AND PHYSICAL DEPENDENCE, and abrupt cessation of daily ingestion can result in WITHDRAWAL symptoms that are quite similar to those seen in barbiturate withdrawal. Fatal convulsions have resulted from sudden withdrawal. Fatal overdoses can occur when the drug is used alone, but especially when it is mixed with ethanol (ALCOHOL) and/or barbiturates. Because it was so commonly abused in the United States, the drug was shifted to Schedule I of the CONTROLLED SUBSTANCES ACT in the 1980s. Thus, it can no longer be prescribed and its nonmedical use is subject to severe criminal penalties. Although it is rarely used illicitly in the United States, it is still available in other countries and is a drug of abuse in some.

METHEDRINE Methedrine was the proprietary name given METHAMPHETAMINE hydrochloride by the pharmaceutical company Burroughs Wellcome. It was sold in ampules and until 1963–1964 was readily available by prescription. Methedrine (or "meth") became one of the street names of

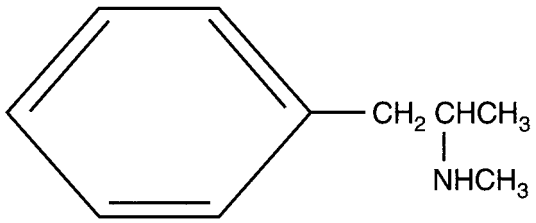

Figure 1
Methedrine

methamphetamine during the 1960s and early 1970s when high-dose methamphetamine ("speed") was a major drug of abuse. It was a particular problem in northern California where, after the manufacturer withdrew commercially made Methedrine from the market in 1963, large quantities of black-market, illicitly synthesized methamphetamine became available for sale.

METHYLPHENIDATE This is a central nervous system STIMULANT, structurally related and with similar effects to AMPHETAMINE. It is used by prescription as Ritalin. It was initially marketed as a mood enhancer in the mid-1950s and described as having less abuse potential than amphetamine; however, within a few years a number of dramatic reports of its abuse and toxicity were published. Methylphenidate is commercially available (by prescription) in pill form, reaching peak effect in one to two hours. Like the amphetamines and other stimulant drugs, methylphenidate is a controlled substance, placed in Schedule II of the CONTROLLED SUBSTANCES ACT to indicate that although it has medical utility it also has substantial ABUSE LIABILITY.

In most people, methylphenidate increases general activity, decreases food intake, produces positive subjective effects (an elevated mood), and can interfere with sleep. With continued use, tolerance can develop to these effects and users will often escalate their doses to achieve the desired effects of their initial doses of methylphenidate. Continued high-dose methylphenidate use can result in toxic consequences similar to those seen after amphetamine use—with ANXIETY, sleeplessness, and even-

tually a toxic paranoid psychosis. High-dose users often begin with oral methylphenidate use but switch to injecting the drug in order to maximize the effect and achieve the initial "rush" that is typical of intravenous drug abuse. Commercially manufactured methylphenidate pills (the only form available) contain talcum, an insoluble substance, which can cause toxic effects (such as abcesses) when the pills are dissolved in water and injected intravenously or under the skin.

Laboratory animals tested with methylphenidate show increases in locomotor activity after single doses, increased sensitivity to this effect after repeated doses, and the development of stereotyped repetitive behavior patterns after chronic dosing. In addition, these animals remain more responsive to methylphenidate even after the drug treatment has been discontinued. It has been suggested that the continuous repetition of behavior that characterizes the response to chronic methylphenidate treatment is a good model for the human stimulant psychosis and, as in animals, humans who use high doses become increasingly sensitive to stimulants such as methylphenidate, with psychosis increasingly likely at lower doses after its initial appearance. There are, however, no data to support this hypothesis.

In addition to its action as an appetite suppressant, methlyphenidate has been found to have other therapeutic utility. Like *d*-amphetamine, it has been used successfully in the treatment of ATTENTION-DEFICIT HYPERACTIVITY DISORDER (ADHD), a syndrome that first becomes evident during childhood and is characterized by excessive activity and difficulty in maintaining attention. Because of its relatively short half-life, two or three doses of methylphenidate are required each day, although recently a slow-release form of the medication has become available, promising more stable blood levels with only a single daily dosing. Methylphenidate has been shown to alleviate or moderate many of the symptoms of this disorder, although it is not effective in all cases and its long-term efficacy is not well understood.

Side effects of treatment can include insomnia, loss of appetite, and weight loss, all effects of stimulant drugs in general. In addition, concern about the longer lasting effects on learning and cognition in youngsters maintained on this drug for many years has made practitioners cautious and often unwilling to prescribe it. Recent research and practice, however, has supported methylphenidate as the stimulant of choice for treating this disorder. As with the amphetamines, methylphenidate is also effective in the treatment of narcolepsy, in which sudden attacks of sleep can occur unexpectedly.

MEXICO AS DRUG SOURCE Drug control in Mexico is unique—the reason both for Mexico's paradoxical success as well as for its ongoing difficulty in managing the issue. Believing that destruction at their agricultural source is the most effective way to reduce supplies and halt trafficking, Mexico began to spray the OPIUM poppy (PAPAVER SOMNIFERUM) and MARIJUANA plant (CANNABIS SATIVA) in late 1975 with the herbicides paraquat and 2,4-D. Plants, not people, became the target in the 1970s and 1980s. Until the early 1990s, the drug-eradication program was the centerpiece of Mexico's program. With the 1990s increase in Colombian cocaine transiting Mexico, the Mexican government increased its efforts to work with the United States in halting COCAINE smuggled through Mexico, sharing intelligence, extraditing non-Mexican nationals, and reducing drug-related corruption. However, by 2000 the government's efforts remained hampered by corruption in the police and military. Tensions between the United States and Mexico increased as U.S. officials and legislators questioned the ability of Mexico to curb drug trafficking, which had grown dramatically as more enforcement efforts were placed on other South American countries, including Columbia. Several prominent officials were found to have worked with drug traffickers to subvert reform efforts. Finally, the election of Vicente Fox as Mexico's president in 2000 signaled the possibility of political change, as Fox became the first president not elected from the Institutional Revolutionary Party (PRI) in the modern era.

Mexico's principal agency for drug control is the attorney general's office, but the Mexican military has also been involved with manual crop eradication and operational support for herbicidal spraying. The Mexican military has also become involved in tactical reconnaissance, interdiction, and destruction of secret landing strips. In the late 1990s, the Mexican government established the Federal Preventative Police (FPP) to integrate the law enforcement responsibilities of several existing federal agencies and to focus on crime prevention and public security. Historically, the government of Mexico has increased its effectiveness in the drug-control field as a positive response to U.S. diplomatic and enforcement pressures. During the 1990s, under increased U.S. pressure, the two countries agreed to a Binational Drug Strategy.

UNIQUENESS OF MEXICO

At least four factors set Mexico apart from its drug-producing neighbors to the south, creating an environment for drug control. First, Mexico is the only country in the Western Hemisphere that produces significant amounts of opium poppy and HEROIN with little use by its people. Although large numbers of its people abuse marijuana and INHALANTS, Mexico may be the only opium-producing country in the world with almost no domestic market. Yet, Mexico shares a 1,900-mile (3,057-km) border with the U.S.—a country that has one of the world's largest and most lucrative markets for heroin.

Second, powerful drug rings have bought power and influence in several Latin American countries, yet, unlike their Peruvian and Colombian counterparts, Mexican drug traffickers have no symbiotic relationship with ideological, terrorist-oriented, political factions—whose goal is to change the prevailing political order. Nevertheless, during the 1990s drug-influenced political corruption became a very public problem, one which contributed to the election of President Fox in 2000.

Third, growing opium in Mexico is relatively recent; it has always been illegal and involves only a small number of citizens. Illicit opium and marijuana are grown not on privately owned plots but on open unowned (hence, government) land, largely as extra-cash crops, not as subsistence crops. If these illicit crops were all destroyed, growers would not starve. Unlike coca—which is a legal crop (that can provide the raw material for an illegal commodity) and has been cultivated for centuries in Bolivia and Peru—Mexico's opium crop has never become the center of a social, cultural, or agricultural economy.

Fourth, Mexico is a relatively wealthy country with vast natural and human resources. Mexico has shown its ability to build an infrastructure to implement an ongoing drug-control campaign. Beginning in the mid-1970s, Mexico started the world's first successful herbicidal opium-eradication program, which continues today. However, these strengths have been severely tested, as an economic downturn in the 1990s and increased drug trafficking has strained the nation's ability to control drug crime.

CAMARENA MURDER

Drug control has been an important issue between the United States and Mexico since the 1960s. The abduction and murder of U.S. DEA agent Enrique Camarena in Mexico in February 1985 elevated the drug issue on the bilateral diplomatic agenda of the two countries. The murder focused public attention on the perhaps decreasing effectiveness of Mexican drug-control efforts and represented a turning point in U.S.-Mexican relations. After Camarena's murder, drugs became a confrontational issue at uncharacteristically high levels of the two governments. Both the U.S. secretary of state and Mexico's foreign minister discussed the murder and subsequent government response as a paramount diplomatic issue; drug control was no longer treated only as a law-enforcement issue between the two countries. In response to continuing U.S. pressure, the Mexican government took a series of actions that resulted in the apprehension and incarceration of the several drug traffickers responsible. Nevertheless, tensions between the two governments remained high throughout the 1990s, as trafficking and corruption increased.

HISTORICAL ROOTS

Mexico's international drug-control efforts have their roots in the SHANGHAI Convention of 1909 and the Hague Opium Convention of 1911–1912. In 1923, Mexico's President Alvaro Obregon prohibited the production of opium and condemned

Officials from the Mexican Attorney General's office display to the media one ton of confiscated marijuana and three suspects in Mexico City, March 1, 1996. (AP Photo/Jose Luis Magana)

what was then widespread and increasing drug-induced violence. In 1934, President Cardenas del Rio created the first centralized narcotics administrative unit in the government.

After the United States entered World War II in 1941, Mexico was asked to provide opium for the war effort, since it was processed into MORPHINE, a medication used extensively for war-related wounds. In both Mexico and the United States, HEMP was grown to fill U.S. military need for rope and cordage; hemp is processed from *Cannabis sativa*, which is also used as marijuana. By mid-1943, opium constituted the most profitable cash crop in Mexico's northwestern state of Sinaloa. Despite Mexico's efforts to control the production of these crops after the war, drugs were grown, processed, and smuggled into the United States from Mexico.

In the late 1960s and early 1970s, Mexico soon became the major supplier for the illicit U.S. heroin market when Turkey prohibited opium cultivation and the French Connection had been ended. Consequently, in the fall of 1969, the U.S. BUREAU OF NARCOTICS AND DANGEROUS DRUGS (the predecessor organization of DEA) and the U.S. Customs Service initiated Operation Intercept—a three-week operation that subjected every person crossing the border in the San Ysidro, California, area to intensive baggage and body searches. The economic losses and dismay on both sides of the border prompted termination of the operation—but not before focusing attention on the volume of drugs entering the United States from Mexico. The Mexican government then began to locate and manually destroy the poppy fields—the source, at that time, of all the heroin produced in the Western Hemisphere. Originally, the search for poppy fields was made in small planes that flew over mountain zones where crops were suspected to be growing on remote plots of government land.

Prior to 1975, once the poppy had been spotted and the approximate location registered in official correspondence, military squads were sent to destroy the plants by cutting them down. In 1975, the Mexicans began to use the most modern technology—a system called Multi-Opium Poppy Sensing (MOPS), which used multispectral sensing cameras on board low-flying aircraft to read and print images from the electromagnetic spectrum. In nature, every substance emits its own unique electromagnetic waves that can be read on the color spectrum using special cameras. The fields were then destroyed by aerial application of the contact herbicides 2,4-D and paraquat. By the 1990s, a fleet of nearly 120 aircraft were being used.

MEXICAN GOVERNMENT ORGANIZATIONAL STRUCTURE

Organizationally, the Mexican attorney general's office plans and implements the drug-eradication campaign. Nearly 700 civilian pilots, mechanics, communications experts, and technical personnel make the campaign as effective as possible—working specific zones and sectors, with a coordinating office in each zone. Forward operating bases connect all the zones to Mexico City via a sophisticated communications system. Mexico's military is also used to stop the illicit cocaine that transits Mexico from South America to the United States, exchanging intelligence and training, and destroying clandestine trafficker landing strips.

ERADICATION RESULTS

Between 1982 and 1989, Mexico's rapidly deteriorating economy, bureaucratic inertia, technical inefficiency, poor management, low morale, complacency, and corruption led to the decreased effectiveness of the eradication program. Countermeasures by growers who planted smaller fields, at higher altitudes, under cover of foliage, during more than the two traditional growing seasons, fur-

ther decreased program success. In the mid-1970s, the eradication campaign was managed in large part by specialized organizations of both governments (Mexico's attorney general and U.S. law-enforcement units). In the mid-1980s, the Camarena murder took the campaign out of the strict purview of the specialist law-enforcement agencies and into the diplomatic arena. In the 1990s, the drug-control efforts increased to include interdiction of South American cocaine traveling through Mexico but destined for the United States. In 1991, the Mexican government increased its eradication of opium by 40 percent over 1990; and its eradication of marijuana by 60 percent. The drug eradication program has had dramatic results during the 1990s. Marijuana production dropped steadily during the 1990s, while opium production dropped to its second lowest level in the 1990s. Nevertheless, the U.S. government has found that most of the cocaine and much of the marijuana, heroin and methamphetamine consumed in the U.S. comes through Mexico. Mexican drug networks control a substantial part of the illicit drugs distributed in the United States.

JAMES VAN WERT
REVISED BY FREDERICK K. GRITTNER

MICHIGAN ALCOHOLISM SCREENING TEST (MAST) This is a brief self-report questionnaire designed to detect ALCOHOLISM (Selzer, 1971). It is widely used in clinical and research settings. The twenty-four scored items assess symptoms and consequences of ALCOHOL abuse, such as guilt about drinking; blackouts; DELIRIUM TREMENS; loss of control; family, social, employment, and legal problems following drinking bouts; and help-seeking behaviors, such as attending ALCOHOLICS ANONYMOUS meetings or entering a hospital because of drinking. Several shorter versions of the MAST have also been developed including the thirteen-item Short-MAST (Selzer, Vinokur, & van Rooijen, 1975) and the ten-item Brief-MAST (Pokorny, Miller, & Kaplan, 1972).

To complete the MAS, individuals answer yes or no to each item. The items are weighted on a scale of 1 to 5, with items concerning prior alcohol-related treatment experiences and help-seeking behaviors receiving higher weights. The total MAST score (range: 0–53) is derived by adding the weighted scores from all items that are endorsed. Studies indicate that the long version of the MAST possesses good internal-consistency reliability, as indicated by Cronbach's alpha coefficients of .83 to .93 (Gibbs, 1983). Therefore, the scale does appear to measure a unitary construct.

Selzer (1971) originally recommended adopting a cutting score of 5 or higher for a diagnosis of alcoholism with the MAST. However, since this cutting score was shown to produce a relatively high percentage of false positives (Gibbs, 1983), Selzer, Vinokur, and van Rooijen (1975) suggested the following cut points: 0 to 4, not alcoholic; 5 to 6, maybe alcoholic; 7 or more, alcoholic. Skinner (1982) recommended that scores of 7 to 24 be regarded as clear evidence of alcohol problems, and

that scores of over 25 be considered evidence of substantial alcohol problems. In a recent study, Ross, Gavin, and Skinner (1990) compared scores on the MAST to diagnoses of alcoholism obtained from the National Institute of Mental Health Diagnostic Interview Schedule (NIMH-DIS) (Robins, Helzer, Croughan, & Ratcliff, 1981). In this study, the MAST cutting score that yielded the highest overall accuracy was 13 or greater.

The validity of the MAST has been examined in a number of studies in which MAST scores, or scores from the shorter versions of the instrument, were compared to other measures of drinking status, including diagnostic interviews, physicians' diagnoses, and other self-report instruments. In reviewing twelve of these studies, Gibbs (1983) concluded that MAST diagnoses agreed with diagnoses of alcoholism reached through other assessment procedures in about 75 percent of cases. Where inconsistencies between results were found, it was found that the MAST tended to overdiagnose alcoholism. This probably reflects the fact that a cutting score of 5 or higher on the MAST was used in these studies. By adopting a cutting score of 13, Ross et al. (1990) were able to achieve a greater degree of agreement when comparing MAST scores to DIS-derived diagnoses.

As with any instrument that relies on the veracity of self-report information, the reliability and validity of the MAST is dependent on the willingness of the interviewee to answer the items truthfully. All the items possess high face validity, which means it is relatively easy to answer them so as to appear non-alcoholic. The MAST may therefore not be a useful screening tool with individuals who are motivated to conceal their alcohol problems.

A. THOMAS MCLELLAN

MIDDLE EAST AS DRUG SOURCE *See* International Drug Supply Systems

MILITARY, DRUG AND ALCOHOL ABUSE IN THE UNITED STATES Drug and alcohol use have historically been common among military personnel. Drugs have been used by soldiers to reduce pain, lessen fatigue, and increase alertness, or to help them cope with boredom or panic that accompany battle. During the U.S. Civil War, medical use of opium resulted in addiction among some soldiers. In the modern U.S. military, drug use became a recognized problem during the Vietnam War in the late 1960s and early 70s. Approximately 20 percent of Vietnam War veterans reported having used narcotics (e.g., heroin, opium) on a weekly basis, and 20 percent also were considered to be addicted based on reported symptoms of dependence (Robins, Helzer, & Davis, 1975). Although few personnel continued using heroin when they returned home, there were concerns about addiction.

Similar to drug use, heavy drinking in the military has been an accepted custom and tradition (Bryant, 1979; Schuckit, 1977). In the past, alcohol was thought to be a necessary item for subsistence and morale and, as such, was provided as a

daily ration to sailors and soldiers. Within the predominantly male U.S. military population, heavy drinking and being able to "hold one's liquor" have served as tests "of suitability for the demanding masculine military role" (Bryant, 1974). A common stereotype has been to characterize hard-fighting soldiers as hard-drinking soldiers. Alcoholic beverages have been available to military personnel at reduced prices at military outlets and until recently during "happy hours" at clubs on military installations (Bryant, 1974; Wertsch, 1991). In addition, alcohol has been used in the military to reward hard work, to ease interpersonal tensions, and to promote unit cohesion and camaraderie (Ingraham, 1984).

Drug and alcohol abuse are strongly opposed within the U.S. armed forces because of their negative effects on the health and well-being of military personnel and because of their detrimental effects on military readiness and the maintenance of high standards of performance and military discipline (Department of Defense, 1997). In the U.S. military, drug abuse is defined as the wrongful use, possession, distribution, or introduction onto a military installation of a controlled substance (e.g., marijuana, heroin, cocaine), prescription medication, over-the-counter medication, or intoxicating substance (other than alcohol). Alcohol abuse is defined as alcohol use that has adverse effects on the user's health or behavior, family, community, or the Department of Defense (DoD) or that leads to unacceptable behavior.

DEVELOPMENT OF MILITARY POLICY

The DoD convened a task force in 1967 to investigate drug and alcohol abuse in the military and in 1970 formulated a drug and alcohol abuse policy based on task force recommendations. The policy emphasized the prevention of drug and alcohol abuse through education and law enforcement procedures focusing on detection and early intervention (DoD, 1970, 1972). However, treatment was provided for problem users with an emphasis on returning them to service.

In response to continuing public concern about reports of serious drug addiction among U.S. forces in Southeast Asia, President Nixon in 1971 directed the DoD to take additional measures to address the drug problem. The result was the establishment of a urinalysis testing program that initially consisted of mandatory testing for service members leaving Southeast Asia and grew to include mandatory, random urinalysis for all U.S. forces worldwide. The program was discontinued for a period because of difficulties implementing it on a large scale, its high costs, and a court challenge that the Fifth Amendment protection against self-incrimination was being violated (U.S. v. Ruiz 1974).

The reaction to the crash of a jet on the aircraft carrier *Nimitz* in 1981 again focused public attention on the military's drug abuse problem, particularly marijuana use. Autopsies of fourteen Navy personnel killed in the crash showed evidence of marijuana use among six of the thirteen sailors and nonprescription antihistamine use by the pilot. The armed forces reinstituted urine testing for drugs in 1981 as a result of this incident and other concerns about drug use in the military. New breakthroughs in drug- testing confirmation procedures and more rigorous procedures for tracking urine samples overcame earlier legal objections. Urine tests, which are conducted either randomly or when a person is suspected of using drugs, are a major tool for the detection and deterrence of illicit drug use (DoD, 1997).

U.S. military substance use policy has been updated periodically since the early 1970s and currently is one of zero tolerance that includes an emphasis on preventing and detecting abuse and either discharging abusers from the military (the approach generally followed for drug abuse) or providing treatment and rehabilitation (the approach generally followed for alcohol abuse) (see Bray et al., 1993, 1999a for more detailed discussions of the development of military policy).

WORLDWIDE SURVEY SERIES

To help monitor the extent of drug and alcohol abuse, the DoD initiated a series of worldwide surveys among active-duty military personnel in the Army, Navy, Marine Corps, and Air Force. The first survey was conducted by Marvin Burt Associates in 1980 (Burt et al., 1980) and the others by Robert Bray and his colleagues at Research Triangle Institute in 1982, 1985, 1988, 1992, 1995, and 1998 (Bray et al., 1983, 1986, 1988, 1992, 1995, 1999b). The goals of the surveys have been to provide data to help assess the prevalence, correlates, and consequences of substance abuse and health in the military.

The surveys have all been conducted using similar methods. Civilian researchers first randomly selected a sample of about sixty military installations to represent the armed forces throughout the world. At these designated installations, they randomly selected men and women of all ranks to represent all active-duty personnel. Civilian research teams administered printed questionnaires anonymously to selected personnel in classroom settings on military bases. The few personnel (about 10%) who were unable to attend the group sessions (e.g., were on leave, sick, or temporarily away from the base) were mailed questionnaires and asked to complete and return them. Participants answered questions about their use of illegal drugs (e.g., marijuana, cocaine, heroin), the misuse of prescription drugs (e.g., stimulants, tranquilizers), about the frequency and amount of alcohol use, and problems resulting from drug or alcohol use. These data collection procedures yielded from over 15,000 to nearly 22,000 completed questionnaires for the various surveys. From 59 percent to 84 percent of those eligible to take part actually did so.

TRENDS IN DRUG AND ALCOHOL USE

Figure 1 presents trends over the seven worldwide surveys on the percentage of the active-duty military force who engaged in any illicit drug use or heavy alcohol use during the thirty days prior to the survey. Any illicit drug use was defined as use one or more times during the past thirty days of marijuana/hashish, cocaine, inhalants, hallucinogens, heroin, and nonmedical use of prescription-type drugs, including stimulants, sedatives, tranquilizers, or analgesics. Heavy alcohol use was defined as five or more drinks per typical drinking occasion at least once a week. As shown in Figure 1, use of any illicit drug declined sharply from just under 28 percent in 1980 to about 3 percent in 1998; heavy drinking declined significantly from approximately 21 percent in 1980 to just above 15 percent in 1998, although the decrease was less dramatic than for drug use. Heavy drinking by itself does not constitute alcohol abuse, but it does indicate drinking levels that are likely to result in negative consequences.

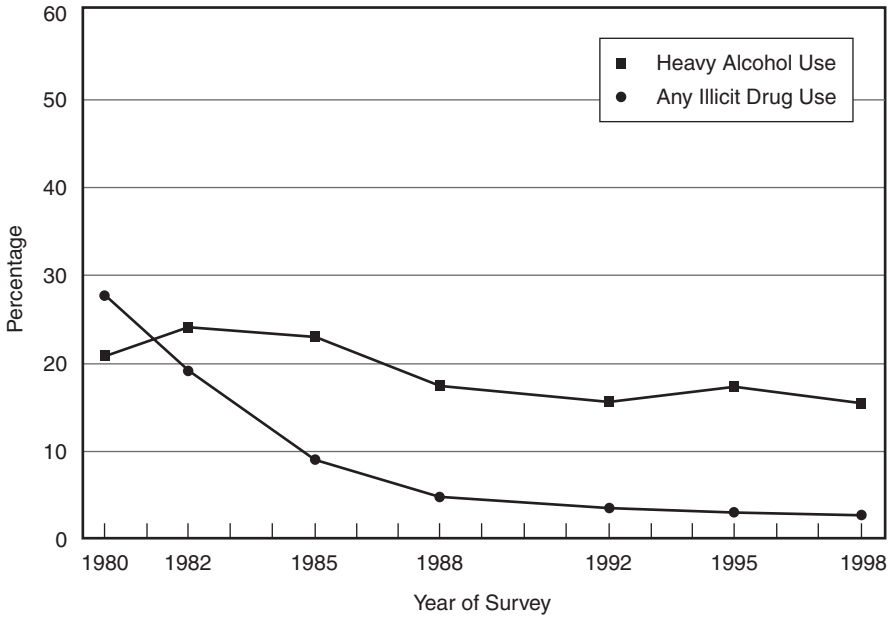

Figure 1
Trends in Any Illicit Drug Use and Heavy Alcohol Use, Past 60 Days, Total Department of Defense, 1980–1998

EFFECTS OF DEMOGRAPHIC CHANGES

Despite the significant downward trends in illicit drug use and heavy drinking noted in Figure 1, the question arises whether these declines are due to military programs and policies or to some alternative explanation. One possible explanation for the changes could be shifts in the demographic composition of the armed forces between 1980 and 1998. Members of the military in 1998, for example, were more likely to be older, to be officers, to be married, and to have more education than in 1980. These characteristics are also associated with less substance use. For example, 60 percent of personnel in 1998 were married compared to 53 percent in 1980; 61 percent were aged twenty-six or older in 1998 compared to 43 percent in 1980.

Analyses that adjusted for demographic differences across survey years from 1980 to 1998 showed that illicit drug use had the same significant decline as found before the adjustment, whereas heavy alcohol use did not. This suggests that the decline in illicit drug use shown in Figure 1 *was not* explained by shifts in the demographic composition of the military population, whereas the decline in heavy drinking *was* largely explained by demographic changes. Stated another way, if the demographic composition of the military in 1998 was like the composition in 1980, rates of illicit drug use in 1998 would still be notably lower, but rates of heavy drinking between these two survey years would have been about the same.

MILITARY AND CIVILIAN COMPARISONS

Another possible explanation for the trends in drug and alcohol use observed in Figure 1 is that the military may simply mirror similar trends occurring among civilians. Drug use among civilians has declined substantially in recent years (Office of Applied Studies [OAS], 1999), whereas declines in alcohol use among civilians have been more moderate (Clark & Hilton, 1991). To address this issue, data were compared for illicit drug use and heavy alcohol use among military personnel and civilians. Military data were drawn from the 1998 DoD survey, and civilian data from the 1997 National Household Survey on Drug Abuse (NHSDA), a nationwide survey of drug abuse. Military and civilian datasets were equated for age and geographic location of respondents, and civilian substance use rates were standardized (adjusted) to reflect the demographic distribution of the military.

Standardized comparisons showed that military personnel (about 3 percent) were significantly *less*

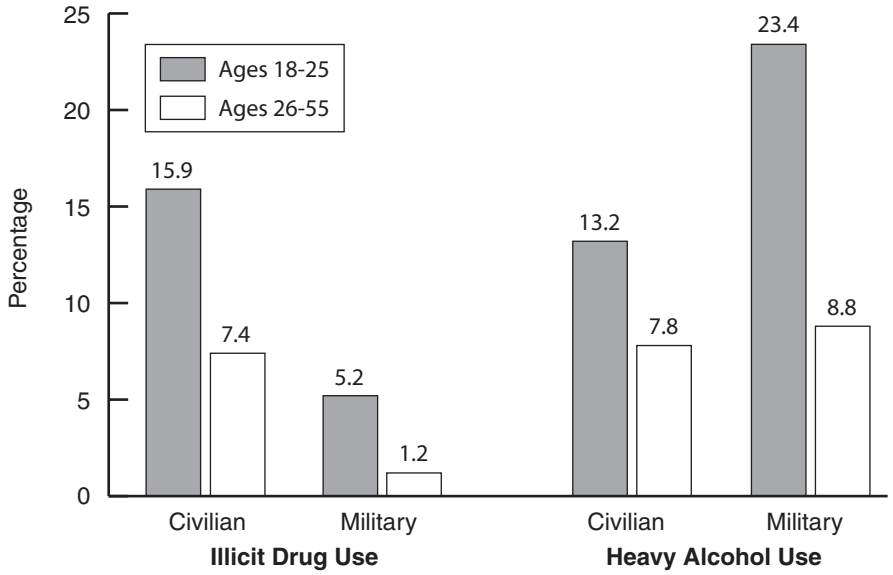

Figure 2
Civilian data have been standardized to the U.S.-based military data by gender, age, education, race/ethnicity, and marital status.

likely than civilians (about 11 percent) to have used any illicit drugs during the past 30 days, but they were significantly *more* likely to have been heavy drinkers (14 percent vs. 10 percent). For illicit drug use, the findings held across both younger (18 to 25) and older (26 to 55) age groups. For alcohol, heavy use was nearly twice as high among younger military personnel compared to younger civilians, but it was about the same among the older age groups. These findings are illustrated in Figure 2. A related analysis using data from the 1985 worldwide survey and civilian data from the 1985 NHSDA showed the same pattern of results (Bray et al., 1991). In the latter study, however, the rates of heavy drinking among military personnel were higher than among civilians for both age groups, which suggests that the rate of heavy drinking among older personnel declined between 1985 and 1998.

The findings indicate that substance-use trends in the military do not simply mirror similar changes among civilians. The lower rates of drug use among military personnel than civilians suggest either that military policies and practices deter drug use in the military or that military personnel hold attitudes and values that discourage substance use. Because of the military's stringent policy about no drug use and the urinalysis testing program to enforce it, it seems likely that the difference between military personnel and civilians results from military policies and practices. In contrast, the higher rates of heavy drinking among military personnel suggest that certain aspects of military life may foster heavy drinking and/or that military policies and programs directed toward reducing heavy alcohol use have not been as effective as similar efforts among civilians.

SUMMARY

Overall, these findings indicate that the military has made steady and notable progress in combating illicit drug use, particularly during the 1980s and 1990s. In 1998, illicit drug use was at minimal levels and rates were substantially lower than among civilians. In contrast, the military has made less progress in reducing heavy drinking. In 1998, heavy drinking affected nearly one in six active-duty personnel and was significantly higher than among civilians. Declines in heavy drinking between 1980 and 1998 were largely explained by changes in the demographic composition of the military. The military appears to have developed an effective formula to reduce illicit drug use and now needs to develop a comparable plan to reduce heavy drinking. Such an effort is currently in the initial stages. The DoD has begun a new prevention initiative that will target alcohol abuse as one of its key components.

MINIMUM DRINKING AGE LAWS

Before the twentieth century, there were few legal restrictions on the consumption of alcoholic beverages by youth. Early in the twentieth century, laws prohibiting alcohol sales to minors began to be implemented, as part of a broader trend of increasing legal controls on adolescent behavior. The temperance movement succeeded in establishing national Prohibition in 1919 but when it was repealed in 1933, all states implemented legal minimum ages for alcohol purchase or consumption, with most states setting the age at 21.

From the 1930s through the 1960s, the issue received little public attention. In 1970, the 26th Amendment to the U.S. Constitution lowered the voting age in federal elections from 21 to 18. By 1974, all fifty states had lowered their voting ages for state elections to 18. As part of this trend of lowering the "age of majority," twenty-nine states lowered their minimum drinking ages between 1970 and 1975, most setting the age at 18 or 19. In the mid-1970s, studies began to emerge that showed significant increases in the rate of young drivers' involvement in traffic accidents following

the reductions in the legal drinking age. The trend toward lower drinking ages was reversed, with Maine being the first state to raise its legal drinking age from 18 to 20 in October 1977. Several other states soon followed, and research studies completed by the early 1980s found significant declines in youth traffic-crash involvement when states raised their legal drinking age. With the support of organized efforts by citizen-action groups such as REMOVE INTOXICATED DRIVERS and MOTHERS AGAINST DRUNK DRIVING, federal legislation was passed in 1984 that called for the withholding of a portion of federal highway-construction funds from any state that did not have a legal drinking age of 21 by October 1986. As a result, all the remaining states with a legal drinking age of below 21 raised their age to 21 by 1988. Thus, all states now have a uniform legal drinking age of 21, although details in regard to the purchase, possession, consumption, sales, and furnishing of alcohol to underage youth vary from state to state.

The legal drinking age became a major issue because of the serious consequences of young people's consumption of alcohol. Most teenagers drink; in addition, almost a third regularly become intoxicated. Damage resulting from the drinking of youth is extensive. Car crashes are the leading cause of death for teenagers (Baker et al., 1992), and one third to one half of the crashes involve alcohol (National Highway Traffic Safety Administration, 1990). Other leading causes of disability and death among youth, such as suicide, homicide, assault, drowning, and recreational injury, involve alcohol in one quarter to three quarters of the cases (Wagenaar, 1992). Injuries are only part of the problem. Early use of alcohol appears to affect multiple dimensions of physical, social, and cognitive development (Semlitz & Gold, 1986). Alcohol use increases the odds of having unprotected sex (i.e., failure to use a condom), which increases the chance of pregnancy and catching sexually transmitted diseases, including the human immunodeficiency virus (HIV), which causes AIDS (Plant, 1990; Strunin & Hingson, 1992). Many "date rape" situations involve individuals who have been drinking (Wagenaar et al., 1993a). Early use of alcohol increases the odds one will move on to using other drugs, such as MARIJUANA, COCAINE, or HEROIN (Kandel, 1989). Finally, the earlier one starts a pattern of regular drinking, the higher the chance of later serious problems with alcohol, including dependence (i.e., getting "hooked" so that it is very hard to quit). Despite the many problems associated with young people's drinking, the most obvious one, and the one that received the most attention in debates on the legal drinking age, is traffic-crash involvement.

EFFECTS OF THE DRINKING AGE ON CAR CRASHES

Seventeen studies of the effects of lowering the legal age for drinking on traffic crashes appeared between 1974 and 1982 (Wagenaar, 1983). Although results varied across studies and across states, most studies found significant increases in traffic crashes among youth after the drinking age had been lowered (usually from 21 to 18). Typically, lowering the drinking age resulted in 5 percent to 20 percent increases in fatal and injury-producing crashes likely to involve alcohol, such as single-vehicle crashes occurring at night.

Thirty-nine studies of the effects on traffic crashes of raising the legal age for drinking have appeared between 1979 and 1992 (Wagenaar, 1993). Twenty-eight of these studies found significant reductions in the involvement of youth in traffic crashes following increases in the legal drinking age. Typically, raising the drinking age resulted in 5 percent to 20 percent declines in fatal and injury-producing crashes likely to involve alcohol. With the aid of the better-designed studies with longer follow-up periods, it could be estimated that the long-term effects of raising the drinking age to 21 would be a 13 percent decline in single-vehicle nighttime crashes among those whose legal access to alcohol was removed (i.e., 18 to 20-year-olds).

The legal drinking age is probably the most extensively researched policy that is designed to reduce traffic crashes and other alcohol problems. Scientists and professionals in the field agree that lowering the legal age for drinking increased car crashes among youth, and that, subsequently, raising the legal age reversed the effect: It lowered car crashes among youth (United States General Accounting Office, 1987). The National Highway Traffic Safety Administration estimates that, even when counting only those states that raised the legal age after 1982, the U.S. age-21 policy now saves over one thousand lives per year in reduced car crashes alone (Arnold, 1985).

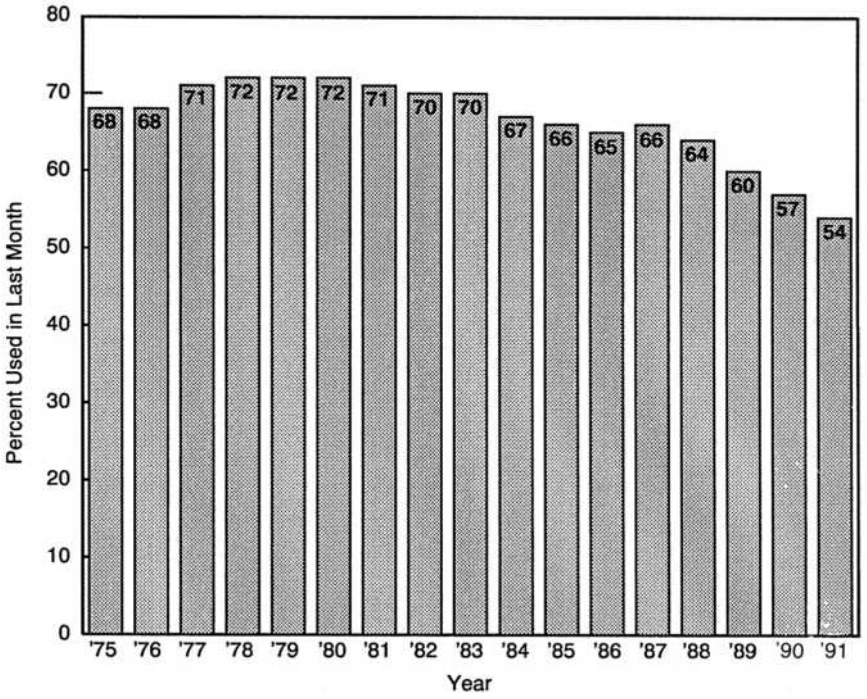

Figure 1
Alcohol Use, U.S. High School Seniors

EFFECTS OF THE DRINKING AGE ON OTHER PROBLEMS

Four studies have appeared on the effects on problems other than car crashes of raising the legal age to 21 (Wagenaar, 1993). One study found that vandalism was down 16 percent in four states that raised the drinking age, and another found that significant reductions in suicides, pedestrian injuries, and other unintentional injuries were associated with higher legal drinking ages. A study of two Australian states that lowered the legal drinking age found 22 percent to 40 percent increases in trauma-hospital admissions for causes other than car crashes, although another study did not confirm these findings. A Massachusetts study found no reductions in nontraffic trauma, suicide, and homicide deaths after the drinking age had been raised, perhaps because many of Massachusetts' residents lived close to bordering states that had lower drinking ages at the time of the study.

EFFECTS OF THE DRINKING AGE ON ALCOHOL USE

Seven studies examined the effect of the legal drinking age on aggregate alcoholic-beverage sales. Effects were mixed—some studies found that alcohol sales were related to the legal age, but others did not find such a relationship. These studies were difficult to interpret because alcohol sales to young drinkers could not be distinguished from sales to older drinkers.

Surveys of the effects on alcohol use among youth of lowering or raising the drinking age have produced conflicting results. Some have found that there was little effect of the legal drinking age on young people's drinking, whereas others have found that lower rates of youth drinking resulted when the legal drinking age was higher (see Wagenaar, 1993, for a review of the fourteen survey studies to date). A major limitation of many of these studies was their use of nonrandom samples of youth from particular high schools, colleges, and local communities rather than samples that were broadly representative of the youth in a state. Surveys of college students, which are usually limited to students in introductory social sciences courses, frequently report finding little effect of the legal drinking age on drinking patterns. In contrast, surveys of random samples of high school seniors and 18- to 20-year-olds across many states, including those entering college and those in the work force, report finding significant reductions in drinking that are associated with higher legal drinking ages

(Maisto & Rachal, 1980; O'Malley & Wagenaar, 1991). It appears, on the basis of the best-designed studies, that raising the legal drinking age results in reductions in young people's drinking. The age-21 policy, however, by no means eliminates this drinking by youth.

ENFORCEMENT OF THE MINIMUM DRINKING AGE

Although drinking among youth is now significantly down from its peak in 1980, when questioned, 54 percent of high school seniors still reported drinking in the last month, and 30 percent reported having had five or more drinks at a time at least once in the previous two weeks (Figures 1 and 2; data from Johnston, O'Malley, & Bachman, 1991). Among the many reasons that youth continue to drink, one important reason is that alcohol remains easily available to them, despite the minimum drinking age law. A recent study by Wagenaar and associates (1993b) indicated that only two of every one thousand episodes of underage drinking resulted in an arrest of the youth involved. More important, only five of every hundred thousand episodes of drinking by underage youth resulted in any action being taken against a store, restaurant, or bar for selling or serving alcohol to a minor. Because the chance of getting caught was so low, half or more of all alcohol outlets tested sold alcohol to youth without requesting any age identification (Preusser & Williams, 1991; Forster et al., 1993).

CONCLUSIONS

Evidence that showed that raising the drinking age to 21 reduced deaths and injuries in car crashes was a major factor in the debate about the drinking age. Other arguments were also heard, such as: Is it unconstitutional to discriminate solely on the basis of age? Federal courts have ruled that the drinking age is not discriminatory, because (1) drinking is not a fundamental right, (2) age is not an inherently suspect criterion for discrimination, (3) and the higher drinking age has a "rational basis" and is "reasonably related" to a legitimate goal of the state to reduce death and injury from traffic crashes (Guy, 1978). In a democracy, laws should have the support of the governed. Repeated polls have shown that the majority of the public clearly supports a legal drinking age of 21. Even among youth under the age of 21, some polls have shown majority support for the minimum drinking age of 21.

Is it logical to set the legal age of drinking at 21, when other rights and privileges of adulthood (e.g.,

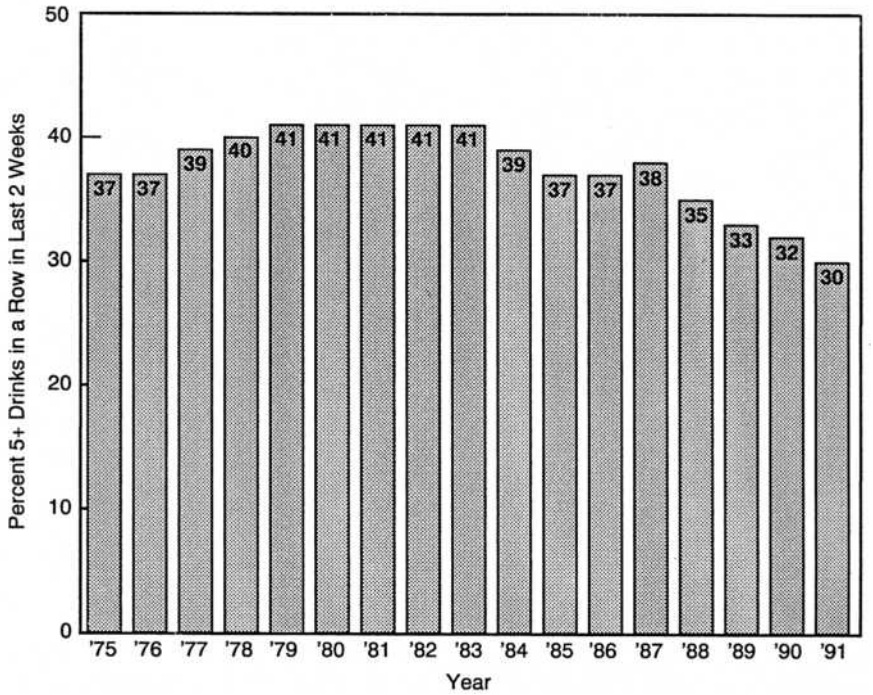

Figure 2
Binge Drinking, U.S. High School Seniors

voting, signing legally binding contracts) begin at age 18? The answer is yes, because we have many different legal ages, varying from 12 to 21, for voting, driving, sale and use of tobacco, legal consent for sexual intercourse, marriage, access to contraception without parental consent, compulsory school attendance, and so forth. Minimum ages are not set uniformly; they depend on the specific behavior involved, and they are arrived at by balancing the dangers and benefits of establishing the particular age.

Some have argued that a minimum drinking age of 21 will make things worse when young people finally get legal access to alcohol. This is the "rubber band" theory whereby it is claimed that prohibiting teenagers from drinking will cause a pent-up demand for the forbidden fruit. At 21, they will break loose and drink at significantly higher rates than they would have if they had been introduced to alcohol earlier. This theory is clearly not supported by research. For example, O'Malley and Wagenaar (1991) found just the opposite results in their nationwide study—that is, persons aged 21 to 24 drank at lower rates if they had to wait until 21 to have legal access to alcohol. A frequently heard related argument is that a minimum drinking age of 21 may reduce car crashes among teenagers, but this will only be a temporary effect if it simply delays those problems until the teenagers reach age 21. This argument is also false. The minimum age of 21 significantly, reduces car crashes among 18- to 20-year-olds, and those injuries and deaths are permanently saved. There is, furthermore, no rebound effect at age 21; in fact, the higher legal age appears to produce benefits, in terms of reduced drinking, that continue into a person's early twenties.

The debate surrounding the legal age for drinking appears settled in the United States. However, other countries (particularly in Europe where drinking ages are typically set at 18) are now examining the research and experience of the United States with increasing interest. Professionals in the areas of public health and traffic safety, as well as other professionals and citizens, are beginning to see the benefits of the age-21 drinking law in the United States, and they are initiating in their own countries the debate on the most appropriate age for legal access to alcohol.

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY (MMPI) This is a self-report test containing 550 statements that can be answered true or false (Levitt & Durkworth, 1984). It was first published in 1943 for use in routine diagnostic assessment. As one of the most widely used psychological tests, the MMPI is sometimes given to alcoholics and drug users to evaluate the psychological effects of substance use as well as the personality characteristics of substance abusers.

The MMPI is scored in subunits or scales. Eight scales comprise the main parts of the clinical profile, which is a standard way of describing the patient's personality features in relation to population norms. The clinical scales measure hypochondriasis, depression, hysteria, psychopathic deviancy, paranoia, psychasthemia, schizophrenia, and hypomania.

The MMPI has three main applications to the diagnosis and study of substance-use disorders. First, it has been used to evaluate the effects of alcohol and drug abuse. Several studies (Pettinati et al., 1982; Babor et al., 1988) have found that MMPI clinical scales measuring depression, paranoia, and other psychiatric symptomatology tend to be higher than normal when alcoholics are drinking—but return to the normal range during periods of abstinence. Second, the MMPI has been used to identify subtypes of alcoholics and drug users that might benefit from specialized treatments. For example, several studies have found three types of alcoholics based on their MMPI profiles: neurotic, psychotic, and psychopathic (Conley, 1981; Nerviano & Gross, 1983). Third, the MMPI has been used in the development of screening tests. The MacAndrew scale (MacAndrew, 1965), for example, is used to measure impulsivity, pressure for action, and acting-out potential that may lead to alcoholism and drug abuse. Persons who score high on the MacAndrew scale are therefore considered to be at risk for substance-use disorders.

MONEY LAUNDERING Obtaining the proceeds of crime has generally been but the first step for profit-motivated criminals. The use of those often has required a second step, whether it be to convert the money into form usable form for licit or illicit purposes, disguise its origins, avoid tax consequences, or make it possible to transport. As the quantity of money to be derived from illegal activity increases, the "laundering" of that money becomes more necessary with the internationalization of commerce, parallel markets, and increased technology. Money laundering has become more sophisticated as a consequence.

The International Financial Action Task Force, convened in 1989 by the G-8 Economic Summit, defines money laundering as "the process by which one conceals the existence, illegal source, or illegal use of the crime proceeds to make those proceeds appear legitimately derived." There are three steps to laundering funds: introducing the proceeds of criminal activity into the legitimate economy (commonly referred to as "placement"), engaging in financial transactions designed to limit the ability to trace the funds (commonly referred to as "layering"); and making the funds available for use (commonly referred to as "integration").

In fact, depending on the objectives of individual criminals as far as convenience and security are concerned, the laundering process can be effected with as few as one and as many as a dozen discrete steps. In its most familiar form, hundreds of thousands of dollars in drug proceeds are taken to a financial institution and exchanged for a cashier's check, which the trafficker can carry around (or out of the country) with much less suspicion than suitcases full of cash. A slightly more involved scenario entails taking the same cash to the same bank, where it is deposited into an account and then sent by wire transfer to a bank in a foreign country, probably a jurisdiction renowned for the relative secrecy it affords customers like the hypothetical drug dealer.

In even more elaborate schemes, the same funds are wire transferred around a circuit of accounts in different countries, bearing the names of legitimate businesses. After the transfer reaches its final destination abroad, the owner in the United States arranges a sham transaction to bring the funds back into this country, often as the proceeds of a purported loan. There are literally countless varieties of laundering schemes, limited only by the imaginations of criminals and a more widespread impatience with transferring one's funds too far away.

Traditionally money laundering was conducted by the same individuals who committed the underlying criminal activity. Today, the sophistication of the process has given rise to the professional money launderer. But as money laundering has become more invaluable for criminals and criminal networks, governments have increasingly come to see the process as a potential vulnerability in the business of crime and have increasingly sought to curtail and prosecute it.

The United States began its legislative efforts to crackdown on money laundering in 1970 by requiring the reporting of cash transactions as part of the Bank Secrecy Act. As now modified, $10,000 in cash deposited in a financial institution or paid to a business will trigger the reporting requirements by the recipient of the funds. And with the Money Laundering Control Act of 1986, codified as 18 USC 1956 and 1957, Congress made it a crime to move certain illegally obtained funds through the commercial or banking system. Enforcement of anti-money laundering legislation was not only accomplished through the traditional penalties of incarceration and fines, but enhanced with powerful forfeiture remedies. Finally, since 1988, federal legislation has required banks to report "suspicious transactions." Individual states have sought to control money laundering with their own statutory and regulatory schemes. Internationally, the Financial Action Task Force and Interpol have approved resolutions, protocols, and recommendations calling for nations to pass legislation that would make money laundering a crime, require reporting of

suspicious transactions, permit forfeiture, and allow extradition in money laundering cases.

U.S. anti laundering legislation is complex and often controversial but, what is perhaps most remarkable is the fundamental change in enforcement policy it represents, wrought by the requirement that non-law enforcement entities be compelled to engage in the systematic reporting of potential illegal activity. As a result, compliance programs requiring the recipient of funds to know its customer's business and to establish baselines from which suspicious activities can be identified are now the norm. For better or for worse, money laundering has brought the private world of commerce into the public field of law enforcement.

MONITORING THE FUTURE *See* High School Senior Survey

MONOAMINE A monoamine is an amine that has one organic substituent attached to the nitrogen atom (as RNH_2). SEROTONIN is such an amine, one that is functionally important in NEUROTRANSMISSION. Chemically, monoamines include the catecholamines (derived from tyrosine) and the indoleamines serotonin and melatonin (derived from the amino acid tryptophan). Acetylcholine also has only a single (but trimethylated) amine, while histamine (a diamine formed from histidine) stretches the condition only slightly. Neurotransmitters in this class share several properties—nanomolar concentrations/milligram protein; neurons (nerve cells) that contain thin, generally unmyelinated axons to many brain regions; and their receptors (except for the cholinergic nicotinic receptor and one of the ten or so subtypes of serotonin receptors) employ second-messenger coupled transduction. Monoamine neurotransmitters are often involved in the action of mind-altering drugs and have been well studied.

MOONSHINE Moonshine (white lightning) is the colloquial term for illegally produced hard liquor—whiskey, rum, brandy, gin, and vodka. The term probably originated around 1785, when it was recorded in a British book on vulgar language—used to describe the white (clear) brandy that was smuggled to the coasts of Kent and Sussex in England. In the New World, moonshine was made in homemade stills, usually from corn, especially in rural areas in the southern United States—before, during, and after Prohibition—and continues to be made today. The ethanol (drinking ALCOHOL) content is usually high, often approaching 80 percent (160 proof). First-run moonshine contains a number of impurities, some of which are toxic, so it is necessary to double and triple distill the liquor to purify it for drinking.

MORNING GLORY SEEDS The seeds of the morning glory, genus *Ipomoea* of the family Convolvulaceae, contain many lysergic acid derivatives, particularly lysergic acid amide. The hallucinogenic properties of some of these derivatives are not known. The seeds can be ingested whole; they can be ground and used to prepare a tea; or the active compound can be extracted using solvents. The seeds have also been used as a source of precursors for the synthesis of LYSERGIC ACID DIETHYLAMIDE (LSD). Since the seeds contain

Figure 1
Morning Glory

lysergic acid derivatives, people ingesting morning glory seeds may feel "different"; however, the experience is not identical to an LSD-type "trip," even though the seeds are marketed on the street as an LSD equivalent.

Although morning glory seeds are easy to purchase legally, many varieties (those sold by reputable garden-supply distributors) have been treated with insecticides, fungicides, and other toxic chemicals—as well as with compounds that will induce vomiting if the seeds are eaten.

MORPHINE Morphine is a major component of OPIUM, a product of the poppy plant (PAPAVER SOMNIFERUM or *P. album*). Named after Morpheus, the Greek god of sleep, morphine is a potent ANALGESIC (painkiller) that is widely used for moderate to severe PAIN. Morphine is one of approximately twenty ALKALOIDS in opium; it was first purified in 1806 and, by the mid-1800s, pure morphine was becoming widely used in medicine. At approximately the same time, the hypodermic needle and syringe was developed, which permitted the injection of the drug under the skin (subcutaneous, S.C.), into muscles (intramuscular, I.M.), or directly into the veins (intravenous, I.V.). Together, these routes of administration are termed parenteral. Injections provide rapid relief of pain and can be used in patients who are unable to take medications by mouth. These advantages led to the wide use of morphine injections during the American Civil War (1861–1865). At that time, the intense euphoria and addictive potential of these agents following injections was not fully appreciated, leading to the addiction of a large number of soldiers. Indeed, morphine was not illegal and was sold over the counter; ADDICTION soon became known as the Soldier's Disease.

Since that time, a major objective of pharmaceutical companies has been to develop, for medication purposes, a nonaddictive analgesic with the potency of morphine. The concepts of PHYSICAL DEPENDENCE and addiction were not clearly differentiated until the late twentieth century, and it is likely that most of those early addicts were attempting to prevent the onset of WITHDRAWAL symptoms. Today very few patients become addicted to opiates, despite the fact that with continued administration all will become physically dependent—this may reflect our better understanding of the drugs plus our ability to take a patient off medications without precipitating withdrawal symptoms.

Morphine produces a wide variety of actions, some desired and others not. The definition of a desired action and a side effect depends on the reason for using the drug. For example, opiates such as morphine can be used to treat diarrhea—but their constipating actions are usually considered an undesirable side effect when they are used to treat pain.

Clearly, the control of pain remains the most important use for morphine. Morphine and other OPIATES relieve pain without interfering with traditional sensations. Patients treated with morphine often report that the pain is still there but that it no longer hurts. Morphine works through *mu* opiate RECEPTORS located both within the brain and the spinal cord. Morphine has a number of other actions as well. Its ability to constrict the pupil is one of the most widely recognized signs of opiate use. In addition, morphine produces sedation and, at higher doses, morphine will depress respiration.

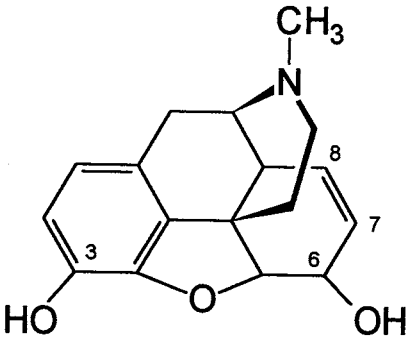

Figure 1
Morphine

Very high doses of morphine will stop breathing entirely—a common occurrence in overdoses.

Morphine also has a major influence upon the gastrointestinal tract, which is the basis for its antidiarrheal effect. Here, morphine decreases the motility of the stomach and intestine, through local actions on the organs themselves, as well as through control systems located within the brain and spinal cord. Other systems can be affected as well. Morphine produces a vasodilation, in which the peripheral blood vessels are relaxed. This can lead to significant drops in blood pressure when a person shifts from a lying to a standing position as the blood is pooled in the legs. This ability to pool blood in relaxed blood vessels can be used clinically to treat conditions such as acute pulmonary edema, an accumulation of fluid within the lungs, which occurs in acute myocardial infarctions (heart attacks). Increasing the capacity of the vascular system by relaxing the blood vessels permits the reabsorption of the lung fluid. Finally, morphine and similar drugs, such as CODEINE, are also effective agents in the control of coughing.

All these effects of morphine can be easily reversed by ANTAGONISTS. NALOXONE is the most widely used antagonist. Given alone, it has virtually no actions; however, low doses of naloxone are able to block or reverse all the actions of morphine described above.

Morphine is given either by mouth or by injection. Oral administration is associated with a significant metabolism of the drug by the liver, explaining its lower potency as compared to that attained by injections. From three to six times more morphine must be taken by mouth to produce the same effects as an injected dose. Thus, higher doses are needed when giving the drug orally. Morphine injections can be given either intramuscularly, subcutaneously, or intravenously. Continuous infusions are also becoming more common, but their use is restricted to physicians expert in the treatment of pain. Morphine has a relatively short half-life in the body, around two hours, and it is usually given to patients every four to six hours. It is extensively metabolized. In the late 1980s, it was discovered that one of these metabolites, morphine-6β-glucuronide, is very potent, far more potent than morphine itself. The importance of this compound with a single morphine dose is probably not great; however, with chronic dosing, the levels of morphine-6β-glucuronide in the blood actually exceed those of morphine—so this metabolite may be responsible for most of morphine's actions. Since this metabolite is removed from the body by the kidneys, special care must be taken when giving morphine to patients with kidney problems.

One common problem associated with morphine is nausea. This is difficult to understand, since nausea does not occur in all patients and often is seen with one drug but not others. This lack of consistency raises questions about whether it is a specific receptor-mediated action or whether it may be a nonspecific side effect.

With chronic use, morphine has a progressively smaller effect, a phenomenon termed TOLERANCE. To maintain a constant action it is necessary to increase the dose. Along with tolerance, morphine also produces physical dependence. Physical dependence (physiological dependence; neuroadaptation) develops as the body attempts to compensate for many of morphine's actions. As long as a person continues to receive the drug, no symptoms are noted. Abrupt cessation of the drug or the administration of an antagonist, such as naloxone, produces a constellation of symptoms and signs termed the withdrawal syndrome. Early symptoms include a restlessness, tearing from the eyes and a runny nose, yawning, and sweating. As the syndrome progresses, one sees dilated pupils, sneezing, elevations in heart rate and blood pressure, and gooseflesh—which is responsible for the term "cold turkey." Cramping and abdominal pains are also common.

Physical dependence (or neuroadaptation) is a physiological response to repeated dosing with morphine and is seen in virtually all patients. Physical dependence, however, is not the same as addiction (drug dependence). Drug dependence (addic-

tion) is defined as drug-seeking behavior, whereas physical dependence is simply a physiological response to the medication. While addiction is common among drug abusers, it is rare when morphine is used for appropriate medical conditions. The reasons for this difference are not clear, and they remain a major issue in understanding and treating morphine addiction.

MOTHERS AGAINST DRUNK DRIVING (MADD) This organization works to reduce DRUNK DRIVING and to help the victims of drunk-driving ACCIDENTS. Many of MADD's members are volunteers who have personally suffered from the results of drunk driving. This national organization was founded by Candy Lightner, whose thirteen-year-old daughter, Cari, was killed by a drunk driver on May 3, 1980. Ms. Lightner was outraged to learn that only two days previously the driver had been released from jail, where he had been held for another hit-and-run drunk-driving crash. Although he had been arrested for drunk driving several times before, he was still driving with a valid California license. Candy Lightner decided to begin a campaign to keep drunk drivers off the road, so that other mothers would not have to suffer the anguish that she was experiencing. On September 5, 1980 (Cari's birthday), MADD was incorporated.

Since then, MADD has evolved into an organization with millions of members and hundreds of local chapters across the United States. Chapters have also been started in Canada, Great Britain, New Zealand, and Australia. Membership is not restricted to mothers of victims or to the victims themselves. Everyone who is concerned about the drunk-driving issue is welcome to join. Funding for

Candy Lightner, the founder of Mothers Against Drunk Driving, holds a photograph of her daughter, Cari, who was killed by a drunk driver on May 3, 1980. (AP Photo)

the organization comes from membership dues and contributions; MADD also applies for and receives grants from federal and state governments and private organizations. Paid staff are employed to provide leadership on the state and national levels. MADD is involved in three major kinds of activity: (1) advocacy for stricter drunk-driving laws and better enforcement, (2) promotion of public awareness and educational programs, and (3) assistance to victims.

THE LEGISLATIVE AGENDA

According to MADD, drunk driving is a violent crime. One of its rallying slogans is, "Murder by Car Is Still Murder!" Over the years, MADD members have worked to generate public support for passage of stricter drunk-driving legislation, punitive sanctions, and more consistent enforcement measures aimed at deterring drunk driving. In the 1980s, intense lobbying efforts were undertaken for the passage of laws making twenty-one the minimum legal age for drinking (now in force in all 50 states). The group believes that this measure has saved thousands of young lives that would have been lost in drunk-driving crashes.

MADD has also lobbied for changes in judicial procedures that would make the system more responsive to victims of drunk driving. For example, in many states victims had been barred from the courtroom during the trial of their own drunk-driv-

ing cases, because their testimony (or even their presence) might prejudice the jury. Owing to the efforts of MADD and other groups, victims' rights bills have now been passed in all states. These ensure that victims will be notified about court hearings and, in most states, allowed to testify about the impact of the crime on their lives. Other lobbying efforts have sought to close legal loopholes that drunk drivers were using to avoid punishment. For example, drivers might have refused to take a breath or blood test for intoxication and have been allowed to plead guilty to a lesser charge. In other cases, drivers were allowed to claim that despite their high blood-alcohol content (BAC), their driving was not really impaired.

MADD has been instrumental in the passage of over 1,000 tougher drunk-driving laws that close these loopholes and institute other deterrence measures, such as mandatory jail sentences for drunk drivers. MADD also supports efforts to require offenders to undergo treatment for alcoholism and/or drug dependency, if this is deemed necessary.

PUBLIC AWARENESS AND EDUCATION

MADD is involved in various efforts to raise public awareness and concern about drunk driving. The "National Candlelight Vigil of Remembrance and Hope" is held in many locations each December, drawing victims together to give public testimony to the suffering that results from drunk driving. During the "Red Ribbon Tie One On for Safety" campaign, which takes place between Thanksgiving and New Year's Day, MADD encourages citizens to attach a red ribbon to their car as a reminder to themselves and others to drive sober. MADD's well-known public awareness campaign of the past used the slogan, "Think . . . Don't Drink and Drive" in public-service announcements on radio and television and in print materials. A more recent campaign, "Keep It a Safe Summer" (KISS) emphasized the need for sobriety during recreational activities that involve driving, boating, or other risky activities. MADD also provides curriculum materials for schools and each year sponsors a poster and essay contest for children on the subject of drunk driving.

ASSISTANCE TO VICTIMS

Programs that provide aid to victims of drunk-driving crashes constitute the heart of MADD's mission. Support groups help victims share their pain with others who understand their feelings. MADD members send "We Care" cards to victims of recent crashes. Specially trained victim advocates offer a one-on-one personal relationship with victims, trying to respond to both their emotional and practical needs. Victims are briefed on their legal rights and on the judicial procedures relevant to their cases. They can call a toll-free number (1-800-GET MADD) for information and for help in case of crisis. MADD also offers death-notification training for police and specialized training for other community professionals, such as clergy and medical workers, who are called upon to assist victims.

"20 × 2000"

Since the founding of MADD in 1980, the percentage of alcohol-related traffic fatalities has steadily decreased from almost 60 percent to around 50 percent. MADD's goal "20 × 2000" seeks to reduce that proportion by an additional 20 percent by the year 2000. Intensified efforts will focus on more effective law enforcement, increased sanctions, and prevention programs that include education for youth and more responsible marketing and service practices in liquor establishments.

DIANNE SHUNTICH

MPTP To circumvent the laws regarding controlled drugs, a chemist attempted to synthesize a derivative of MEPERIDINE. By synthesizing a new derivative not specifically covered by the CONTROLLED SUBSTANCES ACT and existing Drug Enforcement Agency laws and by synthesizing the drug and selling it within the same state, the chemist had hoped to profit but to avoid violation of the laws. This DESIGNER DRUG approach was being widely used to avoid prosecution for selling drugs of abuse—however, in this case a side product was also formed in this reaction, MPTP (1-methyl-4-phenyl-1,2.3,6-tetrahydropyridine). People who bought this mixture on the street quickly developed a neurological syndrome virtually indistinguishable from Parkinson's disease. Initially, the cause of this problem remained unknown. With intense investigation, the blame was placed on the side product in the reaction, MPTP. MPTP had long been used as an intermediate in chemical synthesis and was commercially available. The ability of MPTP to provoke a Parkinson-like syndrome helped explain a report from years ago of a chemist working with this compound suddenly developing a Parkinson-like disease.

The Parkinson-like syndrome is very similar to the symptoms originally described in Parkinson's disease. The most notable aspects of the syndrome are the marked cog-wheel rigidity of the muscles, along with a generalized decrease in movement usually associated with problems initiating the movement. Patients often have difficulty with fine motor skills, such as writing, and with walking, which usually becomes a series of small, shuffling steps termed a "festinating gait"; their greatest problem is starting and stopping. Diminished blinking coupled with a limited facial expression can be very prominent and is termed "masked facies." In Parkinson's disease, patients also have a pill-rolling tremor and a tendency to fall, because

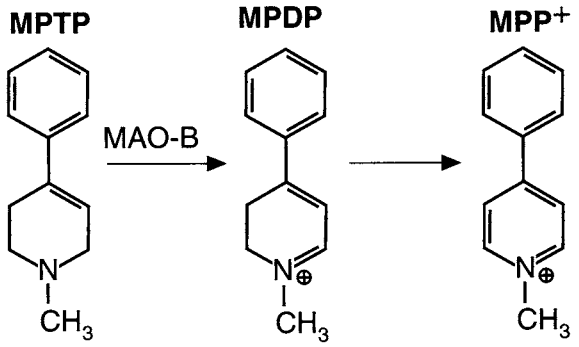

Figure 1
MPTP Conversion to MPDP and MPP+

of problems with blood pressure and the reflexes important to maintaining posture.

Pathologically, Parkinson's disease is noted for a degeneration of pigmented nuclei within the brain, including the substantia nigra. The loss of the dopaminergic NEURONS in the substantia nigra that project to the part of the brain called the striatum is responsible for the motor problems, while the degeneration of other areas of the brain, including the locus coeruleus, are presumably responsible for the autonomic problems. The cause of Parkinson's disease is still not known; treatment is symptomatic. Early studies demonstrated the ability of anticholinergic medications to help with many of the motor symptoms, especially the tremor. However, the drug of choice in the 1990s is L-dopa, a precursor of DOPAMINE. Unlike dopamine, which does not traverse the blood-brain barrier, L-dopa is readily transported into the brain where it is taken up into neurons and converted to dopamine—thereby helping to reduce symptoms caused by loss of dopamine-containing neurons. Replacement of the dopamine can markedly limit the severity of the motor symptoms; however, the duration of this benefit is often limited to only about five years, presumably due to the continued progression of the disease.

MPTP does not bind to OPIOID RECEPTORS and it has no opioid activity, although it is a side product in the synthesis of a meperidine analog. When ingested, it is taken up into neurons containing a catecholamine transporter, greatly limiting the neurons affected. Once in the cell, the drug is converted by the enzyme monoamine oxidase (type B) in a series of steps to another compound, MPP +, which is believed to be responsible for its toxic

actions. The need for the transporter to take up the toxin into the cells partially explains its selective toxicity within the brain. There, this drug destroys the same groups of pigmented catecholinergic neurons affected in Parkinson's disease, including the substantia nigra and the locus coeruleus. The greater sensitivity of pigmented neurons to the toxin is still not completely understood. One hypothesis has been put forward: The color in the neurons is due to the pigment melanin, which actively binds the toxin. Therefore, it has been suggested that this binding results in the accumulation of very high levels of the drug, which persist in the neurons for long periods of time, enhancing its toxicity.

Clinically, MPTP produces a syndrome virtually identical to that seen in Parkinson's disease, but Parkinson's is a progressive degenerative disease, which, over the period of many years, gradually leads to a variety of difficulties with thought and memory. It is not thought that MPTP produces a similar global, diffuse loss of function. The marked similarity, though, has led to the speculation that Parkinson's may be due to the exposure to a toxin similar to MPTP. Since the toxicity of MPTP depends on its conversion by type B monoamine oxidase (MAO-B), it has been suggested that inhibition of this enzyme may prove beneficial. Seligine is a selective MAO-B inhibitor, and early clinical trials suggest that the progression of Parkinson patients taking this medication may be slower than in the control groups.

MULES *See* Slang and Jargon

MULTIDOCTORING Multidoctoring, or double-doctoring, is the practice of obtaining medications from more than one physician without informing the other physician(s) involved of any medication already prescribed. Almost always, the medications involved are PSYCHOACTIVE medications, which may then be abused or misused. Individuals who engage in this behavior may be obtaining the medication for their own use or for the purpose of diverting it to sell on the street. People who seek drugs for the purpose of selling them on the street are often very convincing in their appeals and can get the physician to prescribe the particular drug they are after without even mentioning it by name. In Canada and the United States, legislation prohibits people from acquiring a narcotic prescription without informing the physician of other narcotics that have already been for them prescribed that month. Failure to do so results in criminal charges. Physicians can record a patient's response to the question about other prescribed narcotics, and psychoactive drugs in general, as a means of discouraging multidoctoring.

Physicians themselves may be involved at various levels in multidoctoring and the diversion of drugs to the street. These are the physicians termed "script doctors," who willfully prescribe controlled substances to people seeking them, or who prescribe them as a result of being misled or simply uniformed about the prevalence of multidoctoring and the substances involved. Educating the public regarding the risks of prescription-medication abuse and increasing the skills of physicians in recognizing patients engaged in multidoctoring will help to decrease the diversion and misuse of prescription drugs.

MYTHS ABOUT ADDICTION AND ITS TREATMENT As of the year 2000, many medical facts about the causes of addiction, its nature, the best ways to treat its symptoms, and the possibility of devising a full, permanent cure remain unknown. However, research has already established that the myths listed below are false. Unfortunately, these common myths cause the general public and even many physicians to be needlessly unsympathetic to addicts.

Myth: Addiction is an acute condition, like a broken leg or pneumonia.

Fact: Addiction is a chronic disorder, like arthritis, high blood pressure, asthma, or diabetes.

Myth: Addiction ends when detoxification removes all of the abused substance from the addict's body.

Fact: Changes in the pathways of the brain, which had been caused by the abused substance, persist long after the last particle of the abused substance has left the body.

Myth: Addiction ends when the pain following detoxification (the withdrawal syndrome) is gone.

Fact: At the end of the withdrawal process, pain caused by the body's dependence on the abused substance stops, but the underlying addictive disorder (the cause [or set of causes] which made the person liable to become addicted in the first place) remain.

Myth: When a patient relapses (returns to addiction) after detoxification, then the detoxification of this patient must have failed as a treatment.

Fact: As a chronic disorder, addiction needs ongoing treatment, not just a one-time detoxification. One does not expect a single injection of insulin to cure a diabetic, or any single administration of medicine to relieve a patient forever of arthritis, asthma, or high blood pressure. Each treatment is successful if it improves the condition at the time; each needs to be repeated, often throughout the rest of the patient's life.

Myth: Once an addict is detoxified, as long as he or she does not take the abused substance (or a different abused substance) again, any medical, social, and occupational difficulties that had been associated with the addiction disappear.

Fact: Medical, social, and occupational consequences may last long after an addict has stopped taking any abused substance. Let us assume, for example, that because of alcoholism a person has lost an eye while driving drunk, has been divorced for cruelty and non-support, and has been fired from a job. Getting sober (detoxification) and remaining sober (compliance with the prescribed treatment) do not restore the eye, and usually do not rebuild the broken marriage or regain the lost job. Active alcoholism in an individual may be gone, perhaps forever, but the destruction it may have caused often lasts indefinitely.

Myth: Once an addict is detoxified, as long as he or she does not take the abused substance (or a different abused substance) again, any changes in the pathways of the brain that had been caused by the abused substance disappear, and the brain returns to a more fully healthy state.

Fact: The brain usually returns to a better state of health than when the addiction was at its worst, but it takes a very long time to return completely to the health it enjoyed before the substance abuse began. For many addicts, part of the brain damage is permanent.

Myth: A single, simple course of treatment ought to produce a permanent total cure in an addict.

Fact: As a chronic disorder, addiction needs a lifelong treatment, like diabetes, asthma, arthritis, and high blood pressure.

Myth: Since most persons treated for addiction relapse sooner or later, treatment is by definition unsuccessful, and it makes no sense to try it.

Fact: Treatment is not unsuccessful because further treatments are needed. Suppose a diabetic is brought to the Emergency Room unconscious from extremely high blood-sugar, is treated with insulin, regains consciousness, and reduces the blood-sugar level to normal. The patient will probably need insulin every day for the rest of his or her life, but this emergency treatment was certainly successful. With addiction, as with diabetes, we must see treatment as an ongoing process, successful if at the time it reduces the severity of the disorder. It unfortunately does not have a permanent fix, like setting a broken bone or surgically removing all of a cancer. The goal is improvement, not cure.

Myth: Addiction is voluntary; addicts "bring it on themselves." Everyone has enough free will not to become an addict.

Fact: The choice to try an addictive substance for the first time may be voluntary. Freedom even in this choice may be weakened by such factors as peer pressure, an inherited biological condition predisposing one to a craving for this substance, or a valid reason for taking it once (for example, as a

pain-killer prescribed by one's physician). But as the person slips from the first use to repeated use to misuse to full-fledged addiction and chemical dependence on the substance, freedom of choice diminishes and usually disappears.

Myth: There are no degrees of addiction. It is an all-or-none condition. A person is either a nonaddict and never takes the tiniest amount of an abused substance or is a hopeless addict whose life centers on enjoying maximum amounts of the abused substance (or substances) all day every day for life.

Fact: At one extreme, there is an occasional addict who is satisfied with a low dose of an abused substance and who functions at a normal level at home and on the job. At the other extreme is the addict who regularly takes such huge doses of the abused substance as to pass out in a life-threatening coma. There is, indeed, a formal system for measuring the severity of a patient's addiction and the success of treatment at any given moment. It is called ASI (for Addiction Severity Index). It considers such factors as whether the patient's substance abuse is decreasing, whether the patient is functioning better socially and enjoying better general health (rarely a complete return to the state before the first use of the abused substance), and to what degree, if any, the patient presents a danger to public health and safety (treatment of an alcoholic who continues to drink but has stopped driving after drinking as a result of psychotherapy would be a partial success).

Myth: If treatment were possible, it would cost millions of dollars to treat a single patient. Treatment would cost more than putting a young person in prison for life. In terms of dollar value, treatment would cost even more than a single addict would be apt to steal in a lifetime.

Fact: One study in California showed that the benefits of treatment outweighed the cost of treatment at least four-to-one and as high as twelve-to-one, depending on the type of substance abused and the type of treatment employed. It is nontreatment which costs the United States billions of dollars a year.

Myth: Even if methadone keeps an addict away from heroin, the methadone itself will leave the patient drugged and dangerous, so the patient might as well have stayed on heroin.

Fact: Methadone simply does not cause a drugged state, or even the appearances of a drugged state.

Myth: Even if methadone keeps an addict away from heroin and even if the methadone does not seem to leave the patient drugged and dopey, the patient could function successfully only at undemanding jobs such as raking leaves or checking out books in a library. Even this relatively fortunate patient would be, in effect, in a dangerous position in a job requiring quick reflexes or motor skills, a job such as driving a subway train or operating a fork-lift.

Fact: Many persons on methadone can safely drive trains and run fork-lifts. Some people on methadone cannot do so. The difference between these two groups is not caused by the methadone, but by factors such as lack of education (we don't want people driving trains or busses who can't read traffic signs or safety notices), physical problems (a patient who lost both eyes while driving drunk obviously cannot drive anything), or psychological problems (a patient who panics to the point of paralysis or fainting should not drive). Methadone will not create or increase a danger even for these high-risk jobs, but neither will methadone remove a risk caused by a previously existing condition.

NA *See* Narcotics Anonymous (NA)

NALOXONE Naloxone is an OPIOID ANTOGONIST (i.e., a blocker of morphine-like agents) commonly used to reverse the actions of drugs such as morphine. In the early 1990s, it was the treatment of choice for reversing the life-threatening effects of opioid overdose. Structurally, naloxone is very closely related to OXYMORPHONE, both compounds being derivatives of the opium alkaloid thebaine. Indeed, the structural differences between oxymorphone and naloxone are minimal; they are restricted to a simple substitution on the nitrogen atom. Oxymorphone has a methyl group whereas naloxone has an allyl substitution. This small substitution changes the pharmacology of the compound dramatically. Whereas oxymorphone is a potent ANALGESIC with actions very similar to MORPHINE, naloxone has no analgesic actions by itself and instead has the ability to antagonize, or reverse, virtually all the effects of morphine-like drugs. This ability to reverse opiate actions has proven valuable clinically. However, giving naloxone to opiate addicts will immediately precipitate WITHDRAWAL symptoms.

Naloxone is rapidly metabolized in the liver to inactive compounds, resulting in a relatively brief duration of action. When naloxone is used clinically to reverse the actions of morphine and other OPIATES, care must be taken to ensure that the drug being reversed does not last longer than the naloxone. Should that happen, a patient may be revived by naloxone only to relapse back into a coma or even die from the side effects of the initial opioid AGONIST. Despite its effectiveness following injection, naloxone is not very active when given orally; this, together with its short duration of action, prevents its widespread use as a treatment for opioid addiction.

GAVRIL W. PASTERNAK

NALTREXONE Naltrexone (brand name ReVia) is an OPIOID ANTAGONIST (i.e., a blocker of substances with morphine-like actions), with a structure very similar to another antagonist, NALOXONE. It also closely resembles the potent ANALGESIC (painkiller) OXYMORPHONE. The differences between naloxone and naltrexone are restricted to a simple substitution on the nitrogen atom, with naltrexone having a methylcyclopropyl group, yet this small substitution changes the pharmacology of the compound dramatically. Naltrexone has no analgesic actions by itself and has the ability to antagonize, or reverse, virtually all the effects of morphine-like drugs. Like naloxone, naltrexone will precipitate WITHDRAWAL in physically dependent people.

Naltrexone is rapidly metabolized in the liver, but one of its metabolites is 6-naltrexol, which has some activity and a longer duration of action. In the 1990s, naltrexone was used to treat opiate addiction and for rapid opioid detoxification. Its greater potency than naloxone, along with its greater and longer activity after oral administration, has made this the antagonist of choice (for clinicians) in the treatment of opioid addiction.

In the early 1990s, several research groups reported that naltrexone, when given to alcoholic men following detoxification, reduced the likelihood of relapse to ALCOHOL. This finding secured to support the hypothesis that some of the reinforcing (euphoric) effects of alcohol are due to interactions with naturally occurring opioid systems in the brain.

A study published in 1999 supported this conclusion (Davidson et al., 1999). The findings suggested that naltrexone reduces the desire and craving for alcohol while sometimes increasing the negative side effects, including headaches. Naltrexone has been shown to be especially effective when combined with behavioral therapy.

REVISED BY REBECCA MARLOW-FERGUSON

NALTREXONE IN TREATMENT OF DRUG DEPENDENCE Naltrexone (brand names Trexan^{R}, Revia^{R} [U.S.], Nalorex^{R} [France, U.K.]) is a synthetic antagonist of opiate (morphine-like) drugs, which blocks their actions without itself having any opiate effects. Naltrexone differs from most other pure opiate antagonists in having a relatively long duration of action (at least 24 hours) and being effective when taken by mouth. These characteristics have led to its clinical use as a long-term or maintenance treatment for OPIATE and OPIOID dependence after detoxification. Naltrexone is also being studied experimentally as a possible treatment for cigarette smoking and eating disorders, and was approved in 1995 for treatment of alcoholism.

The use of opiate ANTAGONISTS as treatment for opiate dependence was first proposed by William Martin and Abraham Wikler and their colleagues at the U.S. Addiction Research Center in the early 1960s. They hypothesized that chronic administration of an opiate antagonist, by blocking the pleasurable or rewarding effects of opiate drugs, would lead to the extinction of drug-seeking and drug-taking behavior—since the addict would no longer receive any pleasurable effects from taking

an opiate. With abstinence from opiates, PHYSICAL DEPENDENCE and any chronic withdrawal syndrome would dissipate, removing important factors that cause craving for opiates. They suggested that antagonist treatment would have several advantages over treatment with an opioid such as METHADONE. Since antagonists do not produce any pleasurable effects, the addict would have little incentive to misuse the medication or divert it to illegal channels. Chronic use of an antagonist would not produce physical dependence, and an overdose of antagonist would not cause life-threatening opiate effects such as suppression of breathing. Use of the antagonist in nondetoxified opioid addicts, however, would cause an acute but not life-threatening withdrawal.

HISTORY

The earliest studies of opioid antagonists were not satisfactory, because of drawbacks in the then available antagonists. For example, NALOXONE was short-acting and not very effective when taken by mouth. Nalorphine and cyclazocine had some kappa-opioid effects (i.e., were not pure antagonists), which produced unpleasant side effects.

Further work was stimulated by the SPECIAL ACTION OFFICE FOR DRUG ABUSE PREVENTION created by President Richard M. Nixon in June 1971 as part of a "war on drugs." The 1972 funding legislation for this office called for research on "long-lasting, nonaddictive, blocking and antagonist drugs . . . for the treatment of heroin addiction." Eventually twenty-two studies with naltrexone (which had been synthesized by Blumberg and Dayton in 1965) were conducted at various treatment programs in the United States. These studies demonstrated the safety and effectiveness of naltrexone after detoxification as a long-term treatment for opiate dependence, leading to its marketing in North America and Europe. Its effectiveness, however, was defined in terms of blocking the effects of HEROIN, not in the success of changing the behavior of heroin users.

TREATMENT

Naltrexone is usually used in conjunction with counseling and other rehabilitation services, as part of a structured and monitored treatment program. The best treatment results tend to occur in highly motivated, psychologically healthy addicts who are employed and well-functioning socially, especially when they face severe economic or legal consequences for failing treatment. For example, addicted health professionals whose treatment is required by their professional licensing boards and monitored as a condition of continued licensure will regularly take naltrexone for several years and remain abstinent from opiates. Some programs have reported five-year success rates as high as 95 percent. Most street addicts (e.g., those with unstable living situations who support their drug use by criminal activity) refuse to take naltrexone or, if started in treatment, quickly drop out. This is believed due to the lack of reward effect. Many such addicts prefer maintenance treatment with the synthetic opiate methadone and others find even methadone nonrewarding, so they relapse.

Fifty milligrams of naltrexone block the effects of 25 milligrams of heroin for 24 hours, so the typical weekly naltrexone dose is 350 milligrams. The actual medication schedule is adjusted to the individual patient and may range from 50 milligrams every day to 150 milligrams every third day. Patients are put on the least frequent medication schedule possible to enhance patient cooperation and reduce the number of clinic visits. To further reduce medication scheduling, researchers are working on a depot form of naltrexone that can be injected once a month and which slowly releases the medication into the body.

Care must be taken to avoid administering naltrexone to individuals still physically dependent on opiates. In opiate-dependent individuals, an antagonist will precipitate an acute opiate withdrawal syndrome. While not life-threatening, this syndrome can be extremely uncomfortable, with symptoms such as abdominal cramps; diarrhea; muscle, joint, and bone pain; runny nose (rhinorrhea); and goose bumps (piloerection). To avoid this situation, naltrexone is not administered to patients until they have been free of opiate drugs for at least seven to ten days to allow dependence to wear off. To confirm the absence of dependence, patients may be challenged with the short-acting antagonist naloxone before starting on naltrexone. To shorten the required opiate-free period, some programs are experimenting with combined administration of naltrexone and CLONIDINE, a medication that reduces symptoms of opiate withdrawal.

Naltrexone was shown to reduce the rate of relapse of full-blown compulsive drinking by detoxified alcoholics, although it did not substantially increase the number who were totally abstinent. In one research study, naltrexone seemed to reduce craving for alcohol. In contrast with opioid addicts, alcoholics were more willing to take naltrexone.

NARCANON/SCIENTOLOGY *See* Cults and Drugs

NARCOTERRORISM *See* Terrorism and Drugs

NARCOTIC The term derives from the Greek *narkōtikos*, meaning benumbing. It was originally used (since the fourteenth century) to refer to drugs that produced a stupor associated with pain relief (analgesia), primarily OPIUM and its derivatives, the morphine-like strong ANALGESICS, or the opium-like compounds (OPIOIDS)—these, in moderate doses, dull the senses, relieve pain, and induce profound sleep but in large doses cause stupor coma, or convulsions.

During the nineteenth century, the term was widely used to include a number of agents that produced sleep. Toward the end of the nineteenth century, the term came to imply drugs that could lead to addiction, and so by the turn of the twentieth century, "narcotic" came to describe drugs as diverse as opioids and COCAINE. During the twentieth century, the term became widely used in a legal context to refer to psychoactive drugs and drugs of abuse—those subject to restriction—as "addictive narcotics," whether in fact the agents were physiologically addictive and narcotic or not. This imprecise usage has left the term nebulous, although it is still used extensively in the media and by the general population. The term is no longer used in scientific discourse to categorize drugs.

GAVRIL W. PASTERNAK

NARCOTIC ADDICT REHABILITATION ACT (NARA) Public Law 89-793, the Narcotic Addict Rehabilitation Act (NARA), was passed by Congress in 1966. This legislation was designed to allow the use of the federal courts and criminal-justice system to compel drug addicts to participate in treatment. Several developments provided the context for this legislation. In the early 1960s, the problem of NARCOTIC drug use and ADDICTION were perceived to be increasing. There was also a perception that treatment was not particularly effective and that the RELAPSE rate was high. In response, California, in 1961, and New York, in 1962, passed legislation permitting the CIVIL COM-

MITMENT of narcotic addicts; that is, they could be compelled to accept treatment even if they had committed no crime but could be shown to be using illicit narcotic drugs. In both of these states the legislatures also provided substantial funds to establish residential facilities where addicts could be treated initially as well as aftercare programs to provide supervision following their release from the residential facilities. Several other states, including Illinois, passed similar civil commitment legislation, but only New York and California launched massive programs to implement compulsory treatment and civil commitment.

In January 1963, the Presidential Advisory COMMISSION ON NARCOTIC AND DRUG ABUSE appointed by President John F. Kennedy made a number of recommendations, including the enactment of a federal civil commitment statute that could provide an alternative to prison for confirmed narcotic or marijuana abusers convicted of federal crimes. The advisory commission also recommended increased assistance to states and municipalities to develop and strengthen their own treatment programs.

As passed by Congress, NARA had four titles, or main parts: *Title I* provided that eligible addicts charged with a federal offense could choose civil commitment or treatment instead of prosecution. After being examined by clinicians at a treatment center, an addict, if found suitable, could be committed to the custody of the surgeon general for thirty-six months of institutional treatment and aftercare. *Title II* provided for civil commitment after conviction. *Title III* stated that even if no federal crime had been committed, an addict or a related individual could petition the U.S. attorney in the district of residence and, if local facilities were unavailable, the U.S. District Court could commit the person to custody of the surgeon general for treatment. *Title IV* provided for funding to states and localities to establish or expand treatment for addicts.

Treatment under NARA began to be provided in 1967. The two U.S. PUBLIC HEALTH SERVICE HOSPITALS—in Lexington. Kentucky, and Fort Worth, Texas—which had been treating both addicted federal prisoners and voluntary patients, were redesignated "Clinical Research Centers" and became the sites for the institutional phase of treatment for addicts committed to the Surgeon General under NARA. Aftercare was provided by local programs supported by contracts with the NARA program administered by the Division of Narcotics within the National Institute of Mental Health (NIMH).

From 1967 through 1973, the two clinical centers admitted more than 10,000 NARA patients, 5 percent under Title I, 2 percent under Title II, and 93 percent under Title III. Women made up 15 percent of admissions. Race and ethnicity were noted for admissions between 1970 and 1973, during which time the designations and distribution were as follows: Anglo 43 percent, black 47 percent, Puerto Rican 1 percent, Mexican American 9 percent.

Many of the patients referred were found "not suitable for treatment" (38% at Fort Worth and 51% at Lexington), a designation that generally meant they were too disruptive or antagonistic. Some of this unsuitability was deliberate. Many of those under Title III, while not being charged with a federal crime, were under court pressure because of state or local crimes; as part of plea bargaining with local courts, they agreed to accept commitment under NARA Title III. They quickly learned that the centers would not require them to stay in residence, nor would NARA officials compel them to stay in aftercare. Once released from the centers as "not suitable," they would find ways to convey to the local courts how motivated for treatment they still were and how puzzled they were not to be offered treatment.

The general approach to treatment during the residential phase was based on THERAPEUTIC COMMUNITY principles, which delegate many responsibilities to former addicts and to patients participating in the program. The average duration of the residential phase of treatment was intended to be about 6 months, but of those admitted for examination, only about 35 percent were discharged to aftercare as having completed the residential phase. A number of studies have been conducted on the effectiveness of the NARA program, including aftercare. One study found that only 38 percent of the 35 percent that completed the residential phase remained in aftercare for the full six months after discharge from residential treatment. Reasons for attrition included death, disappearance, recommitment, conviction, and incarceration. One study by Gold and Chatham in 1971 found that 46 percent of addicts in aftercare had used an illegal drug during the month preceding the interview;

about 50 percent were working. Another study found that 87 percent had used narcotics during the first six months after the residential phase; 65 percent had become readdicted.

While this rate of readdiction did not seem as bleak as that seen after the discharge of the early cohorts from Lexington, it was not seen as particularly successful—given the high cost of the six-month residential phase and the high attrition rates. Because of the attrition, the readdiction rate, while not inevitable, was occurring among only the better candidates. Another study by Mandell and Amsel (1973) compared the outcome of those treated compared to those found "not suitable" for treatment. The difference in outcome between the two groups was not significant.

While the legal authority for federal civil commitment remained in effect through the early 1990s, the actual application of NARA felt into disuse in the mid-1970s as more federal prisons developed programs for Title II offenders and as more communities developed their own treatment programs. The use of treatment under civil commitment also declined, because the involvement of courts and expensive legal procedures made it far more expensive than voluntary treatment. In 1971, the Fort Worth facility was closed and turned over to the Bureau of Prisons. The Lexington facility experienced the same fate in 1974.

NARCOTICS ANONYMOUS (NA) Even though the origins and strategies of Narcotics Anonymous (NA) are closely intertwined with those of ALCOHOLICS ANONYMOUS (AA), NA has devised its own unique adaptations to them. There is no question that NA's roots were in the AA program, but it soon came to realize its uniqueness and had to give AA's program its own "spin." Briefly sketched—an energetic, relatively new AA member, while doing twelve-step work in 1944, recruited an alcoholic who was also an abuser of MORPHINE (he used this drug to avoid hangovers). The AA program helped the recruit with alcohol, but not with morphine. He soon found himself an involuntary patient in the U.S. PUBLIC HEALTH SERVICE HOSPITAL in Lexington, Kentucky.

In the meantime, his AA sponsor, who was much puzzled by AA's help with alcohol but not other drugs, was transferred to Frankfort, Kentucky, near the Lexington Hospital. He (dubbed "Houston" in a *Saturday Evening Post* article) reportedly repeated to himself, "I was convinced that the TWELVE STEPS would work as well for drugs as for alcohol" (Ellison, 1954:23). As a result, Houston called on Dr. V. H. Vogel, the director of the Lexington Hospital, and told him of his convictions and his partial success with his AA "pigeon." Further, he offered to start a group directed at drugs in the hospital and Dr. Vogel agreed. The first meeting was on February 16, 1947. Weekly meetings have gone on ever since.

In 1948, an addict known as Dan returned to the hospital from New York City for the seventh time; after a period of severe withdrawal, he began attending the meetings begun by Houston the year before. Dan, Houston, and Houston's former AA "pigeon" spent many hours together apart from the regular meetings. From these discussions Dan experienced a miraculous change, focusing enthusiastically on the twelfth step of AA. In high spirits, he returned to New York hoping to form the first group outside Lexington Hospital—and to call it Narcotics Anonymous. Dan looked up others whom he had known at Lexington and suggested weekly meetings. Only three responded: a barber, a housepainter, and a waiter. No organization was then willing to provide them with a room for a meeting until the Salvation Army provided one. Slips plagued the first few months, but three of the original four remained committed. Slowly, the group grew in size despite disputes over policy—for ex-

ample, should withdrawal from drugs be done "cold turkey" at home or within institutional care? The group finally decided to encourage the latter.

As NA emerged, it faced a dilemma. On the one hand, it wished to use the basic AA strategies and program that were directed solely against alcohol. On the other hand, it attracted, as did AA itself, many who abused a rather wide variety of drugs besides alcohol. At first, NA attracted mainly HEROIN users; later, abusers of BARBITURATES, AMPHETAMINES, and MARIJUANA began to appear at meetings. As the NA groups spread from New York City to other cities, AA groups began to thrash out a policy on the matter that further encouraged the formation of NA groups. The policy came to be known as "cooperation, but not affiliation" between AA and NA. The result was that AA freely offered their steps and traditions to NA for adaptation but steadfastly clung to their singleness of purpose—namely, to encourage alcoholics only to join. Thus, NA had to deal with a variety of drugs, not a sole prominent one, such as alcohol.

In their meetings, NA members tended to focus on the differences between the various drugs they had abused, thereby creating considerable chaos. Slowly, however, they decided on a radical change in the wording of step one. Rather than "We admitted we were powerless over drugs," they decided on "We admitted we were powerless over our ADDICTION." In other words, what all members had in common was a belief that they suffered from a disease of addiction. They pass on their experiences and hopes to the addict who still suffers; they do not become embroiled in the differing features of the various drugs to which members were addicted. In this respect, they are quite different from Cocaine Anonymous, a group that focuses on only one drug, cocaine.

NATIONAL ASSOCIATION OF STATE ALCOHOL AND DRUG ABUSE DIRECTORS The National Association of State Alcohol and Drug Abuse Directors, Inc. is a private, not-for-profit organization comprised of State Alcoholism Agency and State Drug Agency directors. The association promotes and supports the development of alcohol and drug abuse prevention and treatment programs in each state. It provides a variety of services to the states including training, technical assistance, the collection and analysis of data, and the spread of information and technology. It is a tax-exempt organization that does not engage in political activities. It was incorporated in 1971 to support the State Drug Agency Directors and was expanded in 1978 to include The State Alcoholism Agency Directors.

The association's objectives are to:

- Promote the development of alcohol and drug abuse programs in each state;
- Facilitate the evaluation, spread, and exchange of alcohol and drug abuse information among members and other interested parties;
- Aid federal and state governments in the development and execution of alcohol and drug abuse programs;
- Encourage the federal government to interact with the states in the planning and use of government resources;
- Identify common and different alcohol and drug abuse problems among the states and assist in the development of programs tailored to each state's need; and
- Identify problems that require study and research.

In its aim to serve as an educational and informational organization, the association produces several publications. It's studies and publications have been widely cited. The annual report, entitled *State Alcohol and Drug Abuse Profiles*, provides information on state fiscal resources, services, model products, drug trends, and special needs populations. The annual report provides invaluable information which allows for program comparisons between states, replication of creative programs and services by other states, and the dissemination of policy issues. The *State Substance Abuse Quarterly* is distributed to members, National Prevention Network members, and other interested parties. In addition, the association produces "*Special*

Reports", which cover a variety of topics and are published several times each year. Also, it publishes a series of reports covering the effectiveness of alcohol and drug treatment including *Alcohol and Other Drug Treatment: Policy Choices in Welfare Reform* and *Investment in Treatment for Alcohol and Other Drug Problems: It Pays*.

The association has an annual meeting in conjunction with the National Prevention Network.

BELINDA ROWLAND

NATIONAL COMMISSION ON MARIHUANA AND DRUG ABUSE In response to a substantial increase in drug-use patterns in American society during the 1960s and a swirling controversy about changing the marijuana laws to legalize the substances, in 1970, the U.S. Congress established the National Commission on Marihuana and Drug Abuse. The commission was directed to conduct a two-year study, the first on MARIJUANA and the second on "the causes of drug abuse and their relative significance." The commission was composed of thirteen members, four appointed by the Congress (two each from the Senate and the House) and nine appointed by the president. The chair of the commission was Raymond P. Shafer, former governor of Pennsylvania, and the vice chair was Dana L. Farnsworth, M.D., the director of Student Health Services at Harvard University.

In March 1972, the commission issued its first report, *Marihuana: A Signal of Misunderstanding*, which recommended decriminalization of possession of marijuana for personal use. The commission's final report, *Drug Use in America: Problem in Perspective*, was issued in March 1973. The 500-page report was supplemented by 1,000 pages of appendices. In its report, the commission summarized its findings concerning the patterns of drug use in the United States, psychosocial and institutional influences on drug-using behavior, and the social impact of drug dependence and drug-induced behavior. The commission also proposed a framework for policymaking and made specific recommendations in the areas of legal regulation, prevention, treatment and rehabilitation, and research.

The most enduring impact of the commission's final report probably lies in its efforts to revise the vocabulary of the drug field. The commission insisted that ALCOHOL be recognized as the major "drug" problem in the United States; it recommended that the term "drug abuse" be eschewed in favor of more descriptive terminology concerning drug-using behavior. For example, the commission developed a typology of drug-using behavior (experimental, recreational, situational, intensified, and compulsive use) and emphasized the need for different social responses for different patterns of use. In another important contribution, the commission fostered the development of information systems for monitoring changes in drug-using behavior in U.S. society, including national surveys of drug-using behavior among high-school students and in the general population.

The commission strongly endorsed the national treatment strategy, codified in the Drug Abuse Office and Treatment Act of 1972, which aimed to create a national network of treatment services and to establish appropriate incentives for people to seek these services voluntarily. In addition, the commission sought to reorient the rule of the criminal law in implementing a policy of discouraging drug use. In the short term, the commission concluded, the criminal sanction should be retained, but should be utilized primarily as leverage for entry into prevention and treatment programs. In regard to government organization, the commission recommended that the law-enforcement and public-health dimensions of national drug-abuse prevention policy be combined into a single agency.

NATIONAL COUNCIL ON ALCOHOLISM AND DRUG DEPENDENCE (NCADD)

This is the ninth largest voluntary health organization in the United States and the country's major public advocate for the prevention and treatment of alcohol and other drug problems. Working through hundreds of local affiliate councils, state councils, and its New York City and Washington offices, NCADD sponsors prevention and education programs, information and referral services, scientific and clinical consensus development, public policy advocacy, and other related activities.

NCADD was established in 1944 as the National Committee for Education on Alcoholism. As the organization grew, its name and scope enlarged. It became the National Committee on Alcoholism in 1950, was renamed the National Council on Alcoholism in 1957, and assumed its present name in 1990.

The NCADD was the idea of a single individual, Marty Mann; she was its director until her retirement in 1968 and its guiding spirit until her death in 1980. Mrs. Mann was the first woman to recover from alcoholism through the fellowship of Alcoholics Anonymous (AA). During the early years of her recovery, she became increasingly aware that the United States was uninformed about the disease of Alcoholism. The resulting stigma and prejudice kept alcoholics and their families from receiving the medical, social, and spiritual help they needed to recover. The structure and traditions of AA prevented it from becoming a public-health agency similar to those concerned with promoting prevention, treatment, and research for polio, tuberculosis, cancer, and heart disease. With the support of the Yale Center of Alcohol Studies, the council was incorporated and an office was established in the New York Academy of Medicine building in New York City. In 1950, it became independent of Yale. Ruth Fox, a psychiatrist who had helped found the council, became its first medical director in 1958. In 1969, she was succeeded by Frank A. Seixas, an internist.

During its early years, the council's activity consisted mainly of developing literature and presenting lectures to professional and lay groups on the concept of alcoholism as a disease and of organizing local affiliates to pursue this educational process in their own communities. By 1947, a survey of American adults showed that 36 percent believed alcoholism to be a disease, a remarkable increase from 6 percent who held this view in 1943. As interest in alcohol and drug problems expanded, the council developed and then published in 1972 the first set of medical criteria for the diagnosis of alcoholism. In 1976, it sponsored Operation Understanding, in which fifty-two men and women known for their contributions in the areas of government, medicine, industry, science, journalism, and the arts publicly revealed their histories of recovery from alcoholism.

These and other activities have made NCADD an important force in the nation's development of service systems and health policy related to alcohol and other drug problems. NCADD helped establish the first industrial alcoholism programs, the first research society devoted to alcoholism, the first public education campaigns to promote the concept of alcoholism and other drug dependence as diseases, the movement to recognize the special needs of Women with substance-related problems, and the nation's effort to understand and prevent Fetal Alcohol Syndrome (FAS) and other effects in the fetus.

NCADD is also a leader in the U.S. campaign against alcohol-related highway Accidents and in promoting appropriate treatment services for substance-dependent pregnant and postpartum women and their children. Through its local affiliates, NCADD provides direct services, including education and prevention, in school and community settings, as well as information, intervention, and referral counseling, local alcohol- and drug-awareness campaigns, and other related activities.

NATIONAL HOUSEHOLD SURVEY ON DRUG ABUSE (NHSDA) The National Household Survey on Drug Abuse (NHSDA) is the primary source of statistical information on the use of illegal drugs by the population of the United States. Conducted periodically by the federal government since 1971, the survey collects data by administering questionnaires to a scientifically selected sample of persons age twelve and older living in the nation. The primary purpose of the survey is to estimate the prevalence of illegal drug use (i.e., the number of people using illegal drugs) in the United States, and to monitor changes in prevalence over time.

Legal drugs, such as ALCOHOL and TOBACCO, are also covered by the survey. Prevalence rates (the percentage of the population using any type of drug) for various population subgroups and for various types of drugs are generated from the survey data; these rates are compared by analysts to provide insight into which population groups are most prone to illicit drug use—which drugs are most commonly used. These basic statistics are used by the federal government in planning federal policies and funding priorities related to substance abuse. Statistical reports, containing the survey estimates and descriptions of the surveys, have been routinely published. The raw survey data are also available on data tapes, which are widely used by substance-abuse researchers studying the EPIDEMIOLOGY of substance abuse, and the results of these studies are published in professional journals.

HISTORY OF THE NHSDA

The NHSDA traces its origin to a survey conducted by the NATIONAL COMMISSION ON MARIHUANA AND DRUG ABUSE (1970–1972). The commission required baseline data on the public's beliefs, attitudes, and use of marijuana, to satisfy its charge of developing recommendations for legislation and administrative actions in helping to deal with the illicit drug problem. Through a private contractor, they conducted two surveys, in 1971 and 1972. The NATIONAL INSTITUTE ON DRUG ABUSE (NIDA) continued the survey in subsequent years (1974, 1976, 1977, 1979, 1982, 1985, 1988, 1990, and 1991) to satisfy the continuing need for current data. Starting in 1990, the survey was conducted annually. In 1992, sponsorship of the survey was transferred to the newly created SUBSTANCE ABUSE AND MENTAL HEALTH SERVICES ADMINISTRATION (SAMHSA). All the surveys were conducted by private contractors selected by the government.

Expansion of the survey took place in 1985 with the implementation of a new sample design that had larger samples of African Americans and HISPANICS (resulting in a sample size of 8,038). Further expansions took place in 1990, with the intensive sampling of the Washington D.C., metropolitan area as a part of the survey and in 1991, with the addition of five more oversampled metropolitan areas and an increase in the national sample component (for a total sample of 32,594 in 1991). The metropolitan oversampling was continued through 1993, but beginning in 1994 the survey was scaled back to a national sample of about 18,000 interviews. All surveys conducted from 1971 through 1991 were done at a particular time of year, usually spring or fall. In 1992, a continuous data collection design was implemented—with quarterly samples and January to December data collection. A major revision to the survey questionnaire was also implemented in 1994, to improve the validity and reliability of the survey estimates. That year, the NHSDA began using an improved questionnaire and estimation procedure based on a series of studies and consultations with drug survey experts and data users. Because this new methodology produces estimates that are not directly compa-

rable to previous estimates, the 1979-1993 NHSDA estimates presented in the 1998 report were adjusted to account for the new methodology that was begun in 1994.

The 1998 NHSDA employed a sample of 25,500 persons. This sample included augmented samples in California and Arizona (4,903 and 3,869 respectively).

DESCRIPTION OF THE SURVEY METHODOLOGY

Since its inception, the NHSDA has undergone various design changes affecting primarily the sample design, as described above.

Target Population. Prior to 1991, the NHSDA covered all persons age twelve and older living in households in the forty-eight contiguous states. Beginning in 1991, this was modified so that the survey covers the civilian noninstitutionalized population aged twelve years old and older within the fifty states. In addition to including all household residents (except persons on active MILITARY duty), it includes the residents of noninstitutional group quarters (e.g., shelters, rooming houses, dormitories) as well as residents of civilian housing on military bases. Persons excluded from the target population are those with no fixed address, residents of institutional quarters (e.g., jails and hospitals), and active-duty military personnel.

Sample Selection. A complex multistage sample design is used to select people to be respondents in the survey. The first stage of sampling is the selection of nonoverlapping geographic primary sampling units (PSUs), consisting of counties or metropolitan areas. For the second stage of sampling, area segments (constructed from U.S. Census block groups or enumeration districts) are selected within each PSU. Field staff count and list all dwelling units within sample segments and mark their location on a map. A *dwelling unit* is either a housing unit, such as a house or apartment, or a group-quarters unit, such as a dormitory room or a shelter bed. From these listings, a sample of dwelling units is then selected by sampling staff, and interviewers are assigned to contact these dwelling units.

Prior to arrival at the sample dwelling unit (SDU) an introductory letter is mailed to the SDU, briefly explaining the survey and requesting participation. When the interviewer visits the SDU, a brief screening interview is conducted that involves listing all SDU members along with their basic demographic data on a screening form. The interviewer identifies which SDU member(s) will be asked to participate in the survey, based on the composition of the household. This selection process is designed to provide the necessary sample sizes for specified population groups.

Questionnaire Administration. Interviewers control the questionnaire administration, but to enhance respondent confidentiality, drug-use questions are answered by respondents on self-administered answer sheets that are not reviewed by interviewers. As the respondent records the answer choices and completes each answer sheet, they are placed in an envelope. At the end of the interview process, all materials are sealed in this envelope by the respondent and mailed to the data-processing site with no personal identifying information attached.

Data Processing. All questionnaires are received by mail at a data-processing site, where they are checked for critical identification and demographic data and then all data are entered onto a computer data base. Consistency checks and other editing is done, after which statistical tables showing estimates of prevalence rates for various drugs are produced. Data are generally released to the public about six months after the end of data collection. Public use data files are available one to two years after completion of data collection.

STRENGTHS AND LIMITATIONS OF THE NHSDA

Strengths. The major strengths of the NHSDA are its size, continuity, and national representativeness. The survey has a sample large enough to allow comparisons of drug-use prevalence among many different population subgroups each year and over time. The length of the questionnaire and amount of data collected provides a rich data base for examining the characteristics of drug abusers, the relationships of drug use with many demographic and other variables, and the changing patterns of drug use over time. The methodology used, while expensive, has been extensively evaluated and found to be effective (relative to other methodologies) in eliciting valid data from respondents. Through intensive call-back procedures, participation rates in the NHSDA have been excellent. The

1998 participation rate for the screening questionnaire was 93 percent and the participation rate for the main questionnaire was 77 percent.

Limitations. The survey does not cover certain populations likely to have heavy illicit drug use, such as the homeless and prison populations. While these missing populations, because they are small, make little difference in estimating MARIJUANA or ALCOHOL prevalence, rarer behaviors such as HEROIN or CRACK use may be severely underestimated by the NHSDA. Data validity from the survey is also in question because of the self-report methods employed and the voluntary nature of the survey.

MAJOR FINDINGS OF THE SURVEY

The NHSDA has tracked the changing nature of drug abuse since 1971. At the time of the first survey, about 10 percent of the population age twelve and older had ever used illicit drugs. This was estimated to be more than double the rate of lifetime use as of the early 1960s. In 1998, an estimated 13.6 million persons or 6.2 percent of the American population of 12 years of age or older were current illicit drug users, meaning they had used an illicit drug in the month prior to interview. The report for current use showed that more than one drug had been used by some of the total 13.6 million, with a breakdown of this figure as follows: Some 11 million reported using marijuana or HASHISH; an estimated 1.8 million cocaine; and 130,000 heroin. The rate of current use of inhalants by Americans has remained steady since 1991 (between 0.3-0.4 percent of the population). The rate of current use of HALLUCINOGENS and PRESCRIPTION DRUGS was estimated at 0.7 percent and 1.1 percent respectively in 1998. By 1998, the estimated number of persons who had tried methamphetamine in their lifetime was 4.7 million (2.1 percent of the population). Current use of illicit drugs reached a peak in 1979 when the estimate was 25 million, or 13.7 percent of the population.

All the NHSDAs conducted since 1971 have shown that marijuana is the most commonly used illicit drug, with current use at 5 percent in 1998. Marijuana initiation among youths 12-17 was at its highest level ever from 1995-1997. Current cocaine use reached a peak in 1985 at 3.0 percent, but the survey showed declines in cocaine use after 1985, to 0.7 percent in 1992. The percentage of current cocaine use did not change significantly between 1992 and 1998.

The NHSDA has shown varying rates of use in different segments of the population. The highest rates of current illicit drug use were found among young people age 18-20 (19.9 percent) in 1998. The rates of use generally decline in each successively older age group, with only 0.7 percent of persons age 50 and older reporting current illicit use.

The surveys have also shown that while illicit drug use occurs in all segments of society, prevalence rates have been greatest among males; in metropolitan areas; and among high-school dropouts. According to the 1998 report, although the rate of drug use was higher among the unemployed, most drug users were employed. The rate of current illicit drug use was also found somewhat higher among blacks (8.2 percent) than among whites (6.1 percent) and Hispanics (6.1 percent). With respect to absolute numbers in the 1998 report, however, most current illicit drug users were white.

The increase in marijuana use among youths age 12-17 has important implications for substance abuse prevention and treatment efforts. In terms of prevention, there is an obvious need to focus immediate attention on children and adolescents. In the long run, the expanding pool of young people using illicit drugs will probably result in continuing pressure on the substance abuse treatment system in future years, as many new drug users progress to addiction and require intervention.

NEEDLE AND SYRINGE EXCHANGES AND HIV/AIDS The first syringe exchange (SE) program was begun in 1984 in Amsterdam, the NETHERLANDS, out of concern for the spread of hepatitis B among INJECTING DRUG USERS (IDUs). While the hepatitis B virus, hepatitis C virus, and human T cell lymphotropic virus can all cause fatal illness and are all spread through multiperson use (''sharing'') of drug-injection equipment, the threat of human immunodeficiency virus (HIV) has clearly become the dominant force in implementing needle- and syringe-exchange programs throughout the world.

HIV is the causative agent for ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS). As of 1995, HIV infection is eventually fatal; there is no permanently effective treatment for HIV infection. Large-scale vaccination studies began in the late 1980s, and have continued through the 1990s, focusing on some 27 different vaccines (Henderson, 1999). HIV has now been reported among IDUs in sixty countries, from all continents except Antarctica, and from both industrialized and developing nations.

A disturbing facet of HIV infection among injecting drug users is the potential for the rapid spread of the virus through a local population of IDUs. In Edinburgh, Scotland, HIV spread, after the introduction of the virus, into the local population to infect over 40 percent of the local IDUs within two years (Robertson, 1990). In Bangkok, Thailand, the percentage of HIV-infected IDUs (HIV seroprevalence) increased from 2 percent to over 40 percent in less than one year (Vanichseni et al., 1992). In the state of Manipur, India, over 50 percent of the local population of IDUs were infected with HIV within one year after the introduction of the virus into the group. The rapid spread of HIV among IDUs results from a lack of awareness of HIV/AIDS as a local threat and from mechanisms, such as shooting galleries (places where addicts ''shoot up'' together) and dealers' works, that allow large numbers of the population to be exposed to the virus through infected needles and syringes (Des Jarlais et al., 1992). In the United States, injection drug use accounts for 36 percent of AIDS cases overall. In 1998 alone, 31 percent of the 48,269 AIDS cases reported were IDU-related.

Once HIV becomes well established within a population of IDUs, their homosexual and heterosexual partners and transmission to developing fetuses (perinatal) become additional significant problems. In most developed countries, IDUs are the predominant source for both heterosexual and perinatal transmission of HIV. Since AIDS was identified as an epidemic in the United States, 31 percent of all AIDS cases among men have been attributed to injection drug use as compared to the 59 percent of all cases among women (CDC, 1999).

The need to reduce HIV transmission among and from injecting drug users has led to a variety of prevention programs; as a result, there are approximately 113 exchange programs active in 80 U.S. cities in 30 states (Bowdy, 1999). The programs have had differing degrees of effectiveness, although there is evidence that ''education-only'' programs (i.e., those that do not provide the physical means for behavior change) are the least effec-

tive. In almost all industrialized and in some developing countries, increasing legal access to sterile (or uncontaminated) injection equipment has become the most common HIV/AIDS prevention strategy for IDUs. This strategy has included both increased over-the-counter sales of sterile injection equipment and syringe-exchange programs, in which IDUs can turn in used injection equipment for sterile equipment at no cost. A study of a Canadian program in the province of Quebec showed that simple equipment exchanges were not enough. To succeed in reducing the total number of IDUs, transitional and basic support services needed to be part of the program (Belanger, et al., 2000).

Increasing legal access to sterile injection equipment has been politically controversial in several industrialized countries, notably the United States and Sweden, and in many developing countries. Concerns have been raised as to whether increased legal access would lead to increased injection of illicit drugs and whether increased legal access would appear to "condone" illicit drug use or "send the wrong message" about illicit drug use (Martinez, 1992). The decision to support needle exchange programs (NEPs), often lies at the state level. Perhaps the more controversial issue is legalization—or criminalization—of syringe possession. As of 2000, in an effort to reduce the spread of HIV through injection drug use, many states changed laws making it illegal to purchase, sell, or possess syringes without prescriptions. Other states (e.g., New Hampshire) renewed their NEPs. Unfortunately, in most states it is more a political, rather than a public health issue (*AIDS Alert*, 2000).

The empirical data on these questions will be reviewed below, but first it is important to address operational issues involved in needle-exchange programs—to specify how needle exchanges actually work before addressing evaluations of their outcomes.

ORGANIZATIONAL CHARACTERISTICS OF PROGRAMS

At first glance (and regrettably, in much of the public debate about needle-exchange programs thus far), the operation of a program seems quite simple—one would merely select a location and provide staff who could trade new injection equipment for used. In practice, since the exchanges are service-delivery programs, the organization of the services is critical to their effectiveness. Some programs are heavily utilized—for example, the Amsterdam programs exchange approximately 6 million needles and syringes per year in a city with an estimated 3,000 injection drug users. In contrast, the first legal program in New York City traded fewer than 1,000 needles and syringes per year in a city with an estimated 200,000 injecting drug users.

As of 2000, there have been only two comparative studies of the organizational characteristics of the programs (Stimson et al., 1988; Lurie & Reingold, 1993). According to the Stimson study, the most important aspect of an exchange program is "user-friendliness"—which includes such practical considerations as convenient location and convenient hours of operation but also addresses some of the philosophical issues involved.

Perhaps the most vital element of user-friendliness is the nonjudgmental attitude of the staff toward the participants in the exchange. Participants in a user-friendly program are treated with dignity and respect. They are not stigmatized as morally and psychologically impaired simply because they inject psychoactive drugs. The participants are presumed to care about their health and to be capable of taking actions to preserve their health and the health of others.

User-friendliness also requires that exchanges offer multiple services. Other concerns need to be addressed beyond the provision of sterile injection equipment; the sexual transmission of HIV also needs to be prevented, which includes the distribution of condoms without cost. Moreover, the trusting relationships that gradually develop between staff and participants lead to the discovery of other health and social-service needs, especially the need for drug-abuse treatment. The exchange service should be able to respond positively to such needs, either through referral or through on-site provision of assistance. Failure to do so would undermine the trusting relationships between staff and participants.

There is as yet no consensus as to which additional services should be offered on site and which ones through referral—or even a set of available guidelines for how an individual exchange program should decide which additional services to offer on site and which to offer through referral. However, a broad range of additional services are presently being offered on site, with some programs offering conventional drug-abuse treatment, self-help re-

covery groups, women's support groups, tuberculosis screening and treatment, and Bible study groups.

The need to provide on-site (or link to other) services means that exchange programs should be considered a part of a system of services for preventing HIV infection among injecting drug users, rather than as self-sufficient HIV prevention programs.

THE EFFECTIVENESS OF THE EXCHANGES

Studying the effectiveness of an HIV prevention program that facilitates sustained risk reduction is extremely difficult. Research ethics require that comparison subjects be provided with some intervention to reduce their chances of HIV infection, and it is not easy to determine an appropriate comparison condition for a program. Should the comparison subjects be told/permitted to purchase sterile injection equipment from pharmacies? Should they be told to purchase sterile injection equipment through an illicit market? or find some method of disinfecting their own injection equipment?

The logical unit of analysis in an exchange evaluation would be the needs of the local population of injecting drug users rather than the needs of individual drug users. If HIV-infected drug users participate in exchanges—returning their needles and syringes to the exchange rather than passing them on to other injectors—those who do not participate in the exchange would then still be protected against HIV infection. Using communities as the unit of analysis in a clinical trial, however, would be extremely expensive, and it is doubtful that many communities would accept random assignment to experimental or control conditions.

No needle-exchange study as of 2000 has approached a randomized clinical trial. Most studies have measured HIV risk behavior prior to and after participation in an exchange, or have compared risk behavior among exchange participants with that of some other group of injecting drug users. Conclusions about the effectiveness of needle-exchange programs must thus be drawn from the consistency of findings across many methodologically limited studies, rather than rely on a single or small group of methodologically rigorous tests of needle exchange. It should be noted, however, that a consensus panel of the National Institutes of Health in February 1997 concluded that needle exchange programs in general, "show reduction in risk behavior as high as 80 percent in [IDUs], with estimates of a 30 percent reduction of HIV" (Fuller, 1998). In addition, the Centers for Disease Control, the American Medical Association, and the American Public Health Association, have all in some measure acknowledged the amalgam of data pointing toward needle exchange programs as being successful in reducing the incidents of HIV (*AIDS Alert*, 2000).

Jason Farrell, Executive Director of the Positive Health Project, shows syringes to Senior Peer Educator Virgilio Cintron at the agency's offices in New York City, March 6, 2000. The project runs 160 syringe exchange programs for drug users in the U.S. (AP Photo/Jeff Geissler)

Drug Injection. A common concern expressed by opponents to exchange is that the programs would increase the frequency of illicit drug injection. However, research studies have consistently found that such exchange is not associated with any

detectable increase in drug use on either a community or an individual level (Des Jarlais & Friedman, 1992). The most recent review emphasized that "there is no evidence that needle exchange programs increase the amount of drug use by needle exchange clients or change overall community levels of noninjection or injection drug use" (Lurie & Reingold, 1993). Of the eight relevant studies analyzed in this review, three found reductions in injection associated with needle exchange, four found mixed or no effect, and one found an increase in injection compared with the controls. Data from the New York City exchange evaluation (which were not available at the time of Lurie & Reingold's 1993 review) indicate a modest *decrease* in the frequency of injection among participants using needle exchange (Paone et al., 1995).

Moreover, although opponents have often expressed an additional concern—that exchange programs would attract new injectors—the overwhelming number of IDUs participating in exchanges have long histories of drug injection. The mean length of time usually ranges from five to ten years or more. Typically only 1 to 2 percent of exchange participants initiated drug injecting within the previous year. If providing sterile injection equipment had induced large numbers of people to begin injecting drugs, then the numerous studies to date should have observed substantial numbers of new injectors participating in programs.

HIV Injection Risk Behavior. Consistent findings across studies indicate declines in self-reported frequencies of injection with potentially HIV-contaminated needles (Paone et al., 1993). The magnitude of the reduction is difficult to estimate, because studies have used different metrics for risk behavior; some studies have used differences in pre- and post-exchange measurements, while other studies have compared participants with various other groups of drug injectors. Nonetheless, the trend observed from participants in a program has been a reduction in risk behavior, through injection of contaminated equipment, ranging from 50 percent to 80 percent. No studies, however, have shown anything approaching complete elimination of risk behavior among needle-exchange participants.

Exchange programs probably attract drug injectors who are relatively concerned about their health, and it is possible that, even in the absence of exchange programs, these injectors would seek alternative ways of reducing HIV injection risk, such as purchasing sterile injection equipment from pharmacies or on the illicit market. Thus the present data do not permit a conclusion that exchange programs are necessary to reduce risk behavior leading to HIV infection. However, the possibility of alternative methods for reducing injection risk behavior does not imply that an exchange program is not effective in reducing such behavior.

Nevertheless, the fact that very few new injectors participate in exchange programs may be considered a limitation on their current effectiveness. Since IDUs are typically exposed to hepatitis B and C within the first few years of injecting drugs (Hagan et al., 1993), new injectors may already be infected with these blood-borne viruses before they start to obtain sterile injection equipment from an exchange program. Moreover, in cities with high HIV-seroprevalence, even new injectors may be at high risk for HIV infection. In New York City, the estimated seroconversion rate among new injectors is 6.6 per 100 person-years at risk (Des Jarlais et al., 1994). The new injectors may become infected with HIV before they even begin to participate in an exchange program.

Sexual Risk Behavior. While all exchange programs address sexual transmission of HIV to some extent, fewer studies have examined the effect that the program has had on sexual-risk reduction among participants. Moreover, the findings from these few studies are ambiguous. Very few HIV prevention programs for injecting drug users have had consistent success in changing the sexual behavior of IDUs, particularly those with "regular" sexual partners (Friedman et al., 1994). The one exception might be programs that provide HIV counseling and testing, since drug injectors who know they are infected with HIV are more likely to change their behavior to reduce the chances of transmitting HIV to others (Vanichseni et al., 1993).

Effects on HIV and Hepatitis B Transmission. Research data on exchange programs has produced a body of consistent findings with regard to reduced risk behavior through drug injection. Studies within the programs of HIV seroprevalence and HIV seroincidence tend to validate the self-reported risk reduction. Seroprevalence rates have usually stabilized after a program has been implemented, and the rates of new infections among

participants have ranged from zero to less than 1 per 100 person-years at risk to a moderate 4 per 100 person-years at risk in Amsterdam. While there is as yet no definite evidence that participation in a needle exchange reduces the chances of HIV infection, the available HIV seroprevalence and seroincidence data are largely consistent with this hypothesis.

The same behaviors that transmit HIV infection (multiperson use of injection equipment and unprotected sexual behavior) also transmit hepatitis B. The epidemiology of these viruses is similar in most countries, and injecting drug users are at high risk for infection with both viruses.

Studies on the effects of exchange-program participation and new hepatitis B infection among drug users in several cities have shown actual declines (Hagan et al., 1991), further validating self-reported risk reduction and indicating that exchange programs do have a large-scale effect on AIDS risk behavior among injecting drug users.

Discarded Syringes. Exchange programs create an economic value for used needles and syringes—they can be traded for new injection equipment. Thus exchanges have the potential for reducing the amount of used and damaged equipment that is just discarded in the community. Indeed, the one study that systematically examined the amount of discarded injection equipment before and after implementation of an exchange program found a significant reduction in needles and syringes left on sidewalks and in the streets (Oliver et al., 1992)—where anyone might touch it and become a potential victim.

THE "MESSAGE" OF EXCHANGE PROGRAMS

Objections that exchange programs will lead to increased illicit drug use or that they will not lead to reductions in HIV risk behavior can be addressed through empirical studies. Such studies show consistent findings of *no* increase in illicit drug injection and consistent reductions in HIV risk behavior (although it has not yet been possible to translate the reductions in risk behavior into empirically grounded reductions in HIV transmission rates).

A common objection to the programs, however, is that they "condone" or "send the wrong message" about illicit drug use. The symbolism of a government providing the equipment needed for the injection of illicit drugs seems to contradict society's fundamental disapproval of illicit drug injection; and exchange participants do not misinterpret a need to prevent HIV infection as indicating a reversal of prevailing societal attitudes toward the injection of psychoactive drugs.

The important political message in the programs is not that the injection of drugs like HEROIN and COCAINE is a social good but that previous policies on illicit drug use cannot cope with a public-health catastrophe such as HIV infection among injecting drug users, their sexual partners (and theirs), and their children. The "war on drugs" or "ZERO TOLERANCE" approach focused on reducing the use of illicit drugs. It was clearly impractical, however. The ability to treat drug users so that they will never take drugs again is also clearly limited, and letting drug injectors, their sexual partners, and their children die of HIV infection is clearly inhumane—and they have potential for spreading HIV into the rest of society.

Needle-exchange programs suggest the possibility of greatly reducing the individual and social harm associated with drug use through means other than simply reducing drug use or the drug supply. Making the distinction between reducing drug-related harm and reducing drug use per se is the fundamental premise of a new approach to drug policy that has been termed "harm reduction" or "harm minimization." Harm-reduction practices existed before HIV/AIDS and exchange programs and extend well beyond HIV/AIDS issues, but they have come to be recognized as a prototype of the harm-reduction approach in general.

The harm-reduction perspective itself is in a period of rapid development, so it is not possible to state its fundamental principles definitively, but there are at least four common assumptions in descriptions of the approach:

1. Pragmatism is valued over idealism. The nonmedical use of both licit and illicit psychoactive drugs is likely to continue indefinitely, so policies should be formulated on a realistic basis rather than on the basis of a utopian drug-free society.
2. Reducing drug use, particularly very heavy (dependent, addictive) drug use, is the most desirable but not the only means of reducing the individual and social harms associated with psychoactive drug use. Exchange programs to pre-

vent HIV infection are a clear example of reducing harm without necessarily reducing drug use. (Designated-driver programs are another example of harm reduction—reducing the harm associated with alcohol use without necessarily reducing alcohol use.)

3. In general, drug-related harm is likely to be reduced through integrating drug users into society rather than stigmatizing them and treating them as social outcasts.
4. While drug addiction clearly restricts an individual's ability to control his or her own behavior, drug users are still capable of making rational choices and should be offered choices among different ways of reducing the harm that drug misuse causes them and society.

The harm-reduction perspective is thus quite different from the war on drugs-zero tolerance perspective. Harm reduction is also distinct from the LEGALIZATION of all psychoactive drugs. The individual and social harms of drugs are not likely to be minimized by the mass marketing of drugs. NICOTINE/TOBACCO is a prime example of how large-scale harm has been created through uncontrolled merchandising of an addictive drug.

Rather than base policy on a utopian ideal of a drug-free society or the equally implausible ideal of a society that freely uses psychoactive drugs without problems, the harm-reduction perspective calls for basing policy on a flexible pragmatism. Specific harms associated with specific types of drug use can be identified, and concrete steps can be taken to reduce those specific harms. Exchange programs to reduce HIV infection among injecting drug users and their social contacts are a prototypical example of a concrete action for reducing drug-related harm. The message sent by exchange programs thus should not be read as "drug injecting is good" but rather that drug policies should be based on their pragmatic effects instead of on their symbolism.

NETHERLANDS, DRUG USE IN THE Since the 1970s, drug use in the Netherlands has been shaped by a national policy that the Dutch characterize as "harm reduction." To other nations, however, the policy has made the Netherlands the center of European drug use and drug trafficking. The continuing clash between the Dutch perception and the perception of outsiders shows no signs of abating. Dutch officials argue that heroin use is declining, while critics contend that Dutch youth have access to every type of drug.

After the explosion of drug use in the 1960s and 1970s, the Dutch government moved away from prohibition policies. The primary goal of the new policy was to reduce the harm that drugs caused to both the individual and to society. A corollary to this approach was that the efforts to control drugs should not cause more harm than the drugs themselves. The pursuit of this policy by the Netherlands has often resulted in bitter controversy with neighboring countries, which complain that the Dutch drug policy had undermined their own drug-control efforts.

The drug policy of the Netherlands has been characterized by two main principles—the separation of markets and the normalization of drug problems. The separation of markets principle is based on the idea that drugs can be classified pharmacologically according to their socially acceptable risks and that drug markets should be controlled on the basis of this classification. For example, in many societies ALCOHOL is a drug regarded to have acceptable risk, and the market for alcohol is legal for adults, with varying degrees of government regulation. The Dutch have decided that cannabis (MARIJUANA, HASHISH) is also a drug of acceptable risk and therefore should be separated from the markets for HEROIN and COCAINE, which have an unacceptable risk. Because of international regulations, however, the cannabis market cannot be equated with the alcohol market. Thus cannabis trafficking still remains illegal in the Netherlands, although it has a low law-enforcement priority in many jurisdictions. The so-called AHOJ-G policy for marketing cannabis requires limited advertising; no hard drugs—cocaine or heroin—are allowed to be sold or on the premises; no social nuisance; no youths under 16 years of age; only small amounts—less than 30 grams—can be sold. This policy regulates the system of cannabis-selling coffeehouses that have sprung up in most Dutch cities. Additional local regulations require that the coffeehouses provide recreational facilities, such as pool tables, so that something more than cannabis is offered to the customers.

The second main principle of the Netherlands drug policy is the normalization of drug problems. This principle recognizes that much of the harm attributed to the use of hard-drugs, such as heroin, is based on negative definitions that are held by

A man lights up a pipe at "Cannibis Castle" outside Nijmegen, the Netherlands, November 24, 1998. A marijuana user's mecca, the castle, owned by Sensi Seed Company, produces some of the most potent strains of the drug. (AP Photo/ Dusan Vranic)

society and internalized by the drug users. The principle of normalization leads to multiple efforts to reintegrate the heroin user into the community and to fight against his or her stigmatization. This is done by an extensive system of METHADONE MAINTENANCE PROGRAMS (a widely used pharmacotherapy for heroin users), counseling, and social-service support. In addition, drug users are encouraged to organize self-help groups and to mobilize for positive changes in their own subcultures, all in the interest of increasing both their participation in and their responsibility for the development of the drug-use context.

Although the Dutch maintain these policies on drug use, the laws against drug trafficking and the consumption of hard drugs are at least as tough as those of other European nations. However, the Netherlands had emerged in the late 1990s as the leading manufacturer of synthetic drugs such as ecstasy. Moreover, drug enforcement officials in Europe and the United States see the country as a drug supermarket, where smugglers are relatively free to move drugs across borders.

The Dutch government has argued that its policies are working. It cites evidence that the population of heroin addicts is stable and rapidly aging, suggesting that heroin is out of fashion with young people. However, critics note that between 1988 and 1997, heroin addicts treated at Dutch methadone programs increased from 6,500 to 9,800, an increase of 50 percent. In addition, the government points out that the mortality rate among drug users is low, due to effective methadone programs. The number of addicts infected with HIV is very low, which is attributed to methadone programs, needle-exchange programs and counseling. While the government acknowledged that marijuana use had gradually increased in the 1990s, the rate of cannabis use was lower than that of the United States.

Research continues to play an important role in reformulating the system of Dutch drug use. A number of universities, along with private and governmental institutions, conduct research in almost every area of drug use. In general, this research seems to show that the drug policy of the Netherlands has been functioning positively. For example, it seems that the goal of reducing the secondary effects of drug abuse (e.g., AIDS, VIOLENCE) is being reached. Studies of cocaine use in nondeviant social groups in Amsterdam and in the general population of Rotterdam provide evidence that patterns of use do not always lead to negative consequences, although it is difficult to say who can use without experiencing harm. A longitudinal study of heroin addicts indicates that the normalization policy has been effective in diverting the career of heroin addicts from criminal to conventional, but has been less effective in getting heroin users clean. Nevertheless, Dutch policies remain controversial.

CHARLES KAPLAN
REVISED BY FREDERICK K. GRITTNER

NEUROLEPTIC Neuroleptic includes any of a group of drugs that are also called ANTIPSYCHOTICS. Neuroleptics are used as medications in the treatment of acute psychoses of unknown origin, including mania and SCHIZOPHRENIA. The prototype neuroleptic drugs are chlorpromazine (Thorazine), haloperidol (Haldol), clozapine (Clozaril), lithium (Lithonate), and thioridazine (Mellaril). Some of the newer drugs include risperidone (Risperdal), quetiapine (Seroquel), and olanzapine (Zyprexa). The site of action for these drugs (receptor site) is the central nervous system where they produce antipsychotic effects.

These drugs are also used for antianxiety, although other agents are more effective and do not have the long-term side effects that neuroleptics do. Drug therapy alone is not entirely effective in treating psychoses, and it is used in combination with acute and long-term support and medical care. Some neuroleptics are also used in the treatment of nausea, vomiting, alcoholic hallucinosis, neuropsychiatric diseases marked by movement disorders (e.g., Huntington's disease and Gilles de la Tourette's syndrome), pruritus, and intractable hiccough.

REVISED BY DONNA CRAFT

NEURON The gross anatomy of the central nervous system—the brain and spinal cord—was studied in some detail during the seventeenth and eighteenth centuries, but not until the nineteenth century did scientists begin to appreciate that the central nervous system (CNS) was composed of many millions of separate cells, the neurons (also called nerve cells). This discovery had to await technical improvements in the microscope and the development of specialized stains that permitted scientists to observe the microscopic anatomy of the nervous system.

HISTORY

In the 1870s, the Italian anatomist Camillo Golgi developed such a special staining technique, and he and other scientists were then able to observe, under the microscope, the fine structures of the cells of the nervous system. Yet Golgi may not have fully appreciated that what seemed to be an extended network of nerve tissue, in reality, were millions of distinct neurons with fine fibrils touching each other. It was the Spanish scientist, Santiago Ramón y Cajal, who was credited with expounding the neuron theory. In 1906, Golgi and Ramón y Cajal shared the Nobel prize in physiology/medicine for their discoveries on the nature of the nervous system.

Even after the concept of separate neurons was generally accepted, there was controversy for many years about how the separate neurons communicated with each other. At the end of the nineteenth century, many scientists believed they did so by means of electric impulses. Others believed there was a chemical messenger that allowed neurons to influence each other. Around 1920, ACETYLCHOLINE was discovered, the first of many nerve messengers that would be discovered during the subsequent decades.

FUNCTION

The neuron is the basic functional cellular unit of nervous system operations; it is the principal investigational target of research into the actions of addictive drugs and ALCOHOL. An essential feature of the cellular composition of the brain is the high density of extremely varied, heterogeneously shaped neuron groups (see Figure 1). To understand the specialized aspects of neurons and their

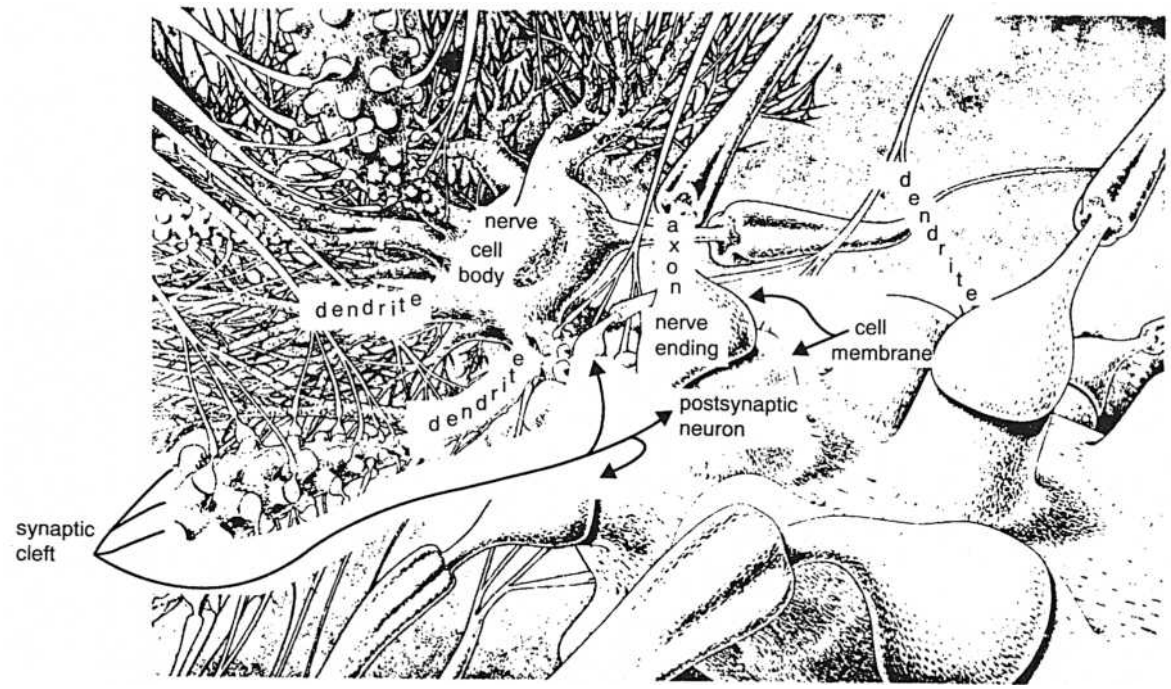

Figure 1
Neuronal Complexity. The complexity of the neuronal network in the brain is demonstrated by this bundle of neurons, which form a vast and ramified structure with their cell bodies, outgrowths, and intercellular contact points.
SOURCE: Modified from Figure 1, in M. J. Kuhar's Introduction to Neurotransmitters and Neuroreceptors, in *Quantitative Imaging*, edited by J. J. Frost and H. N. Wagner. Raven Press, New York, 1990.

function, therefore, requires a discussion of the general structural and functional features characteristic to all neurons and the degree to which unique variations form consistent subsets of neurons.

Neurons share many cellular properties that distinguish them significantly from other cell types in other tissues; those changes within the cell's regulatory processes of greatest interest to researchers of addictive drugs, however, depend on features that form distinctions within the class of cells called neurons. Furthermore, the assembly of individual neurons into functional systems, through highly precise circuitry employing highly specified forms of chemical interneuronal transmission, allows for the sensitivity of a brain to addictive drugs.

In some organs of the body—such as the liver, kidney, or muscle—each cell of the tissue is generally similar in shape and function. Within that tissue, all perform in highly redundant fashion to convert their incoming raw material into, respectively, nutrients, urine, or contractions, which establishes the function of the specific tissue. In the nervous system, the variously (heterogeneously) shaped neurons (see Figure 2), supported by an even larger class of similarly (homogeneously) shaped non-neuronal cells, termed *neuroglia*, convert information from external, or from internal, sources into information ultimately integrated into programs for the initiation and regulation of behavior.

This integrative conversion of sensory information into behavioral programs results from the rich interconnections between neurons, and it depends on the extremely differentiated features of neurons—their size and shape; their extended cell-surface cytoplasmic processes (dendrites and axons); and their resultant interconnections that establish the sources of their incoming (afferent) information

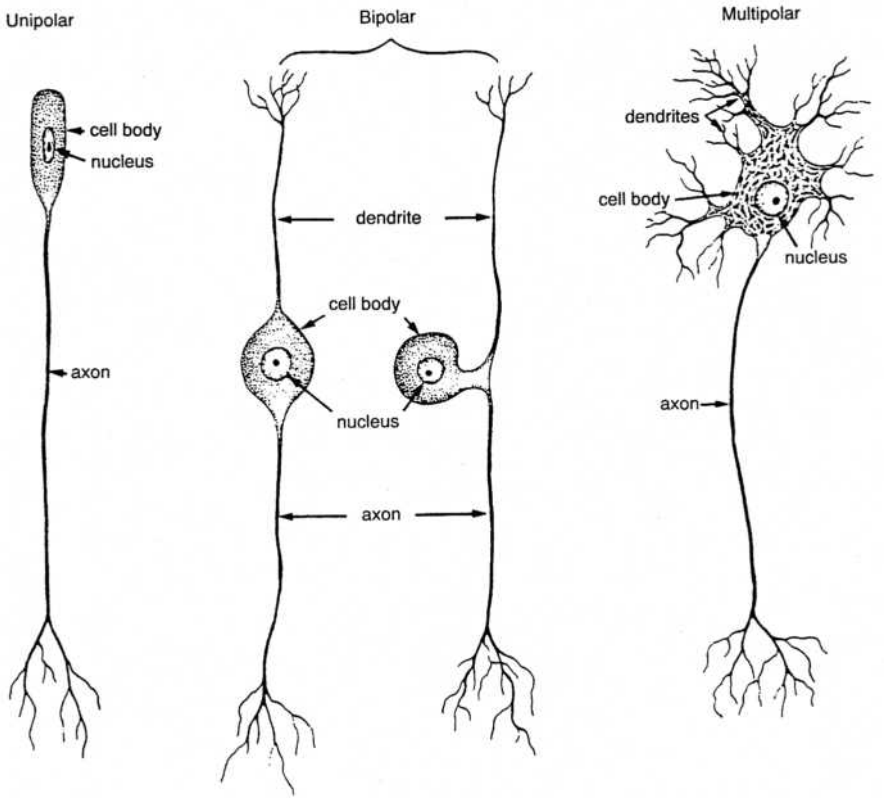

Figure 2
Three Types of Neurons

and the targets of their outgoing (efferent) communication (see also Figure 4).

COMMON FEATURES

As cells, neurons share some features in common with cells in all other organ systems (see Figure 3). They have a *plasma membrane* acting as an external cell wall to form a distinct boundary between the environment inside (intracellular) and outside (extracellular) the cells. The intracellular material enclosed by the plasma membrane is termed the *cytoplasm*. Like all other cells (except red blood cells), neurons have numerous specialized intracellular organelles, which permit them to maintain their vitality while performing their specialized functions.

Thus, neurons have *mitochondria* (singular, mitochondrion), by which they convert sugar and oxygen into intracellular energy molecules, which then fuel other metabolic reactions. Neurons have abundant *microtubules*, thin intracellular tubular struts, by which they form and maintain their often highly irregular cell structure. Neurons are also rich in a network of intracellular membranous channels, the *endoplasmic reticulum*, through which they distribute the energy molecules, membrane components, and other synthesized products required for functioning. Like other cells that must secrete some of their synthesized products for functioning, as neurons do with their neurotransmitters, some parts of the endoplasmic reticulum, the *smooth endoplasmic reticulum*, are specialized for the packaging of secretion products into storage particles, which in neurons are termed *synaptic vesicles*. At the center of the pool of cell material, the *cytoplasm*, neurons possess a *nucleus*, which, as in other nucleated cells, contains the full array of the genetic information characteristic of the individual organism. From this nucleus, selected subsets of genetic information are expressed to provide for the general shared and the specific unshared features of the cell. The nucleus of the neuron cell is enclosed within a membranous envelope that, as in

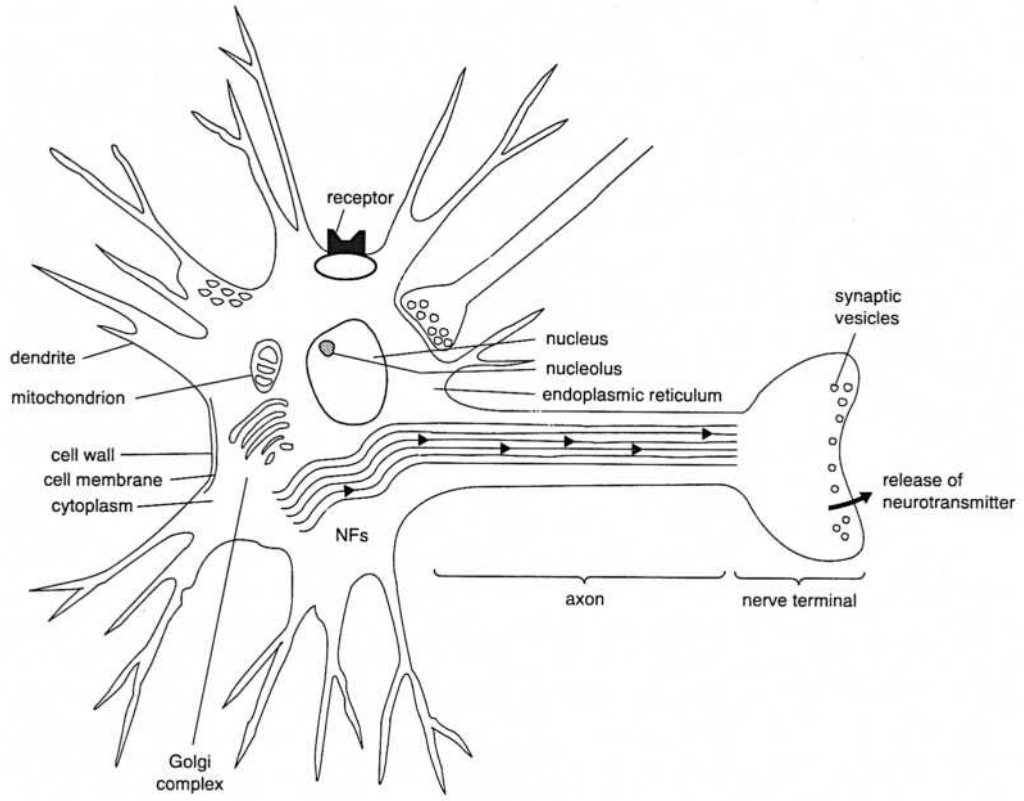

Figure 3
Features of the Neuron

many other types of cells, exhibits multiple nuclear pores through which information can be conveyed to and from the nucleus.

UNIQUE FEATURES

The plasma membrane of neurons differs from that of non-neuronal cells in that it contains special proteins, termed *voltage-sensitive ion channels*. Such channels are conceptually small tubular proteins embedded in the membrane of the neuron, which, when activated under specific conditions, allow positively charged ions of sodium, potassium, and calcium to enter the neuron. The existence of such electrically sensitive channels permits the neuron to become electrically excitable. The expression and selective distribution (compartmentalization) of such electrically excitable channels along its efferent processes, the axons, permit neurons to conduct signals efficiently for long distances; this also accounts for the bioelectrical activity of the brain assessed by *electroencephalography (EEG)*. Similarly, the distribution of such electrically excitable ion channels along the receptive surfaces of the neurons (its dendrites and cell body [soma]) allows them to conduct and integrate signals from all over the extended shape of the neuron.

The smooth endoplasmic reticulum of the neuron is somewhat more elaborate and extensive than other cells that secrete their products; this specialized and extensive smooth endoplasmic system is termed the *Golgi complex* (or *Golgi apparatus*). Discovered accidentally, it was a useful marker for staining the nervous system to distinguish neurons from other cells of the brain when under inspection by microscope.

The nucleus of neurons is often highly elaborated, with multiple creases or infoldings, exhibiting complex configurations, within which are typically dense accumulations of cytoplasmic organelles, and almost always a very distinctive intranuclear clustering of genetic material, the *nucleolus*. Differentiated neurons—neurons whose developmental stage is past the step at which cell-

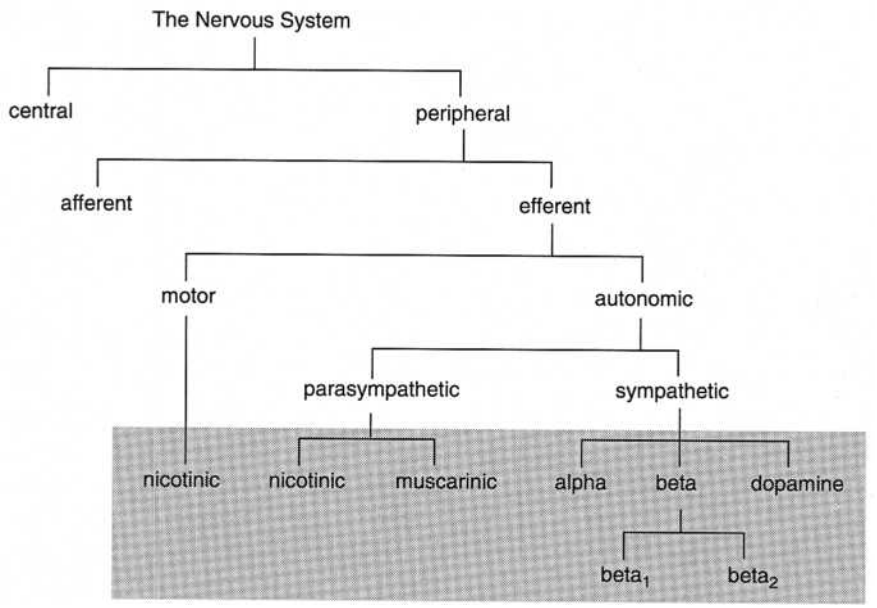

Figure 4
Relationship of Receptor Types. Efferent nerves in the peripheral nervous system. (Receptor subdivisions for alpha and dopaminergic receptors are not included.)

type dedication has occurred—are unable to undergo cell division, in distinct contrast to comparably metabolically active cells in such complex tissues as liver, kidney, muscle, or skin. As a result, mature neurons can repair themselves, up to a point, but are unable to regenerate themselves or respond to their growth factors in a manner that would in other tissues lead to cell division and replacement.

The most distinctive cellular feature of neurons is the degree to which they express unique patterns of size and shape. In mammals, all neurons have highly irregular shapes; such shape variations are categorized in terms of the number of cell surface extensions, or neuronal processes, that the neuronal subset expresses, as in Figure 2.

Some neurons have only one cellular process extending from the surface of a round or nearly round cell body; this form of neuron, a *unipolar* neuron, is typical of invertebrate nervous systems. Typical unipolar neurons are the cells of the dorsal root ganglia, in which a single efferent axon conducts information toward or away from the cell body through a branched axon.

Most neurons of the central nervous system of mammals are multipolar. That is, in addition to the efferent axon, which may also have many subsets of secondary axons, called *collateral branches*, that stem from the main efferent process axon, elaborations may also be expressed from the cell body surface. The latter elaborations are termed *dendrites*, because their shape resembles the limbs of trees. Dendrites protrude from the cell body, and they, as well as the cell body, constitute the receptive surfaces of the target neuron onto which the afferent connections make their synaptic connections.

DISTINGUISHING NEURONS

Since neurons come in so many shapes and sizes, early investigators of the brain sought to make distinctions among them, based in part on their locations, their sizes and shapes, and the connections they could be shown to receive or emit. Every scientist who worked in the formative era of brain research sought to describe a unique subset of neurons that were forever after named for their initial describer or the unique property defined. Thus, we have *Betz neurons*, large layer V-VI neurons of the motor cortex, and *Purkinje neurons*, the major output neurons of the cerebellar cortex, as well as neurons named for their shapes and appearance—*pyramidal neurons* of the cerebral and hippocampal cortices, *mitral* and *tufted neurons* of the olfactory bulb, and *granule cell neurons* of the cerebellar, hippocampal, and olfactory cortices. The last mentioned have relatively compact cell bodies, densely packed together, giving the brain a granular appearance by optical microscopy.

Dendrites and axons exhibit highly distinctive morphological patterns. The surfaces of dendrites and axons can be distinctive in the shapes of their branches. This permits fine discrimination among neurons (stellar, or star-shaped, neurons; chandelier neurons; or mossy or climbing axon fibers). Some neurons exhibit dendrites whose surfaces are smooth (aspiny); others are highly elaborated (spiny), which may serve to enlarge the receptive surfaces and enhance the degree to which such neurons may integrate afferent information.

Similarly, the morphology and stability of the axons may also be highly variable. Some neurons direct their axons to highly constrained targets in a more or less direct route; others may be highly branched, with multiple collateral branches to integrate communications from one cell cluster to many divergent targets. To provide the essential support of anabolic and secretory materials within these highly elaborated cellular structures, neurons have evolved an efficient form of intracellular transport, an energy-dependent, microtubule-guided, centripetal and centrifugal process by which organelles are dispensed to and returned from the distal processes (as well as probable macromolecular signals sensed by pinocytotic-like [fluid uptake] incorporation of such signals by distal dendrites and axons). Such signals may serve as local growth-regulatory factors, allowing even the nondividing neurons to alter their shape and connections in response to activity and signals received from their afferent sources.

NEURONAL IDENTITY

An individual neuron may be referred to on the basis of its size (magnocellular, parvicellular). A layer or "nuclear" cluster of neurons may be referred to by shape (pyramidal, mitral), the morphology of its axon terminals (i.e., *basket cells*, whose axon terminals make basket-shaped terminations on their targets), and its position in a sensory or motor circuit. In the latter classification scheme, those neurons closest to the incoming sensory event or to the outgoing motor-control event are termed *primary sensory* or *motor* neurons, respectively, whereas neurons at more distal positions of circuitry from the primary incoming or outgoing event are termed *secondary*, *tertiary*, and so on, depending on their position in that hierarchy.

In addition to these morphological qualities, neurons may also be separately distinguished on the basis of the functional systems to which they are connected (visual, auditory, somatosensory, proprioceptive, attentional, reinforcing, etc.) and on the basis of the neurotransmitters they employ to communicate with the neurons to which they are connected (cholinergic, adrenergic, GABA-ergic, etc.). Each of those features provides for a multidimensional definition of virtually every neuron in the brain.

FLOYD BLOOM

NEUROTRANSMISSION NEURONS (nerve cells) communicate chemically by releasing and responding to a wide range of chemical substances, referred to in the aggregate as NEUROTRANSMITTERS. The process of *neurotransmission* refers to this form of chemical communication between cells of the central and peripheral nervous system at the anatomically specialized point of transmission, the SYNAPSE (synaptic junctions). Thus, it is convenient to conceive of "the" neurotransmitter for a specific instance of synaptic connections between neurons in one brain location (the source neurons) and their synaptic partner cells (the target neurons) in another neuronal location. For example, the phrase "dopaminergic neurons of the nigro-accumbens circuit" refers to the DOPAMINE-transmitting synaptic connections between the brain neurons of the substantia nigra and their targets in the NUCLEUS ACCUMBENS. Current concepts of neurotransmission, however, require a broader view; they would consider as neurotransmitters all the chemical substances that a given neuron employs to signal the other neurons to which it is anatomically connected (its synaptic targets) and through which that neuron may also be able to influence other neuronal and nonneuronal cells in the adjacent

spatial environment of its circuitry (nonsynaptic targets).

In some cases—more frequent in invertebrate nervous systems, in more primitive vertebrates, and in the embryonic nervous system than in the adult mammalian nervous system—neurons may also communicate "electrically," by direct ionic coupling between connected cells, through specialized forms of intercellular junctions referred to as "gap junctions," or *electrotonic junctions*. Such electrotonic transmission sites are of relatively little direct concern to the actions of addictive drugs and ALCOHOL. In contrast, it is the more pervasive process of chemical neurotransmission that underlies the main molecular and cellular mechanisms by which addictive drugs act—and through which the nervous system exposed to such drugs undergoes the adaptations that may lead to DEPENDENCE, HABITUATION, WITHDRAWAL, and the more enduring changes that persist after withdrawal from the once-dependent state.

The critical characteristic of a substance designated as a neurotransmitter is the manner in which it is made and secreted. To qualify as a neurotransmitter, the release of the substance must be coupled to neuronal activity according to two rather stringent functional rules (see Figure 1).

1. The transmitter substance must be synthesized by the transmitting neuron. In most cases, the substance is made well in advance and stored in small organelles (synaptic vesicles) within the terminal axons of the source neuron, ready for eventual release when called upon.
2. The transmitter substance must be released by that neuron through a special form of activity-dependent, calcium ion (Ca^{2+})-selective, excitation-secretion coupling. Substances released through other nonactivity-coupled and non-Ca^{2+}-coupled mechanisms may be regarded as excretion (as with metabolic byproducts to be degraded), rather than secretion.

The synaptic junction is the site at which the axons of the source neuron physically make most intimate contact with the target neuron to form an anatomically specialized junction; concentrated there are the proteins that mediate the processes of transmitter release (from the presynaptic neuron) and response (by the postsynaptic neuron). Indirect evidence for some neurotransmitter systems has suggested to some scientists a general concept of *nonsynaptic* interneuronal communication, sometimes also referred to as *paracrine* or *volume-transmission* communication, in which the neurotransmitter released by a designated set of presynaptic terminals may diffuse to receptive neurons that are not in anatomic contact. The sets of chemical substances that neurons can secrete when they are active can also influence the non-neuronal cells, such as the cells of the vascular system (the glia) and the inflammatory-immune cells (the microglia).

The activity of neurons can also be modified by substances released from the non-neuronal cells of the central or peripheral nervous system, substances often termed *neuromodulators*. This same term, however, is frequently applied to the effects of neuron-produced transmitter substances whose mechanisms of action and whose time course of effect differ from those of the classic junctional neurotransmitter acetylcholine.

The current research on neurotransmitters and neuromodulators pertinent to drugs and alcohol is devoted to (1) understanding how exposure to addictive drugs may regulate the genes that control the synthesis, storage, release, and metabolism of known neurotransmitters; (2) identifying new substances that may be recognized as neurotransmitters, whose effects may be related to the effects of or reactions to addictive drugs and alcohol; (3) understanding the molecular events by which neurons and other cells react to neurotransmitters in both short-term and long-term time frames (a process often termed *signal transduction*, which cells of the nervous system share with most other cells of the body) and how these processes may themselves be perturbed by the influence of addictive drugs and alcohol; and (4) understanding the operations of neuronal communication in an integrative context of the circuits that release and respond to specific transmitters, and the way in which these neuronal circuits participate in defined types of behavior, either normal or abnormal.

NEUROTRANSMITTER ORGANIZATION

There are three major chemical classes of neurotransmitters.

1. *Amino acid transmitters*: glutamate (GLU) and aspartate are recognized as the major excitatory

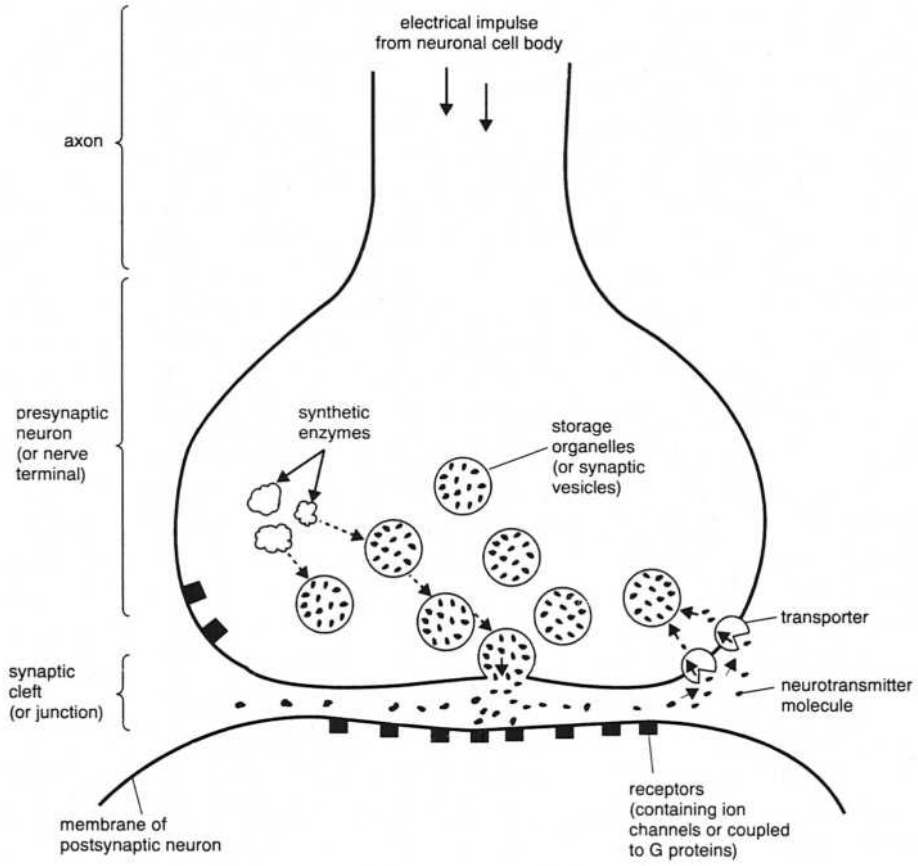

Figure 1

Synapse. Nerve ending from one neuron forms a junction, the synapse, with another neuron (the postsynaptic neuron). The synaptic junction is actually a small space, sometimes called the synaptic cleft. Neurotransmitter molecules are synthesized by enzymes in the nerve terminal, stored in vesicles, and released into the synaptic cleft when an eletrical impulse invades the nerve terminal. The electrical impulse originates in the neuronal cell body and travels down the axon. The released neurotransmitter combines with receptors on postsynaptic neurons, which are then activated. To terminate neurotransmission, transporters remove the neurotransmitter back into the nerve terminal that released it.

transmitting signals; GAMMA AMINOBUTYRATE (GABA) and glycine are the major inhibitory transmitters. These transmitter substances occur in concentrations of one millionth part per milligram (μM/mg) protein. Since they are considered the most frequently employed transmitter substances, they have been linked to many aspects of the actions of addictive drugs.

2. *Aminergic transmitters*: ACETYLCHOLINE, epinephrine (also called adrenaline), NOREPINEPHRINE (also called noradrenaline), DOPAMINE, SEROTONIN, and histamine. The aminergic neurons constitute a minor population of neuronal transmission sites, as reflected in the fact that their concentrations in the brain are roughly 1/1000th that of the amino acid transmitters or one billionth part per milligram (nM/mg protein). Because of their divergent anatomy (a few clusters of aminergic neurons may project onto literally millions of target neurons in many locations of the brain) and the ability of their synaptic signals to produce long-lasting effects, the aminergic neurons represent a very powerful subset of transmission conditions that is important to the effects of addictive drugs. Of particular relevance are the dopaminergic neurons—for their pertinence to the sites of reward for stimulants, opiates, and certain aspects of etha-

nol (alcohol) action—and the noradrenergic and serotonergic neurons—for their association with the phenomena of drug adaptation and tolerance.

3. *Neuropeptides*: of which there are dozens. Peptides are molecules containing a specific series of 2–50 amino acids, chemically arranged in a specialized "head-to-toe" chemical linkage known as a peptide bond. The order and number of the linked amino acids determine the linear structure of the peptide. In the nervous system, peptides, in general, occur in still lower concentrations than do the two prior classes of transmitter, namely at 10–100 trillionth part per milligram (pM/mg) protein. A revolutionary finding has emerged here in concepts of brain system interactions: It would now seem that neuropeptides are almost certainly never the sole signal to be secreted by a central neuron that contains such a signaling molecule, but rather accompany either an amino acid or an amine transmitter (at intrasynaptic terminal concentrations a thousand to a millionfold higher), such sites may even contain a second or third peptide as well.

Neuropeptides are of interest to the molecular and cellular mechanisms of addictive drug and alcohol action, because they may provide the postsynaptic receptors through which the drugs act (as in the case of the opiates and possibly the case for the natural BENZODIAZEPINES) or modify the effects of the presynaptic transmitters (as in the case of the peptide cholecystokinin that accompanies some forms of dopaminergic transmission, through which stimulants act and may modify responses to that amine if cosecreted).

Because of the ability to read the linear sequences of the amino acids, it has become clear that many of the neuropeptides share select small sequences and thus conceptually constitute "families" of peptides. For example, the opioid peptides all share one or more repeats of the amino-acid sequence tyrosine-glycine-glycine-phenylalanine; thus, each of the opioid-peptide genes leads to the expression of a different pre-prohormone by different sets of neurons of the central and peripheral nervous system. The existence of the shared amino-acid sequences implies that at some point in evolution, there may have been only one opioid-peptide signal, which was then duplicated and modified for use by the increasing number of neurons that came with the evolution of the mammalian brain. Such family relationships also exist for other peptide families (oxytocin/vasopressin; the tachykinin peptides; the secretin/glucagon-related peptides; the pancreatic polypeptide-related peptides), whose amino-acid sequences have shown great conservation over large domains of the evolutionary tree, attesting to the high signal quality of these molecules and the transductive mechanisms of their receptors. Other peptides, such as somatostatin and gonadotropin-releasing hormone, have no known family relationships as yet—but the discovery process here is probably not complete.

OTHER TRANSMITTER CANDIDATES

Other kinds of molecules may also be made within neurons to play auxiliary roles in intercellular transmission in the nervous system—from purines like Adenosine Triphosphate, lipids like arachidonic acid and prostaglandins, and steroids similar to those made and released by the adrenal cortex and the gonads. These substances may, in some cases, act as intracellular second messengers to underlie the effects of the aminergic and peptidergic transmitters (see below); they therefore have implicit relevance to the effects of the addictive drugs whether or not they may also serve as primary transmission signals.

Investigators have revealed that under some conditions active neurons may synthesize gaseous signals, such as nitric oxide and carbon monoxide, which can carry rapidly evanescent signals over short distances. The effects of these transmission-related substances will undoubtedly become of increasing importance to the explanations of the mechanisms of action or adaptation to the addictive drugs.

SIGNAL TRANSDUCTION ORGANIZATION

Aside from the chemistry of the neurotransmitter substances, further insight into their role in the actions of addictive drugs arises from the viewpoint of their synaptic physiology and their underlying mechanisms of signal transduction. When neurons respond to neurotransmitters, the ultimate changes in the excitability and metabolic activity of the

responding neuron generally require changes into or out of the cell in the flow of ions (natural chemical elements of the extracellular fluid)—some with positive charge (sodium, potassium, and calcium) and others with negative charge (chloride).

As a general rule, it would appear that every neurotransmitter has more than one form of postsynaptic receptor through which its effects are mediated. Before the ability to characterize these receptors through molecular genetics, such receptor subtypes were identified on the basis of the comparative pharmacological potency of synthetic AGONISTS or ANTAGONISTS of the natural transmitter. With the advent of molecular cloning, however, an even finer subtyping would appear to be required, since many of the conclusions on receptor pharmacological patterns were based on analyses of tissue fractions that undoubtedly contained many molecular forms. A major effort in the future will be to link more explicitly the molecular and pharmacological characterization of neurotransmitter receptor subtypes and to determine which of them are most critical to the effects of, and adaptations to, addictive drugs.

Three major formats have been revealed for the transductive process.

1. *Directly regulated ion channels*. Here the ion channel to be opened is formed by the units of the receptor molecule itself, as recently established by direct cloning of several such receptor-ionophores. Such receptors are now known to be the motif of the nicotinic-cholinergic receptors of the neuromuscular junction and the central nervous system, as well as for the three types of glutamate receptor, the several isoforms of the $GABA_A$ receptor, the glycine receptor, and at least one form of a serotonin receptor.

   Common features of these receptors are (a) they are composed of several (3–5) subunits, called monomers, that apparently may be combined in differing ratios (so-called multimeric recombinations) by various neurons to constitute the "holoreceptor"; (b) each monomer consists of four presumed transmembrane domains; and (c) discrete sections of the receptor monomer, either within the membrane or the cytoplasm, account for their voltage and chemical sensitivity, and for the ease and duration of openings in the ion channel.

2. *Indirectly regulated ion channel-receptors*. This form is based on the similarities between the visual pigment rhodopsin—the molecule used by photoreceptor neurons (rods, cones) to transduce light into signals to other neurons of the retina—and the beta-adrenergic receptor—one of the types of receptors regulated by the amine norepinephrine. This general form of transducing molecule was later found to be the form also used by the cholinergic muscarinic receptor, as well as by most serotonin and all known dopamine receptors, plus all the known peptide receptors.

   The common features of this class are (a) the receptor is a single molecule, with seven transmembrane domains; (b) activation of these receptors by their signaling molecules leads to further interactions of the receptor with other large proteins, some of them enzymes, within or near the plane of the membrane; and (c) the eventual indirect regulation of the ion channel, either the opening or closing of the channel, is then mediated through small molecular intracellular second messengers, such as the calcium ion (Ca^{2+}) or the products of the associated enzymes, yielding intracellular second-messenger molecules, such as cyclic adenosine monophosphate (cAMP), or a lipid such as an inositol phosphate, diacyl-glycerol, or an arachadonic acid catabolite. The essential common second step of such transduction cascades is that the activated receptor interacts with a guanosine triphosphate (GTP)-binding protein (termed a *G-protein*) composed of three monomer subunits. The G-protein complex dissociates to activate the enzyme making the second messenger and, at the same time, hydrolyses the GTP and reassociates to end the cycle of signal generation. The second messenger consequences of this form of transduction, however, may be more enduring—activating one or more enzymes (protein kinases or phosphatases) that can add or remove phosphate groups on structural proteins or other enzymes, to activate or inactivate them. Such events can significantly shift the metabolic state of the responding cell and eventually regulate the expression of its specific genes. One such gene target is the immediate early genes of the nervous system, the proto-oncogenes, discovered some years ago because

of the mutated forms used by oncogenic viruses, which induce cancer in non-neuronal cells.

3. *The receptor-enzyme*. This third major molecular motif of signal transduction has been elucidated recently; although it is already clear that this form does exist in the mammalian brain, it has been studied more in non-neuronal systems. This motif's characteristics are that the receptor for some peptides is itself the enzyme guanylate cyclase, which is directly activated by receptor-ligand binding, leads to an intracellular generation of cyclic guanosine monophosphate, and then to a cascade of events similar to that described for AMP.

SYNAPTIC INTERACTIONS

Most neurons receive synaptic input simultaneously from hundreds of other neurons, each of which employs its own mix of transmitters. The transductive processes underlying these individual events can influence the intensity and duration of the subsequent responses, thereby integrating incoming signals and providing the basis by which activity in assemblies of interconnected neurons results in behavioral output by the brain.

To gain insight into the basis by which the events of neurotransmission can lead to multineuronal programs of interaction, such as those required to initiate responding for an addictive drug, requires knowledge both of the anatomical substrate over which such programs of neuronal activity take place and of the effects of the neurotransmitters at each of the cellular elements of such an interactive ensemble of neurons.

FLOYD BLOOM

NEUROTRANSMITTERS A neurotransmitter is any chemical substance (the first recognized was ACETYLCHOLINE) that NEURONS (nerve cells) secrete to communicate with their target cells (glands, muscles, and other neurons). Neurotransmitters diffuse from their sites of release—from the presynaptic nerve terminal—across the synaptic cleft, to bind to receptors on the external surface of the postsynaptic cell. Activation of these receptors allows for the transmission of commands (excitation, inhibition, and other more complex forms of regulation) from the presynaptic neuron to the postsynaptic cell.

A neurotransmitter is released from a nerve ending, interacts with specific RECEPTORS, and is then either transported back into the presynaptic neuron or destroyed by metabolic enzymes in the synaptic cleft.

Chemically, neurotransmitters are amino acids, amines, or peptides. Peptide transmitters commonly coexist and may be cosecreted with amino acid or amine transmitters.

NEW YORK STATE CIVIL COMMITMENT PROGRAM The New York State Civil Commitment Program was the largest and most expensive drug treatment program of its kind during the 1960s and 1970s. Modeled after the CALIFORNIA CIVIL Addict Program (CAP), it was established in the early 1960s in response to the dramatic rise of New York's heroin-addict population. The first reaction to the problem was expressed in the Metcalf-Volker Narcotic Addict Commitment Act of 1962, which sent arrested addicts to state mental-hygiene facilities for treatment. The total failure of this program prompted New York Governor Nelson Rockefeller to substantially modify and expand the program in 1966 by creating a Narcotic Addiction Control Commission (NACC). NACC was established to administer the New York State Civil Commitment Program, which involved a major statewide network of residential treatment centers.

Six different types of centers handled the following phases of treatment: examination and detention; detoxification, orientation, and screening; residential treatment and rehabilitation; temporary return; indefinite return; and halfway houses. Those who were eligible for treatment at a center included addicted individuals who had been arrested or convicted for a felony or misdemeanor, who had been involuntarily committed by their family or a friend, or who had volunteered to be treated. The treatment process consisted of a period of commitment within the institution, followed by community aftercare. Clients were under the control of the agency for an average of twenty-five months, of which ten months was spent in residence at the institution (Winick, 1988).

THE PROGRAM'S DEMISE

The program reached its peak in 1970 when twenty-four state facilities with 4,100 beds and a staff of over 5,000 provided services to 6,600 addicts. Followup studies of the program at this time were few, but they tended to indicate some positive outcomes (Winick, 1988). After 1970, the program began to lose public support and became a regular political target because of charges of cost overruns, allegations of staff brutality, and questionable administrative procedures (Winick, 1988). There was also a general change in philosophy that drew politicians away from supporting state-run institutions and toward recommending community-based treatment. In addition, political leaders began to move away from rehabilitation and toward harsh criminal sanctions for persons possessing or selling narcotics.

Governor Rockefeller announced in 1971 that he had lost confidence in the New York program and initiated a two-thirds cutback in budget and clients. The number of occupied beds steadily diminished because of these cuts and by 1979 the last two centers shut down(Winick, 1988). From 1966 to 1979, the program had cost approximately $1 billion. By the time the program was closed, each resident was costing an average of $29,000 per year, as compared with $8,500 for a resident in a THERAPEUTIC COMMUNITY and $14,500 for a prison inmate (Winick, 1988). In 1980, the state legislature repealed the civil commitment law.

WHY THE PROGRAM FAILED

Poor planning played a major part in the failure of the program (Winick, 1988). Due to political pressure, the first eight facilities opened in less than a year. Staffing was an immediate problem. The directors of the treatment facilities had inadequate administrative or clinical experience, since they were mostly political and civil service appointees (Inciardi, 1988). Facilities also were ill chosen and they too contributed to staffing deficiencies. NACC purchased underused prisons from the New York Department of Corrections and used them as treatment facilities. Many of the former prison guards were maintained as rehabilitation officers who performed both a counseling and custodial function. These officers were inadequately trained for their new positions, and they often disciplined program participants too harshly (Inciardi, 1988). The result was an environment that did not offer therapeutic benefits and was not conducive to behavioral change.

The screening of candidates for the program, moreover, was not consistent, and the criteria for completion of the program were ambiguous. The reentry and aftercare programs were equally ill

equipped to handle the task at hand. The aftercare "officers" had no authority to arrest a client for violation of aftercare conditions, and their caseloads were too large to allow close supervision. As a consequence, a great number of parolees fled or stopped reporting (Winick, 1988).

Apart from programmatic failings, the civil commitment program began just as political leaders started to move away from rehabilitative models. Governor Rockefeller provides a telling example. By the early 1970s, when heroin addiction showed no signs of abating, Rockefeller decided that the criminal justice system should be directed more forcefully at drug users. In 1973, a group of statutes, popularly known as the Rockefeller laws, went into effect. These laws imposed mandatory prison sentences on those that possessed or sold drugs. These sentences, even for first-time offenders, were very long. Repeat offenders could receive life imprisonment. With the Civil Commitment Program unable to produce reliable and cost-effective results, the impulse to incarcerate drug users proved almost irresistible.

NICOTINE This is a PSYCHOACTIVE chemical substance found in TOBACCO products, including cigarettes, cigars, pipe tobacco, and smokeless tobacco such as chewing (spit) tobacco and oral and nasal SNUFF. The nicotine molecule is composed of a pyridine ring (a 6-membered nitrogen-containing ring) with a pyrrolidine ring (a 5-membered nitrogen-containing ring).

Nicotine can occur in two forms. The active form, called L-nicotine, is found in tobacco plants of the genus Nicotiana. These are chiefly South American plants of the nightshade family (Solanaceae)—annuals cultivated since pre-Columbian times for their leaves, especially *Nicotiana tabacum*. The inactive form, D-nicotine, is not present in tobacco leaves but is formed, to a small extent, in the combustion of tobacco during smoking. These two forms are stereoisomers, meaning that even though they are both nicotine, they have different three-dimensional structures. In pure form, nicotine is a colorless liquid, but it turns brown on exposure to air.

Nicotine is water-soluble and transfers from tobacco to cigarette smoke readily, because it vaporizes easily. Once it is in the body, conditions are ideal for rapid distribution to blood and tissues because nicotine is a weak base, and when un-ionized under alkaline conditions, such as those found in the blood stream, it crosses cell membranes easily.

The primary natural source of nicotine is the tobacco plant, but nicotine is also found in some amount in related plants. Small amounts are in foods of the nightshade family, such as tomatoes and eggplants. Consumption of nicotine has not been limited to the use of plants in which it naturally occurs. In 1828, the German scientists Posselt and Reiman isolated nicotine from tobacco leaves, and since then it has been added to other products. For example, it is widely used as an insecticide in such products as Black Leaf 40, which contains 40 percent nicotine sulfate.

EFFECTS OF NICOTINE

The first pharmacological studies of nicotine were initiated in 1843 by Orfila. Nicotine is an

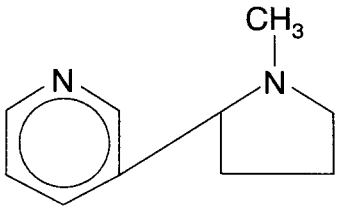

Figure 1
Nicotine

alkaloid that affects major organs, such as the heart and brain. It also affects the body at the cellular level.

Effects in the Body. The actions of nicotine in a human body are complex. They depend on the amount of nicotine given, the route of administration (e.g., by mouth or intravenously), the time over which the dose is given, and the individual's history of exposure to nicotine. In high doses, nicotine produces nausea, vomiting, convulsions, muscle paralysis, cessation of breathing, coma, and circulatory collapse. Such high doses are seen after accidental absorption of a nicotine-containing insecticide or an overdose of nicotine.

In lower doses, such as those used by people who consume tobacco products, the effects are very different. They include a speed up in heart rate and blood pressure; increased force of contraction of the heart; constriction of blood vessels in the skin, producing cool, pale skin; constriction of blood vessels in the heart; relaxation of skeletal muscles; increased body metabolic rate; and the release of hormones such as epinephrine (adrenaline), NOREPINEPHRINE, and cortisol into the bloodstream. Nicotine's effects on the brain are very complex because nicotine works in part by enhancing the release of chemicals that transmit information from one neuron to another (NEUROTRANSMITTERS) by brain cells. For example, nicotine enhances the release of DOPAMINE, which may produce pleasure; norepinephrine, which may suppress appetite; acetylcholine, which produces arousal; SEROTONIN, which may reduce anxiety; and beta ENDORPHIN, which may reduce pain. The development of addiction to nicotine in tobacco users is attributed in part to many of the effects of nicotine that people find desirable.

Effects of Nicotine in Cells. Nicotine binds (attaches) to RECEPTORS on cell membranes that normally bind a neurotransmitter called ACETYLCHOLINE. Acetylcholine, like other neurotransmitters, is a chemical released by nerve endings in the body that binds to certain receptors on cells and activates them. The activated cells communicate messages to other nerves or produce specific actions on body organs. Nicotine activates only certain of the receptors that bind acetylcholine. These receptors are now called nicotinic cholinergic receptors. Using the selective action of nicotine on cholinergic receptors, scientists are able to observe their activity separately from muscarinic cholinergic receptors, receptors activated by a chemical called muscarine. Nicotinic cholinergic receptors are located at the ganglia in the autonomic nervous system, where there are specialized areas for communications between nerves, in the adrenal gland, at the neuromuscular junctions, where nerves attach to and activate muscles, and in many parts of the brain.

The greatest number of nicotine cholinergic receptors in the BRAIN are found in the hypothalamus, hippocampus, thalamus, midbrain, brain stem, and many parts of the cerebral cortex. Nicotine acts on sensory receptors, including those that mediate pain sensations. The effects of nicotine on these specific receptors have been an important tool in studying the effects of neurotransmitters on cell receptors and on the nervous system as a whole. In addition, these studies provide information about the widespread effects of nicotine introduced into the body during tobacco use.

DEVELOPMENT OF PHYSICAL DEPENDENCE ON NICOTINE

Nicotine is the chemical substance responsible for PHYSICAL DEPENDENCE on tobacco products. During the development of physical dependence on a drug such as nicotine, brain chemistry and function change. They return to normal in the presence of nicotine and come to depend on the drug for normal function.

The change that results in normal function in the presence of nicotine is called neuroadaptation or TOLERANCE. When tolerance develops after a period of use of nicotine, or of any drug, the same dose produces less of an effect than previously. Tolerance develops to many of the effects of nicotine. It is well-known that people smoking their first cigarette often experience nausea and vomiting. However, after repeated exposure to cigarette smoke,

these effects disappear. Their disappearance is the development of tolerance to the toxic effects of nicotine in the cigarette smoke. Tolerance also develops to the more desirable effects of nicotine such as pleasure and alertness.

The development of tolerance is associated with changes in the brain, such as an increased number of nicotinic cholinergic receptors found in the brains of smokers studied at autopsy. The changes in the brain correspond to a state in which the tolerant brain comes to depend on nicotine for normal functioning. This state is called physical dependence.

Physical dependence also means that abstinence or WITHDRAWAL symptoms occur when a person who has taken a drug on a regular basis stops taking it. Physical dependence on nicotine has been clearly demonstrated. Thus a person who stops using tobacco after his or her body has adapted to the presence of nicotine will experience withdrawal symptoms in the form of irritability, restlessness, drowsiness, difficulty concentrating, impaired job performance, anxiety, hunger, weight gain, sleep disturbances, slow down in heart rate, and a strong urge for nicotine. In general, withdrawal symptoms are opposite to the effects produced by nicotine when a person who is not tolerant uses it. Thus a person will start using tobacco primarily to experience the desired effects of nicotine, but once the ADDICTION develops, use of tobacco may be chiefly to prevent the emergence of unpleasant withdrawal symptoms. Use of a drug to prevent withdrawal is common in people who are addicted to a drug.

ABSORPTION OF NICOTINE FROM TOBACCO

Nicotine, which is absorbed into the body when tobacco products are used, can be absorbed by different routes and at different rates. Some products deliver nicotine in smoke that is inhaled. In tobacco smoke, nicotine is present in droplets that also contain water and tar. These droplets are carried by gases that include carbon monoxide, hydrogen cyanide, and nitrogen oxides. Such suspended droplets carried by gas are called an aerosol. When the aerosol is inhaled, the droplets are deposited in the small airways of the lungs, from which nicotine is absorbed into the blood stream. After absorption through the lungs, blood containing nicotine moves into the heart and then into the arterial circulation, including the brain. Nicotine reaches the brain within 10 to 15 seconds after a puff on a cigarette. This rapid delivery of nicotine to the brain produces more intensive effects than following slower delivery and provides the close temporal link between SMOKING and the development of addiction.

Nicotine is absorbed into the body in other ways. It can be absorbed in the mouth even if not inhaled in pipe or cigar smoke. In addition, not all tobacco products deliver nicotine through smoke. Chewing tobacco consists of shredded tobacco or plugs of tobacco that are enhanced with licorice and other flavorings. These products are periodically chewed, and the saliva generated is spat out, hence the term *spit tobacco*. Oral snuff is finely cut tobacco. A portion of oral snuff, called a pinch, is placed between the lip and the gum. Nicotine is absorbed from these forms of tobacco more slowly than from inhaled smoke, but the total amount absorbed is similar. Nasal snuff is finely powdered tobacco that is sniffed into the nose, where nicotine is rapidly absorbed.

DOSES OF NICOTINE TAKEN IN TOBACCO

The dose of nicotine absorbed from a cigarette is on average about 1 milligram (mg). The average user smokes about 25 cigarettes a day, an average nicotine intake of 20 to 30 mg daily. The average amount of nicotine absorbed from chewing tobacco or snuff per day is similar to that obtained from cigarettes. A person who smokes 25 cigarettes a day will absorb about 200 grams of nicotine in 20 years of smoking.

NICOTINE-CONTAINING MEDICATIONS

Nicotine is available as a medication, used to assist people in quitting smoking (see articles on NICOTINE DELIVERY SYSTEMS and TREATMENT of smoking and TOBACCO abuse). These medications are meant to provide nicotine to smokers as a substitute for nicotine formerly consumed from tobacco use. Nicotine medications reduce withdrawal symptoms and increase the likelihood that the individual will quit tobacco use. Two forms of nicotine medication are currently available. Nicotine chewing gum (nicotine polacrilex, also known as Nicorette) consists of nicotine in a gum that slowly

releases nicotine during chewing. Each gum is typically chewed for about 30 minutes. People chew up to 16 pieces per day when trying to quit smoking.

Nicotine patches are applied to the skin. They release nicotine slowly through the skin over 16 or 24 hours, depending on the patch used.

Both forms of nicotine-replacement medication deliver doses of nicotine equivalent to that taken in by the average tobacco user. Nicotine chewing gum delivers about 1 to 2 mg per piece. Nicotine patches deliver from 5 to 21 mg, depending on the patch and its strength.

ELIMINATION OF NICOTINE FROM THE BODY

Nicotine in the body is eliminated primarily by breakdown by the liver. The rate of breakdown is such that the level of nicotine in the blood falls about one-half after two hours. This rate is also known as a half-life of two hours. The primary breakdown product of nicotine is cotinine. Cotinine levels in the body are about 10 times higher than those of nicotine. The half-life of cotinine is 16 hours, and cotinine persists in the body for 4 days after a person stops smoking. Cotinine levels can be measured as an indicator of how much nicotine a person is taking in.

NICOTINE ADDICTION

Addiction to nicotine is well documented. The development and characteristics of nicotine addiction are described in detail in a report from the U.S. Surgeon General published in 1988. In this report, *The Health Consequences of Smoking: Nicotine Addiction*, the surgeon general presents criteria for nicotine addiction including the following:

1. Highly controlled or compulsive use. Smokers have great difficulty abstaining. Seventy percent of the 45 million smokers in the United States today report that they would like to quit and can not.
2. Psychoactive effects. Nicotine, as described earlier in this article, has pronounced effects on the brain.
3. Drug-reinforced behavior. Tobacco use is motivated by a desire for the effects of nicotine. People do not smoke cigarettes that do not contain nicotine. Very few people choose to smoke cigarettes that deliver very low doses of nicotine. (See also the article on tobacco.)

Other factors lead to the conclusion that nicotine is addictive:

1. It is used despite harmful effects. Most people know that smoking is harmful to their health and continue to smoke. Many people who have nicotine-related diseases are still unable to quit.
2. RELAPSE following abstinence. Most smokers can quit for a few days or even weeks (abstinence), but most of these smokers return to smoking within a month. Typically, it takes four or five attempts before a smoker is successful at quitting permanently.
3. Recurrent drug cravings. Most smokers have an intense craving or urge to smoke when they have not smoked for some period of time.
4. Tolerance
5. Physical dependence
6. Pleasurable effects

The last three factors were described previously.

Smokers carefully regulate nicotine intake to maintain desired levels of nicotine in the body. Such careful regulation is further evidence that nicotine is addictive. Smokers keep the amount of nicotine obtained from cigarettes constant in two ways.

1. When people are given cigarettes that are labeled as low-yield (see tobacco history for detailed discussions of yields), they smoke more intensively to obtain the same dose of nicotine they were used to obtaining from the higher-yield cigarettes.
2. When they are forced to cut down on the number of cigarettes they smoke each day, they will take in more nicotine per cigarette. Thus when smoking is restricted, smokers tend to maintain the nicotine in their bodies at close to levels maintained during unrestricted nicotine intake.

BEHAVIORAL ASPECTS OF TOBACCO ADDICTION

People continue to smoke both because they enjoy the direct drug effects of nicotine and because use of nicotine becomes associated with other pleasures through learning—for instance, when the pleasurable effects of nicotine occur repeatedly in the presence of specific cues or events in the envi-

ronment. Eventually, those cues and events become a signal to smoke. For example, people often smoke after meals, while drinking a cup of coffee or an alcoholic beverage, during a break from work, while talking on the phone, or while with friends who smoke. After smoking in these situations hundreds of times, the user may find that these situations themselves produce a powerful urge for a cigarette.

There are other learned pleasures that keep people smoking independent of the pharmacological effects of nicotine. Handling of smoking materials, and the taste, smell, or feel of tobacco smoke in the throat, all can become associated with the effects of nicotine and then become pleasurable in themselves. A person who tries to quit must learn to give up not only the pharmacological actions of nicotine but also the aspects of smoking that have become pleasurable through learning. Urges aroused after learning an association between aspects of the environment and the pleasures of smoking prompt relapses in many people who have already overcome withdrawal from nicotine and quit tobacco use.

Smokers report many other reasons for their habit. For example, many smokers, particularly women, smoke to maintain lower body weight. Others seem to use tobacco to control mood disturbances, such as DEPRESSION or ANXIETY.

COMPARISON OF ADDICTION TO NICOTINE AND OTHER DRUGS

Nicotine addiction is similar to and as powerful as addiction to other drugs, such as HEROIN, ALCOHOL, and COCAINE. All these drugs have psychoactivity and produce pleasure. They increase the likelihood that people will spend time looking for them and engaging in rituals while taking them and that users will continue to take them in the face of risk to their well-being and health. The psychoactivity of nicotine is subtle and does not interfere with normal functioning in daily life. Thus nicotine's psychoactivity differs from that of heroin and cocaine, which produces more intense euphoria and may be disruptive to everyday functioning. Despite this difference, nicotine is addictive. A subtle psychoactive effect, especially when experienced with each puff of smoke, taken hundreds of times a day, exerts a powerful effect on behavior over time. The magnitude of effect becomes apparent when each puff of cigarette is considered as a dose of nicotine. A smoker who takes 8 puffs per cigarette and smokes 20 cigarettes per day is receiving up to 160 doses of nicotine per day. The dosing is equivalent to 58,400 doses a year, or 1,168,000 doses after 20 years of smoking.

When difficulty in quitting and relapse after attempting to quit are compared, it becomes apparent that nicotine is even more addictive than other drugs of abuse. Ninety percent of all people who smoke cigarettes are addicted and have difficulty quitting. In contrast, only about 10 percent of people who drink alcohol at all have difficulty controlling use and would be classified as addicted. The percentage of occasional versus addicted users of heroin and cocaine is not known, but when multidrug users are asked about which drug they would have most difficulty giving up, the choice is most commonly nicotine (that is, cigarettes). Relapse rates among adults after cessation of alcohol, heroin, and tobacco use are similar.

NICOTINE ADDICTION IN YOUTH

Ninety percent of all tobacco users begin smoking before the age of 20. The earlier in life one starts smoking, the more likely he or she is to become a regular smoker and the more cigarettes he or she will smoke as an adult. The development of addiction in youth involves a series of steps including

- a trying stage
- experimentation
- regular smoking
- nicotine addiction

The typical interval between trying and addiction is 2 to 3 years.

Initially, young people smoke for social and psychological reasons. The motivations include the influence of parents and friends who are smokers, and the positive images of smoking perpetuated in television and movies and in advertisements in magazines, at music and sports events, and on billboards. Personal factors also play a role. Some include poor school performance, low self-esteem, poor self-image, sensation seeking, rebelliousness, failure to take seriously the adverse effects of tobacco use, and depression or anxiety. While early stages of smoking usually consist of occasional sessions with friends, tolerance develops and withdrawal symptoms are experienced between cigarettes as smoking becomes more frequent. Many

youths report withdrawal symptoms and difficulty quitting. They consider themselves addicted to tobacco.

TREATMENT OF NICOTINE ADDICTION

Treatment of nicotine addiction is discussed in the articles entitled *Treatment: Tobacco*. The approach may be summarized as follows. Initial therapy usually does not include drugs. Smokers are encouraged to pick a day and just stop (go cold turkey). Some smokers participate in formal behavioral therapies, such as those available in smoking-cessation clinics. Those who are unable to stop on their own or with behavior therapies are more likely to be highly addicted to nicotine and are candidates for pharmacological (drug) therapy. The main drug therapies for smoking are nicotine-containing medications such as chewing gum or transdermal (skin) patches.

NICOTINE DELIVERY SYSTEMS FOR SMOKING CESSATION Several nicotine delivery systems have been devised to assist nicotine-dependent cigarette smokers to quit smoking. The aim of nicotine replacement therapy (NRT) is to provide temporary relief of smoking withdrawal symptoms such as irritability, anxiety, hunger, restlessness, drowsiness, and craving for cigarettes. Meanwhile, the smoker learns to resist smoking in a variety of situations that have been repeatedly associated with smoking in the past. Eventually, the goal is to relinquish the alternative source of nicotine, which is not as addictive as cigarettes. Quitting smoking, which is such a difficult task for many, is thereby simplified by breaking the process into two steps:

(1) giving up the habit of smoking while retaining some of the effects of nicotine, and
(2) relinquishing the nicotine, perhaps weeks or months later.

While using an alternative nicotine delivery system, smokers also avoid the intake of hazardous smoke components such as carbon monoxide and cancer-causing "tar."

Nicotine chewing gum. Nicotine chewing gum was the first alternative nicotine delivery system to be approved as a smoking cessation aid. Nicotine is contained in a gum resin and is slowly released upon chewing. Nicotine gum is available in two strengths, containing either two milligrams or four milligrams of nicotine. Of that amount, about half is released on chewing, which is comparable to the amount of nicotine delivered from one or two cigarettes. Unlike cigarette smoking, which delivers the nicotine rapidly into the bloodstream through the lungs, nicotine from the chewing gum is slowly absorbed through the cheeks. Most of the nicotine that is swallowed does not reach the general circulation, because after being absorbed from the small intestine, it is destroyed as it passes through the liver. The use of nicotine gum has been shown to double success rates in smoking cessation. Problems with the gum include unpleasant taste, jaw soreness, stomach upset from nicotine that is swallowed, and inconsistent levels of nicotine in the bloodstream.

Nicotine skin patches. Partly to overcome the unpleasant side effects of nicotine chewing gum, nicotine skin patches were developed to release a controlled amount of nicotine directly through the skin. Nicotine is easily absorbed through the skin, and it is possible to provide a steady delivery of approximately 21 to 22 milligrams per day, equivalent to the amount of nicotine delivered from about twenty cigarettes (one pack). However, as with nicotine chewing gum, the nicotine is delivered much more slowly than from cigarettes, and the peak blood levels are thus lower than those obtained from cigarettes. The patches are applied once a day, and after using full-strength patches for at least 4 weeks, reduced-strength weaning patches can be used to gradually withdrawal from nicotine.

Use of the patch has been shown to double or triple success rates in quitting smoking; a small proportion of patients (less than 10%) do experience skin irritation from wearing the patches.

Nicotine nasal spray. Some researchers have speculated that a more rapid absorption of nicotine than is achieved with patches or gum would more closely simulate the effects of cigarettes desired by smokers and increase success rates in smoking cessation. A nicotine nasal spray is available for smoking cessation treatment; it delivers 1 milligram of nicotine (equivalent to the delivery of a typical cigarette) with each use (one spray per nostril). Unlike other modes of NRT, the nasal spray delivers nicotine to the bloodstream very rapidly, within a few minutes. Some studies have suggested the nasal spray might be particularly advantageous for more highly dependent smokers. Problems with the spray include local irritation caused by nicotine, which can result in sneezing, a runny nose, watering eyes, and a cough.

Nicotine inhaler. A fourth mode of NRT resembles a cigarette in size and shape, and releases a nicotine vapor when a smoker puffs on it. However, the dose of nicotine released in each puff, which is limited by the vaporization of nicotine at room temperature, is much less than with cigarette smoking. Intensive use (eighty inhalations over 20 minutes) releases, on average, 4 milligrams of nicotine, of which 2 milligrams is absorbed. Although termed an ''inhaler,'' studies have shown that the nicotine vapor is deposited mainly in the mouth, and hence absorption rates resemble that of nicotine gum. The inhaler can provide some of the behavioral and sensory characteristics associated with smoking and may therefore be appealing to smokers seeking a weaning tool that provides these components. However, the sensory effects of nicotine also can produce adverse effects, including mouth irritation and cough.

Commonalties across NRT products. Each of the four NRT systems discussed has been shown to facilitate smoking cessation, approximately doubling or tripling abstinence rates over placebo. They are effective even in the absence of a formal behavior therapy program, although behavioral treatment in combination with the nicotine replacement further enhances success rates. Interestingly, success rates are similar across the different methods, although more research needs to be done to determine whether different types of smokers will benefit more from one treatment than another.

What is missing from nicotine replacement? One might suppose that with the varied nicotine replacement techniques available, success rates in smoking cessation treatment would be higher than the typical long-term outcome (e.g., at one year) of 10 to 20 percent. Unfortunately, the vast majority of smokers relapse to cigarettes, raising the question of what is missing from NRT that cigarettes provide. It has been widely believed that the rapid absorption of nicotine from the lung during cigarette smoking accounted for the unique addictiveness of cigarettes; however, some doubt has been cast on this interpretation in view of the modest efficacy of the nasal spray despite extremely rapid absorption of nicotine, and by laboratory studies indicating that even rapid intravenous nicotine injections do not reproduce the enjoyable aspects of cigarette smoking. Research has suggested at least two other key components may be missing from NRT. One component alluded to above, consists of the sensory and behavioral cues associated with inhalation upon which smokers have become dependent. Although the nicotine inhaler provides some of these cues, it does not deliver tobacco taste or replace what smokers find to be enjoyable sensations of inhaling cigarette smoke. A second component that may also be important entails non nicotine constituents in tobacco that inhibit an enzyme (monoamine oxidase) important to the breakdown of neurotransmitters in the brain (e.g., dopamine), which in turn may mediate the chemical reward of nicotine. Methods of replacing these missing components are being developed and may yield further improvements in treatment efficacy.

Bupropion. Bupropion was the first non nicotine pharmaceutical to be approved by the U.S. food and Drug Administration for smoking cessation treatment and had been marketed previously as an antidepressant. However, it is efficacious in smoking cessation treatment even for smokers who are not depressed. Although the mechanism of action relevant to smoking cessation has not been elucidated, bupropion raises the level of brain neurotransmitters involved in drug reward, such as dopamine and norepinephrine. Bupropion has also been shown to block the action of nicotine at certain receptors. Clinical trials have demonstrated that bupropion approximately doubles success

rates over placebo, and the most frequent side effects include insomnia and dry mouth.

Combination approaches. Many potential combination approaches have yet to be thoroughly evaluated; they may increase success rates beyond those of any one technique alone. This has already been seen in the enhancement of success rates with NRT by behavior therapy programs. Additional treatment combinations may include the use of two or more nicotine delivery systems at the same time. A patch might provide a steady baseline level of nicotine, which could be supplemented as the need arises by the use of gum, nasal spray, or the inhaler. Another promising combination may be NRT plus bupropion, which some research suggests may have additive benefits. Combinations of NRT and techniques that provide some of the missing components of tobacco discussed above may also be considered. These and other possibilities need to be tested in future research because smoking has proven to be a more formidable adversary, as well as a more tenacious addiction, than many would have initially suspected.

NOREPINEPHRINE Also referred to as adrenaline, it is a catecholamine NEUROTRANSMITTER known to be involved in the action of some addicting drugs. It is the biochemical product of DOPAMINE and the enzyme dopamine-beta-hydroxylase. It is the major neurotransmitter for the sympathetic nervous system, as well as for several sets of long axon, multiple-branched neurons (nerve cells) of the central nervous system. After release from nerve terminals onto its RECEPTORS, much of it is recaptured or removed from extracellular spaces by an uptake mechanism, or TRANSPORTER, located in the nerve terminal membrane. This transporter is an important drug target for antidepressants and psychostimulants. Monoamine oxidase is a well-known enzyme that breaks down norepinephrine.

Norepinephrine holds an important place in the history of drug studies. It was discovered as an active chemical in the body many years ago. The availability of pharmacological agonists and antagonists helped reveal its physiologic role in the body. Also the development of histochemical methods in the 1960s and 1970s for its direct light microscopic visualization led to a detailed understanding of the many neurons that contain it. Noradrenergic receptors, termed alpha and beta, can act independently or synergistically to mediate the activity of norepinephrine and related drugs. Brain noradrenergic neurons in the nucleus locus ceruleus are well char-

acterized in general and are activated during withdrawal from addictive drugs.

FLOYD BLOOM
REVISED BY MICHAEL J. KUHAR

NUCLEUS ACCUMBENS The nucleus accumbens is a group of NEURONS that is part of the limbic system and located near the midline in the frontal region, beneath the frontal lobe. Anatomically, it has been divided into the shell and core, with the shell perhaps being more important for the actions of drugs of abuse. It is one of the most important structures in the brain for studies of drug addiction because it is believed to be involved in reward, reinforcement, and unpredictably positive experiences. Nucleus accumbens is known to include neurons that contain GABA and acetylcholine and other neurotransmitters. It receives important input from dopaminergic neurons located in the ventral midbrain that are also involved in reward and reinforcement. It has output projections back to the ventral midbrain and other areas.

This nucleus is thought to be involved in the action of many different drugs of abuse, especially psychostimulants whose actions on the nucleus accumbens have been well studied. Destruction of neurons in this structure or its inputs disrupts psychostimulant self-administration by rodents, and psychostimulants and other drugs of abuse cause an efflux of dopamine from this structure. Because of its small size, it has been difficult to study, and, at this time, it is being studied in humans and nonhuman primates to determine its relevance to human drug and stimulant abuse.

NUTMEG Nutmeg, the common spice obtained from the aromatic seed of the tree *Myristica fragrans* (native to the Moluccas, the spice islands of the East Indies), has been used for centuries for food and medicinal purposes. It has some HALLUCINOGENIC activity when consumed in large amounts. Since nutmeg is found in most kitchens, including food-preparation areas found in prisons, it has been used by prisoners. Therefore, it has been removed from ready access in prisons to the tighter control of drugs of abuse; Malcolm X wrote about such use.

Figure 1
Nutmeg

Nutmeg contains elemicin and myristicin, whose structures have some similarities to the hallucinogen MESCALINE as well as to the Psychostimulant AMPHETAMINE. It has been hypothesized that elemicin and myristicin might be metabolized in the body to form an amphetamine- and/or mescaline-like compound, but this has not been proven. The effects of nutmeg have been reported to have some similarities to those produced by MARIJUANA; however, the large amounts of nutmeg that must be ingested to get behavioral effects can cause dry mouth and thirst, increases in heart rate, vomiting and abdominal pain, severe headaches, agitation, and panic attacks.

O

OBESITY This term derives from the Latin (*obesus*, meaning "to eat up"), and it came into use in English in the early 1600s to mean a condition characterized by excessive bodily fat. Excess body weight is associated with the increased storage of energy in the form of adipose tissue. Standard criteria for obesity are (1) greater than 20 percent above ideal body weight (IDW) for a given height, as determined from actuarial tables, or (2) body mass index (BMI), defined as weight in kilograms divided by height in meters squared ($kg \div m^2 =$ BMI), greater than 27 for men and greater than 25 for women.

Obesity represents the upper end of a body-weight continuum, rather than a qualitatively different state. Obesity can derive from a variety of causes, but a significant genetic contribution has been demonstrated.

Being overweight to a statistically significant above-average degree or having proportionately more body fat than average is believed to be due primarily to genetic factors that influence appetite, metabolism, and activity levels. Most notably, obesity is more prevalent (ten times more likely) in persons whose parents, brothers, or sisters are obese. Studies in identical twins have clearly demonstrated that genetics plays a major role. For example, nonidentical twins raised together were less similar in weight than identical twins raised apart.

Beyond the genetic component, researchers have been examining the role of hormones, most specifically leptin, a hormone secreted by fat tissue that affects the brain's appetite control centers. In some studies, mice given injections of leptin lost their appetites and, consequently, lost weight. The human response to leptin varies dramatically, and the relationship between plasma leptin levels and obesity in humans is not yet clear or confirmed. According to one study, mutations in the leptin gene are indeed responsible for obesity in both mice and humans, but these mutations are quite rare outside of the laboratory setting. Another study shows that leptin is a signal to the hypothalamus of peripheral fat deposits, but further studies are being conducted to determine if obese individuals have trouble with leptin access into the brain. Other researchers have found that lean, physically active men have lower levels of leptin than heavier, sedentary men (ages 47 to 83).

Leptin research continues since solid findings could help in the treatment and prevention of obesity and diseases and health problems linked to obesity, such as hypertension, stroke, and type 2 diabetes (diabetes mellitus).

The *prevalence* of obesity (in this case defined as having body fat in excess of 25% for males or 30% in females) varies remarkably across ethnic groups and cultures, and across age groups. In the United States, obesity is consistently less common among African-American men than among white men across the entire age range; is consistently more common among African-American women than among white women; and tends to be more com-

mon among women of Eastern European and Italian ancestry than among those of British ancestry. Socioeconomic factors affect the prevalence of obesity, but men and women are affected differently: It is more common among all women in lower socioeconomic groups, but men in lower socioeconomic groups are leaner than average. Overall, approximately 40 million Americans are obese.

Some researchers and clinicians see similarities among certain patterns of overeating and other excessive behaviors such as drinking too much ALCOHOL, compulsive GAMBLING, engaging in "too much" sexual activity, and even exercising compulsively. Although there may be such similarities, the semantics attached to problems of overeating and OBESITY are formidable.

Not all persons whose weight is above average are obese (they may have excess muscle mass); not all who are obese eat excessively; not all who eat excessively become obese; and some individuals who have clinically recognized disorders centered on eating and body weight, such as BULIMIA, may or may not be obese.

TIMOTHY H. MORAN
REVISED BY REBECCA MARLOW-FERGUSON

OPERATION INTERCEPT Described by government sources as the largest peacetime search-and-seizure operation in U.S. history, Operation Intercept was launched along the United States—Mexico border in September 1969. This unilateral program was instituted, ostensibly, to halt the flow of MARIJUANA, HEROIN, and other dangerous drugs from MEXICO into the United States. However, Intercept's true goal was not to interdict narcotics but to publicize the war on crime promoted by President Richard M. Nixon, who had taken office the previous January, and to force Mexican compliance with Washington's antidrug campaign. Fashioned by well-meaning but short-sighted law-enforcement officers, who all but totally neglected the State Department and knowledgeable border-state residents, Operation Intercept constituted a classic example of international pressure politics and became a serious incident between Mexico and the United States.

On September 16, 1968, presidential candidate Nixon had pledged to an Anaheim, California, audience that, if elected, he would move against the source of drugs and accelerate the development of tools and weapons to deter NARCOTICS in transit. As president, he came face-to-face with the reality of a staggering national drug abuse problem and accelerating drug-related street crime. With the director of his own BUREAU OF NARCOTICS AND DANGEROUS DRUGS contending that the United States had "failed miserably" in controlling narcotics abuse, Nixon chose to couple a highly publicized law-and-order campaign at home with an international offensive against foreign sources of heroin and marijuana. Attorney General John Mitchell was chosen to implement the program, and in April 1969 he assembled a multiagency task force to attack the importation into, and illegal sale and use of illicit drugs in, the United States.

Establishing a linear relationship between marijuana, deteriorating health, heroin usage, and increased crime, the task force turned its attention to the border problem. Mexico was correctly deemed

the primary source of high-potency marijuana entering the United States. Officials noted further that (1) a significant percentage of the heroin was of Mexican origin, (2) substantial quantities of European heroin were being smuggled across the southern frontier, (3) Mexico served as an in-transit point for South American COCAINE, and (4) considerable amounts of AMPHETAMINES and BARBITURATES entered the United States surreptitiously from Mexico. In the midst of so much smuggling, Mexico's resources and efforts remained inadequate. Something had to be done to elicit a concerted, sustained antidrug program from Mexico City. That something was Operation Intercept.

On Sunday afternoon, September 21, 1969, at exactly 2:30 P.M. Pacific standard time, "the biggest, broadest-based enforcement task ever mounted" was launched. Noting that the Mexican government had been kept "fully informed" of the operation, a U.S. Treasury Department news release termed Intercept a "coordinated effort" encompassing the law-enforcement resources of several branches of the federal government. Involving intensified land, sea, and air surveillance along the entire 1,945-mile U.S.—Mexico border, the effort would continue "for an indefinite period," as everything and everyone, no matter their nationality or status, was thoroughly and painstakingly searched.

More than 4.5 million individuals and their belongings were ultimately inspected. Vehicles, their component parts, personal baggage, purses, books, lunch boxes, jackets, toys, and in some cases even blouses and hairdos were searched. The daily routine of life in Mexican border cities was radically altered, as traffic backed up for miles, car radiators boiled over, and tempers, both private and diplomatic, flared. No person or object—including diplomatic and consular officials, their children, possessions, and even their diplomatic cargo—was spared during Intercept's 20-day existence. In the process, the maneuver encompassed some 2,000 personnel, intensified inspections, heightened air and sea surveillance, and the expenditure of some 30 million dollars.

Analyzed solely on the basis of drugs confiscated, Intercept surely was not worth the cost and effort it entailed. Seizures, however, were of minor importance. The primary objective was to "bring the Mexicans around, get them really moving against cultivation and trafficking." In this regard, the operation must be judged a qualified success. Diplomatic outcries notwithstanding, Intercept did play an undeniably important role in energizing Mexico's moribund antidrug program during the 1970s.

Viewed retrospectively, Operation Intercept's basic weakness was embodied in its title, for its purpose was not to interdict drugs at the border but to pressure Mexico through economic denial. Seeking a politically expedient solution to the highly complex problem of domestic drug abuse, the Nixon administration chose Mexico. Unfortunately, the White House failed to recall the salient fact that Mexico is a foreign country, and a friendly one at that.

Neglect of the State Department proved a serious blunder. Overlooked or overpowered by law-enforcement officials during Intercept's crucial formative stage, U.S. diplomats ultimately terminated the ill-advised project before it became an even greater diplomatic disaster. More important, if its supporters had managed to prolong the unilateral maneuver for an extended period, U.S. authorities probably would have never secured the level of cooperation they sorely needed to impair the cultivation of drugs in Mexico and the trafficking of drugs across the border.

Equally damaging was the failure of Intercept officials to gauge the impact of such a blockage on the U.S. border's economy. Highly dependent on Mexican shoppers, American border merchants reacted angrily and effectively through professional and civic groups. Pressure on the administration from border-state members of Congress was intense, and its impact increased as the project was prolonged. Along with diplomatic protests, this proved crucial to Intercept's demise.

Additionally, the operation was poorly timed; it came on the eve of *tapadismo*, the process through which Mexico chooses its next president, but before the Nixon administration's announcement of a Latin American policy. Furthermore, Mexico played host during the Intercept period to a regional meeting of the United Nations Commission on Narcotic Drugs and the thirty-eighth annual assembly of INTERPOL, thereby compounding its embarrassment over the blockade's indignities.

Yet despite its numerous shortcomings, Operation Intercept was not entirely void of accomplishments. Because of the tremendous publicity it en-

gendered, the program made Mexican officials keenly aware of a reality heretofore ignored or slighted—that nation's own burgeoning drug problem. Politicians and journalists became introspective and reluctantly admitted that the availability of domestically produced drugs posed a danger to the health of *nuestra juventud* (our youth) as well as providing an everyday pastime for "gringo jippies" (American hippies).

Intercept also helped spur a previously lagging Mexican campaign against the cultivation, manufacture, and shipment of illicit drugs of all kinds. Since the fall of 1969, the government of Mexico has budgeted ever increasing funds for *la campaña permanente* (the permanent campaign) and is presently conducting (mid-1990s), with U.S. assistance, the world's most comprehensive eradication program against opium poppies and marijuana plants. As a corollary to this effort, cooperation between Mexican and American narcotics officials improved dramatically during the 1970s, only to tail off during the 1980s. Thus, while Intercept proved a short-term diplomatic blunder, it indirectly and somewhat ironically became a long-term catalyst to an accelerated Mexican antidrug campaign and a springboard to more effective international cooperation.

OPIATES/OPIOIDS The *opiates* are central nervous system depressants that are found in OPIUM or are derived from a substance found in opium, which is the juice of the opium poppy (*Papaver Somniferum*). The *opioids* include the opiates, along with totally synthetic agents, and naturally occurring peptides that bind to one or more opioid receptors found in a number of animal species. In general usage, both terms are often used interchangeably—but opioids is the larger grouping.

The effects of opium have been known for several thousand years. For most of this time it was not clear which of the ingredients in opium provided its analgesic (painkilling) and other therapeutic properties. Regardless of their benefits, health care providers are often afraid to prescribe them for fear of psychological dependence and sale to illegal markets (Carver, 2000). Still, the medical community has been increasing the use of opioid analgesics (Increasing Use, 2000).

MORPHINE and CODEINE, two of the most abundant constituents of opium, were the first pure opiates isolated—morphine in 1806 and codeine in 1832. Chemical modifications were soon attempted in an effort to eliminate their problematic side effects. One of the first attempts (in the 1890s) produced 3, 6-diacetylmorphine, which is commonly known as heroin. This agent did not eliminate the problems of tolerance, dependence, or abuse. Since then, extensive studies of the important components of morphine's structure have led to the development of a number of different classes of organic compounds. In 1939 and 1940, the first synthetics were discovered. The recent discovery of the opioid peptides have provided even more diversity in drug design.

AGONISTS, ANTAGONISTS, AND PARTIAL AGONISTS

Some drugs have very complex actions and many drugs act at specific RECEPTOR, locations on the surface of a cell. All of the drugs that belong to the class of drugs called opioids act at opioid receptors on the surface of cells. Usually these cells are neurons, but there are also opioid receptors on white blood cells. Once a drug binds to a receptor, it can either turn it on (AGONIST) or do nothing (ANTAGONIST). Even if a compound does nothing once it binds to the receptor, it still blocks the site and prevents an active compound from binding to the receptor. The situation is much like a key in a lock; some keys fit into the lock but will not turn, and as long as they remain in the lock they prevent the insertion of keys that would turn the lock. Finally, there are drugs known as *partial agonists*; these compounds bind to the receptor and turn it on but not nearly as well as pure agonists.

Again, using the key analogy, these partial agonists will turn in the lock, but only with some jiggling, lowering the efficiency in opening the door. Pharmacologically, partial agonists have limited effects at the receptor, termed a *ceiling* effect. This means that increasing the dose further will not give a greater response. To further complicate understanding of these drug actions, it is important to recognize that the opioid receptors (and many other types of receptors as well) are actually families of similar but subtly different receptor types. Some opioids are agonists at one receptor type and partial agonists or even antagonists at another receptor type. These drugs are termed mixed agonist/antagonists and they can have complex pharmacological profiles. For this reason it can be difficult for pharmacists to determine conversion amounts (for example, to methadone) (Magill-Lewis, 2000).

RECEPTORS

Morphine and drugs with similar actions work through specific recognition sites, termed *receptors*, located on the outside of cells (see Table 1). A number of general classes of opioid receptors have now been identified and it is likely that even more will be discovered. The major types of opioid receptors have been designated mu, kappa, and delta. From the clinical perspective, the mu opioid receptors are the most important. This class, comprised of two subtypes, mu_1 and mu_2, have high affinity for morphine and most of the clinically used agents. Both mu subtypes mediate analgesia, but through different mechanisms and locations within the brain and spinal cord. Mu receptors have been implicated in euphoria and mu agonists have often been abused. Equally important, activation of mu receptors depresses respiration and inhibits gastrointestinal transit. In addition to analgesia, euphoria, respiratory depression, and decreased activity in the stomach, mu agonist opioids produce

some actions that are clinically useful, such as cough suppression. However, most of their actions are considered unwanted side effects; for example, they affect endocrine function, constrict pupils, induce sweating, and cause nausea and vomiting. All mu agonist opioids also induce increasing tolerance and physical dependence in the user.

Kappa opioid receptors were defined using ketocyclazocine, an experimental benzomorphan derivative, and subsequently with dynorphin A, an endogenous opioid, which is believed to be the natural ligand for at least one of the kappa receptor subtypes. Morphine has relatively poor affinity for kappa receptors, but other drugs, such as pentazocine and nalbuphine (analgesics in clinical use), interact with kappa receptors quite effectively. The importance of kappa mechanisms in their actions have only recently been appreciated. The pharmacology of kappa receptors in humans has not been extensively studied; however, animal studies indicate that the kappa receptors also can relieve pain through receptor mechanisms distinct for each of the subtypes. Many of the clinically used drugs active at kappa receptor are mixed agonists/antagonists. Although they are agonists at kappa receptors, they are antagonists or partial agonists at mu receptors. In contrast to mu agonists, which can produce mood elevations and euphoria, drugs that activate kappa agonists appear to produce weird feelings and dysphoria.

The discovery of the enkephalins—endogenous peptides with opioid properties—soon led to the identification of delta receptors. The clinical pharmacology of delta receptors is not well known, primarily because so few agents have been tested in humans. Again, animal testing indicates an important role of delta receptors in analgesia, which is supported by a few studies with humans. However, there are no pure delta agonists clinically available yet.

Although all the various receptor subtypes examined can relieve pain, each receptor represents a different mechanism of action. Their sites of action within the brain differ and, most importantly, agents highly selective for a specific subtype do not show cross-tolerance. While tolerance develops with continued activation of any of the various receptors, tolerance to one does not lead to tolerance to another. For example, tolerance to morphine does not diminish the response to a kappa or delta drug. Similarly, mu agonists produce a characteristic variety of physical dependence, and there is cross-dependence among mu agonists (that is, people dependent on heroin will not experience withdrawal if given methadone.) However, there is no cross-dependence between mu agonists and kappa agonists.

All the various subtypes produce a number of actions other than analgesia. Most of the nonanalgesic actions of opiates can be explained by considering the receptors to which they interact. An excellent example is mu_2 receptors, which mediate respiratory depression and the constipation seen with morphine. Drugs that are agonists at these receptors also produce these side effects while compounds lacking affinity for these receptors do not. The role of multiple receptors is important clinically, primarily since few drugs are specific for one receptor. Even morphine, which is highly selective for mu receptors, interacts with two mu subtypes, and at higher doses with delta receptors as well.

CLASSES OF OPIOIDS

Opioids can be divided into a series of classes based upon their chemical structures, illustrated by prototypic compounds from each group (see Figure 1). These include morphine and its close analogs, the morphinans, the benzomorphans, the phenylpiperidines, and methadone. The pharmacology of agents within each category can be quite varied and often can be predicted from their affinity for various opioid-receptor subtypes. Most of the clinically relevant drugs will interact with more than one receptor. Thus, their actions can be ascribed to the summation of a number of receptor actions.

The importance of various regions of the morphine molecule has been well studied and a number of related compounds are widely used (see Figure 2). Early studies examined small changes in morphine's structure. One of the critical groups is the hydroxyl group at the 3-position on the molecule. Blockade of this position by adding chemical groups markedly reduces the ability of the drug to bind to opioid receptors. Although this may seem at odds with the analgesic activity of codeine, which lacks a free hydroxyl group at the 3-position, evidence indicates that codeine itself is not active and is metabolized to morphine, which is responsible for its actions. A similar situation exists for OXYMORPHONE and OXYCODONE.

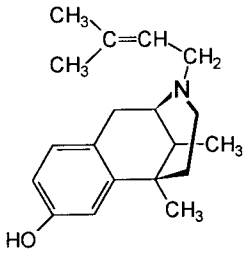
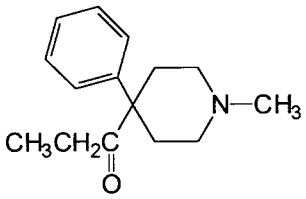
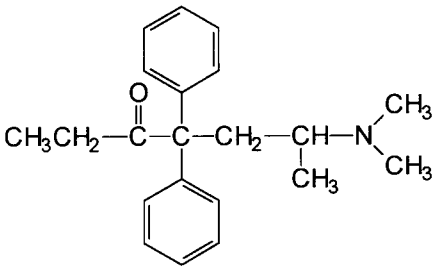
(morphinan)



Pentazocine
(benzomorphan)



Meperidine
(phenylpiperidine)



Methadone

Figure 1
The Classes of Opioid Compounds, Based on Structure

The morphine molecule has a single nitrogen atom. The substituent on the nitrogen in these series of opiates can have major effects on activity. Morphine and most of the mu agonists contain a methyl (CH_3-) group on the nitrogen, but a number of other compounds with different substituents have been developed. Replacing the methyl group with an allyl (-$CH_2CH=CH_2$2) or methylcyclopropyl (-$CH_2CHCH_2CH_2$) group does not have much effect upon the ability of the compound to bind to opioid receptors, but it markedly changes what happens when they do bind. For example, oxymorphone, with its methyl group on the nitrogen, is a clinically useful analgesic many times more potent than morphine. Replacing the methyl group with an allyl group produces NALOXONE. Naloxone is an antagonist, a drug that blocks or reverses the actions of other opiates. Clinically, naloxone is used as an antidote to opiate overdose. This shows how simple changes can profoundly influence the pharmacology of these agents.

Further investigations revealed that Ring C of morphine can be eliminated, enabling use of the benzomorphans—many of which are potent analgesics. The major drug in this group is pentazocine (Talwin). Even simpler structures produce potent

analgesics, such as methadone. The phenylpiperidines comprise another large group of opioids. The first of these to be used clinically was meperidine, which was first prescribed in 1939 and which still is extensively used. Modifications of the phenylpiperidine structure led to a subgroup of drugs, with fentanyl as a prototype. Fentanyl is approximately 80-fold more potent than morphine, but its very short duration of action requires continual infusions. An advantage is that once the infusion is discontinued, the effects of the drug clear rapidly. This ability to quickly turn on or off the drug's actions, along with its great potency, has made this agent a valuable tool in anesthesia. Recently, this high potency has been exploited to develop skin patches which give a constant release of fentanyl into the body as the drug is absorbed through the skin. Other agents within this series, such as sufentanil and alfentanil, are even more potent than fentanyl. Two other members of this series, loperamide and diphenoxylate, have activity but very poor solubility. This property has led to

their use as antidiarrheal agents since they cannot be made soluble and injected and are therefore less likely to be abused.

Together, these structure activity studies reveal that the basic requirements needed for opioid activity are quite simple. However, the wide variety of structures becomes even more intriguing since morphine and the other opioids act within the brain by mimicking naturally occurring peptides—the endogenous opioids. The enkephalins were the first such naturally occurring substances to be isolated and sequenced (Table 2). Initially, these results were somewhat confusing since the two enkephalins—both pentapeptides—contain the identical first four amino acids and differ only at the fifth. The complexity of these peptides became more clear with the subsequent isolation and characterization of β-endorphin, a 31 amino acid peptide derived from a larger protein, which also gives rise to active compounds, including ACTH and α-MSH. The first five amino acids in β-endorphin are identical to [met^5]enkephalin, but [met]enkephalin and β-endorphin derive from different gene products. There are also a series of compounds containing the sequence of [Leu^5]enkephalin, including dynorphin A, dynorphin B and α-neoendorphin. All these compounds (the ENKEPHALINS, ENDORPHINS, and dymorphine) have distinct genes and are expressed independently from one another. Thus, they comprise a family of similar, but discrete NEUROTRANSMITTERS.

The opioid peptides are only now becoming important clinically. A major difficulty in the use of peptides is the fact that they are broken down when taken by mouth, and thus, most have very limited oral activity. However, new derivatives specifically designed to be more stable have been developed, which will provide new leads. The enkephalins are potent at delta receptors, and many of their derivatives are delta-selective. Some of the more recent derivatives label delta receptors more than 10,000-fold more selectively than others. Yet other peptides are very much like morphine in terms of their pharmacology and receptor binding. Finally, peptides with opioid actions are now being identified in a variety of other tissues; for example, toad skin has dermorphin, a potent and stable opioid peptide.

REVISED BY REBECCA MARLOW-FERGUSON

OPIOID COMPLICATIONS AND WITHDRAWAL Opioids are frequently used in medicine for pain relief. The most commonly used opioids include morphine sulfate (Duramorph, MS Contin, Roxanol); meperidine (Demerol); hydromorphone (Dilaudid); oxymorphone (Numorphan); methadone; codeine phosphate and codeine sulfate; oxycodone (Percocet, Percodan); and hydrocodone (Hycodan, Vicodin). These substances are also, however, among the most common drugs of abuse. When taken under medical supervision, opioid drugs have a low level of serious toxicity. The most common side effects are nausea, drowsiness, and constipation—but when self-administered, not under medical supervision, their use is associated with a high incidence of untoward actions and side effects, as well as with a high death rate when used alone or in combination with other drugs (including ALCOHOL).

Table 1 presents estimates of untoward actions of opioids, derived from data collected by the DRUG ABUSE WARNING NETWORK (DAWN), which appeared in the *Annual Emergency Room and Medical Examiner Data, 1992*. As can be seen,

opioids account for approximately 16 percent of emergency room and 64 percent of medical-examiner death reports. (Suspicious and accidental deaths are sent to the county medical examiner.) More than 76 percent of the medical-examiner opioid mentions involve death by opioid drugs in combination with either alcohol or COCAINE, whereas more than 20 percent occur in combination with other opioids. It is further estimated that about 67 percent of all such deaths were unintentional overdoses (ODs). Adverse results also occur in patients given opioids for therapeutic reasons, including, although uncommonly, serious respiratory depression.

RESPIRATORY DEPRESSION

It is generally believed that the most common life-threatening complication of opioid use, whether therapeutic or illicit, is respiratory depression (loss of the ability to breathe automatically). Probably the most important action of morphine-like drugs in producing respiratory depression is the lessening of the sensitivity and responsivity of the brain's medullary respiratory center to carbon dioxide (CO_2—the metabolic waste that circulates in the blood, derived from carbonic acid during animal respiration). Therefore, CO_2 becomes an inefficient respiratory stimulant, and automatic breathing ceases.

Administering a specific opioid ANTAGONIST such as NALOXONE to patients with severely depressed respiration frequently produces a dramatic increase in the rate of respiration and the volume of air taken in per breath. This occurs when a partial or completely resensitized respiratory center is confronted with high brain levels of CO_2. When the brain CO_2 levels are dissipated as a consequence of the evoked excessive rate and volume of breathing (hyperpnea), the minute volume (the volume of air breathed per minute) decreases. Yet when brain levels of the antagonist decrease, the respiratory depressant action of the opioid may assert itself again. Naloxone is a relatively short-acting antagonist. Patients who, for example, have received an overdose of long-acting opioids (e.g., METHADONE) have experienced a fatal respiratory depression following successful treatment with naloxone.

TOLERANCE AND PHYSICAL DEPENDENCE

Another group of complications associated with chronic use of opioids is the development of tolerance and dependence.

Tolerance. The most common concept of TOLERANCE to opioid drugs is that following chronic administration of a drug, its effects are diminished. Several mechanisms have been demonstrated to be involved in the development of tolerance to drugs, and these include (1) the induction of drug-metabolizing enzymes; (2) the development of coping strategies; (3) the exhaustion or depletion of NEUROTRANSMITTERS; and (4) an alteration in the number of active and inactive RECEPTORS. These mechanisms have, by and large, failed to provide adequate explanations for tolerance to opioid drugs. This may stem in part from the complexity of the results of chronic administration of opioids, the involvement of multiple mechanisms, and the influence of the dose, route, and frequency of drug administration.

Opioids, for example, alter the functioning of some body homeostats, and apparent tolerance is related to the establishment of new equilibrium conditions. This is clearly evident in respiratory depression, where opioids depress both the sensitivity and the reactivity of the brain-stem respiratory CO_2 homeostat, causing CO_2 to be a less effective respiratory stimulant. Yet when CO_2 accumulates because of depressed respiration, the increasingly higher concentrations will cause stimulation of respiration to the degree that the altered homeostat dictates. The ability of opioids to constrict pupils is dose-related, and patients receiving opioids frequently have miosis—near-maximally constricted pupils; hence, it is difficult to determine if tolerance develops to opioids' miotic effect. This has given rise to the commonly accepted view that tolerance does not develop to the miotic effects of opioids.

In former opioid addicts, morphine-like drugs produce dose-related feelings of enhanced self-image, of being more efficient and effective, and of well-being. These related subjective states form the essence of opioid-induced euphoria, which is produced in patients who are plagued by feelings of inadequacy. This can be quantitatively measured using the Morphine-Benzedrine Group scale of the Addiction Research Center Inventory.

Tests in many normal subjects (nonabusers) who are not suffering from pain indicate that opioids do not produce euphoria—but in sufficiently large doses instead produce feelings of apathy and ineffectiveness, which can be dispiriting (dysphoric). When opioids are administered chronically to addicts, the subjective effects they produce change from feelings of well-being to feelings of being withdrawn, tired, and weak. With regard to these effects of chronic opioid administration, they are not simply diminished but rather changed.

The development of tolerance can be a problem when opioids are used in the treatment of pain. Although some degree of tolerance to ANALGESIC effects is expected when opioid drugs are used repeatedly, in practice there is a great deal of variability among patients. Some patients with CANCER pain appear to derive satisfactory relief from the same dose of MORPHINE or similar drugs over a period of many months. For these patients, a need to increase the dose can be a signal that the disease is progressing. Other patients with terminal disease can develop remarkable tolerance. There are reports of patients who have been given the equivalent of 1000 milligrams of morphine per hour intravenously. This is an impressively large dose, since the usual starting therapeutic doses of morphine are 10 to 15 milligrams by injection every 4 to 6 hours, and doses of more than 60 milligrams by injection can cause potentially fatal respiratory depression in nontolerant individuals. It is not usually of much benefit to change to another opioid that acts at the same receptor. For example, morphine acts at the mu-opioid receptor. When tolerance develops to morphine, other opioids acting at mu receptors will be less effective, a phenomenon referred to as "cross-tolerance."

Physical Dependence/Withdrawal. Closely related to the phenomenon of tolerance is the phenomenon of physical dependence. Subjects given repeated doses of opioid agonists exhibit a syndrome when the drug is withheld or when the subject is administered an opioid antagonist. The resulting group of signs and symptoms is called the WITHDRAWAL or precipitated abstinence syndrome; subjects who exhibit an abstinence syndrome are termed *physically dependent* on the opioid. The degree of physical dependence and the intensity of the abstinence syndrome are related to the dose of the opioid agonist chronically ingested. In general, the intensity of all signs and symptoms covary together.

The abstinence syndrome includes restlessness, weakness, chills, body and joint pains, gastrointestinal cramps, anorexia (loss of appetite), nausea, feelings of inefficiency, and social withdrawal. Signs of abstinence include activation of the autonomic nervous system, lacrimation (tearing eyes), rhinorrhea (running nose), piloerection (gooseflesh), tachypnea (rapid breathing), mydriasis (dilated pupils), hypertension (high blood pressure), tachycardia (rapid heart beat), muscle spasms, twitching, restlessness, vomiting, and diarrhea. The waves of gooseflesh that occur during severe opioid withdrawal reminded some observers of the look of a plucked "cold turkey," a term that has come to be used not only for any abrupt discontinuation of a drug, but also for sudden cessation of any habit or pattern of behavior. The twitching and kicking movements of the lower extremities that can occur during opioid withdrawal have given the English language another widely used term, "kicking the habit," to denote the process of giving up any pattern of behavior or drug use.

The time of onset of opioid abstinence depends on the length of activity for the dependence-producing opioid. The abstinence syndrome of subjects dependent on morphine or HEROIN is well developed within 24 hours after the last dose of the opioid, peaks after 48 hours of abstinence, and gradually subsides thereafter. Signs of abstinence in patients dependent on METHADONE begin to emerge 24 to 48 hours after the last dose and may not peak for 2 weeks.

After this early abstinence syndrome subsides, a protracted abstinence syndrome emerges. The protracted abstinence syndrome becomes manifest 5 to 10 weeks after acute or early withdrawal in humans. It differs from the early abstinence syndrome in some ways but not in others. In subjects who were dependent on morphine or methadone, protracted abstinence is characterized by the following signs: a modest hypotension (low blood pressure), bradycardia (low heart rate), hypothermia (lower than normal body temperature), miosis (small, constricted pupils), and tachypnea. Other signs of protracted abstinence may include an inability to concentrate and a decrease in fine-motor control. Symptoms associated with protracted abstinence in patients who were dependent on methadone in-

clude feelings of tiredness and weakness, withdrawal from society, inefficiency, decreased popularity and competitiveness, and loss of self-control. Patients withdrawn from methadone have also exhibited a significant elevation of the Sc (schizophrenia) scale of the MINNESOTA MULTIPHASIC PERSONALITY INVENTORY (MMPI). This elevation of the Sc scale may be related to feelings of social withdrawal that patients in protracted abstinence experience. Protracted abstinence persists for at least 25 weeks after withdrawal. Protracted abstinence following addiction to morphine has also been demonstrated in rats and in dogs.

The patterns of abstinence and time course of symptoms described above are those seen when opioid drugs that have been used for weeks or months are discontinued. However, opioid withdrawal can also be observed when a drug-dependent person is given an opioid antagonist (a drug such as naloxone that competes with opioid agonists for the opioid receptor). In a matter of minutes, this will produce a precipitated abstinence syndrome that can be severe, with vomiting, cramps, and diarrhea. This precipitated abstinence is usually brief, however, because as soon as the antagonist is metabolized (usually less than an hour for naloxone), the opioids still in the body can again attach to the opioid receptors and suppress the abstinence syndrome.

The biological mechanisms that are responsible for the development of opioid physical dependence are set into motion with the very first doses of an opioid drug. If volunteer subjects are given standard doses of morphine (15 to 30 mg) and then, after an interval varying from 6 to 24 hours, they are given naloxone, they report nausea and other feelings of dysphoria and exhibit yawning, dilated pupils, tearing, sweating, and runny nose. Changes in endocrine levels are also seen that are in the same direction, although not as extreme, as those seen when chronically administered opioids are abruptly discontinued.

TREATMENT OF OPIOID WITHDRAWAL (DETOXIFICATION)

The opioid withdrawal syndrome varies in severity depending on the amount of opioid used and the duration of use. For the average user of illicit opioids, withdrawal is rarely severe because the amount of drug used typically is not high. The withdrawal syndrome from such a level of use can be uncomfortable, but it is not life-threatening in otherwise healthy individuals. However, death can occur if severe withdrawal is left untreated in individuals who are weakened by other medical conditions.

The process of treating someone who is physically dependent so that acute withdrawal symptoms are controlled and the state of physical dependence is ended is usually referred to as detoxification. For opioid drugs, this process can be managed on an ambulatory (outpatient) basis or in a hospital or other residential (inpatient) setting. The most common approach to easing the severity of opioid withdrawal is to slowly lower the dose of opioid over a period of days or weeks. However, in the United States, if the drug has been heroin, a substitution technique is used instead. Since virtually all opioids that are abused act as AGONISTS at the mu-opioid RECEPTOR, any mu agonist could be a suitable substitute, but the only ones approved for this purpose in the United States are methadone and LAAM (L-ALPHA ACETYLMETHADOL). These medical agents are effective when taken by mouth. Methadone can completely suppress the opioid abstinence syndrome. This capacity of one opioid to prevent the manifestations of physical dependence from another is called cross-dependence.

Outpatient detoxification using methadone typically involves using doses of 20 to 40 milligrams per day for a few days and then gradually reducing the dose over several weeks. Because so many patients return to illicit drug use as the dose of methadone approaches zero, government regulations controlling methadone permit a long period (up to 180 days) of slow dose reduction.

When detoxification takes place in a hospital or other residential setting, where the patient is presumably not as likely to be exposed to environmental cues that elicit CRAVING for opioids, dose reductions of methadone can be more rapid (e.g., over 8 to 10 days), although the intensiy of discomfort will be higher.

Other opioid agonists and partial agonists that have been used satisfactorily to facilitate detoxification include BUPRENORPHINE, (Buprenex) a partial mu agonist, and LAAM (Levomethadyl acetate). The opioid withdrawal syndrome can also be modified and reduced in severity by using agents that do not act at the mu receptors, but instead act on some of the physiological systems that exhibit

hyperactivity as part of the syndrome. The use of CLONIDINE (Catapres) is an example.

The opiate antagonist NALTREXONE (Trexan) can be used to detoxify patients rapidly and to help detoxified addicts stay off opioids. Naltrexone binds more strongly than heroin to the specific brain receptors to which heroin binds. The withdrawal is usually more severe than that which comes from simply stopping the heroin, but it also has the effect of detoxifying more quickly. Thus, a combination treatment of clonidine to suppress the intensity of withdrawal symptoms and naltrexone to accelerate the pace of withdrawal has been used for rapid detoxification.

Because opioid withdrawal is time-limited and rarely life-threatening, many nonmedical treatments have also been used, including ACUPUNCTURE and herbal medicines. Another nonmedical treatment that has been used in addicts is transcutaneous electrical nerve stimulation (TENS). It is thought that both acupuncture and TENS may be helpful because they stimulate the parts of the central nervous system that release natural opioids. At present, further research is needed because opioid addicts are very suggestible and may feel better after acupuncture or TENS because of the placebo effect.

NAUSEA AND VOMITING

Nausea and vomiting are common side effects associated with the use of opioid analgesics. These effects are experienced following administration of opioids orally, by injection, or by injection into the spinal canal (epidurally)—they are worsened by movement and the resulting stimulation of the vestibular (inner ear organ responsible for balance). The site and mechanism responsible for these actions of opioids is presumed to be a special area in the brain stem or medulla, the chemoreceptive trigger zone of the area postrema.

CONSTIPATION

Constipation, an often undesirable effect of opioids, is sometimes a useful effect for which opioids can be prescribed. It is undesirable when opioids are used for the relief of pain and in opioid-dependence maintenance therapy.

The oldest of the therapeutic actions of opiates is their antidiarrheal and constipating effects. It is now known that the extrinsic innervation (nerves leading from the central nervous system to the gut) and the intrinsic innervation (nerves within the wall) of the gastrointestinal (GI) tract are complex and vary from species to species. A variety of naturally occurring neurones with diverse neurotransmitters have been identified, including neurones and their process that contain opioid peptides: the enkephalins, B-endorphin, dynorphins, and other ligands derived from pro-opiomelanocortin. Further mu and delta opioid receptors have been identified in the GI tract. The vagus nerve also has fibers that contain enkephalins, and the central nervous system has opioid mechanisms that modulate GI movement (motility).

Several influences must play a role in the constipating effects of opiate agonists—these include increased segmental activity, decreased propulsive activity, and decreased secretory activity. Naloxone, even when administered in high doses for a long period of time in antagonist therapy of opioid abusers, does not produce an overt stimulation of the GI tract resulting in diarrhea. When opioid antagonists are administered to opioid-dependent subjects, however, GI cramps and diarrhea develop as classic opioid withdrawal signs.

PRURITUS

The ability of morphine-like drugs to produce the sensation of itching (pruritus) is well known, and it is a discomforting complication when opioids are administered for therapeutic reasons. Further, many morphine-like drugs (e.g., codeine) release histamine from white blood cells that store it (mast cells and basophils). When morphine is administered intravenously, wheals (hives—raised red lumps) may appear at the site of the injection and along the course of the vein. The wheals may be associated with the sensation of itching. Occasionally, large doses of morphine may produce generalized itching. Rarely does morphine produce pulmonary edema (fluid in the air sacs of the lung), bronchoconstriction (narrowing of the air tubes in the lungs), or wheezing. With the advent of the use of intrathecal and epidural morphine (injection of morphine into spinal fluid or around the lining of the spinal canal) in pain management, the incidence of morphine-induced pruritus has become greater. Under this circumstance, the distribution of itching may be segmental (limited to the part of the spinal

cord involved). Itching remains an elusive phenomenon and is harder to define and investigate than pain. It is thought that it may be mediated by a subgroup of nociceptive (pain-carrying) C fibers. Further, morphine's histamine-releasing property has been implicated in its ability to produce itching, as histamine does in allergic reactions.

CONVULSIONS

Although most opiates produce convulsions when administered in very large doses, convulsions are most frequently observed when excessively large doses of MEPERIDINE (Demerol) or *d*-propoxyphene (Darvon) are administered. Emergent meperidine seizures are characterized by tremors and twitching, which may evolve into tonic-clonic (epileptic) convulsions. Focal and tonic-clonic seizures have been observed in patients overdosed with *d*-propoxyphene. The mechanisms whereby opioid drugs produce convulsive phenomena are not well understood and may involve several mechanisms, including (1) direct and indirect dysinhibition of glycine and GABA-mediated inhibition and (2) excitatory actions that are probably mediated by yet-to-be-classified receptors. The convulsant effects of *d*-propoxyphene can be readily antagonized by naloxone; however, meperidine's convulsant effects may be more resistant. Meperidine probably has a convulsant effect in its own right when administered in very large doses acutely, yet convulsant phenomena seen following the administration of multiple doses of meperidine are produced by the accumulation of a metabolite, normeperidine.

DYSPHORIA, DELUSIONS, AND HALLUCINATIONS

It is rare for morphine-like analgesics to produce psychotic reactions. In patients with severe pain and discomfort and in opiate addicts, single doses of morphine-like drugs most commonly produce feelings of well-being. In normal subjects with no pain or with only modest levels of discomfort, morphine produces feelings of apathy and enervation, which are somewhat dysphoric. The drug *d*-propoxyphene (Darvon) has been reported to produce bizarre reactions—delusions and hallucinations—particularly when taken chronically in large doses and when used to suppress opioid abstinence. Some agonists-antagonists (e.g., pentazocine [Talwin], nalorphine, and cyclazocine) produce feelings of apathetic sedation, perceptual distortions, anxiety, delusion, and hallucinations.

STREET DRUGS

The complications described in the preceding sections are most commonly associated with pure, unadulterated opioids. When street drugs are used, which are typically diluted by the seller with quinine, lactose, or other powdered materials—and injected by the user in an unhygienic manner, in doses that vary significantly—the range of complications widens. These are described fully in the entry on neurological complications, but among the complications of heroin use reported in the medical literature are strokes, inflammation of cerebral (brain) blood vessels, toxic amblyopia, bacterial meningitis, aneurysms and brain abscesses, disorders of peripheral nerves, impairment of segments of the spinal cord, and widespread injury to muscle tissue (rhabdomyolysis)—which by releasing muscle protein can denote damage to the kidneys.

OTHER MEDICAL COMPLICATIONS

Medical complications of opioid addiction may result from unsanitary administration of the drug, from overdosing, from intoxicated behavior (e.g., unsafe sex), or from the chemical properties of opioids themselves.

Lungs. Opioid addiction may lead to pneumonia, aspiration pneumonitis, lung abscess, or septic emboli in the lungs. It also decreases the vital capacity and diffusion capacity of lung tissue. Opioid addicts who also smoke tobacco are at increased risk of lung infections.

Liver. Opioid addicts frequently develop viral hepatitis (types A, B, and C). In addition, addicts who are also heavy drinkers have a high incidence of cirrhosis and other disorders of liver function.

Immune System. Hypergammaglobulinemia (an abnormally high level of gamma globulin in the blood) develops in about 90 percent of opioid addicts. As of 1999, it is unclear whether this change in the immune system is caused by infections or by daily injections of foreign substances. It diminishes in addicts on methadone maintenance. In addition to hypergammaglobulinemia, opioid addicts are at

a very high risk of contracting HIV infection from shared needles.

Muscles and Bones. Osteomyelitis (inflammation of bone and the bone marrow caused by bacterial infection) is a common complication of opioid addiction. Drug abuser's elbow is a complication in which the muscles of the lower arm are damaged by repeated needle punctures and tears.

Skin and Lymphatic System. Opioid addicts frequently develop skin abscesses and ulcerated areas from injecting heroin under the skin ("skin popping"). Using contaminated needles may result in cellulitis, lymphangitis, lymphadenitis, and phlebitis (inflammation of a major vein).

Pregnancy and Lactation. Infants of opioid-addicted mothers are born physically dependent on the drug, because both heroin and methadone cross the placental barrier. They may also acquire HIV infection or hepatitis from an infected mother. Pregnant addicts should be encouraged to enter a methadone maintenance program rather than attempt complete withdrawal, because withdrawal in the last trimester of pregnancy may cause early labor. Mothers on methadone maintenance can nurse infants without harm to the child, because breast milk will not contain large amounts of the methadone.

REVISED BY REBECCA J. FREY AND
REBECCA MARLOW-FERGUSON

OPIOID DEPENDENCE: COURSE OF THE DISORDER OVER TIME Opioid dependence is the modern diagnostic term for narcotic addiction, but the older term is still often used. This entry, however, uses the modern term. The term *opioid* refers to natural and synthetic substances that have morphine-like effects. The term *opiate* is generally used in a more restricted sense to refer to MORPHINE, HEROIN, CODEINE, and similar drugs derived from OPIUM. OPIOID dependence is defined as a cluster of symptoms related to continued use of an opioid drug. One of the prominent features of the disorder is the inability to stop using the drug. Persons with repeated periods of opioid dependence are often called narcotic addicts. Because they are not always dependent (that is, addicted), the term *opioid users* seems more suitable and therefore is used here. During the late nineteenth and early twentieth centuries the principal opioid drugs used were LAUDANUM (a solution of opium in alcohol, taken orally) and morphine (usually injected by needle). During the latter half of the twentieth century, heroin has been the principal drug of opioid users. It is usually taken by intravenous injection, but sometimes by insufflation, that is, by sniffing it into the nasal cavities.

The course of opioid dependence is affected by multiple interacting conditions in the person and in the environment. The combined conditions create thresholds for the onset, continuation, and relapse after remission of opioid dependence. Different methods of investigation (for example, pharmacological, psychological, sociological, psychiatric) have led to different theoretical conceptions of the causal conditions and processes in opioid dependence. These conceptions, however, tend to be compatible and supplementary rather than contradictory. In the following description of the course of opioid dependence, the principal conditions thought to affect its onset and course will be identified.

In the United States, legal and medical conditions affecting opioid use and dependence have changed since the nineteenth century. In the nineteenth century many persons regularly used laudanum or morphine that they obtained legally from physicians, retail drug stores, or other sources. Physicians often prescribed or recommended these drugs for treatment of chronic physical PAIN or psychological distress. Although daily use of an opioid drug with consequent dependence on it probably impaired the social performance of many persons, reports exist of persons—including some with distinguished careers—who acceptably filled social roles during years of opioid drug dependence. Though some antisocial persons used opioid drugs, such use itself did not lead to criminal behavior.

In the twentieth century, opioid dependence became closely associated with criminal behavior. Enactment and enforcement of federal and state laws to control the production and distribution of opioid drugs (mostly called narcotic drugs in the laws) became prominent features of the twentieth-century environment of opioid use. Physicians could no longer prescribe opioid drugs to maintain dependence, and opioid users now had to obtain their drugs from illicit sources. Furthermore, because the illicit opioid drugs were expensive, users often engaged in illegal moneymaking activities—especially theft, burglary, fraud, prostitution, and illicit drug traffic—to pay for their drugs. In addition, twentieth-century opioid users have often had histories of delinquent behavior that preceded their opioid use.

WHO IS SUSCEPTIBLE?

At the turn of the century, when opioid drugs were legally and easily available to all adults, only a few persons became dependent on them. Although the exact scale of opioid dependence at that time is not known, it probably did not exceed 2 percent of the adult population. An interview survey conducted in the 1970s of a national sample of young men in the United States revealed that 5.9 percent had used heroin at some time in their lives, but only 1.7 percent ever considered themselves dependent on this drug (O'Donnell et al., 1976). Other studies indicate that normal people free from physical pain tend to react to the effects of opioid drugs with indifference or dislike. With rare exceptions, patients who receive opioid drugs to relieve pain after surgery make no effort to continue drug use after they become free from pain. It is now well-known that opioid dependence develops in only a small proportion of those exposed to the effects of the drugs.

The characteristics of persons susceptible to opioid dependence have not been clearly defined, but clinical and other studies point to three personality

problems that probably increase susceptibility. First, chronic emotional distress, such as DEPRESSION, tension, ANXIETY, anger, or mixtures of these, is relieved by opioid drugs, and this relief probably prompts repeated use of the drug. Second, impaired capacity to regulate emotional distress increases the urgency of the need for relief. Third, an antisocial attitude makes it easy for the person to perform the illegal actions needed for regular illicit opioid use. The notion that opioid drugs are used to relieve emotional distress is called the self-medication hypothesis. The origins of the personality problems that increase susceptibility probably lie partly in genetic inheritance and partly in adverse psychosocial experience. Modern opioid users often come from dysfunctional parental families.

Environmental conditions in the deteriorated areas of large cities in the United States place young persons living there at special risk for opioid dependence. Most of the retail illicit drug traffic and much of the opioid use takes place in these areas. Young persons are consequently exposed to available heroin and heroin-using role models and associated criminal behavior. Since these areas are heavily populated by minority groups—primarily African Americans, Puerto Ricans, and Mexican Americans—these groups are at special risk. The experience of POVERTY and adverse discrimination may contribute to emotional distress in members of these groups and thereby increase their susceptibility to opioid dependence. Apart from environmental conditions, ethnic status as such does not seem to affect susceptibility. Men seem to develop opioid dependence more often than women do; the ratio of men to women in treatment programs is about three to one.

ONSET OF OPIOID DEPENDENCE

Opioid use is usually preceded by use of tobacco, ALCOHOL, and MARIJUANA. Before their first opioid use, most users dropped out of school and began to associate with opioid users. Heroin is nearly always the drug of choice. With few exceptions, it is first used within a few years of the user's twentieth birthday. Users report that they were not coerced or urged to use heroin by either their associates or drug dealers. In a typical sequence a person becomes aware of drug use by his friends or relatives, becomes curious about its effects, and asks for the first injection. As already noted, most persons exposed to the effects of heroin do not become regular users.

Susceptible persons rarely become compulsive daily users immediately after first use. A variable period of occasional use—once a month or more often, but not daily—usually ensues. Curiosity fades as a motivation; the effects of the drug are what prompt repeated use. The drug users call these effects the "high." The high is not described as exhilaration or excitement but rather as relaxation and mood elevation. Descriptions of the high offered by many drug users suggest that it amounts to relief of the chronic emotional distress mentioned before as a factor in susceptibility. Susceptible persons increase the frequency of use until it reaches once or several times daily. From first use to daily use typically takes about one year, but it may take much longer. In a study of opioid users in San Antonio, one man reported that he first used heroin at the age of sixteen. He did not like it and did not use it again for fifteen years. At that time he felt depressed following the death of a friend and decided to try heroin again. This time the heroin made him feel better, and he quickly became a daily user (Maddux & Desmond, 1981).

With daily or nearly daily use, the user develops physiological DEPENDENCE on the drug. This means that when the drug use is reduced or stopped, the user develops distressing symptoms called the WITHDRAWAL illness. The threat or the onset of withdrawal symptoms provides additional strong motivation to continue daily use of the drug.

In the progression from initial use to daily use, heroin users learn how to inject heroin intravenously, how to acquire the drug and injection equipment, and with some exceptions, how to conduct illegal moneymaking activities to pay for the heroin. Those who began a delinquent career before their initial use of heroin were already oriented toward criminal activity. In some cases, heroin users or dealers provide a regular supply of heroin to their spouses or live-in companions; the latter thus do not have to engage in regular illegal activity to pay for their drug. Another exception to the pattern of illegal moneymaking activity is linked to opioid dependence among physicians and other health professionals. Health professionals rarely purchase heroin from street retailers. They have access to meperidine or other opioids available in pharmacies and hospital supplies, and they use these drugs instead of heroin.

Probably the most serious and disabling feature of opioid dependence is the inability to put a stop to it, also called loss of control of the drug use. After drug use has become daily and physiological dependence has developed, many opioid users try to stop using it and find themselves unable to do so. This inability to stop is a subjective mental state reported by drug users. It probably starts as a mild impairment of control and progresses to complete or nearly complete loss of control.

EARLY TERMINATION OF OPIOID DEPENDENCE

Continued daily use with loss of control depends partly on the availability of the drug and other environmental conditions. American soldiers serving in VIETNAM during the Vietnam War were exposed to an environment in which heroin was easily available and heroin use was common. An interview survey of a sample of returning veterans revealed that 35 percent had tried heroin while in Vietnam and 19 percent (about half of those who tried it) considered themselves addicted to it. During a three-year period after return to the United States, however, only 12 percent of those addicted in Vietnam became readdicted in the United States. These represented about 2 percent of the entire sample interviewed (Robins et al., 1980). Other studies of early termination of opioid dependence in the United States have identified various life events as probable causative factors in the termination. Among these are change of residence, marriage, a drug-related arrest, and death of a friend from overdose. Many persons who terminate their opioid dependence do so without treatment.

CHRONICITY, REMISSION, AND RELAPSE

With continued daily use and physiological dependence, the user's bond to the drug becomes stronger. Drug use, drug seeking, and illegal activity become the dominant activities of the user's life. Psychosocial development is retarded. Those who become dependent during adolescence often fail to complete high school and never develop regular work habits or job skills. With continued dependence, opioid users become impaired marital partners or parents.

Daily use does not continue indefinitely. In some cases, as noted, an important life change leads to cessation of use. In other cases, pressure from family or friends or other sources prompts entry into a treatment program. In still others, arrest, conviction, and incarceration interrupt the daily use. Sometimes conviction leads to probation with treatment as a requirement of the probation. After treatment or incarceration, the majority of chronic users resume opioid use within six months. The common long-term pattern consists of initial use followed by irregular sequences and varied durations of occasional use, daily use, treatment, abstinence, and incarceration. Remissions enduring for three years or longer followed by relapse are not unusual. Variations in the course of opioid dependence are illustrated in the following case summaries.

> An employed man first used heroin at the age of twenty-six and after two months of occasional use began daily use. He continued working but engaged in the illicit heroin traffic to pay for his heroin. Two years after first use, he was arrested and convicted for sale of heroin. In lieu of prison, he was sent to a federal hospital for treatment. Released on parole at age twenty-nine, he remained abstinent for ten years, when he was last interviewed at age thirty-nine. He abstained from heroin, he said, because he did not want to return to "that miserable life."
>
> Shortly after release from an institution for delinquents, a boy had his first injection of heroin at the age of sixteen. He became a daily user in about three months. During the next thirteen years he had two brief periods (each of about five months' duration) of abstinence from heroin. He used heroin occasionally or daily during the remaining time, except for four years in prison. He was murdered by gunshot at the age of twenty-nine.
>
> After dropping out of school, a fourteen-year-old boy learned to make money by selling marijuana and heroin. He tried heroin at age sixteen, liked it, and promptly became a daily user. He used heroin daily for the next twenty years, except for relatively brief periods when he was in prisons and hospitals. Then, at age thirty-six, he was sent to prison for two years. During this period in prison, he felt some change in himself while participating in a THERAPEUTIC COMMUNITY program. After release, he abstained from heroin for the next

eight years. He obtained employment as a counselor in a drug-abuse treatment program. He was aged forty-six when last interviewed.

Modern TREATMENT of opioid dependence includes drug withdrawal done as an inpatient or outpatient procedure, residential treatment, therapeutic community, drug-free outpatient treatment, the use of opioid ANTAGONISTS, and METHADONE MAINTENANCE. Prompt abstinence from opioid drugs is the goal of the first five of these types of treatments. Methadone maintenance, in contrast, consists of continued substitution of methadone, itself an opioid drug, for the illicit opioid. In addition to these forms of treatment, self-help groups such as NARCOTICS ANONYMOUS are available as well as special religious programs for drug users.

Opioid users who enter treatment aimed at prompt abstinence reveal mixed motivations for the treatment. They would like to become free of the burden of their drug dependence, but they do not want to give up the effects of the drug. Most leave treatment before completing it. Relapse after treatment is common, but the severity of the dependence is usually reduced, short periods of abstinence are often achieved, and for a small proportion of users, enduring cures of opioid dependence are attained. Methadone maintenance aims for social rehabilitation, with opioid abstinence as a possible distant goal. It has become a major mode of treatment for chronic opioid users and benefits many of them by helping them reduce or stop illicit opioid use and stop their criminal activity. This treatment, however, only infrequently leads to enduring abstinence.

USE OF MULTIPLE SUBSTANCES

In the early twentieth century, many alcoholics were converted from ALCOHOLISM to opioid dependence. If the opioid dependence was terminated, alcohol dependence often replaced it. In the later twentieth century, the patterns of use of other psychoactive substances during the course of opioid dependence have become more complex. Heroin users often substitute alcohol when they become abstinent from opioids, but, in addition, many use alcohol regularly while using heroin daily. They also use TOBACCO, marijuana, and cocaine. In a recent interview study of opioid users in California, 75 percent reported current use of tobacco, 20 percent reported being drunk on alcohol in the previous seven days, 38 percent reported use of marijuana in the previous thirty days, and 18 percent reported use of cocaine in the previous thirty days (Hser, Anglin & Powers, 1993).

WHY DOES OPIOID DEPENDENCE BECOME INTRACTABLE TO TREATMENT?

This important question can be answered only partially and tentatively. The conditions that contribute to the onset of opiod dependence also support the tendency to continued use. These, as previously noted, include chronic emotional distress, drug-using models, an available opioid drug, and withdrawal symptoms. Two other effects of the drug dependence probably contribute to relapse after treatment or incarceration. First, mild withdrawal symptoms such as muscular aching, insomnia, and irritability often persist for six months or longer after the last dose. These symptoms (called protracted withdrawal) are promptly relieved by an opioid drug, and they probably contribute to relapse after treatment. Second, the opioid user becomes conditioned to environmental conditions associated with withdrawal symptoms, so that after a period of abstinence, exposure to a conditioned stimulus will evoke withdrawal symptoms. This conditioned withdrawal probably contributes to relapse.

Three other changes in the mental state of the user probably also contribute to the intractable quality of the disorder, but these have not been as well defined and studied. First, over time the drug-using habit tends to become automatic, requiring no conscious decision to use or abstain. Second, the drug-seeking and the associated criminal behavior seem to become a part of an established lifestyle, and the user becomes enmeshed in a social network that includes illicit drug users and criminals. Third, with repeated relapses after treatment or incarceration, the opioid user comes to a self-perception as an addict with a diminishing capacity for change. This complex of learned attitudes and behaviors amounts to a personality change, which is probably accompanied by change in the brain. Such change may not become permanent, but it tends to endure.

LONG-TERM OUTCOMES

In follow-up studies extending from five to more than twenty years after admission to treatment, the percentages of users reported abstinent from opioid drugs have varied from 9 percent to 21 percent (Maddux & Desmond, 1992). Some of this variation was due to different ways of counting abstinence. In some studies the users were counted as abstinent only if they remained so during the entire period from treatment to follow-up, whereas in others the users were counted as abstinent if they were found so at the time of follow-up. Despite these differences, the studies collectively indicate that only a minority of opioid users are found to be abstinent on long-term follow-up.

Although only small to medium percentages were found to be abstinent, it should not be assumed that the remainder of people were using opioid drugs. Some were dead, some were in prison, and some were in treatment. The death rate of opioid users is about three times the expected rate. Overdose, homicide, suicide, accidents, and liver disease account for many of the deaths. In the 1980s the acquired immunodeficiency syndrome appeared as an additional hazard for drug injectors. A follow-up of opioid users in San Antonio revealed the following different statuses twenty years after first use: 16 percent were abstinent, 29 percent were using heroin, 30 percent were in prison or other institutions, 8 percent were maintained on methadone, and the remaining 17 percent were dead or their status was unknown (Maddux & Desmond, 1981).

WHAT CAN BE DONE?

Since policies and programs to reduce drug abuse are described elsewhere in this encyclopedia, only a brief comment will be offered here. Two broad approaches—supply reduction and demand reduction—have been put in place in the United States. Supply reduction consists of the enactment and enforcement of drug control laws. Although the supply-reduction effort has undoubtedly reduced the supply of illicit opioid drugs, it has failed by far to eliminate them from the environment of susceptible persons.

Demand reduction consists of treatment and prevention. Treatment of opioid dependence produces short-term abstinence and reduces the pool of daily users in the community, but it achieves few enduring cures. Publicly supported treatment programs in the United States are insufficiently financed to provide prompt treatment to all who seek it. A few pilot projects have been developed for reaching out to young persons at risk for opioid dependence and providing special services for them, but more research is needed on this type of preventive effort. Finally, opioid use in the United States seems embedded in a complex matrix of family dysfunction, poverty, undereducation, unemployment, and crime. Anything that reduces these problems would likely reduce illicit opioid use. Easy solutions seem unlikely.

JAMES F. MADDUX
DAVID P. DESMOND

OPIOIDS AND OPIOID CONTROL: HISTORY Throughout recorded history and in most parts of the world, OPIATES have occupied a central place in medicinals. They have been used popularly against a wide range of ills and to produce calm or well-being. Opiates are renowned for their powerful ability to relieve PAIN. They also have been used for their PSYCHOACTIVE properties and, within the last 100 years, have come to symbolize the problems with attempts to control drug use through legislation and enforcement. (Technically, opiates are a subset of the OPIOIDS, which also include synthetic agents and naturally occurring peptides that bind to opioid RECEPTORS found in certain animal species.)

The OPIUM poppy (*Papaver somniferum*) grows easily in semiarid parts of the Middle East and southern Asia, including dry or steep locales where other crops are difficult to cultivate. For thousands of years, farmers in these regions have grown the poppy as an important staple crop. For traditional poppy farmers, opium is a cash crop that supplements an agricultural livelihood. The entire plant is used: Poppy seeds are baked into breads, or oil for cooking or fuel is extracted from them and the body of the plant is fed to cattle. The labor-intensive aspect of collecting the sap for sale means that whole families are pressed into service at harvest time. The desire for opium in other parts of the world has long made it an important commodity in international trade networks.

References to opium appear in inscriptions and texts of ancient Sumer, Egypt, and Greece. The Greek physician Galen, in the second century C.E., noted that opium cakes were widely sold in Rome. This observation highlights an important difference between drug use before the twentieth century and contemporary drug use. Currently, drug use is divided into medical and nonmedical (or recreational) uses. Nonmedical use for opiates is banned in most countries, and persistent demand fuels a large and vigorous illicit trade. Medical uses are defined exclusively by physicians, and consumption of these drugs is allowed only in the context of treatment by a physician.

The sharp separation between medical and nonmedical uses of drugs is comparatively new in human history, although attempts to control drug use legislatively are not. In the past, physicians constituted only a small group of specially trained professionals who found their clientele primarily among the rich and powerful. A wide range of healers provided different kinds of health care; for example, in Europe from the Middle Ages to about the mid-nineteenth century, apothecaries prepared and sold drugs to anyone seeking treatment. Apothecaries consulted with the patient, helping diagnose an ailment and suggesting a remedy, but they charged a fee only for the sale of the drug.

Opium became an important European drug in the sixteenth century. During the Middle Ages, the severing of ties between Europe and the Middle East meant that large amounts of opium were not shipped to Europe. In the Middle East, however, the ancient Roman and Greek texts remained important sources of knowledge, and medical, as well as scientific and mathematical, theories were developed and debated among scholars like the Arab physician Avicenna. In these Moslem countries, where alcohol was absolutely forbidden, both opium and cannabis were widely used.

During the European Renaissance, renewed ties with the Middle East brought the ancient texts and their Arab interpretations to the attention of Euro-

pean scholars. Galen, who had systematized humoral theory in his writings, was recognized as an important authority in sixteenth- and seventeenth-century Europe. Galen's views were challenged by the sixteenth-century Swiss physician Paracelsus, who favored chemical remedies (such as mercury) to herbal ones. Paracelsus valued opium highly. He devised a mixture of alcohol, opium, and other ingredients that he called "laudanum" (from the Latin for "praise") to suggest its superiority.

Thomas Sydenham, the influential English physician, wrote in 1680: "Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium." This valuation of opium (and later of its derivatives) has been repeated by physicians in the centuries since as ongoing testimony to the drug's central role in medical treatment.

The medical use of opium grew more widespread in eighteenth-century England; for example, the relief of pain at the time of death was seen as an important adjunct to preparing the patient for death in a blessed state of peace. England was an important commercial power in this period, and new kinds of goods from distant parts of the world became increasingly plentiful. Opium was a valuable commodity, and, as such, it was handled commercially like any other. Individuals seeking to treat themselves for aches or ailments, or wanting to relieve drudgery or sleeplessness or persistent coughs, could buy pellets of opium from various merchants, innkeepers, or apothecaries. This pattern persisted through most of the nineteenth century, although by the late eighteenth century a particular effect of chronic opium consumption was described: If a habitual user stopped taking the drug, a clearly recognizable syndrome of symptoms ensued. These included runny nose, tearing, sweating, aches, muscle tremor, vomiting, and diarrhea. These problems were seen as an expected difficulty connected with taking medicines; they were not portrayed as a unique and devastating kind of problem that threatened the social fabric.

In the United States, also, opiates were freely sold. In the first half of the nineteenth century, neither medications nor medical practice were regulated. During the presidency of Andrew Jackson, antimonopolistic sentiment had led many states to repeal licensing requirements for physicians, on the grounds that such licenses created artificial elites. Many people saw no physician at all; they treated themselves or their family members with homemade or purchased remedies. Taking charge of one's own medical care also reflected the kind of broadened democratic spirit that characterized the Jacksonian age. In home treatment, opiates were valued for their wide-ranging effects, including quick and dramatic improvement in how one felt. Physicians also administered opium generously as part of the heroic brand of therapy favored in the nineteenth century. Based on humoral theory, "heroic therapy" sought to provide clear evidence of its effects on body fluids by promoting fluid discharges. Emetics and cathartics were the hallmarks of such practice, but the ability of opiates to produce sweat in addition to their other valuable effects made them a component of heroic therapy.

For individuals who appeared chronically weak, perhaps as the result of lingering fever, opium improved spirits and energy and was considered by many medical practitioners to have a STIMULANT effect (although it is now classed as a DEPRESSANT). Individuals who took the drug to relieve vague feelings of unease, or in the absence of serious medical conditions, were said to take the drug for its stimulant properties.

Rapid industrialization caused profound social shifts in England in the first half of the nineteenth century. People whose families had worked on the land for generations became part of the first large-scale factory work force. Working conditions were brutal; men, women, and children worked 14 hour days, 6 days a week. Working women often had to bring young children to the factory with them. For working people, opium was an easily available source of relief for many complaints of both adults and children.

Early in the nineteenth century, Thomas De Quincey and Samuel Taylor Coleridge wrote about opium-induced reveries. Although their works were widely read, their opium use was treated more as a curiosity than a cause for alarm. The earliest concerns about excessive or indiscriminate opiate use centered on adulteration or on deaths due to accidental OVERDOSE. These were voiced by a new group of professionals, public health workers. Extensive surveys of health conditions in England in the 1840s both highlighted problems and created opportunities for government and professional workers to expand their professional arenas. At the

same time, the old three-rank system of health-care givers, in which physicians treated the well-to-do while surgeons and apothecaries met the health needs of those of more modest means, was giving way. Surgeons and physicians joined a unified healing profession, whereas pharmacists prepared and sold drugs without providing diagnostic or therapeutic advice. As physicians worked to increase their professional authority, they sought to gain control over the use of drugs, defining them as medicines that only the medically trained could use or prescribe with safety. Toward the middle of the nineteenth century, a few physicians expressed concern about opium use for its "stimulant" effects. These voices foreshadowed an alarm about nonmedical use of opiates that would transform how this behavior was viewed. In the meantime, the 1868 Pharmacy Act called for precise labeling of any preparation containing opium.

The incidence of addiction also worried some observers, and this phenomenon became increasingly visible in part as a result of new pharmacological discoveries and changing medical technology. In 1806, Frederich Sertürner of Hannover, Germany, announced that he had isolated the chief active component of opium. He named this new drug MORPHINE, after Morpheus, the Greek god of dreams. Morphine was the first drug compound to be isolated from the plant that contained it, and as such it marked the first step in the development of scientific pharmacology. Drug effects could not be precisely described and measured until individual compounds were isolated. The isolation of CODEINE followed in 1832. In time, the systematic modification of the molecular structure of such compounds would be an important source of new medications and the basis of the modern pharmaceutical industry.

In the 1840s, the invention of the hypodermic syringe provided a new means of administering drugs. Morphine was among the first drugs to be administered by syringe, and the immediate introduction of the dose into the bloodstream provided stronger and faster drug effects than by swallowing and digesting the drug.

During the American Civil War (1861–1865), the combination of the more potent morphine, the hypodermic syringe, and wartime conditions contributed to widespread hypodermic morphine use. Large numbers of wounded soldiers and relatively few physicians meant that many soldiers were given syringes and supplies of morphine to treat their own pain. Many soldiers inevitably became addicted. Following the war, some of these soldiers phased out opiate use as their wounds healed, while others continued their pattern of morphine use for years. In the postwar period of industrial and commercial expansion, a wide variety of preparations containing opium were sold through vigorous advertising in an unregulated market. Physicians prescribed opiates, including morphine and codeine, for a wide variety of conditions. Many preparations were advertised specifically for women's health problems or for children bothered by colic or teething pain.

After 1850, Chinese laborers were brought to the American West to work on railroad building and other forms of gang work. As they moved away from these forms of labor, some Chinese took up placer mining in the Sierra Nevada or settled in Pacific coast cities like San Francisco. There, as white laborers sought to exclude them from the labor market, many opened and operated small businesses. The Chinese brought with them the practice of smoking opium to induce a 2 to 3 hour state of dreamy relaxation. Prejudice against Chinese people was based largely on fears that they would displace white laborers by accepting wages that white people considered to be below subsistence level; this prejudice focused on Chinese customs such as opium smoking. The U.S. Congress passed several laws in the 1880s to reduce the importation of opium intended for smoking into the United States.

In 1898, the Bayer company of Germany began marketing the newly trademarked drug Heroin, produced by modifying the morphine molecule. At first, HEROIN was valued for its apparent ability to cure morphine addiction; a dose of heroin quickly relieved all symptoms associated with morphine withdrawal. Within a few years, heroin's addictiveness was recognized and physicians stopped prescribing it, despite its effectiveness in relieving pain and coughing.

For many who became addicted through self-medication, addiction was a source of shame of which they could not free themselves. They sought treatment in privately run clinics that promised anonymity and offered little more than a place to rest while they went through withdrawal; or they purchased purported cures that, in fact, merely contained more opiates. Others continued to take

opium or morphine and managed their jobs or other responsibilities as long as their drug supply remained uninterrupted. The initial response to rising rates of addiction was to blame unscrupulous medicine merchants and physicians who administered opiates too readily.

In the United States, the concerns about adulteration, overdose, and addiction associated with an unregulated drug market became acute around the turn of the twentieth century. In the context of Progressive Era reform, the 1906 Pure Food and Drug Act required that any medication containing opiates state their presence and the amounts on the label.

In both the United States and England, what is now called recreational use of drugs emerged around the 1890s. People began taking opiates for pleasure, or to provide a novel experience, in a social setting with no medical overtones. Rising alarm about drug use as a particularly dangerous kind of social problem dates from this period, which also saw the rising political power of the Temperance Movement and its efforts to enact a total prohibition on the use of alcohol. Unfamiliar drug-use practices provided an additional focus for social anxieties in a time of rapid economic change. A Protestant middleclass ethos helped burgeoning new groups of professionals and business people adjust to new kinds of economic opportunity in an industrial age. Behaviors that challenged that ethos with pleasure seeking, new modes of entertainment, and unfamiliar druguse practices proved disturbing.

In the 1890s in England and the United States, small numbers of artists and bohemians, seeking to challenge what they saw as restrictive Victorian artistic and social standards, visited Chinese opium dens where they learned to smoke opium. For some Chinese in London or Liverpool, opium smoking provided a means of relaxation from a life of hard work in an alien land. As the existence of opium dens became more widely known, however, images of ghostlike, numb pipe smokers began to appear in popular literature. The middle- and upper-class pleasure seekers who smoked opium prompted a compassionate response, but British working-class use of opium was viewed as an indication of laziness, poor child-rearing habits, or loose morals.

In the United States, the 1880s and 1890s brought waves of new immigrants from southern and eastern Europe—and they brought new customs to the American cities they settled. By the early 1900s, sniffing heroin, for example, had become a practice of some young adults in urban neighborhoods crowded with large immigrant families or for some single adults making their way alone in a new industrial setting.

In this drawing from the Illustrated London News, *July 1857, workers at Hong Kong harbor transfer bales of opium from one ship to another for export to the West.* (© CORBIS)

Rising concern about opiate use in this period was only partly a reaction to incidence of opiate addiction, which, with alcoholism, was classed as a psychiatric condition called inebriety. In the late nineteenth century, many troubling conditions were redefined as diseases, especially as forms of psychopathology, and opiate addiction was among them, although many physicians even decades later saw addiction as resulting from a moral failing.

Worldwide missionary activity also resulted in concerns about opiate addiction. Christian missionaries in China and the Philippines, for example, believed that opiate addiction among the local populations helped explain what they perceived as economic backwardness. Like some temperance advocates in the United States, reformers concerned about addiction portrayed it as a form of slavery that followed a collapse of moral will. In such a framework, opiate addiction appeared as a scourge to be eradicated. Between 1911 and 1914 reformers met at The Hague to urge worldwide control of opiate supplies so as to prevent any nonmedical use of the drugs. Some countries joined in signing and ratifying a treaty that marked the first attempt to develop a coordinated international system for controlling worldwide opiate supplies. The U.S. representatives to these meetings were

embarrassed by the lack of any U.S. legislation for controlling access to opiates. A lobbying effort to bring U.S. legislation into line with the goals of The Hague resolutions led to passage of the Harrison Narcotics Act in 1914, the first U.S. law enacted to control who could buy a drug. The act banned sale of opiates and cocaine except for use by physicians or through a doctor's prescription. The American Medical Association (AMA), sensitive to charges that physicians' overprescribing of opiates was the chief cause of addiction, supported the legislation.

Following implementation of the HARRISON NARCOTICS ACT in 1915, health authorities in several American cities were worried that the sudden lack of opiate supplies for addicted individuals would create great personal stress and a possible public crisis. They opened clinics that were intended to dispense opiates to addicts so that they would not go suddenly into withdrawal when legal supplies were cut off. In many cases, the mission of a clinic was unclear: Were patients expected to reduce their doses gradually and wean themselves off opiates, or would some be permitted to continue to maintain their addiction by means of opiates supplied through the clinics? The U.S. Treasury Department, charged with enforcing the Harrison Act, moved vigorously to enforce it by charging certain physicians with the excessive prescription of opiates and by arguing in court cases that the act specifically disallowed addiction maintenance. In 1919, the Supreme Court ruled that the Harrison Act meant that physicians could not prescribe opiates to addicts except as part of a shortterm program of detoxification. Again, the AMA agreed. Armed with this legal support, the Treasury Department continued its enforcement activities against the maintenance clinics, and by the mid–1920s all had been closed.

The Harrison Act was envisioned by its proponents as part of a planned worldwide system of treaties in which each country that imported opiates would allow only the amounts needed for medical treatment to cross its borders. Opium-producing countries and the European countries where, in this period, most of the world's opium was refined into drugs like morphine or codeine would also cooperate to limit supplies of the drug. This approach to drug control has characterized the drug policies of most countries ever since.

Meanwhile, morphine and heroin use became part of a new urban social scene that included new kinds of entertainment. Concerns about opiate addiction shifted from compassion for innocent victims of improper medication to alarm about new centers of vice in urban neighborhoods. Inner cities became populated with groups whose social and political behaviors worried some business leaders, middle-class reformers, and workers who felt their jobs were threatened.

The passage of the Harrison Act was followed by the creation of federal enforcement bodies to prohibit unauthorized entry of opiates into the country, and to arrest and convict unauthorized sellers and possessors of opiates. In the 1920s, psychiatric theory held that chronic addicts suffered from personality deficits that caused them to feel inordinate pleasure from opiates and thus become mired in addiction. Opiate addiction was now viewed as both a medical and a criminal problem. The creation of the Federal Bureau of Narcotics in 1930, and the appointment of HARRY J. ANSLINGER as its head, moved drug enforcement out of the Prohibition Unit that oversaw enforcement of the Volstead Act. Following repeal of alcohol prohibition in 1933, the Federal Bureau of Narcotics continued to carry out the enforcement of the prohibition of opiates and cocaine. Anslinger was a skillful administrator with a background in diplomatic service. He oversaw American participation in the activities of the League of Nations' Opium Advisory Committee, which furthered the work on international control of opium supplies that had been initiated through the Hague Opium Treaty. On the domestic front, Anslinger managed an efficient team of nationwide enforcement officials. Believing that harsh and early punishment would be effective deterrents, he supported increasingly severe punishments for drug offenders, including mandatory minimum sentences for first offenders. For decades, the "drug problem" remained in the background of public consciousness as a kind of exotic problem associated with a city world of jazz, marijuana, and beatniks, but the threat carried enough symbolic weight to cause penalties for drug trafficking and possession to be stiffened in 1951 and again in 1956. Anslinger remained the U.S. government's chief drug-enforcewment official until his retirement in 1962, when, in both medical and legal circles, a new generation of observers were urging less punitive responses to drug offenses and greater emphasis on medical approaches to treating addicts.

The British approach to controlling opiate use in the twentieth century proceeded along a policy basis that was different from that of the American approach, despite some similarities in legislation. The Dangerous Drugs Act of 1920, like the American Harrison Act, restricted the use of opiates to legitimate medical needs. However, the British government did not seek to define the limits of those medical needs. The government-appointed ROLLESTON Committee, which met in 1924, recommended that addiction be regarded as an illness to be treated by physicians. Reacting in part to perceived difficulties in enforcing America's prohibitions of both alcohol and opiates in that period, the Rolleston committee members sought to avoid stimulating an illicit market by banning opiates. Rather, they favored allowing individual physicians to prescribe opiates to selected addicts—that is, they recommended a policy of addiction maintenance. British policy was also conditioned by the demographics of opiate use in Britain, which differed from patterns in the United States. In Britain, opiate use continued to be associated with affluent bohemianism and those addicted through legally prescribed medication, and the powerful stigma against addicts that characterized the American scene did not develop to the same degree in Britain. In such an atmosphere, nonpunitive policies appeared appropriate.

In the 1960s, startling new patterns of drug use brought the issue to mainstream consciousness in the United States and throughout Western Europe. Since the nineteenth century, the leaders of American reform efforts aiming to curb drug use had typically couched their rhetoric as concern about use patterns among specific population groups—foreigners (as in opium use by Chinese people) or the working class. Now, illicit drugs were typically being used by young, white, and middle-class persons.

Events of the 1960s prompted a generation of young people raised during the prosperous 1950s to question the ideals of the relatively calm and affluent world that they knew. These events included the ongoing civil-rights movement, the assassinations of President John F. Kennedy, Martin Luther King, Jr., and presidential candidate Robert F. Kennedy, and the escalating war in VIETNAM. As they questioned and challenged the establishment, young people disregarded old prohibitionist messages about illicit drugs; at the same time that they sought to forge new values, they also hoped they could eliminate the superficial and hypocritical aspects in American life. MARIJUANA and psychedelic drugs most closely symbolized the new spirit, but young people buying drugs on the illicit market and sharing lore about highs also encountered amphetamines and opiates.

For the young men who went to Vietnam to fight the war, the ready availability of heroin provided one possible avenue of escape from the horrors some of them experienced and witnessed daily (although boredom was often reported as a common motive for use). Southeast Asia remained an important source for the world heroin market, even more so as the trade from Turkey through southern France became hampered by enforcement activity. It was relatively easy for many returning veterans to stop using heroin once they returned to the United States. The men came back, however, after fighting a losing war to a United States deeply divided over the conflict. Receiving little welcome, many veterans had difficulty in readjusting to civilian life; for some of these, continued drug use remained part of a web of problems made up of chronic medical conditions or difficulties in finding work, although opiate use specifically was remarkably uncommon.

In 1972, President Richard M. Nixon was reelected on a platform that included bringing an end to the war and responding to growing American fears about crime. He united these concerns by increasing enforcement resources directed against drug use. In 1971, Nixon had proposed the most significant federal drug-policy initiatives since the passage of the Harrison Anti-Narcotic Act of 1914. He announced the creation of the Special Action Office for Drug Abuse Prevention (SAODAP). This office, administratively located in the White House and headed by Jerome H. Jaffe, M.D., led an expanded federal funding for drug treatment and special programs to identify and treat addicted soldiers returning from Vietnam. Jaffe had been director of an innovative program in Illinois that offered a range of treatment services, including methadone maintenance. The previous U.S. policy toward opiate addiction, which placed emphasis on law enforcement, was for a time replaced by one that emphasized concern for treatment and prevention in addition to control of the drug supply. Beginning in 1963 in New York, Vincent Dole and Marie Nyswander had demonstrated that longtime heroin

users, stabilized on daily doses of oral methadone and supported with a range of rehabilitative services, showed reduced criminal activity and improved functioning in social and employment areas. Nixon came to believe that methadone maintenance would provide a cost-effective means of reducing the money-seeking crimes committed by street addicts. Previously viewed as an experimental treatment, methadone maintenance, though subjected to special regulations, was made an accepted element in the treatment of opiate addiction. In the same legislation that created the Special Action Office, Congress included language that authorized the formation of the National Institute on Drug Abuse to coordinate federal funding of treatment services and research on drug abuse.

Meanwhile, in the 1970s, under federal leadership, treatment programs were expanded and new ones created in cities across the United States. Increasingly, those running the programs encountered patients who did not fit the model of the criminally involved longtime heroin addict. Younger patients, more women, and those using a variety of drugs reflected changing U.S. drug-use patterns. As these patterns were recognized, opiates ceased to dominate images of drug abuse in both the popular mind and in policy circles. Rather, opiates became just one group among many that were traded on the illicit market and used for philosophical, lifestyle, political, recreational, and even habitual reasons.

The CONTROLLED SUBSTANCES ACT of 1970, also passed at Nixon's initiative, reformulated how drugs were assigned legal status. The act created five schedules for categorizing psychoactive drugs, ranging from those considered to have no medical use and high risk of abuse to those having important medical use and only a mild risk of abuse potential.

In Britain, as in the United States, drug users in the 1960s and 70s experimented with a growing range of drugs besides opiates. New patterns of chronic drug use, new, flamboyant behaviors symbolized by the lives of celebrities and rock stars, and a sharp escalation in the absolute numbers of heroin addicts prompted some divisions in Britain's medical community about the wisdom of continuing Britain's nonpunitive maintenance policy toward opiate addiction. Some physicians became unwilling to treat addicts, whereas others remained committed to a purely medical approach to addiction with maintenance as an important component of the policy. In 1968 new laws were passed that limited the role of the general physician in the prescribing of heroin and that established a system of clinics supervised by specialists.

The early 1980s advent of ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) has added a new dimension of concern about drug use by injection, the preferred mode of administration of many heroin users. Because sharing used syringes can transfer the human immunodeficiency virus (HIV) from one person to another, drug use by injection has been named a high-risk behavior for its transmission.

In the late 1990s, heroin addiction once again is escalating and has moved from center city shooting galleries and dope houses (places people gather to use drugs) to more middle-class neighborhoods. There has also been a change in the ways people use heroin. Indeed, these changes in use patterns and user groups are comparable to those last seen during the Vietnam-era epidemic of the late 1960s and 70s. The so-called new heroin users are younger, smokers and snorters.

The new millennia heroin user is much *less* likely to start out injecting heroin. Snorting and smoking heroin is not, however, without inherent health risks. Heroin snorters risk neurologic complications, respiratory infections, and problems associated with other forms of heroin use, such as dependence, withdrawal, and vulnerability to future injection drug use and its associated diseases. Heroin smokers share these same health risks plus the added problem of respiratory infections through "shotgunning" or inhaling smoke and then exhaling it into another individual's mouth. This practice has the potential for the efficient transmission of respiratory pathogens, particularly tuberculosis.

Most of these young heroin users move on to injection drug use at some point in their drug using careers. In the absence of an effective treatment or vaccine, efforts to control the spread of HIV and hepatitis C (HCV) infections depend on reducing risk behaviors. Public health interventions have taken the form of prevention campaigns employing the media, educational groups or seminars, and street outreach workers. However, we also know that knowledge of health risks is not enough to help injection drug users to change their behaviors.

The availability of drug-using paraphenalia and the problems associated with finding clean and sterile equipment play a major role in disease transmission. One response has been to reduce the sharing of paraphernalia through the creation of needle exchange programs that distribute sterile needles and syringes, as well as other drug-using equipment. Assessments of the impact of such programs, in Australia, Europe, and in the United States, suggest that syringe exchanges play an important and significant role in reducing the rates of sharing for drug-using equipment.

All modes of heroin ingestion increase heroin users' vulnerability to hepatitis infection through the sharing of drug-using equipment (e.g., needles, straws, pipes, receptacles to cook or mix drugs). The spread of HIV/AIDS, hepatitis, tuberculosis, and other pathogens and infections among youthful drug-using populations poses not only serious public health threats, but also potentially large increases in public and private health-care costs.

Opiates remain important medication for the treatment of pain, cough, and diarrhea. Recent discoveries that opiates achieve their effects by mimicking compounds occurring naturally in the body (e.g., ENDORPHINS and ENKEPHALINS) have spurred exciting neuroscience resesearch about how the brain works. After millennia of use, then, opiates continue to be one of the most interesting classes of drugs.

CAROLINE JEAN ACKER
REVISED BY SHEIGLA MURPHY

OPIUM The milky juice derived from the unripe seed capsules of the poppy plant *Papaver somniferum* is called opium. This material, which dries to a brownish gum contains a large number of alkaloid compounds. These ALKALOIDS can be categorized into two major groups—the benzylisoquinolines and the phenanthrenes. The phenanthrene group includes the OPIOIDS, the most important of which is MORPHINE, which constitutes approximately 10 percent of opium. CODEINE is present in far smaller quantities, at 0.5 percent, and thebaine is only 0.2 percent. Both morphine and codeine can be extracted from opium and each crystallized to yield pure compounds. Virtually all morphine is derived from opium, since to synthesize it is complex and expensive. Although morphine and codeine have been used extensively in the clinical treatment of PAIN, thebaine is equally important—it is the starting material for the synthesis of many semi-synthetic opioid analgesics (painkillers). Of these, the most widely used include oxymorphone, oxycodone, and naloxone. Thebaine, itself, has no opioidlike effects.

Opium has a long history of use and abuse. It was initially used for the treatment of diarrhea and then for the relief of pain. Today, opium still has a number of medicinal uses, primarily as tincture of opium, a concentrated alcoholic extract of opium. Although this is occasionally used for extreme diarrhea, most physicians prescribe paregoric, a camphorated opium-tincture preparation containing approximately 0.4 milligrams per milliliter of morphine in 45 percent alcohol. The concentration of morphine in paregoric is far smaller than in opium tincture, so doses are adjusted accordingly. Doses that effectively treat diarrhea typically do not cause

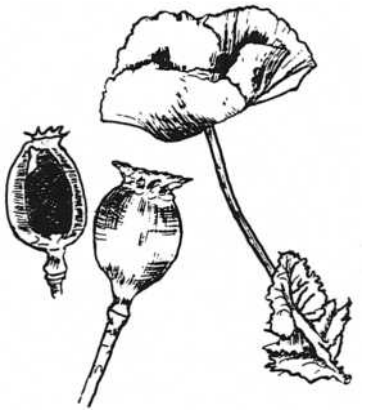

Figure 1
Opium Poppy and Pod

euphoria or analgesia—however, excessive doses can be abused and can lead to dependence.

History. The plant grows wild in the Middle East—especially in the Turkish plateau region—and has been known and used since antiquity. Opium was introduced into India by Arab traders of the thirteenth century. By the seventeenth century, along with the spread of TOBACCO use, the Chinese had devised a method of smoking opium—using small sticky balls of opium gum in opium pipes. It is said that by 1900, about 25 percent of the Chinese smoked opium, although it was banned by the emperor. This high level of use was the result of the British East India Company's practice, beginning in the mid-eighteenth century, of shipping opium to China from their conquered lands around Bengal (1750)—one of the major opium-producing areas of the subcontinent. Export of opium to China helped balance the company's trade deficit, caused by tea purchases. After 1780, opium was produced as a monopoly by the company.

China was at that time basically closed to all kinds of outside trade, except for certain port cities, where special concessions were granted by the emperor. Indian opium was auctioned to British traders in Calcutta, who carried it to Southeast Asia and China, often by way of shippers and smugglers off the South China coast and the islands there, including Hong Kong. British concern for the security of their opium trade led to the colonization of Malaysia and Singapore and, eventually, to the Opium War of 1840–1843, with China, where the emperor's troops were outmaneuvered. The series of treaties that ended that conflict "opened" China to trade with the West and to European political and economic domination.

Suppression of the trade began with the concerns of Protestant missionaries and physicians in China—which outweighed the concerns of the emperor for keeping his people producing for him, not enslaved by opium dreams. International bodies were formed in the late nineteenth and early twentieth centuries to restrict the opium trade, but the British refused to move toward any kind of regulation until 1905. The international conferences and conventions of 1909, 1915, and 1930 led to the restriction and prohibition of traffic in opium and opium derivatives—morphine, codeine, and heroin.

In the United States, opium abuse is not anywhere near the problem of HEROIN abuse, as of the early 1990s. Opium smoking and opium eating are the two major forms of abuse. Some immigrants to the United States have brought these customs with them, but on a small scale. When smoked, opium is prepared by heating it over a flame until a small ball of roasted opium gum is formed. The ball is then pushed into a pipe, where it is held over either a flame or a coal and smoked. Opium eating is widely practiced in India and in other countries where the opium poppy is cultivated—Turkey, Afghanistan, Southeast Asia, and so on. It is used as a household remedy for pain and other ailments, much as it has been for hundreds of years. Approximately 50 percent of opium eaters in India, for example, use it for medicinal purposes, taken as a pill or as a solution.

While the legitimate opium trade had slowed by the 1930s, illegal production continued in several places. In Southeast Asia, colonial governments drew revenues from opium monopolies until 1942, when the invading Japanese suppressed it during World War II. With the victory of the Communists in China in 1949–50, steps were taken to eradicate the growing of opium and its use. By 1960, opium production was confined to a few isolated areas of Burma, Laos, and Thailand. During the VIETNAM War, various tribal peoples were encouraged to grow opium by a number of politically motivated groups, resulting in the establishment of the GOLDEN TRIANGLE as one of the major centers of illegal opium production.

GAVRIL W. PASTERNAK

OVERDOSE, DRUG (OD) Administration of a drug in a quantity that exceeds that which the body can metabolize or excrete before toxicity develops constitutes an overdose. Whether it is accidental or deliberate, drug overdose is a significant problem that is encountered by providers of emergency medical care. Accidental overdose is common among users of illegal substances of abuse, since little reliability can be placed on the potency, presence of adulterants, and even identity of the street substance. For example, HEROIN potency has been demonstrated to range from 3 to 90 percent. Overdoses and deaths from heroin are therefore common. The prevalence of comorbid disorders in substance-abusing populations, particularly DEPRESSION, has been found to be high. Thus, deliberate drug overdoses taken in the attempt to commit SUICIDE are frequently encountered in this population. Also, people with a psychiatric illness but no drug-abuse problem most often attempt suicide with a drug overdose. Substances frequently implicated in drug overdose involve nonnarcotic ANALGESICS (painkillers), BENZODIAZEPINES (tranquilizers), OPIATES, or ANTIDEPRESSANTS—often in combination with alcohol.

The treatment of a drug overdose begins by providing basic supportive care (i.e., ensuring that there is adequate ventilation and monitoring the heart), calling 911, an emergency medical service (EMS), or the Poison Control Center (see Appendix I in Volume 4). If little time has elapsed since ingestion, efforts may be made to prevent further absorption of the drug by such means as gastric lavage or by administration of activated charcoal. Other treatments include increasing the rate of excretion through forced diuresis or giving specific antidotes (e.g., NALOXONE for opiate overdose) when the substance is known or can be identified from the presenting clinical syndrome. Obtaining a careful drug history from the patient or accompanying individuals is of paramount importance in effectively treating and minimizing risks from a drug overdose, which often results in death.

OVEREATING AND OTHER EXCESSIVE BEHAVIORS Overeating, a behavior not always limited to persons with BULIMIA, is grouped together with substance abuse and dependence in a superfamily of disorders designated as behavioral (non-substance-related) addictions. The term *impulse control disorders* has been used by some clinicians to describe these behaviors. In this context the notion of ADDICTION centers on the repetitiveness of the behavior and would include such behaviors as compulsive spending, compulsive gambling, pathological overeating (bulimia), hypersexuality, kleptomania (repetitive, compulsive stealing when there is no need), as well as miscellaneous obsessive-compulsive behaviors such as tics and hair-pulling (trichotillomania). Some researchers have pointed out similarities among these disorders and believe that there may be similar brain mechanisms involved in some of them. For example, it has been shown that DOPAMINE levels in certain areas of the brain (such as NUCLEUS ACCUMBENS) are elevated by the ingestion of reinforcing drugs including COCAINE, AMPHETAMINES, OPIOIDS, and, to some degree, NICOTINE. However, increased dopamine levels in these same brain circuits have been shown to occur when animals an-

ticipate food or sexual activity. Also, learning, conditioning, and reinforcement play important roles in these repetitive behavior disorders as well as in the more traditional chemical or substance-abuse and -dependence disorders. It has also been pointed out that treatments for nonchemical "addictive" disorders often follow principles used in substance-abuse disorders; for example, identifying trigger and high-risk situations, teaching alternative coping behaviors, and emphasizing relapse prevention. Self-help groups using AA principles have also been organized, such as Overeaters Anonymous or Gamblers Anonymous. Some pharmacologic agents appear to alter both drug ingestion and obsessive-compulsive behaviors that are not drug related. For example, SEROTONIN UPTAKE INHIBITORS, now used as ANTIDEPRESSANT medications, seem to help alcoholics decrease alcohol consumption and compulsive hair-pullers reduce that behavior.

Such broad definitions of addictive behaviors have disadvantages when they focus too much attention on the commonalities among the diverse behaviors while minimizing the differences and particularities. At a time when rapid progress is occurring in the understanding of the biological processes associated with substance dependence, focusing only on commonalities may obscure the value of therapeutic interventions aimed at specific disorders. For example, nicotine transdermal patches seem to have considerable value in treating tobacco dependence but are probably of no value for cocaine dependence or compulsive gambling.

The way society (or science) chooses to categorize behaviors—desirable or undesirable, repetitive or episodic—is determined in large measure by the objectives of developing the categorization. There are probably some circumstances where it is helpful to think about a broad category of problematic excessive behaviors encompassing everything from substance abuse to television watching. There is also the risk that in doing so we convey the notion that excessive drug use is no more serious or refractory to intervention than watching television or jogging. Certainly at the present time the social costs and medical consequences of the substance-use disorders are so great that we should be cautious about embracing any conceptual scheme that tends to trivialize or make these problems seem less serious than they are.

OVER-THE-COUNTER (OTC) MEDICATION This class of medication can be purchased without a prescription. Which medications require prescriptions and which do not varies widely from country to country. Common examples of OTC medications in the United States include ANALGESICS (aspirin, Tylenol®), cough and cold products (Sinutab®, Drixoral®), allergy medications (Benadryl®, Tavist), gastrointestinal products (Maalox®), antidiarrheals (Imodium®), and nicotine replacements (e.g., Nicorette® Gum, Nicoderm® Patch). Recently, a number of medications that previously were sold only by prescription have been made available over-the-counter. These include medications that block the production of gastric acid to relieve heartburn (Axid AR®, Tagamet HB 200®, Zantac 75®) and nicotine gum (Nicorette CQ®) and the nicotine patch (Nicotrol®, Nicoderm CQ®) for smoking cessation.

Prescription medications are labeled with patient-specific instructions determined by a physician whereas OTC products provide general information for use by consumers. OTC products *are drugs*, and as such they may cause side effects or adverse effects, or they may interact adversely with foods, ALCOHOL, or other medications. Some of the

A drugstore clerk in Deerfield, Illinois removes Tylenol capsules from the shelves after reports of tampering, February 18, 1986. (© Roger Ressmeyer/CORBIS)

more than 500,000 OTC products that are available have the potential to be misused or abused. Antihistamines, hypnotics, decongestants, analgesics, laxatives, and diet pills are often consumed in higher than recommended quantities; they have caused physical and/or psychological dependence. An epidemic of the early 1990s among adolescents has been "baby speed," the combining of OTC CAFFEINE pills with the decongestant pills pseudoephedrine. Handfuls cost only a few dollars and are responsible for overstimulating the heart and central nervous system, causing strokes and death.

An estimated 28 percent of adults in the United States use all kinds of OTC products, often responsibly but also in combination with prescription medications or alcohol. The high cost of visits to a physician and stays in a hospital has generated heightened interest in self-medication, which has increased opportunities for pharmacists to counsel patients. This situation is also contributing to the increased availability of medications as products are transferred from prescription to OTC status. The legislation that controls OTC products is quite recent. It was in 1951 that the United States first separated drugs into the two categories—prescription and OTC. A drug that is available only on prescription cannot be made available as an OTC product until its relative safety and efficacy have been reviewed by the U.S. Food and Drug Administration.

OXYCODONE Oxycodone is one of the most widely used OPIOID ANALGESICS in the United States, and it is usually used in conjunction with the analgesics aspirin or acetominophen. The combinations have proven effective and are, in some ways, superior to oxycodone alone, since they permit a lower dose of the opioid—and are therefore less likely to produce constipation, drowsiness, and nausea. Oxycodone is a derivative of OXYMORPHONE, the relationship being the same as that between CODEINE and MORPHINE. Like codeine, oxycodone is metabolized to oxymorphone, which is assumed to be responsible for its activity. Pharmacologically, the actions of oxycodone and oxymorphone are quite similar to those of morphine, so toxicity and ADDICTION can occur.

GAVRIL W. PASTERNAK

OXYMORPHONE Oxymorphone is a potent semisynthetic OPIOID ANALGESIC derived from thebaine, one of the twenty ALKALOIDS occurring naturally in OPIUM. It is approximately fivefold more potent than MORPHINE and has very similar actions and side effects. It is used to treat moderate to severe PAIN. Oral formulations are not available in the United States, but it is available by injection or by rectal suppository. Like morphine, continued use of oxymorphone leads to TOLERANCE AND PHYSICAL DEPENDENCE. It is interesting that oxymorphone shares the same basic chemical structure as the ANTAGONISTS NALOXONE and NALTREXONE, the only difference being the substituent on the nitrogen. Neither naloxone nor naltrexone have analgesic activity; in contrast to oxymorphone, they are instead capable of blocking opiate actions.

P-Q

PAIN: BEHAVIORAL METHODS FOR MEASURING ANALGESIC EFFECTS OF DRUGS Pain is a sensation produced by potentially harmful stimuli, such as intense heat, stretching, cutting, or chemical irritation. The ways in which information about these stimuli is carried to the brain and the interpretation that results are very complex. Pain sometimes occurs in the absence of a harmful stimulus, such as in phantom-limb pain (where the limb has long been missing). In other instances, pain is not even felt, although harmful stimuli are present. Thus pain is both a sensation and a response to that sensation. The response to pain can vary depending on the individual and the circumstances. Given this complexity, it is not surprising that pain can be modified in many ways—by a variety of drugs, by hypnosis, and by stimulation such as acupuncture.

PAIN TRANSMISSION

The transmission of pain involves two systems—an ascending and a descending neural system. Ascending neural systems carry information about potentially harmful stimuli from peripheral nerves to the spinal cord and from there to the brain, where information about the emotional and psychological aspects of painful stimuli is incorporated. In addition, the perception of painful stimuli is altered by descending neural systems, which send information from the brain back to the spinal cord. Pain transmission can be altered at any point in this loop. Drugs such as aspirin (an analgesic) relieve pain by reducing pain sensitivity in the periphery. Local anesthetics such as lidocaine (Xylocaine) and procaine (Novocaine) relieve pain by blocking nerve conduction in specific areas. Morphine and other opioids (narcotics) alter pain transmission by interfering with the processing of painful stimuli in the spinal cord and the brain.

MORPHINE AND OTHER OPIOIDS IN HUMAN PATIENTS

Among all the drugs that relieve pain, opium and its derivative morphine, are certainly the best known. When morphine is given to patients who are experiencing severe pain, they often say the pain is less intense or that it no longer exists. Other patients say the pain is still present, but it just does not bother them. Thus, morphine affects both the sensation of pain and the patient's response to the painful stimulus. It is generally believed that morphine acts in both the spinal cord and the brain. In the spinal cord, morphine inhibits the flow of information about painful stimuli from the spinal cord to the brain. In the brain, morphine alters pain perception by modifying activity in the descending pain-control system. In addition to relieving pain, morphine-like drugs produce a sense of pleasure (or euphoria) in some patients. Morphine and other opioids are the most effective drugs known for the relief of pain. Although their usefulness is sometimes limited by the fact that they can produce DE-

PENDENCE, this is generally not a problem in clinical settings.

NONOPIOID ANALGESICS

Although the opioids are considered the most effective drugs for the treatment of pain, THC (delta^9-TETRAHYDROCANNABINOL), the active constituent of MARIJUANA, has some pain-relieving properties, but it is not as effective as morphine in this respect. Very large doses of drugs such as ALCOHOL and the BARBITURATES also appear to relieve pain; however, these effects do not represent true analgesia, since they only occur at doses of alcohol and the barbiturates that produce a loss of consciousness. Thus, the organism's lack of response to painful stimuli is simply an inability to respond.

STUDIES IN LABORATORY ANIMALS

To determine whether a newly-developed compound has pain-relieving properties, scientists use behavioral procedures developed in laboratory animals. In general, these procedures measure the time it takes an organism to respond to a painful stimulus, first when no drug is present and then after a drug is given. Morphine and other opioids consistently alter this and other measures of pain perception. For example, morphine increases the time it takes an animal to remove its tail from a warm water bath, as illustrated in Figure 1. It takes about 2 seconds for the monkey to remove its tail from a warm water bath if morphine is not given. A small amount of morphine increases tail-removal time to about 8 seconds; larger amounts of morphine increase the time to as much as 20 seconds. Modification of pain perception also depends on the intensity of the painful stimulus. If the water in the bath is very hot, only very large amounts of morphine will increase the time it takes animals to withdraw their tail, whereas a lesser amount of morphine will increase response time at lower temperatures. Similarly, some drugs such as BUPRENORPHINE are most effective in relieving pain when the pain is mild. Since buprenorphine also produces less dependence than morphine, it may be a very useful drug for treating mild forms of pain. By combining data about the pain-relieving effects of a drug with data about its likelihood to produce dependence, information is obtained about the usefulness of a new drug in a clinical setting.

LINDA DYKSTRA

PAIN, DRUGS USED FOR Pain is a sensation unique to an individual. Its perception depends on the injury involved and the situation or context. A bruise obtained in a football game may not be appreciated at the time of the injury, yet in other circumstances the pain from a minor injury, such as stubbing a toe, may be overwhelming. The extent of the injury does not predict the amount of pain experienced; it is this wide variability that makes the treatment of pain difficult.

Within the brain, there are two systems that can appreciate the sensation of pain. One deals with the objective component and tells the exact location of the injury and what type of injury it is. The other is more diffuse and comprises the "hurt." Many people have experienced both types of pain. Touching a hot object or stubbing a toe is quickly followed by the appreciation that an injury has occurred, followed an instant later by the pain. It is this second pain that contains the "suffering," the "hurt," and the elimination of this second pain is the goal of ANALGESIC therapy.

Physicians have divided pains into three general categories. The first, and most common, is termed somatic pain. This results from tissue injury, such as a broken leg, metastases in the bone from cancer, muscle pulls, or ligament sprains. The second is termed visceral pain, which results from activation of pain fibers in internal organs, typically in the abdomen or chest. This category includes discomfort associated with gall bladder disease, peptic ulcers, or pancreatitis, to name a few. Unlike somatic pain, visceral pain is poorly localized. The most difficult pain to understand and to treat is deafferentation, or neuropathic pain, which is a consequence of injury to nerves. It is difficult for patients to describe these sensations, but they often use terms such as "burning," "shooting," or "electriclike." This type of pain is commonly seen in cancer patients where tumors invade nerve bundles. It also is seen with mild damage to nerves. The most common class of injury is the peripheral neuropathies. This collection of disorders results from a wide variety of causes; it affects nerves as they course through the body. The longest nerves are most sensitive to injury, which explains why this type of pain is most likely to develop in the feet. Diabetes is one of the most common causes. A special type of pain also falling in this classification is postherpetic neuralgia, a burning and/or shooting pain associated with *Herpes zoster*, known as shingles.

When considering pain, it is important to classify it as either acute (short-term) or chronic (long-term). The duration of many kinds of pain can be anticipated. The acute pain associated with surgery is usually limited in duration and, over the period of several days, decreases markedly. In contrast, the chronic pain associated with disseminated cancer can often be severe and persistent, actually increasing over time. Acute pain is associated with a number of very specific symptoms that are usually recognized by others—making it relatively easy to be believed. Patients may be pale and sweaty, the heart may be beating rapidly, and they may be grimacing. Chronic pain is different; it is usually defined as pain that persists for six months or longer. Many of the signs we see acutely wear off during this time, despite the continued pain, leading some observers to conclude that the pain is minimal or even absent; this conclusion is incorrect and often leads to undertreatment and therefore unnecessary suffering. Despite the sophistication of modern medicine, the most accurate estimate of pain remains simply to ask the patient. Chronic pain may seem to have no cause, at times, may be difficult to evaluate or treat, and often requires specialists. Special pain clinics exist for such cases.

Pain medicines (analgesics) are often broken into three major groups. The first group comprises the most commonly used drugs—aspirin, acetaminophen, and related compounds; these drugs are effective for mild to moderate pain. The second group include the OPIOIDS (OPIATES). Some opioids are used for moderate pain while others are typically employed for more severe pain. Thirdly, there are a number of drugs used either for specific pain syndromes or in conjunction with the first two groups. The agents in this last group are termed adjuvant drugs.

The choice of analgesic is based on both the type of pain and its intensity. Most pain is treated in a standardized fashion. Initial therapy often utilizes aspirin, ibuprofen, or acetaminophen. These agents are available without prescription and can be very effective for mild to moderate types of pain. They have a number of properties that make them excellent analgesics. Their effectiveness against a wide variety of different types of pain and their oral dosage greatly enhance their utility. Unfortunately, these agents exhibit relatively low ceiling effects. This means that the maximal degree of analgesia that can be obtained by a drug can be limited, regardless of the dose. These drugs also reduce fevers and help with the muscle aches commonly associated with viral diseases, such as colds and influenza.

Typically, these agents act at the site of injury, leading to their classification as peripherally acting drugs as opposed to centrally acting drugs, such as the opiates, which work within the brain and spinal cord. These nonsteroidal anti-inflammatory drugs

TABLE 1
Commonly Used Analgesics

	Average Oral Dose (in milligrams)	*Frequency (in hours)*	*Comment*
Nonnarcotics			
Aspirin	650	4–6	No prescription needed
Acetaminophen (Tylenol)	650	4–6	No prescription needed
Ibuprofen (Motrin)	200–400	4–6	No prescription needed
Fenoprofen (Nalfon)	200–400	4–6	Nonsteroidal anti-inflammatory
Diflunisal (Dolobid)	500–1000	8–12	Nonsteroidal anti-inflammatory
Naproxen (Naprosyn)	250–500	8–12	Nonsteroidal anti-inflammatory
Piroxicam (Feldene)	20–40	8–12	Nonsteroidal anti-inflammatory
Narcotics (opioids)			
Codeine	32–65	4–6	Often used in combination with aspirin or acetominophen (Tylenol#3)
Oxycodone	5–10	3–5	Often used in combination with aspirin (Percodan) or acetaminophen (Percocet)
Propoxyphene HCl	65–130	4–6	Used alone (Darvon) or in combination with aspirin and caffeine (Darvon Compound)
Propoxyphene napsylate	65–130	4–6	Used alone (Darvon-N) or with acetaminophen (Darvocet)
Morphine	30–60	4–6	Also available in slow-release formulations
Meperidine (Demerol)	50–100	3–5	Not very effective orally
Pentazocine (Talwin)	50–100	4–6	Partial agonist with tendency to produce unpleasant, subjective feelings; can precipitate withdrawal in dependent people
Hydromorphone (Dilaudid)	4–8	4–6	Very potent analgesic
Methadone (Dolophine)	5–20	8	Very effective analgesic; also used in maintenance programs
Levorphanol (Levo-Dromoran)	2–4	4–6	Potent analgesic used for cancer pain
Oxymorphone (Numorphan)	1–2	4–6	Only available by injection
Nalbuphine (Nubain)	10	4–6	Only available by injection
Butorphanol (Stadol)	2	4–6	Available by injection or by nasal inhalation; partial agonist; avoid using in dependent patients

(NSAIDs) and aspirin work directly on the mechanisms of inflammation, which explains their effectiveness against arthritis. Ibuprofen became the first nonsteroidal drug approved for sale without a prescription, based on its long use and excellent safety record. Over the years, a number of additional drugs have been developed, many with analgesic potencies approaching those of morphine (Table 1). All of these require prescriptions and carry risks greater than the drugs available over the counter. Side effects include a tendency to irritate the stomach and to interfere with the actions of platelets, a blood cell important in clotting; therefore, aspirin and the nonsteroidal anti-inflamma-

tory drugs should be avoided in patients with ulcer disease, since the drugs can cause bleeding. Acetaminophen does not irritate the stomach and does not interfere with platelets—however, it has its own potential problems. Although it is one of the safest drugs available when used as directed, overdoses with acetaminophen can be very dangerous. Overdoses are associated with major damage to the liver, which can be life-threatening. Care must be taken to use only the recommended doses of acetaminophen.

As an alternative to NSAIDs, a new class of drugs, COX-2 (cyclooxygenase-2) inhibitors, are being used to treat and manage arthritis pain and inflammation. Three COX-2 inhibitors have been developed: celecoxib (brand name Celebrex), rofecoxib (brand name Vioxx), and meloxicam (brand name Mobic). Meloxicam is the most recent of the three, having been approved by the Food and Drug Administration (FDA) in April 2000, while Celebrex, the first to be marketed, became the fastest-selling drug in history.

COX-2 inhibitors, when compared to NSAIDs, are better for the intestinal and stomach linings (Kubetin, 2000). On the other hand, like NSAIDs, they have been found to cause renal (kidney) side-effects, such as reductions in filter rates (McCarthy, 2000).

Opioids work within the brain and spinal cord to relieve the second pain—the hurt—described above. In this regard, they are amazing, since they take away pain without interfering with other sensations, unlike local anesthetics. It is this ability to selectively act on the hurt that makes them so valuable. A number of opioids are used for moderate pain (see Table 1). Of these, CODEINE is the most widely used, both alone and in combination with the nonopioids described above, followed by OXYCODONE. Both are usually used in combination with either aspirin or acetaminophen. The peripheral and central analgesics's work complement

TABLE 2
Comparison of Analgesics

	Action	*Potential Side Effects*	*Special Comments*
Nonnarcotic			
Aspirin	Relieves pain, reduces fever and inflammation, inhibits blood clotting	Gastrointestinal irritation, allergic reactions; reduced blood clotting may harm mother or fetus if taken during pregnancy; has been linked to Reye's syndrome in children	Especially effective for pain from inoperable cancer and dental surgery; inhibiting effect on bloodclotting can reduce incidence of heart disease
Acetaminophen	Relieves pain, reduces fever	Liver and kidney damage	Effective for mild-to-moderate pain but not for inflammation
Ibuprofen	Relieves pain, reduces inflammation and fever	Gastrointestinal irritation, allergic reactions	Especially effective for menstrual cramps as well as pain and inflammation in muscles and joints
Narcotic			
Codeine	Reduces pain, suppresses cough	Drowsiness, nausea, moderate physical and psychological dependence, constipation, respiratory depression	Effective for mild-to-moderate pain; especially effective against cough
Meperidine	Reduces pain and anxiety	Drowsiness, respiratory depression, high physical and psychological dependence	Effective for moderate-to-severe pain
Methadone	Reduces pain, alleviates heroin withdrawal symptoms	Drowsiness, respiratory depression, high physical and psychological dependence	Effective for severe pain

SOURCE: U.S. Department of Health and Human Services, Washington, D.C.

each other. If they work well together, they also bring with them the side effects of all the ingredients. Thus, both codeine and oxycodone produce constipation and sedation, along with occasional nausea, while the aspirin or acetaminophen have the problems noted above. Propoxyphene is another opioid used for mild to moderate pain. Like the others, it is most often used in combination with aspirin or acetaminophen. Standard doses are not much more effective than aspirin or acetaminophen alone, but at sufficiently high doses propoxyphene is an effective painkiller.

Pentazocine is a relatively unusual analgesic. It is an opioid indicated for moderate pain, but unlike morphine and codeine, which act primarily through mu receptors, pentazocine works in part through kappa receptors. Caution must be used when taking this agent along with other opioids, since it is a mixed AGONIST/ANTAGONIST and can precipitate WITHDRAWAL symptoms in dependent people. Many opioid addicts report an "allergy" to pentazocine when being treated by physicians, to avoid the possibility of withdrawal.

For more severe pain, a number of highly potent opioids are available (see Table 1). They include MORPHINE, hydromorphone, levorphanol, MEPERIDINE, and METHADONE. All are available orally. Morphine is now available in special slow-release formulations, which permit dosing as infrequently as every twelve hours. This is much more convenient for patients, particularly at night, when they no longer have to awaken to take their medicines. Special care must be taken when using these long-acting analgesics. Slow-release morphine, like methadone, may take days to reach stable levels in the blood. Thus, it can be difficult to adjust dosages without "overshooting"—which, if severe, can lead to OVERDOSES that may be life-threatening.

In hospitals, many patients receive opiates by injection or intravenously. Doses need to be adjusted to compensate for differing distributions and metabolism, but these changes are relatively straightforward for physicians working in the area of pain. Special devices are also available that permit patients to dose themselves, as needed, within specified guidelines. This approach is termed *patient controlled analgesia* (PCA). Even more sophisticated routes of administration are available. Some medications can be injected deep in the back, adjacent to the spinal canal (epidurally) where they can act primarily on the spinal cord. Localizing the medication to the spinal cord can minimize the side effects produced in the brain, such as nausea and respiratory depression.

The chronic use of opioids leads to a lessening of potency, which is termed *tolerance*. To overcome this, it may be necessary to increase the dose to maintain a constant effect. Furthermore, all patients taking sufficient quantities of drug for an extended time will become physically dependent—that is, they will experience some withdrawal if the drug is stopped. Very few patients taking opioids for medicinal purposes will ever become addicted, as the term is now used by psychiatrists. This distinction between the standard physiological responses of TOLERANCE/DEPENDENCE and ADDICTION is important, because fear of addiction should not interfere with the appropriate medical therapy of pain.

REVISED BY REBECCA MARLOW-FERGUSON

PAPAVER SOMNIFERUM Poppy plants, of the genus *Papaver*, are long-stalked flowers of varying colors encompassing approximately 140 species. Of the many types of poppy plants, *Papaver somniferum* is known as the OPIUM poppy. It has white or blue-purple flowers and is widely cultivated in Asia, India, and Turkey, which supply much of the world's opium. Cultivation requires a tropical or subtropical climate without excessive rainfall. In the Northern Hemisphere, the plant flowers in late spring, after which the petals fall in a short time. This is followed by the rapid growth of the capsules (the plant's ovaries) for about two weeks. Incisions are carefully made in the capsule to obtain the milky juice, which is then dried as a gum that yields opium. The yield of opium can vary widely, but is typically about five pounds (2.25 kilograms) per acre.

The opium serves as a source of MORPHINE, CODEINE, and thebaine and is widely used in the production of important painkillers (ANALGESICS).

Typically, morphine comprises 10 percent of opium and most of the morphine used in medicine is obtained by purifying opium.

Illicit uses of opium are also widespread. In many parts of the world, opium is still smoked or eaten. Morphine extracted from opium may in turn be converted to HEROIN in clandestine laboratories. Heroin is the major opioid used illicitly in the United States. To prevent the collection and sale of opium for illicit conversion to heroin, new ways of processing the poppy plant have been developed. The most widely used consists of mowing the poppy fields before the pods are ripe enough to yield opium. The mowed stems, immature pods, and plant matter, referred to collectively as poppy "straw," are then shipped in bulk to large processing centers where the active ALKALOIDS are extracted under careful supervision.

Other species of *Papaver* also contain alkaloids that can be converted into potent opioids. For example, *Papaver bractiatum* contains high concentrations of thebaine, which can be used to produce compounds several hundred times more potent than morphine.

PARAPHERNALIA LAWS AGAINST Drug paraphernalia are articles that facilitate or enable the use of illicit drugs, such as hypodermic syringes for HEROIN or pipes for smoking MARIJUANA. Laws prohibiting the possession and use of paraphernalia have been adopted in every state of the United States despite significant constitutional objections to them.

The first drug-paraphernalia laws, prohibitions against possessing opium pipes, were enacted by western states in the late nineteenth century as part of broad statutory efforts to suppress opium smoking by CHINESE immigrants. During the first third of the twentieth century, some states, in conjunction with a legislative attempt to criminalize the nonmedical use of OPIATES and COCAINE, also prohibited the possession of hypodermic syringes without a medical prescription. By 1972, when the NATIONAL COMMISSION ON MARIJUANA AND DRUG ABUSE conducted a survey of state drug laws, about twenty states had adopted some type of drug-paraphernalia prohibition.

Commercialization of drug paraphernalia, especially through so-called head shops, in the early 1970s triggered a new generation of paraphernalia prohibitions, many of which criminalized the sale as well as possession of these articles. Such laws attempted to enforce comprehensive bans on drug-related devices or articles intended for use with illicit drugs.

The drug-paraphernalia industry responded to the enactment of these laws by challenging their constitutionality on vagueness and overbreadth

Since the late nineteenth century, the federal and state governments have enacted laws to regulate the possession and sale of drug paraphernalia, like the crack pipes pictured here. (© Bettmann/CORBIS)

grounds. In most cases, courts struck down the laws as unconstitutionally vague: first, because they applied to objects that had lawful as well as unlawful uses, these laws failed to provide fair notice of prohibited conduct; and second, the lack of explicit standards left police with discretion to enforce these laws in an arbitrary and discriminatory manner.

In 1979, the U.S. Drug Enforcement Administration (DEA) stepped into the fray. In an attempt to assist states and localities in drafting laws that might withstand constitutional scrutiny and at the same time effectively combat the drug-paraphernalia trade, the DEA drafted a Model Drug Paraphernalia Act (MDPA). Unlike prior state laws, the MDPA explicitly requires prosecutors to prove that the defendant knew the alleged paraphernalia would be used with illegal drugs. The addition of the so-called intent requirement was designed to alleviate the fair-warning concern associated with the earlier generation of statutes. In addition, the MDPA attempts to provide a more specific definition of drug paraphernalia by listing objects included within the category and by providing factors that judges should consider in determining whether an object falls within the definition. Finally, the act prohibits placement of an advertisement when one knows, or "reasonably should know," that it is intended to promote the sale of objects "designed or intended for use as drug paraphernalia."

A majority of states have adopted the MDPA or an equivalent statute, but its constitutionality has yet to be ruled on by the U.S. Supreme Court. In 1982, however, the Court upheld a local ordinance that required businesses to obtain a license in order to sell articles designed to be used with illegal drugs. Although this law did not involve a criminal statute prohibiting sale or possession of paraphernalia, most lower courts have subsequently upheld criminal laws modeled after the MDPA against vagueness and overbreadth challenges.

In the wake of the HIV/AIDS epidemic, another feature of traditional drug-paraphernalia laws has become controversial. In an effort to reduce the risk of transmission of the HUMAN IMMUNODEFICIENCY VIRUS (HIV) and other blood-borne diseases among needle-sharing illicit drug users, state and local public-health authorities have sought to establish clean-needle exchange programs, usually through hospitals and clinics. To implement these programs, lawmakers have had to repeal the paraphernalia laws or prosecutors have agreed not to enforce them in this context. Many states and local governments have refused to support needle-exchange programs, and the federal government has not funded them due to concerns that dispensing needles will encourage illicit drug use. However, the National Academy of Sciences has concluded that these programs reduce the risk of HIV transmission and has found no evidence that they encourage drug use.

In general, drug-paraphernalia laws represent a type of drug legislation aimed mainly at declaring and symbolizing society's intolerance of illicit drug use. Like other symbolic uses of criminal law, however, these laws are subject to highly discretionary enforcement and can have unintended costs or ramifications.

PARASITIC DISEASES AND DRUGS OF ABUSE A long historical awareness exists regarding the association between heavy ALCOHOL use and an increased risk or severity of symptoms caused by infectious diseases. In the United States, this awareness can be traced back to the medical literature of the late 1700s. It continues to evolve in ongoing research. Historically, most infectious diseases were viral and bacterial and caused death, such as tuberculosis. Some intestinal diseases have been also noted, especially cholera. This is an acute infectious disease of epedemic proportion caused by *Vibrio cholerae* (a gram-negative bacillus) that produces a soluble toxin in the intestinal tract, with profuse watery diarrhea, extreme loss of fluid and electrolytes, and a state of dehydration and collapse with death often following.

Modern research in immunosuppressed humans and animals has isolated a protozoan parasite, *Cryptosporidium parvum*, that affects the gastrointestinal tract. In immunocompetent hosts the disease is self-limiting and recovery is accompanied by resistance to reinfection. *Cryptosporidium* is, however, common in patients with acquired immunodeficiency syndrome (AIDS). It has been noted in 16 to 50 percent of cases, but is rarely manifested in HIV-positive people before loss of CD4 cells. Research with alcohol and COCAINE in AIDS-compromised animals has indicated lessened resistance to *Cryptosporidium*. This is true as well with similar AIDS-compromised animals having colonies of trophozoites (a vegetative protozoan) of Giardia muris infecting the small intestine. The reason parasite infections in addition to some cancers and certain other diseases are more common in heavy or chronic alcohol users relates significantly to suppression of host defenses. Alcohol use lowers production of antibodies. Cocaine suppresses the functioning of T-lymphocytes, critical to the activation of immune defenses. Some infections, particularly parasitic ones, require a substantial lowering of natural immunity and resistance to be able to grow for more than a few days. Alcohol and drugs of abuse are strong suppressors of resistance mechanisms. Thus, their adverse effects are even more pronounced in the elderly, AIDS patients, transplant recipients, and others with damage to their immune system. In addition, alcohol and drugs of abuse lower intakes and tissue levels of antioxidant vitamins and nutrients, important for optimum functioning of host defense systems. Supplementation with antioxidant vitamins helps overcome some of the damage due to AIDS, age, and drug abuse.

PAREGORIC A camphorated OPIUM tincture; tinctures of opium are alcoholic extracts of opium, widely used in the treatment of diarrhea. Paregoric contains powdered opium, anise oil, benzoic acid, camphor, glycerin, and diluted alcohol. With only 0.4 milligrams per milliliter of MORPHINE in 45 percent alcohol, it is more dilute than opium tincture—and the taste of the camphorated formula is generally disliked, helping to minimize excessive use or abuse.

Although paregoric is not indicated for bacterial or parasitic causes of diarrhea, it can be very helpful for other causes. Taken orally, it effectively slows down the gastrointestinal transit of wastes and enhances resorption of fluid from the intestine. Doses that effectively treat diarrhea typically do not cause euphoria or analgesia; however, excessive doses can be abused and can lead to DEPENDENCE.

THE PARENT MOVEMENT The parent drug-prevention movement emerged in the latter half of the 1970s in response to the greatest escalation in drug use by children and adolescents in the history of the world. It originated with a number of people, who founded several different national organizations to lead the parent movement.

In August 1976, an Atlanta mother, Marsha Keith Mannat Schuchard, Ph.D., and her husband, Emory University professor Ronald Schuchard, Ph.D., discovered at their eldest daughter's thirteenth birthday party that she and most of her friends were using drugs that evening. In response, the family organized the nation's first parent-peer group. Such groups consist of parents whose children are each others friends. The parents come together to establish age-appropriate social and behavioral guidelines they agree to adhere to in order to protect their children and help them avoid unhealthy and destructive behaviors during adolescence. In a very short time, the young people whose parents formed this first parent-peer group stopped using drugs and returned to the productive behaviors in which they'd been engaged before they entered the drug culture. Dr. Schuchard later wrote about this experience in *Parents, Peers and Pot*, a book the National Institute on Drug Abuse published and distributed free to the more than one million people who requested it during the 1980s.

In the fall of 1977 a group of concerned Atlanta citizens formed National Families in Action. Founders included Keith Schuchard and Sue Rusche. Mrs. Rusche later became the organization's executive director. This organization called attention to the social and environmental factors that seemed to promote the use of illicit drugs. Its purpose is twofold: 1) to replace commercial and societal messages that glamorize drug use with accurate information based on scientific research about drug effects, and 2) to help people put this information to use by organizing community-based parent drug-prevention groups. At the time of its founding, National Families in Action responded to the explosion in all communities of head shops, which appeared to target children and teenagers as potential customers. Drug users called themselves "heads"—"acid heads," "pot heads," "coke heads," etc. Head shops were places that sold books and magazines that taught people how to use drugs, and toys and gadgets to assist and enhance drug taking. The materials head shops sold were called drug paraphernalia. In January 1978, National Families in Action succeeded in getting the Georgia Legislature to pass the nation's first laws banning the sale of drug paraphernalia.

At about the same time, Otto and Connie Moulton, of Danvers, Massachusetts, founded Committees of Correspondence. Their goal was to alert citizens about the activities of drug-culture and drug-policy organizations that advocate for the decriminalization and legalization of marijuana, cocaine, heroin, PCP, and other illicit drugs. They began sending out packets they called "Otto Bombs," detailing information about the local, state, and federal lobbying activities of drug-legalization organizations such as the National Organization for the Reform of Marijuana Laws (NORML), whose board and advisory board at the time consisted of many drug-paraphernalia manufacturers and publishers. Patterned after the original Committees of Correspondence, founded by our forefathers to uphold the rights of colonists before and during the Revolutionary War, the modern-day version seeks to uphold the rights of citizens to be drug-free. A periodic newsletter presents information from researchers and doctors that refutes medical and scientific claims made by legalization proponents. Committees of Correspondence also

tracks the lobbying efforts of other organizations that advocate legalizing drugs, including the Drug Abuse Council in the 1970s and the Drug Policy Foundation in the 1990s.

In April 1978, Thomas "Buddy" Gleaton, Ed.D., invited Keith Schuchard and Sue Rusche to address the Fourth Annual Southeast Regional Drug Conference. Gleaton held the conference for drug-education professionals at Georgia State University, where he taught. He also invited officials from various federal agencies. Many accepted, particularly from the National Institute on Drug Abuse. The Parents' Resource Institute for Drug Education (PRIDE) was founded in the summer of 1978, following this conference.

Publicity generated by the passage of Georgia's drug paraphernalia laws, by the Fourth Southeast Drug Conference and, later, by the publication of *Parents, Peers and Pot*, brought requests for help from parents throughout the United States. These parents wanted to form parent groups to ban drug paraphernalia sales in their cities, towns, and states, and to prevent substance abuse among their children in their families and in their communities. For the next several years, leaders from National Families in Action, PRIDE, Committees of Correspondence, and other national organizations, along with leaders of emerging groups from various states, traveled across the nation helping parents form prevention groups. A contract the National Institute on Drug Abuse awarded to Pyramid made much of this work possible. Pyramid hired parent-group leaders as consultants and paid their expenses to travel to communities that sought their help in organizing groups.

One of the first groups to form outside Georgia was Naples (Florida) Informed Parents, led by Pat and Bill Barton. The Florida leaders joined those from Georgia and Massachusetts to help parents in other states form similar groups. By 1979, hundreds and perhaps thousands of parent groups had organized across the nation. In January 1979, Senator Charles Mathias (D-MD) held Congressional hearings on the harmful effects of marijuana, and invited many parent-group leaders, along with scientists, to Washington to testify. The parent leaders took advantage of this opportunity to be together for the first time and discussed the need to form a Washington-based organization that could represent their interests with both Congress and the federal agencies that were making and implementing national drug policy. They agreed to meet at the Fifth Annual Southeast Regional Drug Conference, now known as the PRIDE conference, in Atlanta in the spring of 1979. There, they founded the National Federation of Parents for Drug-Free Youth. Pat and Bill Barton were elected as the group's co-presidents and a Maryland parent group leader, Joyce Nalepka, later became the Federation's executive director.

The summer of 1979 was an election year, and parent groups worked hard to get drug-abuse-prevention policy on the agendas of Presidential candidates. After the election, the National Federation of Parents for Drug-Free Youth led a massive letter-writing campaign to President-elect Ronald Reagan, asking him to bring Carlton Turner, Ph.D., to the White House as his drug-policy advisor. Dr. Turner, of the University of Mississippi, was responsible for growing all marijuana used in scientific research throughout the world. He had devoted much time to educating parents at various conferences about the pharmacological effects of marijuana on the brain and body, and had earned their trust. President Reagan acted on the parent federation's appeals and selected Dr. Turner as his drug advisor.

Shortly after the inauguration, Dr. Turner helped the federation arrange for parent-group leaders to brief Mrs. Reagan on the prevention movement and enlist her support for their cause. She not only responded positively, but served informally as the national spokesperson for the parent drug-prevention movement. A few years later, President Reagan appointed parent-group leader Ian Macdonald, M.D., a pediatrician from Florida, to serve as Administrator of the Alcohol, Drug Abuse and Mental Health Administration (ADAMHA), the federal agency in the Department of Health and Human Services that was responsible for substance abuse and mental health research and services. One of Dr. Macdonald's legacies is the Center for Substance Abuse Prevention (then called the Office for Substance Abuse Prevention, or OSAP), which he created as an office during his tenure at ADAMHA. Congress formally authorized OSAP as a center, changed its name to CSAP, and funded it in the Anti-Drug Abuse Act of 1986.

Through this kind of concerted effort, parents were able to place key policy-makers in the federal government to emphasize and implement their goals: To prevent the use of illegal drugs (and alco-

hol and tobacco among those underage) before it starts, to help drug users quit, and to find treatment for those who are addicted and cannot quit by themselves. The parent movement was the first leg of the national drug-prevention effort that was active in the year 2000. It is generally credited with developing and carrying out strategies that reversed the drug policies of the 1970s, which seemed to increase drug use throughout that decade.

These strategies included outlawing head shops and the sale of drug paraphernalia, stopping the decriminalization/legalization of marijuana (and other drugs), and insisting that drug-education materials contain "no-use" messages, based on accurate scientific information about the effects of drugs on health and on local, state, and federal laws and international treaties. As a result of effectively implementing such strategies, both Robert DuPont, M.D., and William Pollin, M.D., the first two directors of the National Institute on Drug Abuse, credit the parent movement with being responsible for reversing the 1970s escalation in drug use by children, adolescents, and young adults, and for initiating the reduction in regular drug use that took place among all ages between 1979 and 1992.

Beginning in the late 1980s, the Center for Substance Abuse Prevention made demonstration grants available to support local, grass-roots, drug-prevention efforts targeting high-risk youth, primarily in African-American, Hispanic, Asian-American, and Native American Indian communities. Many new parent and family-based groups emerged to join the parent drug-prevention effort as a result. So did national groups representing each of these populations, including African-American Parents for Drug Prevention, based in Cincinnati, Ohio; the National Hispano/Latino Community Prevention Network, based near Albuquerque, New Mexico; National Asian Pacific American Families Against Substance Abuse, in Los Angeles, California; and the National Association for Native American Children of Alcoholics in Seattle, Washington. These groups joined with National Families in Action, PRIDE, and the National Federation of Parents for Drug-Free Youth to form The Parent Collaboration to inspire today's parents to form volunteer parent groups to prevent drug use among their children. An additional group, the Drug Free America Foundation based in St. Petersburg, Florida, works with the collaboration. Unfortunately, economic pressures that drive contemporary parents to work and to devote an average of 50 to 60 hours to their workweeks, mean there is simply no time for parents to volunteer a sustained drug-prevention effort, as the previous generation of parents were able to do. Furthermore, Congress eliminated high-risk youth grants from the Center for Substance Abuse Prevention, and funds were simply not available to enable parents to work full-time, or even part-time, at preventing drug abuse in their families and communities.

As funding to support minority parent- and family-based drug-prevention groups disappeared, a well-funded effort to legalize drugs re-emerged in the 1990s. This effort has contributed to re-establishing conditions that are similar to those that appeared to drive drug use up among young people in the 1970s. Legalization proponents reject abstinence-based drug-education as "unrealistic," and advocate instead for educational materials that teach children how to use drugs "safely." Proponents also are leading efforts to sponsor state ballot initiatives that attack or weaken laws forbidding drug use, drug dealing, and drug trafficking and, at the same time, are launching lobbying efforts to legalize drugs. With the growing popularity of the Internet, the sale of drug paraphernalia, and even of illicit drugs, along with an amazing array of misinformation about drug effects, dominates online drug sites. As these conditions intensify, so does drug use and drug abuse. In the state that has passed the most measures to soften or eliminate its drug laws, Oregon, more citizens now abuse illicit drugs than alcohol, according to a survey commissioned by the Health Division of the Oregon Department of Human Services. Of even more concern nationwide, the 13-year-long, two-thirds decline in regular drug use among adolescents (and the 500 percent drop in daily marijuana use—from 11 to 2 percent among high school seniors) ended in 1992, and drug use doubled among teens throughout the decade. While some government surveys show adolescent drug use is now leveling off, others show drug use continues to rise among teens and young adults.

As drug use rises once again among America's children, America's parents are unavailable to work for drug prevention. Most must work to earn money to provide for their families. They cannot afford to do the long sustained work of drug prevention without pay. No funding mechanisms exist to give parents the opportunity to "switch jobs"

and work full time, or even part time, to prevent children from entering a culture whose lure intensifies each year. Until this changes, the outlook for reducing drug use among the nation's children, adolescents, and young adults remains bleak.

PARTNERSHIP FOR A DRUG-FREE AMERICA The Partnership for a Drug-Free America is a nonprofit coalition of the United States communications industries; its mission is to help reduce demand for illegal drugs by using the media to change the attitudes that affect drug trial and experimental (nonaddicted) use. The key officers of the organization are James E. Burke, chairman; Thomas A. Hedrick, Jr., president; Richard D. Bonnette, executive director; and Robert L. Caruso, chief financial officer.

The partnership was founded by Richard T. O'Reilly in early 1986 as a project of the American Association of Advertising Agencies. It was based on the idea by Philip Joanou, chairman of Dailey & Associates in Los Angeles, that the disciplines of marketing could be used effectively and efficiently over time to help "unsell" illegal drugs. The hypothesis was that prevention could be viewed as trying to affect individual decisions to buy or use illegal drugs in the same way that individual decisions to buy or use legal products and services are affected—except in reverse. Rather than using media messages on the *benefits* of a product, the partnership set out to reduce drug trial by building awareness of the *risks* and danger of using illegal drugs.

The Partnership's early strategy was based on a concept developed by Dr. Mitchell S. Rosenthal, president of the PHOENIX HOUSE treatment programs in New York. He theorized that the epidemic levels of drug use and addiction in the early 1980s was caused by a process of "normalization"—to both the use and users of illegal drugs—since the mid-1960s. According to Dr. Rosenthal, we could not achieve significant progress in "the war on drugs" until we reversed that process and "denormalized" individual and subcultural attitudes toward illegal drugs.

The three primary functions of the partnership are (1) to understand consumer attitudes that affect the trial and use of illegal drugs; (2) to develop messages targeted to specific demographic groups; and (3) to deliver those messages to the public through all forms of the media, but primarily public-service announcements. These functions, managed by a small full-time staff, have been accomplished through the volunteer efforts of research firms, advertising agencies, production groups, and the media. As of the end of 1992, more than 300 antidrug print and broadcast messages had been delivered, at no cost to the partnership and valued at more than 50 million dollars. Since the program's launch in March 1987, the media have donated more than 1.5 billion dollars in advertising time and space.

The partnership's prevention messages are targeted primarily to preteens and young teens, inner-city youth, and also parents, peers, and siblings, who are viewed as the key influencer groups. The focus of the messages is on building perceptions of risk and social disapproval, promoting resistance skills, and reinforcing a consistent tone of social denormalization in regard to illegal drugs. Overall media efforts are directed at achieving the goal of 1 million dollars a day in donated time and space. This results in the delivery of approximately one antidrug message per household per day. All major national media are visited personally by partnership staff to monitor the program. State and local media programs are also developed and supported through staff and volunteer efforts.

The organization's tracking research is funded by the NATIONAL INSTITUTE ON DRUG ABUSE

(NIDA) and directed by the Gordon S. Black Corporation. The annual Partnership Attitude Tracking Survey (PATS) uses a centrally located sampling to evaluate attitudes toward illegal drugs among more than 8,500 preteens, teens, and adults. This research, along with other major NIDA studies and especially the HIGH SCHOOL SENIOR SURVEY done by the Institute for Social Research, suggests that since 1986 attitudes to illegal drugs have been changing. Furthermore, the surveys indicate that the partnership's messages have been a major source of information (among others) that helped effect these changing attitudes.

It is difficult to establish a scientifically conclusive cause-and-effect relationship between the partnership's efforts and U.S. trends in drug-use behavior. Many components are necessary—particularly community efforts—to reduce demand for illegal drugs, and it is unlikely that any one component is sufficient to the task. It is also imperative to note the importance of timing in this media effort, since the media are most effective in accelerating trends that are already in place. The media play a large role in American society and therefore in the lives of the children growing up in that society. The Partnership is mounting a very significant communications effort to influence the way Americans think about illegal drugs.

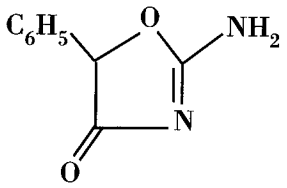

Figure 1
Pemoline

PEMOLINE Although not structurally similar to the AMPHETAMINES, pemoline has similar PSYCHOMOTOR STIMULANT effects but only minimal effects on the cardiovascular system. Pemoline is often used therapeutically (despite being less effective than amphetamine or METHYLPHENIDATE) in the treatment of ATTENTION DEFICIT/hyperactivity disorder (ADHD)—a syndrome that first becomes evident during childhood and is characterized by excessive activity and difficulty in maintaining attention. Pemoline has the advantage of a long half-life, which means that dosing can be once daily, but clinical improvement can be delayed by three to four weeks after initiation of pemoline therapy. In addiction, the likelihood for abuse of pemoline appears substantially less than that of the amphetamines.

PERCODAN *See* Oxycodone

PERSONALITY AS A RISK FACTOR FOR DRUG ABUSE The term *personality* refers to those relatively enduring aspects of attitudes, feelings, responses, and behaviors that permit us to recognize a particular person whom we have known over time. It is, in a way, a fingerprint of an individual's psychological makeup—the framework of how the individual thinks and acts. Psychiatrists believe that this framework arises out of childhood, powerfully shaped by the actions of parenting and the other social and environmental factors on a complex set of genetic and other biological givens. It is then further molded throughout one's development to achieve more or less lasting form in adolescence and early adulthood.

In the nineteenth century, we said that some people had willpower or a strong character; now we might refer to their good coping skills or to their ego

strength—different ways of describing global measures of effective functioning. Current terms for more specific descriptors of personality might include the poles of introversion—extroversion, or approach—avoidance, as well as others.

There is a long tradition linking personality, or character, to alcohol and other substance use and abuse. In the popular imagination, the old usage of "alcoholic" or "drug fiend" conveyed images of weakness, untrustworthiness, and/or viciousness; more sophisticated imagery, "oral character," conveyed ideas of dependency and neediness—analogies to the greedy infant at the breast. Unfortunately, such simple postulates break down in the presence of the complexities of the real world: Not all substance abusers are frightening "drug fiends"; neither are they necessarily dependent, needy, demanding "oral characters."

The explanation for substance abuse is not found purely in the drug. Most adults are able to drink socially without becoming alcoholics; some of us are repeatedly exposed to opiates (e.g., after surgery) without becoming addicts. Clearly, the impact of personality on alcohol and other drug use depends on a variety of factors—the social context, the specific drug, and the stage of involvement with the drug. Is the individual brought up as a rich kid in the suburbs or poor in an inner-city ghetto? Is the person black or white? Do drugs and drug users surround the individual, and are they seen as normative, or are they considered dangerous, rare, and deviant? Is the drug a relatively weak reinforcer such as marijuana, or is it a powerful stimulant such as cocaine? Is the individual experimenting in the early stages of use, struggling with long-term dependency, or dominated by the pangs of withdrawal and craving? Although a number of predictor factors for substance abuse are known, such as age, sex, religiosity, and parental drug use, we do not know why only *some* of those at risk become drug dependent. Personality is another likely predictor of who will try a particular drug, who will continue to use it or abuse it, the success of the struggle with abstaining, and so forth.

As the preceding indicated, early thinking was that excessive drinking (alcohol) and smoking (tobacco) were linked to early childhood experiences of suckling and satiation, of hunger satisfied by taking something in through the mouth that resulted in blissful sleep. That this may, at least at times, be true was seen in one patient who had first been addicted to alcohol and then to a series of barbiturates and other sedatives; he said plaintively, "Doc, I could become addicted to orange juice if it gave me a dreamless sleep." Unfortunately, just as the thumb fails to provide milk, most drugs do not ultimately provide the desired end—the continuing sense of pleasure and/or relief. It was assumed that individuals who had had difficulty in the earliest stages of development might be particularly prone to some kinds of addiction—to depressive drugs, such as alcohol, sedatives, or opiates, which provide dreamy reverie states or sleep—and that difficulty in later stages of development might predispose to use of activating drugs, such as the stimulant amphetamines or cocaine.

Ongoing clinical experience and changing theories led investigators to focus additionally on aggression and on regulation of feelings. For example, many addicts appear to have difficulty distinguishing anxiety and anger, and they experience strong feelings as overwhelming, leading to loss of control. The drug may substitute, both pharmacologically and symbolically, for the parent—to "magically" help the individual maintain control. It has also been noted that many addicts appear not to have learned from their parents how to recognize, evaluate, and appropriately respond to danger. Many, or all, of these additional factors may operate at once: Individuals may be trying to satisfy primitive impulses and needs; there may be a defect in the recognition and control of feeling states; and they may be struggling to adapt to a stressful environment. A particular drug may, for a particular individual, transiently resolve these issues. Heroin may satiate, dampen, and control aggression—and provide relief from environmental pressures—for the moment. Amphetamines or cocaine may provide orgasmic pleasure, in the form of a "rush, as well as provide a sense of control and omnipotence. A patient who was dependent on amphetamines was panicked at the thought of dental anesthesia: "I can't stand the idea of not being in control, of being put to sleep. It's why I take the pills, to stay awake, to know what's happening."

Many individuals who misuse drugs will misuse many different kinds of drugs—the polydrug abusers. There are also people who, even after extensive experimentation with a variety of drugs, will choose to use and/or abuse a single drug or class of drugs—such as opiates, sedatives, or stimulants. It has been suggested that such individuals are driven

to seek a particular drug experience, since the various drugs indeed have differing physiological and psychological effects.

Some studies lend support to this notion of particular personality contributions to drug preference. For example, opiates tend to bolster withdrawal (from others) and repression (not acknowledging reality) by inducing a state of decreased motor activity, underresponsiveness to external situations, and reduction of perceptual intake. Such a state is conducive to reinforcing fantasies of omnipotence, magical wish-fulfillment, and self-sufficiency, but both sexual drive and aggression are diminished. In addition, there is evidence that opiate addicts are, in general, more severely impaired in terms of their ability to function in the ordinary world; they are less able to cope with the activities of daily living. In contrast, amphetamines elevate scores on autonomous functioning and sense of confidence; there is a feeling of heightened perceptual and motor abilities accompanied by a strengthened sense of potency and self-regard. These effects appear to serve the user's need to feel active and potent in the face of an environment perceived as hostile and threatening—and also to deny underlying fears of passivity.

It is important to remember that all of us have some quirks, that we do not always handle all kinds of stress equally well, that we all have some weaknesses in our personalities, some defects in our characters. These may predispose some of us to drug use and to particular drug choice. Others have significant defects in development, disordered adaptations to the real world in which we are expected to function; they may choose a particular drug or drugs to help them adapt to their difficulties—to make up, in a sense, for what is lacking within them. They are in effect choosing and self-administering their own medicine. This has been referred to as the *self-medication* theory of drug abuse. Certainly, drugs are capable of dramatically reversing painful emotional states; they can mute or free us from unmanageable feelings and provide some with the feeling that "It's the only time I've ever felt normal." Unfortunately, these effects are short-lived; side effects and the complications of physical dependance, tolerance, and withdrawal become prominent and even dominate the chronic user, who has become a substance abuser.

Be cautioned: These studies were done on people who had already been using illicit drugs for many years—who had been immersed in the "drug world" of copping (getting the drug), fearing detection and detention, and living with the altered state of consciousness induced by their drug of choice. These studies and others like them can tell us only of a correlation, not a causal relationship, where personality style or defect results in or leads to drug use/ abuse. There are, however, some longitudinal studies that have followed schoolchildren for enough years to have seen some of them enter the drug world. In general, they show remarkable agreement in the descriptions of those children who become seriously involved with drugs. They are the opposite of the stereotype of the Eagle Scout (who is "thrifty, loyal, brave, clean, and reverent"); instead, they may be characterized as impulsive, with difficulty tolerating feelings and delaying gratification, and as possessing an antisocial personality style given to breaking rules, oppositional behavior, risk taking, and sensation seeking. These personality characteristics are present before immersion in the drug culture and are altered as the individual moves from initial use to continuing use, to the transition from use to abuse, to cessation or control of abuse—and, all too often, to relapse.

Be further cautioned: These findings may have been true at the time of the studies but may prove to be specific to that moment of history and no longer true. Zinberg (1984) has pointed out that the setting in which one takes a drug, and therefore the meaning of the drug-induced experience, is continually changing:

> Chronic users [of marijuana], those that began using prior to 1965 were observed to be more anxious, more antisocial, and more likely to be dysfunctional than were the naive subjects who were just beginning to use marijuana in 1968. . . . By the late 1960s, drug use was being experienced as a more normative choice . . . in the early 1970s, controlled marijuana users could not possibly have been described as individuals driven to drug use by deep-seated, self-destructive, unconscious motives [p. 174].

An alternative view that has been suggested is that a series of otherwise accidental environmental reinforcers may so interact as to result in drug use in the absence, or the limited availability, of otherwise more necessary and pleasurable commodities. Experiments have shown just such development of "excessive behavior" in both animals and humans

during conditions of deprivation—of not enough water or food—but they have not yet demonstrated such a role in the induction to drug use.

Despite these cautions, it appears that PERSONALITY is a contributor that predisposes some to substance use and abuse. Different personalities are likely to make differing contributions to drug use, depending on the particular drug, the historical moment, the social surround, and the other determinants of use. Although it is still difficult to demonstrate more than generalities about the personality of addictive behaviors, the construct of addictive personality(ies) may be "theoretically necessary, logically defensible, and empirically supportable" (Sadava, 1978). Without such a construct—which includes the characteristic response patterns of the individual, the symbolic meaning of the experience to the individual (while recognizing that this may be retrospective rationalization), as well as the specifics of the particular drug's pharmacology—it will be difficult to explain the variation in drug use among individuals with apparently comparable life experiences.

PERSONALITY DISORDER The concept of *personality* refers to the set of relatively stable and characteristic behaviors that individuals display in perceiving and responding to the environment, along with a particular way of thinking about themselves. These patterns of behavior and self-perception are called personality traits. They are manifested in a variety of social interactions in day-to-day living, and their diversity is extensive. When these traits become exaggerated, inflexible, and maladaptive, they begin to impair social functioning and can cause subjective distress. Different constellations of maladaptive traits are clinically diagnosed as personality disorders. Frequently, individuals identified as having a personality disorder do not see themselves as others see them, do not recognize the annoyance their behavior engenders in those around them, and hence do not seek to change their behaviors unless there are significant social repercussions. The characteristic traits of a personality disorder typify the individual's long-term functioning and are generally recognizable by adolescence.

In psychiatry, clusters of certain personality traits are recognized in the DIAGNOSTIC AND STATISTICAL MANUAL *of Mental Disorders- 3rd ed.-revised* as constituting particular personality disorders. There is some overlap in the trails of some of the following identifiable personality disorders.

Paranoid
: suspicious, mistrustful, hypervigilant, easily offended, unfeeling toward others

Schizotypal
: odd and eccentric behavior, speech, and manner of thinking; withdrawn and isolated

Narcissistic
: exaggerated sense of self-importance, feelings of entitlement to special favors, exploitation of others, lack of empathy, response of rage to criticism, disregard for social conventions

Histrionic
: dramatic, emotional, erratic, with displays of seductive behavior; attention-seeking

Antisocial
: antisocial behavior in many areas of life: lying, theft, violence, substance abuse, sexual promiscuity, spouse and child abuse, inconsistent work, legal conflicts; impulsivity and lack of remorse for antisocial acts

Borderline
: unstable mood, behavior, relationships, and sell-image; impulsive, self-destructive acts (e.g., suicide attempts, substance abuse); chronic feelings of emptiness, intolerance for being alone

Avoidant
: timid, extreme sensitivity to real or imagined rejection, socially withdrawn, poor self-esteem

Dependent
: avoidance of taking responsibility for their lives and a striving to get others to look after them; passive, submissive, with low self-esteem, and discomfort when alone

Obsessive-compulsive
: perfectionist, orderly, inflexible, indecisive, constricted emotions, obstinate, overly conscientious

Passive-aggressive
: resistance to demands for adequate social and occupational performance indirectly through procrastination, inefficiency, stubbornness, forgetfulness; frequent fault-finding with others

The origins of personality disorders are not well understood, but they clearly can be thought of as reflecting the contributions of genetic, constitutional (temperament), environmental (upbringing, relationships), sociocultural and maturational (psychological development) factors. The need for, and modalities of, treatment of personality disorders varies and can include psychotherapeutic and pharmacologic interventions.

PET SCANNER *See* Imaging Techniques

PEYOTE Peyote (or peyotl) is the common name for the cactus *Lophophra williamsii* or *Anhalonium lewinii*, which is found in the southwestern United States and northern Mexico. Although

there are many compounds found in the cactus, some of which may be PSYCHOACTIVE, the principal HALLUCINOGENIC substance found in peyote is MESCALINE. As the other psychoactive substances may make some contribution to the PSYCHEDELIC experience, there may be some slight difference in the behavioral effects produced by taking peyote and pure mescaline, but the overall effects of peyote are very similar to those produced by mescaline.

Peyote, one of the oldest psychedelic agents known, was used by the Aztecs of pre-Columbian Mexico who considered it magical and divine. Its use spread to other Native American groups who used it to treat various illnesses, as a vehicle to communicate with the spirits, and in highly structured tribal religious rituals. For these rituals, the dried tops of the cactus—the buttons—are chewed or made into a tea. Since peyote may cause some initial nausea and vomiting, the participant may prepare for the ceremony by fasting prior to eating the buttons. Peyote is usually taken as part of a formalized group experience and over an extended period of time; the peyote ceremonies may take place at night and around a communal fire to increase the hallucinogenic effects and visions.

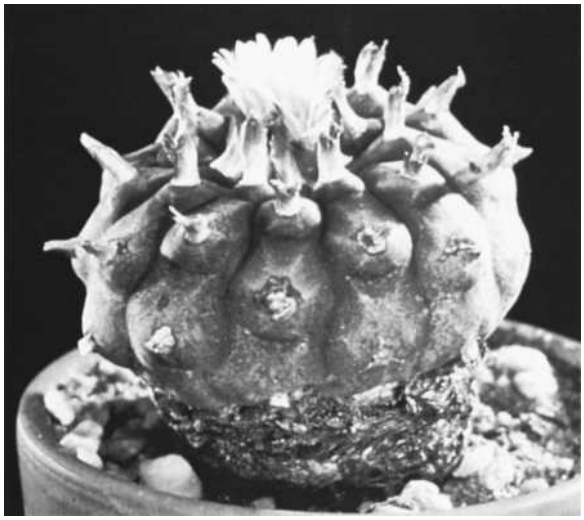
PHARMACODYNAMICS The study of the mechanism of drug actions is called pharmacodynamics. Most (but not all) drugs exert their action by binding to specific RECEPTORS. This binding may initiate changes that lead to the characteristic effects of the drug on body functions.

A central question in drug therapy (medication) is the proper dose of the drug that produces a desired action without many harmful side effects. To clarify this problem, pharmacologists analyze the relationship between dose and response. Most dose-response curves are sigmoidal (shaped like an S).



The peyote cactus, from which is derived the hallucinogenic mescaline. (Drug Enforcement Administration)

The log-dose-response can be viewed as having four parameters: potency, slope, maximal efficacy, and variability. Potency describes the strength of drug effects. It is usually employed to calculate relative strengths among drugs of the same class. Slope is the central part of the curve that is approximately straight. It is used to analyze drug concentration (dose) from the observed corresponding responses. Maximal efficacy, or simply "efficacy," is the greatest effect produced by the drug. This is one of the major characteristics of a drug. Efficacy and potency of a drug are not necessarily correlated, and the two characteristics should not be confused.

Many drugs, including drugs of abuse, produce TOLERANCE—when it becomes necessary to take progressively larger doses to achieve the same drug effect. In some cases, the brain and other tissues on which a drug acts undergo adaptive changes (neuroadaptations) that tend to offset the drug effect. When a drug that produces neuroadaptation is withdrawn, the brain and other tissues have to readapt, because they are no longer balanced by drug effect. The adaptation produces a variety of signs and symptoms called withdrawal syndrome. The severity of this syndrome depends on the degree of adaptive changes in the nervous system—which, in turn, depends on the dose and the duration of exposure to the drug. The particular characteristics of the withdrawal syndrome depend on the pharmacological effects of the drug(s) and typically

are opposite to the drug effects. For example, MORPHINE constricts the pupil; the morphine withdrawal symptom includes pupil dilation.

Most drugs of abuse produce pleasant effects in humans. For example, some people use AMPHETAMINES or other stimulants (e.g., COCAINE) to achieve a sense of well-being and euphoria. Some people use DEPRESSANTS—ALCOHOL, OPIOIDS, or TRANQUILIZERS—to relax. Still others use either stimulants or depressants to relieve boredom or reduce anxiety or pain. The common feature is that people use drugs because somehow the drug is rewarding to the user, either by producing a feeling of well-being (e.g., euphoria, elation) or by taking away a negative feeling (e.g., anxiety).

PHARMACOKINETICS: GENERAL

Pharmacokinetics describes quantitatively the various steps of drug disposition in the body including absorbtion of drugs, distribution of the drugs to various organs, and their elimination by excretion and biotransformation. The rates of these processes are important in characterizing the fate of a medication in the body.

The actual percentage of a drug contained in a drug product that enters the circulation unchanged after its administration, combined with the rate of entry into the body, determines the *bioavailability* of a drug.

Once absorbed, most drugs are carried from their site of action and elimination by the circulating blood. Some drugs simply dissolve in serum water, but many others are carried bound to proteins, especially albumin. Plasma *protein binding* influences the fate of drugs in the body, since only the free (unbound) drug reaches the site of drug action. This interaction with binding sites is reversible.

The intensity of drug action is most frequently related to the concentration of the drug at the site of action. The duration of drug effect is related to the persistence of its presence at this site. The time to reach maximum drug concentrations (or peak effects) is usually referred to as t_{max}.

Whenever the fate of a drug in the body is described by pharmacokinetic parameters, a model of the body is assumed. The fundamental principles of pharmacokinetics are based on the most elementary model. The body is considered a single compartment. Distribution of the drug is considered uniform. The "volume" in which the drug is distributed is referred to as the *volume of distribution* (Vd). It is typically expressed in liters per kilogram (L/kg).

Elimination of the drug is assumed to be exponential. The *rate of elimination* of a drug is usually described by its *half-life* ($t_{1/2}$), which is the time required for 50 percent elimination of the drug. This is typically expressed in hours (h). Another way to express drug elimination is the *clearance*, which represents the volume of drug cleared from the body per unit of time. This is usually expressed in milliliters per minute per kilogram (ml/min/kg) but can also be expressed in liters per hour per kilogram (L/h/kg).

An effect of a single dose of a drug may be characterized by its latency, the time needed for drug concentrations to reach maximum levels (t_{max}). Magnitude of peak effects and duration of action dosage and rates of absorption and elimination are influenced by these parameters. As dosage increases, latency is reduced and peak effect increased without change in the time of peak effect. Reduced elimination (long half-life, reduced clearance) results in an expected prolongation of drug effects and, in some cases, drug accumulation. Using more complex models than a single compartment model, physicians use pharmacokinetic data not only to characterize the fate of a drug in the body but also to calculate doses and frequency of drug administration for each particular patient. This is important because there are wide variations among individuals in the absorption, distribution, and elimination of drugs.

Tables 1 through 4 are a summary of the available data on the kinetic properties of alcohol and other abused drugs. Some of the drugs of abuse included in this summary are illicit drugs (e.g., COCAINE) while others are effective pharmacological agents that have the potential to be abused (e.g., OPIOIDS).

Although some of the drugs included in the tables have been used for centuries (e.g., ALCOHOL, CAFFEINE), knowledge of their kinetics and metabolism is very recent and, in some cases, still incom-

PHARMACOKINETICS: IMPLICATIONS FOR ABUSABLE SUBSTANCES

Pharmacokinetics is the study of the movements and rates of movement of drugs within the body, as the drugs are affected by uptake, distribution, binding, elimination, and biotransformation. An understanding of the biological basis of the clinical actions of abused drugs depends, in part, on knowledge of their neurochemical and neurorecptor actions that reinforce and sustain drug use (Hall, Talbert, & Ereshefsk, 1990). The pharmacokinetic properties of abusable substances represent a second important component of the database. The discipline of pharmacokinetics applies mathematical models to understand and predict the time course of drug amounts (doses) and their concentrations in various body fluids (Greenblatt, 1991, 1992; Greenblatt & Shader, 1985). Pharmacokinetic principles can be used to provide quantitative answers to questions involving the relationship of drug dosage and route of administration to the amount and time course of the drug present in systemic blood and at the receptor site of action.

Before an orally administered PSYCHOACTIVE DRUG can exert a pharmacological effect through its molecular recognition site in the brain, a number of events must take place (see Figure 1). The drug must reach the stomach and dissolve in gastric fluid. The stomach empties this solution into the proximal small bowel, which is the site of absorption of most medications. The drug must diffuse across the gastrointestinal mucosal barrier, reach the portal circulation, and be delivered to the hepatic (liver) circulation. (The liver detoxifies chemicals, including drugs.) Before reaching the systemic circulation, then, the absorbed drug must "survive" this initial exposure to the hepatic circulation—sometimes termed the "first-pass" through the liver (Greenblatt, 1993). After reaching the systemic blood, the drug is transported to the cerebral (brain) capillary circulation as well as to all other sites in the body that receive blood directly from the heart (cardiac output). The drug diffuses out of the

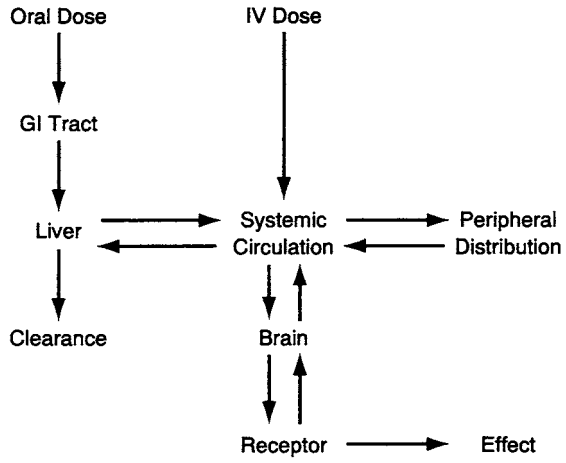

Figure 1
Schematic Representation of Physiological and Pharmacokinetic Events. These occur between administration of a centrally acting compound and the production of a pharmacological effect. If the medication is given orally, it must pass from the gastrointestinal (GI) tract to the portal circulation and to the liver before reaching the systemic circulation. Intravenous administration, however, yields direct access to the systemic circulation. Drugs of abuse may be taken by the intravenous route but are also taken by intranasal, intrabuccal, or inhalational routes, all of which will avoid the initial gastrointestinal-portal-hepatic exposure.

cerebral capillary circulation, crosses the lipoidal (fatty) blood-brain barrier, and reaches the extracellular water surrounding the neuroreceptor site of action. Only then is the drug available to interact with its specific molecular recognition site.

All of these processes take time, and some may serve as obstacles that delay or prevent the drug from reaching its site of action. Pharmacokinetic models incorporate the physiology of these processes, and can allow rational prediction of important clinical questions: How much drug reaches the brain? How fast does it get there? How long does it stay there?

DRUG ABSORPTION

The term *lag time* refers to the time elapsing between ingestion of an oral medication and its first appearance in the systemic circulation (see Figure 2). For most drugs, it generally falls between 5 and 45 minutes. For ethanol (drinking ALCOHOL, which is also called ethyl alcohol), however, the lag time may be very short, because the drug is already a liquid at the time it is ingested, and a significant component of absorption probably occurs across the gastric mucosa as well as in the proximal small bowel (Frezza et al., 1990). The physicochemical features of the drug contribute importantly to the time necessary for dissolution and therefore to the lag time. All else being equal, drugs in solution have shorter lag times than those administered in suspension form; they are, in addition, more rapidly absorbed than capsule preparations and, finally, tablet preparations. For any given solid dosage form, lag time and absorption rate are likely to be shorter if the drug particles are more finally subdivided. Sustained-release (time-release) drug formulations are deliberately prepared to have long lag times and slow absorption rates, thereby avoiding drug effects associated with the peak concentration.

Absorption rate refers to the time necessary for the drug to reach the systemic circulation once the absorption process actually begins. Pharmacokinetic models can be applied to assign a half-life value to the process of absorption. Values of absorption half-life tend, however, to be of low statistical stability, and it is increasingly common to characterize the absorption process using the observed peak plasma concentration (c_{max}) and time of peak concentration (t_{max}). The t_{max} is actually a

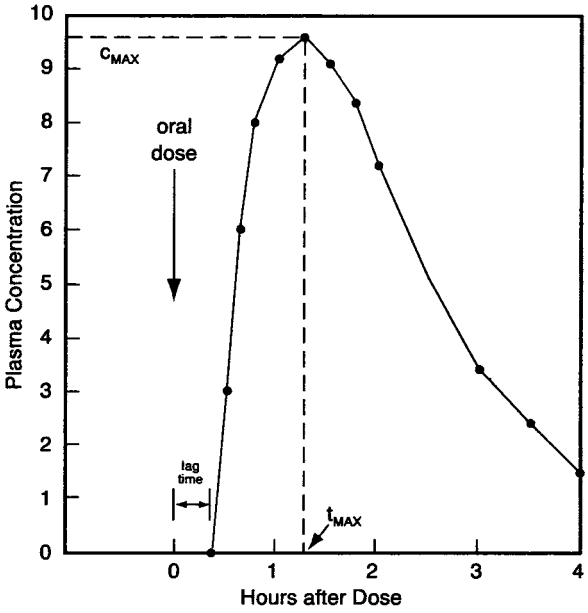

Figure 2
Schematic Plot of Plasma Concentration versus Time after Oral Dosage (given at time zero [arrow]). A lag time elapses between the time of administration and the beginning of appearance in the systemic circulation. Plasma levels then rise, reach a peak, and fall: c_{max} is the peak plasma concentration (9.6 units) and t_{max} is the time of peak concentration (1.25 hours after dosage).

composite of the lag time plus the time necessary to reach peak concentration once absorption starts (Figure 2). In general, fast absorption implies a high value of c_{max} and a short value of t_{max}; slow absorption implies a long t_{max} and a low c_{max}. Again, sustained-release drug preparations are deliberately formulated to produce long lag times and slow absorption, thereby delaying and reducing the c_{max} after an oral dose. Drug absorption tends to be slower when medications are taken during or just after a meal, rather than in the fasting state (before a meal, on an empty stomach).

For these reasons, the ethanol in alcoholic beverages is relatively rapidly absorbed after oral ingestion. The popular lore that alcohol bas a greater effect when taken on an empty stomach probably has a physiological basis, since peak concentrations will be higher and earlier when alcohol is taken in the fasting state. BENZODIAZEPINE derivatives (tranquilizers) clearly are not primary drugs of

abuse and are seldom subject to misuse by the great majority of patients; however, benzodiazepines may be taken for nontherapeutic purposes by some substance abusers (Woods, Katz, & Winger, 1987, 1992; Shader & Greenblatt, 1993). The preference of specific benzodiazepines by drug abusers appears to be closely related to their rate of absorption. That is, rapidly absorbed benzodiazepines, leading to relatively high values of c_{max} shortly after dosage, appear to be preferred by drug abusers. The benzodiazepine diazepam (Valium), for example, is much more rapidly absorbed than is oxazepam (Serax or Serenid). In controlled laboratory settings, diazepam is more easily recognized as a potentially abusable substance by experienced drug users, and it is also preferred by this group to oxazepam (Griffiths et al., 1984a, 1984b). This preference also appears to be supported by epidemiological studies of PRESCRIPTION DRUG misuse (Bergman & Griffiths, 1986).

Some orally administered medications reach the systemic (blood) circulation in small or even negligible amounts relative to the dose ingested. Incomplete absorption from the gastrointestinal tract sometimes explains this. However, oral medications may be poorly available to the systemic circulation even if they are well absorbed. This is explained by the phenomenon termed *presystemic extraction*, which results from the unique anatomy and physiology of the gastrointestinal circulation (Greenblatt, 1993). Orally administered medications are absorbed into the portal rather than systemic circulation (Figure 3), and portal blood drains directly into the liver. Many drugs that are avidly metabolized in the liver may therefore undergo substantial biotransformation before reaching systemic blood. Some drugs may also be metabolized by the gastrointestinal (GI) tract mucosa. First-pass hepatic metabolism together with GI tract metabolism is collectively termed presystemic extraction. COCAINE, for example, is not favored as a drug of abuse by the oral route, because of nearly complete presystemic extraction, allowing only small amounts of the intact drug to reach the systemic circulation (Jatlow, 1988; Jeffcoat et al., 1989).

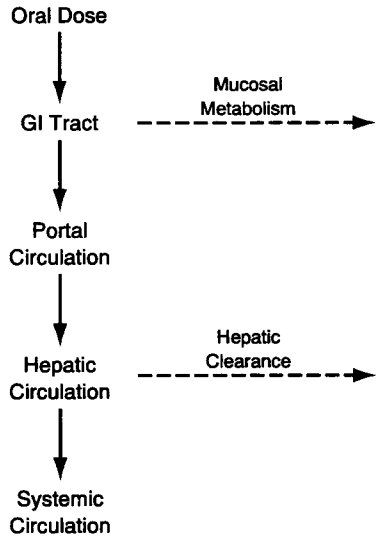

Figure 3
Possible Mechanisms of Presystemic Extraction. Orally administered medications may undergo metabolism as they pass through the gastrointestinal tract mucosa (dashed arrow), which contains significant amounts of Cytochrome P45-3A4. Mucosal metabolism of cyclosporine appears to occur in humans (Kolars et al., 1991). Metabolism may also occur as drug present in portal blood passes through the hepatic circulation (dashed arrow); this is termed "first-pass" metabolism. The net extent of presystemic extraction depends on the combination of mucosal metabolism and first-pass metabolism.

DRUG DISTRIBUTION

The process of distribution is an important determinant of pharmacokinetic properties, as well as the time course of action, of most centrally acting drugs, including those that are subject to abuse. Drugs reversibly distribute not only to their site of action in the brain but also to peripheral sites such as adipose (fat) tissue and muscle, where they are not pharmacologically active (Figure 1). Only a small fraction of the total amount of a psychotropic drug in the body goes to the brain. An even smaller fraction actually binds to the specific molecular recognition site (receptor). The extent of distribution of a psychotropic drug is determined in part by lipid (fat) solubility (how well a substance dissolves in oils and fats; lipophilicity), which is related to molecular structure and charge. Most psychotropic drugs are highly lipid-soluble. Drug distribution is also determined by some characteristics of the organism: the relative amounts of adipose and lean

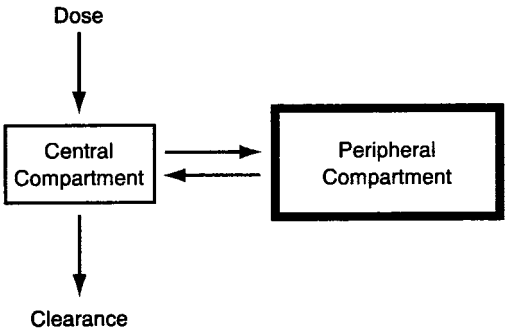

Figure 4
Schematic Diagram of the Two-Compartment Model. It is assumed that medications are administered into and cleared from the central compartment only, and that only the central compartment (which includes blood) is accessible to measurement. Reversible distribution occurs between central and peripheral compartments. For most psychotropic drugs, high lipid solubility favors distribution to the peripheral compartment, producing a large apparent pharmacokinetic volume of distribution.

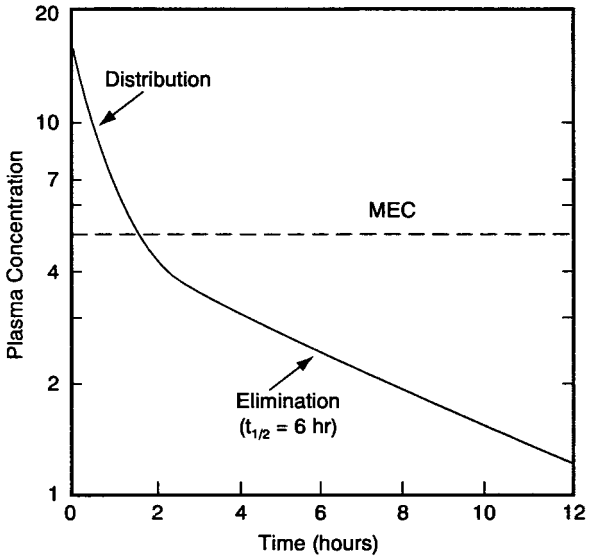

Figure 5
Plasma Concentrations of a Hypothetical Lipid-Soluble Drug after Intravenous Injection. Disappearance from plasma is biphasic. The initial rapid phase is mainly due to drug distribution from central to peripheral compartments (see Figure 4). The slower phase of elimination is mainly due to clearance. For this drug, the elimination half-life in the postdistributive phase is 6 hours. If a plasma concentration of 5 units represents the minimum effective concentration (MEC) below which the drug exerts no detectable pharmacological effect, this drug in the dosage administered has a duration of action of approximately 2 hours.

tissue, blood flow to each individual tissue, and the extent of drug that binds to plasma protein. The overall extent of drug distribution throughout the body can be quantified by the pharmacokinetic volume of distribution, which is a ratio—the total amount of drug present in the body divided by the concentration in a reference compartment, usually serum or plasma. Lipid-soluble psychotropic drugs, as well as drugs of abuse, typically have very large pharmacokinetic volumes of distribution, which may exceed body size by ten-fold or more. Although the drug cannot actually distribute to a space larger than the body, low plasma concentrations resulting from extensive uptake into peripheral tissues can yield a large apparent pharmacokinetic volume of distribution (Figure 4).

Drug distribution influences both the onset and the duration of drug action—as well as the observed value of elimination HALF-LIFE. After an intravenous (IV) injection, lipid solubility allows for the rapid crossing of the lipoidal blood-brain barrier, leading to a rapid onset of pharmacological action (drug effect). In behavioral terms, then, drug-taking produces immediate reinforcement. The duration of a drug's action, however, is determined mainly by the extent of its peripheral distribution. Plasma levels of lipid-soluble psychotropic drugs will decline rapidly and extensively after a single intravenous dose, because of peripheral distribution rather than elimination or clearance (Figure 5). A similar principle holds after oral administration of rapidly absorbed drugs (de Wit & Griffiths, 1991). Since duration of action after a single dose is determined more by distribution than by elimination or clearance, it is generally not accurate to equate elimination half-life and duration of action.

CLEARANCE AND ELIMINATION

The terms *clearance* and *elimination half-life* are commonly used to describe the bodily process of drug removal or disappearance. These two con-

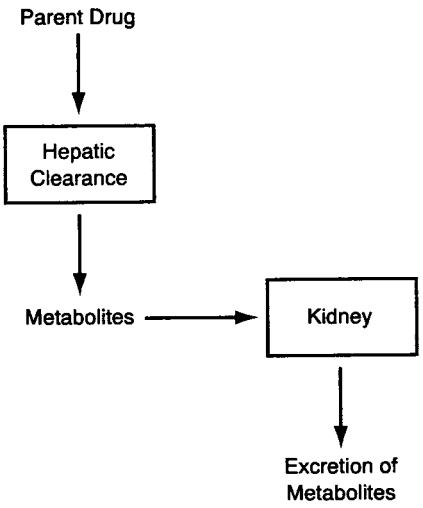

Figure 6
Psychotropic Drugs: Most, including drugs of abuse, are cleared via the liver by hepatic biotransformation to metabolic products. The metabolites may then be released into the circulation and excreted by the kidney.

cepts are related but are not identical. Clearance is the most important, since it is a unique independent variable that best describes the capacity of a given organism to remove a given drug from its system. Clearance has units of volume divided by time—for example, milliliters/minute (ml/min) or liters/hour (L/h)—and is the total amount of blood, serum, or plasma from which a substance is completely removed per unit of time. Clearance is *not* identical either to the rate of drug removal or to the elimination half-life. For most psychotropic drugs, clearance is accomplished by the liver via processes of bio-transformation that change the administered drug into one or more metabolic products (Figure 6); this is commonly called detoxification by the liver. The metabolites may appear in the urine, but the liver is still the organ that effects clearance. For drugs cleared exclusively by the liver, the numerical value of clearance cannot exceed hepatic blood flow.

Elimination half-life is described in units of time; it can be seen as the time necessary for the plasma concentration to fall by 50 percent after distribution equilibrium has been attained. The elimination phase of drug disappearance—at which time the concept of elimination half-life is applicable—may not be attained until completion of an initial phase of rapid drug disappearance resulting from peripheral distribution (see Figure 5). As discussed earlier, the duration of action of a single dose of a psychotropic drug is not necessarily related to its elimination half-life.

Pharmacokinetic theory yields the following relationship between a drug's elimination half-life, volume of distribution (Vd), and clearance:

$$\text{Elimination half-life} = \frac{0.693 \cdot \text{Vd}}{\text{clearance}}$$

The independent variables, appearing on the right side of the equation, are *Vd*, the physicochemically determined property reflecting the extent of distribution, and *clearance*, having units of volume divided by time, quantifying the capacity for drug removal. Elimination half-life is dependent on both of these. Note that a drug may have long elimination half-life, due either to a large Vd, a low clearance, or both.

PHARMACOKINETICS VERSUS PHARMACODYNAMICS

In contrast to pharmacokinetics, PHARMACODYNAMICS is the quantitative study of the time course of drug action. If drug distribution to the site of action occurs by passive diffusion from the systemic circulation, and if the intensity of drug action depends on the degree of RECEPTOR occupancy both in time and in quantity, then pharmacokinetics and pharmacodynamics are necessarily related. Kinetic-dynamic modeling, discussed in detail elsewhere (Greenblatt & Harmatz, 1993), addresses this relationship mathematically, by directly evaluating concentration versus effect. In the fields of psycho-pharmacology and substance abuse, kinetic-dynamic modeling is a major challenge, since (1) clinical drug effect (pharmacodynamic response) often is difficult to measure reliably and since (2) measured drug concentrations in systemic serum or plasma do not always parallel those at the central site of action. Nonetheless, recent advances in kinetic-dynamic modeling have significantly advanced our understanding of the relationship of the pharmacokinetics of psychotropic drugs to their pharmacodynamic effects.

TABLE 1
Principal Urinary Metabolites of Potentially Abusable Drugs

Parent Drug	*Urinary Metabolite*
Marijuana (Tetrahydrocannabinol, THC)	11-nor-delta-9-THC-9-carboxylic acid
Cocaine	Benzoylecgonine
Heroin	Morphine glucuronide

IMPLICATIONS FOR TESTING OF URINE FOR SUBSTANCES OF ABUSE

Mandatory unannounced testing of urine samples for illegal drugs of abuse is conducted to detect and deter the use of these drugs, as well as to prevent potentially dangerous impairment of performance. The application of the fundamental principles of pharmacokinetics and pharmacodynamics, however, clearly indicates that urine testing is the wrong way to approach these objectives (Greenblatt, 1989; Greenblatt & Shader, 1990).

HEROIN, cocaine, and MARIJUANA, the principal illegal drugs of abuse, are subject to hepatic clearance, so urinary excretion is in the form of drug metabolites rather than the originally taken parent compounds (Agurell et al., 1986; Jatlow, 1988) (see Figure 6). As such, analytical methods for chemical testing of urine samples must be devised to detect these metabolites (Friedman & Greenblatt, 1986) (see Table 1). Screening IMMUNOASSAYS are notoriously insensitive, and many actual drug users will escape detection by the screening test if the urine concentrations are below an arbitrary cutoff (Burnett et al., 1990). Negative tests can also be produced by dilution of urine via water loading (Lafolie et al., 1991) or by a variety of adulterants that interfere with analytical procedures (Schwarzhoff & Cody, 1993; Mikkelson & Ash, 1988). To complicate matters, immunoassays are nonspecific and have an unacceptably high false-positive rate. Most urine-testing programs deal with the false-positive problem by performing confirmatory tests on all positive results from the initial screening (Figure 7). However, even a positive test that is confirmed by gas chromatography/mass-spectroscopy does not conclusively identify that individual as a drug user. Positive urine tests may be produced by passive inhalation or dermal absorption, as (ironically) may occur in law-enforcement officials engaged in drug-enforcement activities (Baselt, Chang, & Yoshikawa, 1990; Elsohly, 1991). Recent evidence suggests that some nondrug-using individuals may excrete heroin metabolites resulting from foodstufts (poppy-seed cake) or from endogenous metabolism (Hayes, Krasselt, & Mueggler, 1987; Mikus et al., 1994). Thus evaluation of the problems of analytical chemistry inherent in urine testing indicates that a

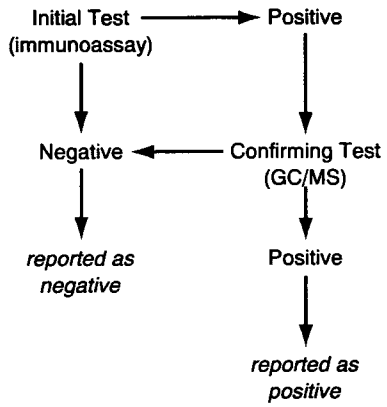

Figure 7
Urine-Testing Programs. Those for drugs of abuse typically use a two-tiered algorithm. An initial screening test is done with a relatively inexpensive, nonspecific, and insensitive immunoassay (such as enzyme-multiplied-, fluorescence-polarization-, or radioimmunoassay). If the initial test is negative, the result is reported as such, and no further testing is done. If the initial screen is positive, a second analysis is done on the same sample using a more accurate and specific method, such as gas-chromatography/mass-spectroscopy (GC/MS). If the confirmation test is negative, the result is reported as negative. If GC/MS confirms the initial screening test, the result is reported as positive.

negative test cannot rule out illegal drug exposure, nor can a positive test confirm it.

From a pharmacokinetic—pharmacodynamic standpoint, urine is an excretory product and not a body fluid. Urine concentrations of drug metabolites bear little relation to parent-drug concentrations in blood or at the site of action—the concentrations that actually determine pharmacodynamic effect (Osterloh, 1993). Even if chemically accurate, a "positive" urine test for a substance of abuse provides no useful information on the quantity of drug exposure, the duration or chronicity of exposure, or the pharmacodynamic effect of the drug at the time the urine sample was taken, or any time prior to or after that. A positive test does not confirm intoxication or impairment from that drug at any time, nor does a negative test rule them out. Thus, as a general rule, urine-testing programs are without adequate scientific foundation and cannot possibly attain the stated objectives (Greenblatt, 1989; Greenblatt and Shader, 1990; Sutherland, 1992). This does not mean that carefully controlled tests do not exist—for a discussion of this see DRUG TESTING AND ANALYSIS.

Detection and prevention of performance impairment in the workplace can, however, be achieved by the systematic testing of performance, using validated methods under properly controlled conditions. Such testing procedures would detect potentially dangerous impairment not only from illegal drugs of abuse but also from other causes, including use of legal substances (such as alcohol or antihistamines), sleep deprivation, other medical or psychiatric illness, or episodes of interpersonal stress. Chemical analysis of blood (not urine) could provide chemical confirmation for cases in which drug-induced performance impairment is suspected, provided a research database is available to link blood concentrations to probable impairment, as exists in the case of alcohol (ethanol). Such an approach would provide a fair and direct method of coping with this problem.

COMMENT

A comprehensive approach to understanding the biological bases of substance abuse must combine the neurochemical and molecular mechanisms that underlie the behavioral effects of these drugs, as well as understanding their properties of absorption, distribution, and clearance. Advances were made in the 1980s and will continue to be made as research techniques in both disciplines become increasingly refined.

DAVID J. GREENBLATT

PHARMACOKINETICS OF ALCOHOL

The discipline known as pharmacokinetics deals with the way drugs are absorbed, distributed, and eliminated by the body and how these processes can be described in quantitative terms. The pharmacokinetics of alcohol (ethyl alcohol or ethanol) is an important issue in forensic toxicology and clinical medicine, when the amount of alcohol in the body is estimated from the concentration measured in a blood sample.

The Swedish scientist Erik M.P. Widmark (1889–1945) made pioneer contributions to knowledge about the pharmacokinetics of ethanol during the early decades of the twentieth century. Widmark observed that after the peak concentration in blood had been reached, the disappearance phase seemed to follow a near straight-line course, suggesting that the system for metabolizing alcohol was saturated (fully occupied), so that the amount of alcohol metabolized each hour did not depend on the amount in the blood. This situation is termed a *zero-order elimination process*. (Zero-order kinetics is contrasted with first-order kinetics, in which the metabolic system [e.g., the liver] is not saturated and in which the amount of drug metabolized per hour increases as the amount presented to the metabolic system increases.) Figure 1 (left

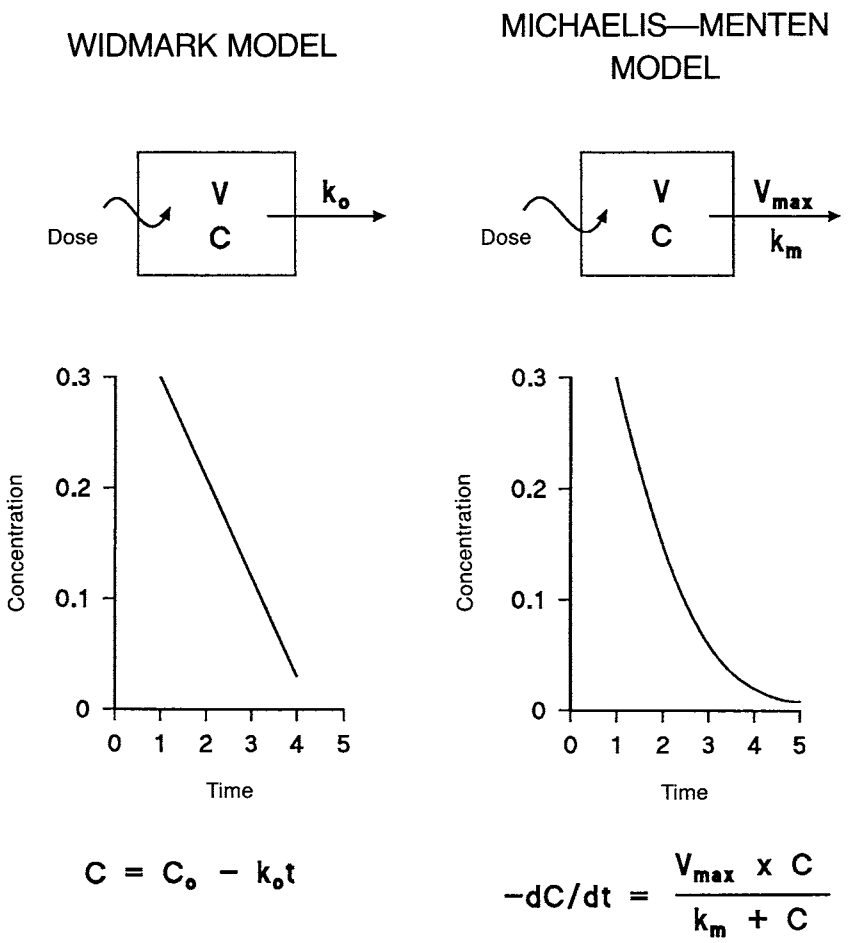

Figure 1
Elimination Kinetics of Ethanol. Schematic diagram illustrating the elimination kinetics of ethanol. The left frame shows Widmark's zero-order model. The right frame shows Michaelis-Menten (MM) capacity-limited kinetics. An intravenous bolus dose of ethanol enters a volume V to produce a concentration C; k_o is the zero-order elimination rate constant; V_{max} is the maximum velocity of the reaction; and k_m is the Michaelis constant—the concentration of ethanol at half maximum velocity. Concentration-time profile are shown for zero-order and MM kinetics, and the mathematical expressions for the elimination rates are given.

frame) depicts zero-order elimination kinetics of ethanol after rapid intravenous infusion. Widmark used the Greek letter β to represent the negative slope of the disappearance phase and not the notation k_o used in Figure 1. The terminology and choice of symbols used in articles and books dealing with clinical pharmacokinetics are often confusing. Moreover, the concentrations of ethanol in blood and other body fluids are reported using many different units, such as g% w/v, mg/dl, g/l, mmol/l; 21.7 mmol/l = 100 mg/dl = 1 g/l = 0.1 g% w/v.

Zero-order kinetics implies that the elimination rate of ethanol is independent of the BLOOD ALCOHOL CONCENTRATION (BAC) and therefore k_o should be the same regardless of the dose of ethanol administered; however, more recent studies have show that the slope of the BAC decay phase is steeper after larger doses of ethanol are ingested. Furthermore, when the BAC declines below about 10 mg/dl (0.01 g%, 2.17 mmol/l) the elimination curve of ethanol from blood flattens out and changes into a curvilinear decay profile.

Two different methods are described in the literature to portray the pharmacokinetics of ethanol. The method of choice seems to depend on the professional interests, the scientific background, and the training of those concerned. Specialists in forensic medicine and toxicology, as well as other disciplines, favor the mathematical approach developed by Widmark. In contrast, scientists with their basic training in pharmacy and pharmacology prefer Michaelis-Menten (MM) kinetics, that is, saturable or capacity-limited enzyme kinetics. The MM model is depicted in Figure 1 (right frame) after intravenous input of ethanol. A pseudolinear phase is evident for most of the elimination profile, provided that the BAC remains sufficiently high (> 10 mg/dl). At low substrate concentrations (C), a hockey-stick shape develops when data are plot-

ted on cartesian graph paper. Accordingly, when C is much greater than k_m, the elimination rate approaches its maximum velocity; $-dC/dt = V_{max}$ (Figure 1, right frame). When C is less than k_m the elimination rate is proportional to the substrate concentration; $-dC/dt = (V_{max}/k_m)\ C$ and the MM equation collapses into first-order kinetics. This collapsing of the model is a consequence of capacity-limited kinetics and does not reflect any sudden change in the order of the biochemical reaction.

ETHANOL AS A DRUG

Ethanol differs from most other drugs in the way it is absorbed into the blood, metabolized in the liver, and how it enters the brain and produces its pharmacological effect. Ethanol (CH_3CH_2OH) has a molecular weight of 46.05, mixes with water in all proportions and carries only a weak charge; this means that the molecules of ethanol easily pass through biological membranes, including the blood-brain barrier. After absorption into the portal blood, ethanol passes through the liver, where enzymes begin the conversion into acetaldehyde and acetate. The end products of ethanol metabolism are carbon dioxide and water. The concentrations of ethanol in biological specimens depend on the dose ingested, the time after drinking, and the water content of the materials analyzed. The concentration-time profiles of ethanol and the pharmacokinetic parameters will differ depending on whether plasma, serum, urine, or saliva are the specimens analyzed. Several detailed reviews of ethanol pharmacokinetics are available and included in the bibliography.

Information about the absorption kinetics of ethanol is much less extensive than that about elimination kinetics. Unlike most other drugs, the dose of ethanol is not swallowed instantaneously because the drinking is usually spread over a period of time. For research purposes, however, ingestion of a bolus dose usually infers drinking times of five to fifteen minutes. The dosage form of ethanol, whether ingested as beer (3–6% w/v), wine (9–12% w/v), spirits (32–40% w/v), or as a cocktail (15–25% w/v) might influence the pharmacokinetic parameters. Absorption of ethanol starts in the stomach where about 20 percent of the dose can become absorbed. The remainder is absorbed from the upper part of the small intestine. The speed of absorption of alcohol depends to a large extent on the rate of gastric emptying, which varies widely among different subjects. Assuming that the rate of absorption from the gut is a first-order process, one can represent the entire concentration-time profile of ethanol with a single equation:

$$C = C_o(1 - e^{-kt}) - k_o t$$

Where C = BAC at some time t after administration
C_o = Initial BAC extrapolated BAC (see Figure 2)
k = First-order absorption rate constant
k_o = Zero-order elimination rate constant
t = Time after drinking

The peak BAC and the time of reaching the peak after drinking are important aspects of the absorption kinetics. Table 1 gives examples of these parameters after healthy men drank neat whiskey (40% v/v or 80 proof) on an empty stomach. The absorption of ethanol occurs more slowly from the stomach than from the intestine owing to the enormous difference in the absorption surface available. Factors that influence gastric emptying, such as food in the stomach before drinking, will alter the rate of absorption and the peak BAC reached. The absorption of ethanol occurs progressively during a drinking binge or spree, and studies have shown that the BAC fifteen minutes after the last drink has reached about 80 percent of the final peak BAC. Because of the saturation-type kinetics, the peak BAC and the area under the curve (AUC) increase more than expected from proportional increases in the dose. The slower the rate of delivery of ethanol to the liver the smaller the AUC for a given dose and vice versa. The systemic availability (bioavailability) of drugs like ethanol with dose-dependent kinetics should not be calculated from the ratio of AUC after oral and intravenous administration.

THE WIDMARK EQUATION

Figure 2 gives examples of the concentration-time profiles of ethanol obtained from oral and intravenous administration of a moderate dose. The ratio of the dose administered (D) to the initial extrapolated concentration of ethanol in blood (C_0) is the apparent volume of distribution (V_d) having dimensions L/kg. This defines the relationship between the concentration of ethanol spread over the body weight (in kilograms, kg) and the concentration in the blood.

TABLE 1
Peak Blood Alcohol Concentration and Time to Reach the Peak after End of Drinking

Dose		*Peak BAC mg/dl*		*k_o mg/dl h*		*Time to peak (min)*[3]			
g/kg[1]	*N*	*mean*	*(range)*	*mean*	*(range)*[2]	*10*	*40*	*70*	*100*
0.34	6	56	(43–67)	12	(9–14)	5	1	—	—
0.51	16	74	(54–91)	13	(10–14)	11	3	1	1
0.68	83	92	(52–136)	13	(9–17)	33	26	21	3
0.85	44	120	(83–178)	15	(12–18)	13	24	7	—

Maximum concentration of ethanol in capillary (fingertip) blood and the time of reaching the peak after end of drinking. The zero-order rate of elimination of ethanol from blood (k_o) is also given. The subjects drank neat whiskey within 15–25 minutes after an overnight 10-hour fast.

[1]g ethanol/kg = 0.036 oz ethanol/kg.
[2]Zero-order elimination rate.
[3]Number of subjects reaching their peak BAC at 10, 40, 70 and 100 min., measured from end of drinking.

$$C_o = D/(kg \times V_d)$$
$$D = C_o \times kg \times V_d \quad [1]$$

Equation [1] is known as the *Widmark equation*; it is widely used to estimate alcohol in the body from measurements of alcohol in the blood. Widmark found that the average V_d for men was 0.68, with a range from 0.51–0.85, but in women the volume of distribution was less—with an average of 0.55 and a range of 0.44–0.66. These differences between the sexes stem from differences in body-tissue composition; proportionally, women carry more fat but less water than do men. Accordingly, women reach higher BACs than men if the same dose of ethanol is given according to body weight. A similar observation was made in studies of men with widely different ages, because body water decreases in the elderly. By dividing the dose of ethanol administered (g/kg) by the time needed to reach zero BAC ($time_0$) one obtains an estimate of the rate of clearance of ethanol from the body. This calculation neglects the nonlinear phase of ethanol elimination beginning at BAC below 10 mg/dl but does include the contribution from any first-pass metabolism occurring in the liver and gut.

If equation [1] is combined with the expression for zero-order elimination kinetics ($C = C_0 - k_0t$) rearrangement gives equations [2] and [3]:

$$D = kg \times V_d \times (C + k_ot) \quad [2]$$

or

$$C = D/(kg \times V_d) - (k_ot) \quad [3]$$

Equation [2] can be used to estimate the amount (dose D) of alcohol a person has consumed from knowledge of his or her BAC (C). Similarly, equation [3] allows estimating the BAC (C) that might exist after drinking a known amount of ethanol. For best results when using these equations, absorption and distribution of ethanol must be complete at the time of sampling blood. Owing to inter- and intra-individual variations in the pharmacokinetic parameters V_d and k_0 the results obtained are subject to considerable uncertainty. This uncertainty should be allowed for when these calculations are made for legal purposes, for example, in trials concerned with DRIVING UNDER THE INFLUENCE of alcohol. A variability of ± 20 percent seems appropriate for most situations.

RESEARCH ON ADH

The enzymes responsible for ethanol oxidation are mostly located in the liver, but recent research has focused on the existence of alcohol dehydrogenase (ADH)—the enzyme that transforms alcohol to acetaldehyde—in the gastrointestinal mucosa. Gastric ADH seems to be less effective in oxidizing ethanol in women (than in men) and in alcoholics (than in moderate drinkers). When a moderate dose of ethanol was ingested on an empty stomach, first-pass metabolism was negligible. This was explained by the ethanol bypassing gastric ADH, owing to rapid absorption occurring. However, the quantitative significance of gut metabolism in the overall disposal of ethanol remains controversial.

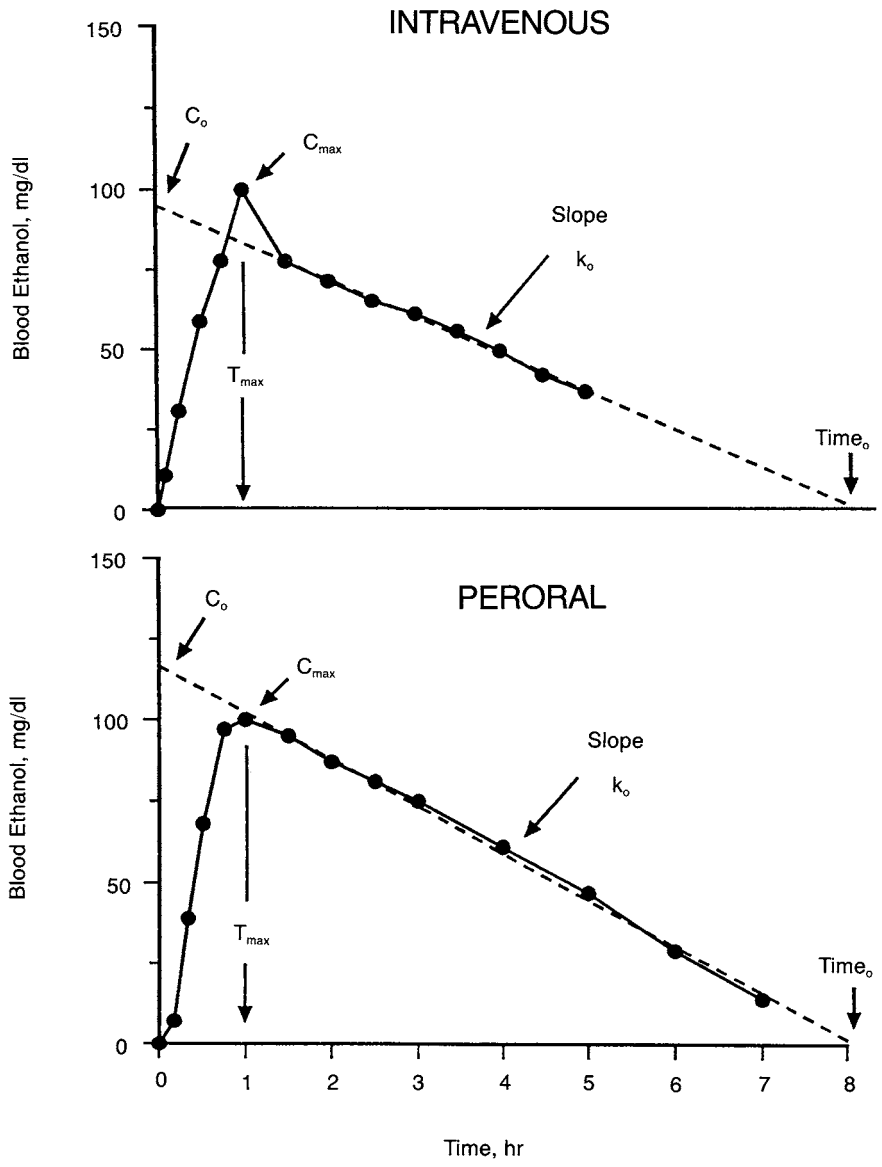

Figure 2
Examples of Concentration-Time Profiles of Alcohol Taken by Intravenous and Oral Routes of Administration. Examples of concentration-time profiles of ethanol obtained after intravenous infusion of 0.4 g ethanol/kg body weight in 15 minutes (upper part) and after ingestion of 0.8 g/kg (lower part). Several key pharmacokinetic parameters are shown.

ELIMINATION RATES AND ENZYMES

Differences in the rate of disappearance of ethanol from blood might depend on genetic and environmental factors influencing an individual's catalytic activity of alcohol-metabolizing enzymes. In humans, the enzyme ADH occurs in multiple molecular forms, designated class I, II, and III. Class I enzymes are located mainly in the liver cytosol and have a low k_m for ethanol. Various isozymes (variations within a class) exist and β_1-ADH (class I) is predominant in Caucasians whereas β_2-ADH (class II) is the most abundant isozyme in Asians. The rate of ethanol elimination in the various racial groups is not much different from the variations seen within a single racial group in well-designed studies that allow for racial differences in body composition—the proportion of fat to lean body mass.

Alcoholics have a greater capacity to eliminate ethanol than do moderate drinkers. Disappearance rates from blood of 30 mg/dl/h are not uncommon—compared with a mean rate of only 15 mg/dl/h (range 8–20 mg/dl/h) in moderate drinkers. The liver microsomes contain enzymes capable of oxidizing ethanol as well as other drugs, organic

solvents, and environmental chemicals. One particular form of the cytochrome P_{450} enzyme (denoted P450IIEI) metabolizes ethanol. This microsomal ethanol oxidizing system (MEOS) has a k_m of 40–60 mg/dl (8.7–13 mmol/l) compared with 2–5 mg/dl (0.4–1 mmol/l) for human ADH. More importantly, the P450IIEI isozyme becomes more active during prolonged exposure to ethanol—a process known as enzyme induction. Accordingly, because of continuous heavy drinking, alcoholics develop a high capacity for eliminating ethanol from the blood. Their enhanced capacity vanishes after a short period of abstinence, however, but liver disease (hepatitis, cirrhosis) in alcoholics does not seem to impair their ability to dispose of ethanol.

BEHAVIORAL EFFECTS OF ALCOHOL

Studies have shown that the behavioral effects of ethanol and its associated impairment of performance are more pronounced when the BAC is rising than when it is falling. This observation seems to depend, at least in part, on the distribution of ethanol between blood and tissue. The arterial blood concentration of ethanol is pumped to the brain and this exceeds the concentration measured in the venous blood, which is returning to the heart from skeletal muscles. This arterio-venous difference is most pronounced shortly after drinking; it decreases as ethanol diffuses equally into all body fluids. It seems that this is not the whole story, because some evidence points to the development of acute cellular tolerance to ethanol's effects—an aspect of tolerance that quickly develops.

Despite extensive studies of ethanol pharmacokinetics spanning many years, there are still a number of unsettled issues and areas of debate. Two such issues are (1) the practical advantages of Michaelis-Menten kinetics as opposed to Widmark's zero-order model and (2) the role of gastric ADH in presystemic disposal of ethanol. The importance of blood source (artery, capillary, or vein) and the sampling site (arm or leg) on ethanol pharmacokinetics deserves further study, as does whether multicompartmental models should be invoked.

PHARMACOLOGY In its broadest sense, pharmacology can be defined as the science dealing with interactions between living systems and molecules—in particular, chemicals (i.e., drugs)—usually introduced from outside the system. This definition also includes medical pharmacology, which is the science of drugs used to prevent, diagnose, and treat disease. Also included are the important roles played by chemicals in the environment that can cause disease, as well as the use of certain chemicals as molecular probes for the study of normal biochemistry and physiology. Toxicology is the branch of pharmacology that deals with the undesirable (i.e., toxic) effects of chemicals in biological systems.

PHARMACOTHERAPY *See* Treatment; Treatment Types

PHENCYCLIDINE (PCP) Although phencyclidine (PCP) and drugs of similar chemical structure (arylcyclohexylamines) are often called HALLUCINOGENS, they rarely produce HALLUCINATIONS, and the sensory distortions or apparent hallucinations that are produced are not the same type as LSD-induced hallucinations. Instead, phencyclidine belongs to a unique class of drugs called the dissociative anesthetics. Phencyclidine was developed in the 1950s as an anesthetic for veterinary medicine and later was tested in human surgical patients. There was great potential for PCP as an anesthetic because it produced minimal effects on the heart and breathing was not suppressed. Unfortunately, the adverse side effects of PCP (e.g., dysphoria [unhappy, ill] and psychotic symptoms) led to a termination of the human clinical trials. The drug is no longer manufactured for veterinary use because supplies were diverted (stolen) and the drug became widely abused in the 1970s. Ketamine, a drug chemically similar to PCP, is now used as a veterinary anesthetic and, in special cases, for anesthesia in humans. This drug is less powerful and shorter acting than PCP.

Phencyclidine abuse, mainly in pill form, peaked in the late 1970s and markedly declined throughout the 1980s and early 1990s. The most common route of administration in use in the 1990s was smoking. Phencyclidine is often added to MARIJUANA cigarettes, and it is commonly used while people are also drinking alcoholic beverages. Street names for PCP are "angel dust" or "crystal"; it is called "space base" when combined with COCAINE.

MECHANISM OF ACTION

Most investigators agree that the behavioral effects of PCP are mediated predominantly through RECEPTORS, which are proteins that are important for the normal functioning of cells within the body. Phencyclidine acts as an antagonist at the N-methyl-D-aspartate (NMDA) receptor-channel complex, which is one type of excitatory amino-acid receptor that is selectively activated by the agonists NMDA and GLUTAMATE. By definition, agonists produce stimulation while antagonists block the effects of agonists. When either glutamate or NMDA bind to the receptor, a channel within the cell membrane opens to allow sodium, calcium, and potassium ions to flow into and out of the cell. This movement of ions across the cell membrane causes a depolarization of the membrane which, if sufficiently large, causes the cell to fire. When the cell fires, an electrical charge passes along its membrane and NEUROTRANSMITTERS (chemicals that allow cells to communicate with each other) are released. Thus, glutamate and NMDA are important for normal cell-to-cell communication within the body.

PCP, as well as TCP, ketamine, dizocilpine (MK-801), and SKF 10,047 is representative of compounds that act as noncompetitive antagonists at the NMDA-receptor complex. The binding site for PCP resides within the channel and binding to this site physically prevents calcium and sodium ions from entering the cell while at the same time preventing potassium ions from leaving the cell. Blocking the movement of ions through the cell membrane in turn prevents the neuron from firing. In contrast to the noncompetitive antagonists, competitive antagonists such as CGS 19755, NPC 12626, CPP, and AP5 bind to the NMDA receptor itself without causing the ion channel to open. By simply occupying the receptor without activating it, competitive antagonists prevent NMDA from binding to and activating the receptor. Unlike noncompetitive antagonists, competitive NMDA-antagonist effects can be surmounted by higher doses of the agonist. However, the end result of both noncompetitive and competitive antagonists is a reduction of neuronal firing.

PHARMACOKINETICS AND METABOLISM

PCP use in humans occurs through several routes of administration, including intranasal (snorted), intravenous, oral, and inhalation (smoked). When PCP is smoked in parsley cigarettes, approximately 70 percent of the total amount of PCP is inhaled. Of this amount, 38 percent is inhaled as PCP and 30 percent is inhaled as phenylcyclohexene, a by-product of PCP created when it is heated. Peak blood concentration of PCP occur after only five to ten minutes, which is occasionally followed by a second peak one to three hours later. PCP is predominantly excreted in urine after intranasal, intravenous, and oral administration. The rate of PCP elimination through the kidneys depends on both urine pH and urine-flow rate. More specifically, PCP elimination occurs more

rapidly when urine is acidic and when urine is passed rapidly.

DISCRIMINATIVE STIMULUS EFFECTS

One useful method of evaluating the pharmacological characteristics of PCP, as well as a variety of other drugs, is the drug-discrimination procedure. Typically, animals that are slightly food restricted are trained to respond for food on one lever after drug administration and on another lever after saline. On days when the drug is administered before the session, responding on the drug-associated lever results in food delivery while responding on the saline-associated lever does not. Conversely, on days when saline is administered before the session, responding on the saline-associated lever results in food delivery while responding on the drug-associated lever does not. After a number of training days, animals learn to reliably respond on the drug lever after the drug injection and on the saline lever after saline injection. Once this discrimination has been established, a number of test drugs can be administered to determine whether or not they produce effects similar to the training drug. Test drugs that substitute for the training drug (i.e., cause responses on the drug-associated lever) are assumed to have discriminative stimulus effects that are similar to the training drug.

Using this procedure, several investigators have shown that PCP and other noncompetitive antagonists produce similar discriminative stimulus effects in a number of different species (see Willetts, Balster, & Leander, 1990 for a review). These results suggest that the mechanisms of action of PCP and other noncompetitive antagonists, such as ketamine and dizocilpine, are similar. Furthermore, the discriminative stimulus effects of competitive antagonists such as CGS 19755, NPC 12626 and CPP were also similar to each other, which is again consistent with the notion that the mechanisms of action of competitive antagonists are similar. Given that competitive and noncompetitive antagonists both reduce neuronal firing, it was of interest to compare the discriminative stimulus effects of these two types of antagonists. In most species, the discriminative stimulus effects of competitive and noncompetitive antagonists are very different from each other.

Another difference between the competitive and noncompetitive antagonists lies in their abilities to antagonize the discriminative stimulus effects of NMDA. While both types of antagonist are effective in blocking the convulsant and lethal effects of NMDA, competitive antagonists in general are much more effective than noncompetitive antagonists in blocking the discriminative stimulus effects of NMDA. The noncompetitive antagonists partially antagonize NMDA but only at doses that produced substantial behavioral suppression. While most effects of NMDA are antagonized by both competitive and noncompetitive antagonists, the behavioral-suppressing effects of noncompetitive antagonists often interfere with their ability to antagonize the discriminative stimulus effects of NMDA.

Finally, another important finding with competitive and noncompetitive antagonists involve their interaction with other receptor systems. Studies show that the discriminative stimulus effects of competitive antagonists such as CPP and NPA 12626 are similar to those produced by the BARBITURATE pentobarbital. Under certain conditions, the discriminative stimulus effects of PCP and pentobarbital were also similar. In addition to the interactions of NMDA antagonists with barbiturate receptors, some investigators have found similarities between PCP and ethanol (alcohol). These studies have proven to be important in describing both the similarities and differences between the noncompetitive and competitive NMDA-receptor antagonists.

TOLERANCE

Tolerance to a drug occurs when increasingly higher doses are needed to produce a specific effect or if drug effects diminish after repeated administration of the same dose of drug. It has not been possible to study tolerance to PCP in human subjects, but when interviewed, PCP users report that they increase the amount of PCP that they take over time (Carroll, 1990). Another indicator of tolerance development is that burn patients treated with ketamine for pain often require higher doses over time. It is easier to study tolerance to ketamine, PCP, and similar drugs in animals. Laboratory studies with rats have shown that tolerance developed to the effects of PCP on food-reinforced responding, to the effects of PCP and dizocilpine on steroid hormone (adrenocorticotropin and corticosterone) release, and to the cataleptic effects of ke-

tamine. Supersensitivity, the opposite of tolerance, occurs when repeated drug exposure produces a greater effect at a given dose. Some investigators have found that tolerance develops to some effects of PCP, such as head weaving, turning, and back pedaling, while supersensitivity occurs with other behaviors, such as sniffing, rearing, and ambulation. Although some scientists have hypothesized that PCP tolerance and supersensitivity are mediated through non-NMDA-receptor systems, others have suggested that PCP tolerance may be mediated through the NMDA receptor system. Repeated administration of dizocilpine, a PCP-like compound, produced a reduction in the number of NMDA receptors in the rat brain, and that was correlated with tolerance to some of the behavioral effects produced by dizocilpine. Further studies will clarify the role of different receptor systems in the development of tolerance to the effects of PCP and related compounds.

Studies indicate that there are interactions between PCP and other drugs with respect to tolerance and supersensitivity of drug effects. For example, dizocilpine blocked the development of tolerance to morphine's analgesic (painkilling) effects, but it did not alter the analgesic effects when MORPHINE was administered acutely. Also, dizocilpine attenuated the development of tolerance to ethanol (ALCOHOL), and it inhibited sensitization to amphetamine and cocaine (*DHHS Fourth Triennial Report to Congress on Drug Abuse and Drug Abuse Research,* 1992).

DEPENDENCE

Physiological dependence on a drug is usually defined by a set of withdrawal symptoms that occur when steady use of the drug is discontinued. The withdrawal symptoms are typically the same for a given drug, and they follow a specific time course which ranges from about six to forty-eight hours, depending on the drug. The withdrawal symptoms may be rapidly reversed after one administration of the drug.

Most of what is known about PCP dependence is from experimental studies with animals. There are only limited reports of PCP withdrawal effects in humans. In 1981, Tennant et al. studied sixty-eight regular PCP users; they found that one-third of them had sought treatment or medication to relieve the effects of PCP withdrawal. Withdrawal symptoms that they commonly reported were depression, drug craving, increased appetite, and increased need for sleep. Another way PCP dependence has been documented in humans is in studies of babies born to PCP-using mothers. Withdrawal signs that have been noted are diarrhea, poor feeding, irritability, jerky movements, high-pitched cry, and inability to follow a stimulus visually.

In laboratory studies with monkeys, similar signs of PCP withdrawal have been noted. Balster and Woolverton (1980) gave rhesus monkeys continuous access to PCP directly into the blood stream for fifty days, using an intravenous cannula system. The monkeys were trained to respond on a lever for an infusion of PCP. When PCP was replaced with a salt and water solution used to dissolve the drug (vehicle), withdrawal signs were noted, such as poor feeding, weight loss, irritability, bruxism (coughing), vocalizations, piloerection (hair standing up), tremors, less exploratory behavior in the cage, and poor motor coordination. The withdrawal syndrome began within four to eight hours, peaked between twelve and sixteen hours, and had disappeared by twenty-four to forty-eight hours. These results have been repeated in studies with rats. Some studies have reported PCP withdrawal effects after as little as two weeks of exposure. Thus, long-term use of the drug may not be necessary to produce physical dependence.

Recent studies with animals have shown that not only a short period of exposure to PCP but low doses of PCP result in withdrawal effects when drug administration is discontinued. Operant conditioning experiments are used as sensitive tests of drug-withdrawal effects in animals. In these experiments, animals are trained to respond on a lever or push a button or other device to obtain a food reward. At the same time they are allowed to self-administer drugs orally or intravenously. When drug access is removed, a decrease in operant responding for food is often seen, even when the drug dose is sufficiently low to produce no observable signs of withdrawal. These measures have also been used to demonstrate withdrawal effects from drugs such as cocaine, caffeine, and nicotine. When regular use of these drugs is discontinued there are no observable signs of withdrawal during abstinence. The most severe reductions in the operant behavioral baselines occur during the first forty-eight hours of drug withdrawal, a time during which

physical signs occur when higher maintenance doses are used; however, the behavioral disruptions often last for long periods of time. During withdrawal, when animals will not respond on a lever for food, they readily consume hand-fed food. Thus, the decrease in feeding may not be due to illness but to a decrease in the motivation to work for food.

In the first study that demonstrated disruption in operant behavior during PCP withdrawal, Slifer and coworkers (1984) treated monkeys with continuous intravenous infusions for ten days. They were required to make 100 responses on a lever for each food pellet. When access to PCP was terminated, responding for food decreased substantially for up to seven days and did not return to normal levels until the monkeys were again allowed access to PCP. Similar results were found by other investigators using monkeys trained to self-administer orally delivered PCP. There was little difference in the results, depending on whether the PCP was self-administered or experimenter administered. In the monkey studies, there was only a weak relationship between dose and the severity of the withdrawal effect, but in rats, PCP dose, blood levels, and magnitude of the withdrawal effect were closely related. Recent studies have shown that there is cross-dependence between drugs that are chemically similar to PCP—such as PCP and ketamine, dizocilpine, and the (+)isomer of SKF-10,047; however, cross-dependence was not demonstrated with either the racemate or (-)isomer of SKF-10,047 or with ethanol.

The PCP-withdrawal effect can be altered by changing schedules of reinforcement. In one study with monkeys, lever-press requirements or fixed ratios (FRs) for food were increased from 64 to 128 to 256 to 512 to 1024, and PCP-withdrawal effects were examined at each value. As the FR value increased, PCP withdrawal effects became more pronounced. At the two higher FRs, body weights declined and the severity of the withdrawal effect showed no further increases. To examine the effects of amount of food available, another experiment was conducted in which the FR was held constant at 1024 and the monkeys were either supplemented with 100 grams of hand-fed food or not. The amount of responding for earned food remained the same during supplemented and unsupplemented conditions, but when the effects of withdrawal were examined, a disruption in responding occurred only under the supplemented condition. When the monkeys had to earn their entire daily food ration, the withdrawal effect disappeared. These studies suggest that the severity of the PCP withdrawal effect is determined by the behavioral economics of food availability. The magnitude of PCP withdrawal increased as the price (FR of food) increased; but as the price became so high that body weight was lost, the PCP-withdrawal effect entirely disappeared. These data also suggest that PCP withdrawal is not necessarily an illness but a decreased level of motivation.

The use of drugs to treat the PCP-withdrawal syndrome has produced mixed results. When monkeys had access to orally delivered (+)SKF-10,047, the PCP-withdrawal-induced disruptions in food-maintained responding were reversed. This was not the case with (-)SKF-10,047 or the racemate (±)SKF-10,047. Injections of dizocilpine before PCP withdrawal, or two days into PCP withdrawal, greatly reduced or reversed, respectively, the disruptions in food-reinforced responding. Dizocilpine also dose-dependently reduced PCP self-administration. In contrast, while BUPRENORPHINE, a partial AGONIST at the mu-opiate receptor, also dose-dependently reduced PCP self-administration, it had no effect on PCP-withdrawal-induced disruptions in food-maintained responding. When PCP was self-administered concurrently with ethyl alcohol (ethanol) and then PCP access was removed, PCP-withdrawal effects were as severe as when ethanol had not been available. Thus, ethanol did not alleviate the PCP withdrawal effect, although, as noted earlier, PCP and ethanol share discriminative stimulus effects (Grant et al., 1991). In other studies, PCP was self-administered concurrently with ethanol or caffeine. When PCP and the other drug were removed simultaneously, the withdrawal disruption was more severe than when PCP alone was withdrawn. (Further details of these withdrawal studies may be found in reviews by Carroll [1990] and by Carroll and Comer in the *DHHS Fourth Triennial Report to Congress on Drug Abuse and Drug Abuse Research*, 1992.)

REINFORCING EFFECTS

The reinforcing effects of a drug are determined by demonstrating that self-administration of the drug plus the solution it is dissolved in (vehicle)

occurs in excess of self-administration of the vehicle alone. When drug-reinforced behavior is readily achieved in the animal laboratory, it is usually a good predictor that the drug has considerable abuse liability in the human population. The reinforcing effects of PCP have been studied using two animal models of self-administration, oral and intravenous. The intravenous route of self-administration requires the animal to make a specified number of responses on a lever or other manipulandum within a predefined time—then a fixed dose of the drug is delivered by an infusion pump via a catheter that is surgically implanted in a large vein that leads to the heart. Studies from various laboratories have demonstrated that intravenously delivered PCP functions as a reinforcer for rats, dogs, monkeys, and baboons.

Drugs that are chemically similar to PCP are also self-administered intravenously. These include drugs that have similar receptor-binding sites in the brain, such as ketamine, (+)SKF-10,047, dexoxadrol, and cyclazocine; and phencyclidine-like drugs that function as noncompetitive antagonists at the NMDA receptor, such as dizocilpine. Phencyclidine and dizocilpine self-administration is more reliably obtained when the animal has a history of self-administration of a drug with similar pharmacological or discriminative-stimulus effects. It has also been found that drugs that share discriminative-stimulus effect with PCP, such as (+)SKF-10,047, ketamine, PCE, TCP, and ethanol, are readily substituted for PCP in self-administration studies.

Oral PCP self-administration is established by presenting gradually increasing concentrations of PCP after the animal is given its daily food ration. After sufficient quantities of PCP are consumed, food is given after the drug self-administration session, and PCP consumption usually persists. This procedure provides a long-term stable baseline to examine variables that affect PCP-reinforced behavior. For example, alternative nondrug reinforcers, such as saccharin, reduce PCP-reinforced responding up to 90 percent of baseline if the FR for PCP is high or if the PCP concentration is very low. Free access to food decreases PCP self-administration, while even small reductions in the daily food allotment markedly increase PCP self-administration. Concurrent availability of ethanol also reduces PCP-reinforced responding.

A limited amount of information is available concerning drug pretreatment and PCP self-administration. Buprenorphine and dizocilpine pretreatment both resulted in dose-dependent decreases in PCP self-administration; however, potential treatment drugs such as fluoxetine and carbamazepine had no effect. Treatment with other drugs such as AMPHETAMINE or PENTOBARBITAL had a biphasic effect on PCP self-administration. Low doses of the pretreatment drugs increased PCP self-administration, and high doses decreased PCP self-administration.

TOXICITY

There is little evidence that long-term PCP use in adult humans (Luisada, 1981) and monkeys (see *DHHS Fourth Triennial Report to Congress on Drug Abuse and Drug Abuse Research*, 1992) results in any detectable organ or cellular damage. In monkeys that had been self-administrating PCP for eight years, tests of all organ systems, clinical chemistries, physical exams, and X rays revealed no differences between PCP-experienced and control animals that were the same age but had little drug experience. In humans, the form of toxicity most commonly associated with PCP use is a change in behavior. There have been a few accounts of bizarre and/or violent behavior associated with PCP use. Such reports have diminished since the preferred route of self-administration has shifted from oral (pill) to inhalation, which offers the users an ability to more carefully control the dose.

In monkeys, PCP produces a calming, tranquilizing effect. The immediate effects in humans are not seen in the hospital or clinic. Instead, the PCP user arrives in the emergency room several hours after PCP use, possibly while suffering acute withdrawal effects. Approximately twelve to fifteen hours after PCP was last taken, monkeys become agitated, violent, and aggressive. It is possible that many of the early reports of human violence and the PCP-related homicides were related to the withdrawal effects. It is necessary to determine the time course of unusual behavior and important to know the time of drug intake, although this is difficult to establish because the patient often loses memory of the drug-taking event.

Another unusual aspect of PCP toxicity is that users often complain of unpleasant effects long af-

ter chronic use has stopped. These reports could be caused by the fact that PCP is highly fat soluble and becomes stored for long periods of time in the body fat. During periods of weight loss, there is subsequent mobilization of fat-stored PCP into blood and brain tissues. Recent laboratory research with rats supports this hypothesis by demonstrating the ability of food deprivation to increase PCP levels in blood and brain (Coveney & Sparber, 1990).

Increasing data has become available on the effect of drugs of abuse on the offspring of dependent mothers, and it appears that the offspring of PCP users may be more vulnerable to the adverse effects of PCP than their adult counterparts. Golden and coworkers (1987) studied ninety-four PCP-exposed newborns and ninety-four nonexposed as controls; they found neurological abnormalities such as abnormal muscle tone and depressed reflexes in the exposed group. Another study followed twelve exposed infants for eighteen months and found a high percentage of medical problems (Howard et al., 1986). At six months the infants were irritable and hyperresponsive, and later they showed varying degrees of abnormalities in fine-motor, adaptive, language and social skills. A recent study of the offspring of forty-seven PCP abusers and thirty-eight nonusers found that neurological dysfunction was common in the infants of PCP-abusing mothers (Howard, Beckwith, & Rodning, 1990). There was greater apathy, irritability, jitters, and abnormal muscle tone and reflexes. Follow-up interviews at six and fifteen months, using the Gesell Developmental Exam, revealed poor language development and a lower developmental quotient in general; however, the long-term outcome for PCP-exposed newborns is unknown.

TREATMENT

There are currently no PCP ANTAGONISTS that are useful for treatment of PCP OVERDOSE. Symptomatic treatment may be given for suppressed breathing rates, fever, high blood pressure, and increased salivation. Convulsions are treated with DIAZEPAM. Elimination of the drug may be enhanced by making the urine more acidic and/or pumping stomach contents. Attempts to minimize environmental stimuli have helped to control violent and self-destructive behavior. Psychiatric care may be needed for an extensive psychotic phase that may follow overdose (Jaffe, 1989).

PHENCYCLIDINE (PCP): ADVERSE EFFECTS Widely known as PCP, PHENCYCLIDINE

is an important drug of abuse in the United States, even though its use has declined since the 1980s. PCP is difficult to classify pharmacologically and is considered separately from the hallucinogens. The drug has not been studied systematically in animals, although research done in 1973 and 1980 indicated that it produces dependence in monkeys. As of 1999, its effects on the human central nervous system are poorly understood. It produces a unique type of hallucinatory effect and is used both by smoking and ingestion. Persons under the influence of PCP experience mood changes, perceptual distortions, and feelings of dissociation from their surroundings. Since their judgment is impaired, they may take unnecessary risks. They may become unpredictable and violent. In certain individuals, PCP use, especially if repeated often, can result in the production of a mental disturbance referred to as PCP psychosis. It is not, however, known with certainty whether PCP itself, or a combination of factors involved in the lifestyle of PCP abusers, is the cause of brain damage or of long-term behavior impairment that also sometimes occurs in PCP abusers.

HISTORY

Phencyclidine was developed in the 1950s for use as an anesthetic, but its use was discontinued because patients developed delusions, severe anxiety, or frank psychosis after their operation. It was also used by veterinarians as an anesthetic for some years; at present, however, all PCP sold on the street is manufactured illegally. The initials "PCP" are derived from a nickname, "The Peace Pill." The history of PCP as a drug of abuse began in the United States in the mid-1960s, when it was primarily taken by ingestion; but the real epidemic of PCP abuse occurred in the 1970s, when smoking and insufflation ("snorting") became the more common forms of use (Burns & Lerner, 1976). Because it is not difficult for an experienced chemist to synthesize the drug, PCP and its abuse spread rapidly, peaking about 1978. After 1980, its prevalence declined—however, PCP abuse continues to occur precisely because the drug is relatively easy to make. National Institute on Drug Abuse surveys show that more Americans have experimented with PCP than with heroin, and the prevalence of recent use of PCP is about the same as with heroin, so it remains a significant public-health problem (National Institute on Drug Abuse, 1991). As of 1999, most PCP abusers either inject the drug or smoke it by sprinkling it on smoking material (mint leaves, parsley, marijuana, or tobacco).

PSYCHOLOGICAL EFFECTS OF PCP

The psychological effects of PCP abuse can be discussed under three headings: (1) the effects accompanying acute intoxication, (2) the personality disturbances that can sometimes develop in PCP abusers, especially when associated with chronic use, and (3) the possible neurobehavioral toxicity that might result from chronic use.

SIGNS AND SYMPTOMS OF PCP INTOXICATION

Low Dose. Dreamy carefree state, mood elevation, heightened or altered perception, impaired judgment, partial amnesia.

Intermediate Dose. Inebriation, motor incoordination, dissociation and depersonalization, confusion and disorientation, perceptual distortions and preoccupation with abnormal body sensations, diminished pain sensitivity, partial amnesia, and sometimes exaggerated mood swings and panic.

High Dose. Catatonia, "blank stare," drooling, nystagmus (eye-rolling), delirium and hallucinations, psychotic behavior, severe motor incoordination, total amnesia.

ACUTE PCP INTOXICATION

As with all drugs, the effects of PCP depend on the dose that is taken. The section above lists the typical effects of PCP at various doses. PCP abusers usually adjust their dosage to experience only the low-dose effects. High-dose effects are similar to a mild type of dissociative anesthesia.

Experienced drug abusers can readily distinguish the experience of PCP intoxication from that produced by other drugs such as MARIJUANA, MESCALINE, and LYSERGIC ACID DIETHYLAMIDE (LSD). Users typically report a feeling of dissociation from the environment and abnormal body sensations and body image. The perceptual distortions often cause things to appear far away or abnormal in size. Compared to LSD, the effects of PCP are not very PSYCHEDELIC.

The most dangerous effects of PCP intoxication arise from the impaired judgment and altered perceptions that occur. People can engage in risk-taking behavior and harm themselves or others. DRIVING, swimming, or other activities requiring coordination and good judgment become extremely dangerous. Someone on PCP may also engage in casual but high-risk sexual behaviors. PCP users experience profound mood swings—where what begins as a pleasant experience can turn into panic and terror—and their behavior is unpredictable. Sometimes these "bad trips" can lead to violent and uncharacteristic behaviors with disastrous results. In cases of high-dose intoxication, users can experience a toxic psychotic episode with DELIRIUM, profound HALLUCINATIONS, and paranoia. In cases of severe overdose, seizures, stroke, or kidney failure may lead to death (Burns & Lerner, 1976).

MEDICAL TREATMENT

As of 2000, there is no medication that can serve as an antagonist to the effects of PCP or that can speed up its excretion. PCP is easily soluble in fats, thus can remain in the central nervous system for long periods. A patient who has overdosed on PCP must be placed on life support. Patients with anxiety or seizures can be given diazepam (Valium). Patients with psychotic episodes are usually treated with haloperidol (Haldol). Chlorpromazine (Thorazine) should *not* be given to patients who have taken PCP, as it may produce hypotension. Patients with severe hypertension due to PCP should be given diazoxide (Proglycem). Gastric lavage has been used successfully to treat patients who have ingested PCP directly.

PCP intoxication is considered a psychiatric emergency. It is recommended that these patients be placed in a secure room under observation. The health professional should not attempt to "talk the patient down." Physical restraints or a sedative such as lorazepam (Ativan) may be needed if the patient becomes violent.

LONG-TERM USE

In persons who abuse PCP in large amounts over a long period, or in those who have psychological problems that make them especially vulnerable, a chronic psychosis may develop. This PCP psychosis is evident even when abusers are not high on PCP, and it may be quite difficult to treat. The symptoms of PCP psychosis differ considerably from person to person, but patients may show many features of SCHIZOPHRENIA, including the appearance of a thought disorder, paranoid ideation, hallucinations, mood changes, and aberrant behavior. These patients often require psychiatric hospitalization and treatment with ANTIPSYCHOTIC medications.

In research studies where PCP has been given repeatedly to animals, it has been possible to show the development of PHYSICAL DEPENDENCE (e.g., Balster & Woolverton, 1980). The doses required for dependence are quite high, so it may be that dependence in human PCP abusers is difficult to develop. There have been some clinical reports of withdrawal effects in heavy PCP abusers, but these do not appear to be present in most individuals needing treatment for PCP abuse. There are no specialized treatment methods for PCP abusers, and since many PCP abusers also abuse other drugs and/or alcohol, they are usually helped by the same counseling and psychotherapy programs that are used for other forms of drug abuse.

NEUROPSYCHOLOGICAL AFTEREFFECTS OF PCP ABUSE

It is not known for certain whether or not PCP causes brain damage or long-term neurological or behavioral impairment in chronic abusers. Although some PCP abusers develop neurobehavioral impairment, controlled experiments of the type that would need to be carried out to show that PCP alone was the cause of the problems have not been done. PCP abusers typically abuse many other drugs in addition to PCP, which may contribute to their problems, and they may have lifestyles and health habits that lead to neuropsychological dysfunction. For example, while under the influence of PCP, they may be involved in an accident resulting in brain injury, so the risk factors that accompany PCP abuse may be responsible for the clinical problems sometimes seen in abusers. It should be pointed out that PCP was used in humans for medical research for a number of years, and ketamine—a close analog of PCP—is, even in the early 1990s, given to thousands of patients. No legacy of neuropsychological impairment is seen in these individuals.

Does this mean that chronic PCP abuse does not cause neuropsychological impairment? Certainly,

PCP—like all drugs—must be considered as a possible source of neural damage. In animal testing, it was found that even a single injection of a fairly high dose of PCP produced reversible pathomorphological changes in neurons of the cingulate and retrosplenial cortex in the brains of rats (Olney, Labruyere, & Price, 1989). Although it is not known if PCP produces these effects in humans, it is possible that it does and that this could lead to adverse health effects. Another possibly important basis for concern comes from studies which show that PCP, and related drugs, impair learning and memory in various animal models. PCP's ability to do this may be greater than for other classes of drugs of abuse, possibly due to PCP's ability to interfere with specific brain mechanisms for learning that involve N-methyl-D-aspartate (NMDA) RECEPTORS.

PCP AND VIOLENCE

Many people associate the abuse of PCP with violence and aggression, so this concern deserves special mention. Those under the influence of PCP often behave erratically and exercise poor judgment. These effects of PCP could certainly lead to violent behavior, and there are certainly numerous examples of extremely violent acts being performed by persons under the influence of PCP. This raises the question of whether PCP is uniquely associated with the production of violence and aggression: Is someone intoxicated with PCP more likely to be violent than someone who is intoxicated with COCAINE or alcohol?

Unfortunately, the answer to this question is not known. A great deal of criminal conduct in the United States is certainly carried out by people under the influence of alcohol or drugs. In addition, the public often associates drug use they do not understand with criminal and violent behavior. Every new drug epidemic is greeted with public concern that this drug causes violence. There is also the common practice of criminal attorneys using the defense of diminished capacity, because of drug use, to lessen the responsibility that their clients might bear for criminal conduct. All these factors undoubtedly contribute to the public attention focused on the relationship of PCP to violence.

Few good research studies have attempted to determine the specific role that PCP abuse may have in crime and violence. In one study (Wish, 1986) of nearly five thousand arrestees in New York City in 1984 who agreed to leave a urine specimen for drug analysis, it was found that 56 percent tested positive for at least one drug of abuse. For those who had used PCP recently, most had committed robbery, not bizarre violent offenses. In fact, assault was more common among arrestees who had not used PCP than among those who had. These results support the conclusion that PCP may be no more likely to cause violence than some other drugs of abuse—but, clearly, more research on this question is needed.

The NATIONAL INSTITUTE ON DRUG ABUSE estimates that as many as six million Americans have tried PCP at least once. The very large majority of these occasions of PCP use were not associated with violent acts; however, if some users prone to violence take PCP and are faced with a threatening situation, they may act unpredictably and violently. Although there is no scientific evidence that PCP actually increases muscular strength, PCP users unmindful of their own potential safety or injuries can be a formidable risk, so law enforcement personnel are on guard against these dangerous situations. Alternatively, it should not be assumed that most people who abuse PCP will become violent—nor should every inexplicable act of violence be casually or speculatively attributed to PCP abuse.

REBECCA MARLOW-FERGUSON

PHENOBARBITAL This is the prototypic BARBITURATE central nervous system (CNS) DEPRESSANT. It is prescribed and sold as Luminal and was introduced into clinical medicine in 1912. It was used for a long period as a SEDATIVE-HYPNOTIC drug but has now largely been replaced by the much safer BENZODIAZEPINES.

Phenobarbital's long duration of action makes it useful for treating many forms of general and partial seizure disorders, such as epilepsy. Chronic use can result in TOLERANCE AND PHYSICAL DEPENDENCE, so it is classified as a Schedule III drug in the CONTROLLED SUBSTANCES ACT. Chronic treatment with phenobarbital can increase the activity of certain liver enzymes that metabolize other drugs. Thus a potential side effect is that other drugs (e.g., steroids, oral anticoagulants, digitoxin, beta-blockers, oral contraceptives, phenytoin, and others) are metabolized more quickly—and their

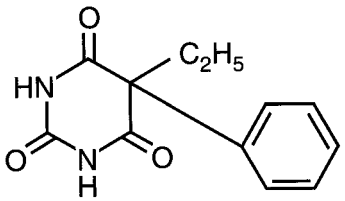

Figure 1
Phenobarbital

effectiveness is reduced. Combinations of phenobarbital and other CNS depressants, such as ALCOHOL (ethanol), can lead to severe motor impairment and reduced breathing.

PHYSICAL DEPENDENCE A state, produced by repeated or prolonged drug exposure, in which the presence of drug in the body is required to maintain normal physiological function. This state is recognizable only by the occurrence of a withdrawal reaction when the drug is removed, that is reversed when the drug is again administered. Such dependence is believed to result from adaptive changes in the nervous system, opposite in direction to the drug effects, which offset these effects when drug is present, and produce a "drug-opposite" effect in its absence. Physical dependence is not synonymous with addiction, and can occur in nonaddicted persons.

PLANTS, DRUGS FROM Humans have used their local plants for medicinal effects since prehistoric times. They gathered and ate plants and noticed the effects that some offered—whether therapeutic, mind-altering, or toxic. From trial and error they fashioned associations between cause and effect, keeping certain mushrooms, roots, barks, leaves, or berries for certain situations—the treatment of accidents, ill health, childbirth, coughs, fevers, rashes, and so on. Over the centuries, they established herbal medicine, as it is now called; they had also found certain plants that produced immediate and mind-altering effects, many of which were relegated to religious ritual. By the nineteenth century, Europeans had developed the science of chemistry to the point where the activator in many plants could be isolated and concentrated.

If experimentation with plant materials has led to cures, such as quinine for malaria or digitalis for heart disease, it has also led to the discovery of unpleasant effects or the discovery of poisons. From the literally thousands of substances that have been self-administered over the centuries, only a few continued to be used for nonmedicinal purposes. Even fewer have given rise to serious problems of chronic use and dependence. The legal and readily available drugs that are found naturally in plants (e.g., NICOTINE, CAFFEINE) or are derived from plants (e.g., ALCOHOL) will be described here first, because the use and abuse of these drugs is more widespread than all the other abused drugs combined. The health problems associated with the chronic use of alcohol and TOBACCO are, therefore, a very serious problem in our society, not only because of the large number of people who suffer and die each year from the direct toxic effects of these drugs but also because of the costs—the absenteeism from work and the unnecessary health-care cost. The illegal drugs will be discussed next; although the illicit use of MARIJUANA, COCAINE, OPIOIDS, and PSYCHEDELICS remains a major social, legal, financial, and health problem in the United States today, the proportion of the population physically dependent on these drugs is actually relatively low—only a small fraction of a percent. Finally, it is important to note that people often do not restrict their drug use to a single type. Alcohol users typically smoke cigarettes and may sometimes use other drugs as well. HEROIN users may also smoke and consume alcohol, marijuana, coffee or COLAS, and, in some instances, various STIMULANTS. Multiple drug use is, therefore, a relatively common occurrence.

ALCOHOL

Alcohol is perhaps the most widespread drug in use. It forms naturally by the fermentation process of plant materials and has been produced on purpose since at least neolithic times, when grains were first farmed, harvested, stored, and processed into gruels, porridges, puddings, and so forth. Often these spoiled, forming a fermented base. Alcohol is made as well from other starchy or sugary plant materials, such as fruits, canes, roots, and such. Fermentation (also called anaerobic respiration, or glycolysis) is the chemical process by which living cells, such as yeast, use sugar in the absence of air to produce part or even all of their energy requirements. In fermentation, sugar molecules are converted to alcohol and lactic acid. BEER, wine, and cheese production, as well as certain modern commercial processes require the fermentation by specific kinds of yeast, bacteria, and molds.

Ethyl alcohol, also called ethanol, is the type of alcohol that is usually produced for human consumption. In its pure form, alcohol is a clear liquid with little odor. People drink it primarily in three kinds of beverages: (1) beers are made from grains through brewing and fermentation and normally contain from 3 to 8 percent alcohol; (2) wines are fermented from fruits, such as grapes, and naturally contain from 8 to 12 percent alcohol (up to 21% when fortified by adding more ethanol); (3) beverages or spirits DISTILLED from a fermented base, such as whiskey, gin, or vodka, contain about 40 to 50 percent alcohol, on average (often expressed in proof, so that 40% equals 80 proof; 50% is 100 proof).

NICOTINE AND TOBACCO

TOBACCO is a tall, herbaceous plant, the leaves of which are harvested, cured, and rolled into cigars, shredded for use in cigarettes and pipes, and processed for chewing or snuff. Tobacco has become a commercial crop in almost all tropical countries as

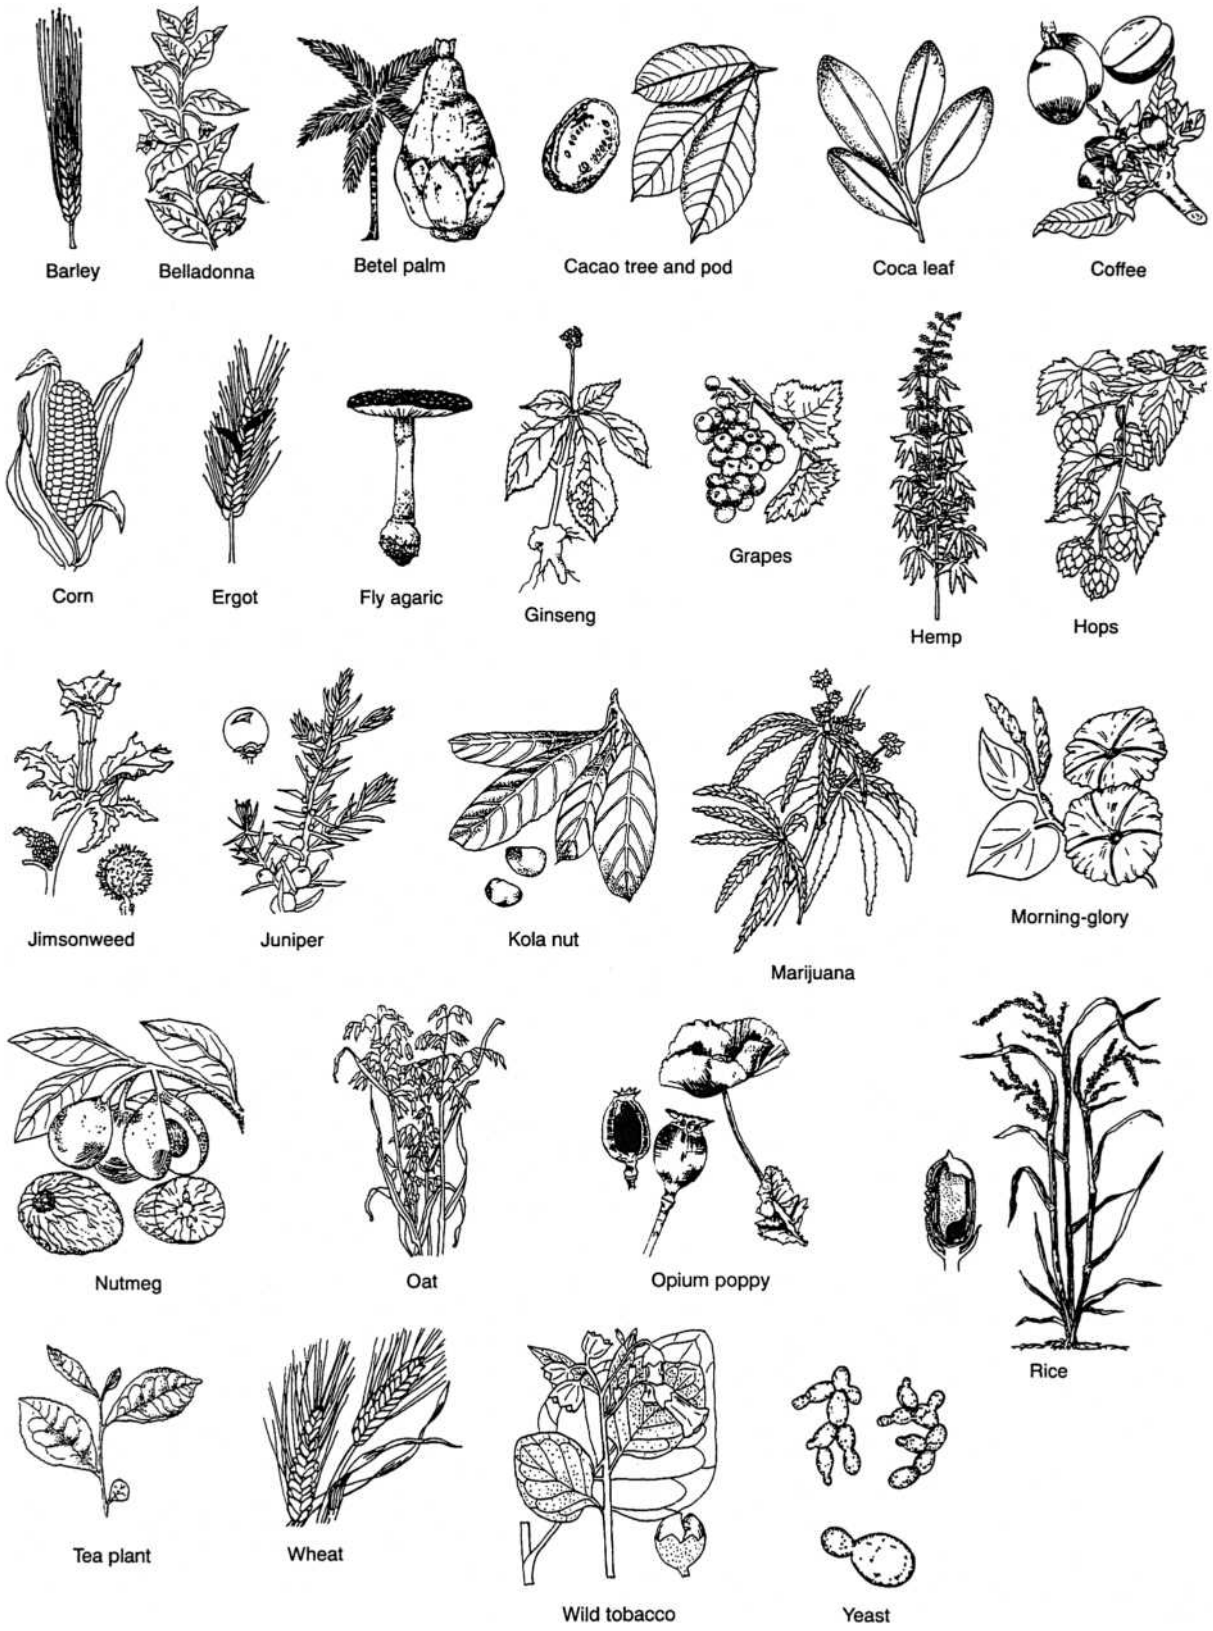

Figure 1
Some of the Plants Used in Making Drugs and Alcoholic Beverages.

well as in many temperate ones. The main source of commercial tobacco is *Nicotiana tabacum*, although *Nicotiana rustica* is also grown and is used in Asian tobaccos. Tobacco has been developed to yield a wide range of morphologically different types, from the small-leaved aromatic tobaccos to the large, broad-leaved cigar tobaccos. Tobacco is native to South America, where it was used in a drink for ritual purposes long before inhaling the smoke of the dried plant material was first documented by the Maya more than 2,000 years ago. Tobacco was then traded and grown in Central America; it moved into Mexico and the Caribbean and eventually into North America by about 800 A.D. The Arawaks of the Caribbean smoked tobacco, and during Columbus's voyage of 1492, he found the Arawaks smoking loosely rolled cigars. The Spanish took tobacco seeds to Europe, where Jean Nicot, France's ambassador to Portugal, sent tobacco to Paris in 1560 and gave the plant its genus (*Nicotiana*). In England, Sir Walter Raleigh began the popularization of pipe smoking in 1586, and the cultivation and consumption of tobacco spread with each voyage of discovery from Europe. Two kinds of tobacco were traded between Europe and America: "Spanish," from the West Indies and South America, and "Virginia," from the British plantations in their colony of Virginia. Despite its popularity in England, King James I forbade its production there since he vehemently disapproved of tobacco. Europeans at first smoked their tobacco in pipes, and later in cigars. It was often provided free to drinkers of coffee in coffee houses and cafés, as was the new product sugar. (Both remain strongly associated with coffee drinking.) Cigarettes spread in popularity only after the Crimean War (1854–1856), and their spread was especially aided by the first cigarette-making machine, developed in the United States in 1881.

NICOTINE is the most powerful ingredient of the tobacco plant, found primarily in the leaves. Nicotine is an extremely poisonous, colorless, oily alkaloid that turns brown upon exposure to the air. Nicotine can affect the central nervous system, resulting in respiratory failure and general paralysis. Nicotine can also be absorbed through the skin. Only two to three drops—less than 50 milligrams—of the pure alkaloid placed on the tongue can be rapidly fatal to an adult. A typical cigarette contains 15 to 20 milligrams of nicotine; however, the actual amount that reaches the bloodstream (and, therefore, the brain) through normal smoking is only about 1 milligram. Nicotine is responsible for most of the short-term as well as the long-term effects of smoking and plays a major role in the reinforcing properties.

CAFFEINE

CAFFEINE is an odorless, slightly bitter, alkaloid chemical found in coffee beans, tea leaves, and kola nuts, and several other plants used by humans such as cacao (CHOCOLATE) and maté (a South American holly used as a popular drink). In small amounts, caffeine acts as a mild stimulant and is harmless to most people. In large amounts, however, caffeine can result in insomnia, restlessness, and cardiac irregularities.

Tea. Tea is the beverage made when the processed leaves of the TEA plant are infused with boiling water. Native to Southeast Asia, the tea plant, *Camellia sinensis*, is a small, shrub-like evergreen tree that belongs to the family Theaceae. The seeds of the tea plant contain a volatile oil, and its leaves contain the chemicals caffeine and tannin. Although second to coffee in commercial value, tea ranks first as the most often consumed beverage. More than 50 percent of the world's population drink some form of tea every day. Many also use tea medicinally, as a stimulant. The tea plant originated in the region encompassing Tibet, western China, and northern India. According to ancient Chinese legend, the emperor Shen-Nung learned how to brew the beverage in 2737 B.C., when a few leaves from the plant accidentally fell into water he was boiling. Tea leaves began to be processed in China (dried, smoked, fermented, pressed, etc.) and were sold in cakes of steamed leaves, as powder, or in leaf form. Tea was introduced by Chinese Buddhist monks into Japan (9th to 13th centuries), where the preparation and consumption of tea developed into the ritual tea ceremony called *cha no yu*. Tea culture then spread into Java, the Dutch East Indies, and other tropical and subtropical areas. British merchants formed the East India Company (1600–1858) and introduced teas from China and India into England, the American colonies, and throughout the British Empire.

Coffee. The COFFEE bean is the world's most valuable legal agricultural commodity. In 1982, for example, the coffee-importing bill for the United States alone was 2.537 billion dollars. Of the many

varieties of the genus *Coffea* (family Rubiaceae) known to exist, only two species have significant commercial importance—*C. arabica* and *C. robusta* together constitute 99 percent of production. Coffee is native to the Ethiopian highlands and has been cultivated and brewed in Arab countries for centuries. The drink was introduced into Europe in the mid-seventeenth century and European colonial plantations were established in Indonesia, the West Indies, and Brazil, soon making coffee cultivation an important element in imperialist economies. Today, Latin America and Africa produce most of the world's coffee. The United States is the largest importer, having broken with the British tea tradition during the Revolutionary War to maintain the new American drink of coffee instead (purchased from non-British sources).

MARIJUANA

MARIJUANA is the common name given to any drug preparation derived from the hemp plant, CANNABIS SATIVA. Two varieties of this plant are *Cannabis sativa* variety *indica* and variety *americana*. The several forms of this drug are known by various names throughout the world, such as *kif* in Morocco, *dagga* in South America, and GANJA in India. HASHISH refers to a dried resinous substance that exudes from the flowering tops of the plant (also known as *charas* in Asia). In Western culture, cannabis preparations have acquired a variety of slang names, including grass, pot, tea, reefer, weed, and Mary Jane or MJ. Cannabis has been smoked, eaten in baked goods, and drunk in beverages. In Western cultures, marijuana is prepared most often from the dried leaves and flowering shoots of the plant as a tobaccolike mixture that is smoked in a pipe or rolled into a cigarette. As one of the oldest known drugs, cannabis was acknowledged as early as 2700 B.C. in a Chinese manuscript. Throughout the centuries, it has been used both medicinally and as an intoxicant. The major psychoactive component of this drug, however, was not known until the mid-1960s. This ingredient is TETRAHYDROCANNABINOL, commonly known as THC. PSYCHOACTIVE compounds (cannabinoids) are found in all parts of the male and female plant, with the greatest concentrations found in the flowering tops. The content of these compounds varies greatly from plant to plant, depending on genetic and environmental factors.

COCAINE

COCAINE is an ALKALOID drug found in the leaves of the coca plant, the common name of a shrub, *Erythroxylon coca*, of the coca family, Erythroxylaceae. Coca is densely leaved and grows to heights of 8 feet (2.5 m). It is cultivated in its native South America but also in Africa, Southeast Asia, and Australia for the narcotic alkaloids of its leaves, particularly cocaine. Whole or powdered dried leaves, usually mixed with lime (calcium carbonate), have been chewed by the people of what is now Colombia, BOLIVIA, and Peru for centuries, to dull the sense of hunger and to lessen fatigue. The coca shrub should not be confused with the cacao tree, the source of cocoa and chocolate.

Cocaine was first used in Western medicine as a local anesthetic. In 1884 it was used by Carl Koller, an ophthalmologic surgeon. Historically, the chief medical use for cocaine has been as a local anesthetic, especially for the nose, throat, and cornea, because of its effectiveness in depressing nerve endings. This has been largely replaced by less toxic, synthetic local anesthetics. Used systemically, cocaine stimulates the central nervous system, producing feelings of excitation, elation, well-being, enhanced physical strength and mental capacity, and a lessened sense of fatigue. It also results, however, in increases in heart rate, blood pressure, and temperature, and its use can result in death. Cocaine use became popular because of its stimulating properties. In Western countries, it is frequently ingested by sniffing its fine white powder, often called snow. It is sometimes injected intravenously, although repeated injections can result in skin abscesses, hepatitis, and the spread of AIDS. Cocaine can also be inhaled (smoked) once it has been converted to its free-base form; some preparations of freebase cocaine are known as rock, or crack. CRACK-cocaine gained popularity in the late 1980s and early 1990s, because it is relatively inexpensive as a single dose, (e.g., $10 to $20 per "hit"); usually smoked in a special pipe, it produces an extreme euphoria as it is rapidly absorbed from the lungs and carried by the blood directly to the brain.

OPIUM

OPIUM is a drug obtained from the juice of the immature seed pods of the oriental poppy, *Papaver somniferum*. There are over 20 natural alkaloids of

opium, including CODEINE and MORPHINE. Morphine is the largest component and it contributes most significantly to opium's physiological effects. HEROIN (diacetylmorphine) was derived from morphine and is the most important drug synthesized from opium's natural alkaloids. As a folk medicine, opium has been used to relieve pain, reduce such drives as hunger and thirst, induce sleep, and ease anxiety and depression. Opium and some of its derivatives are highly addictive, and their use has led to abuse and serious drug problems. Drugs from opium or derived from opium are still used widely in medicine, despite the development of synthetic opioid drugs such as MEPERIDINE (Demerol). The therapeutic effects of the opioids include PAIN relief, suppression of the cough reflex, slowing of respiration, and slowing of the action of the gastrointestinal tract. Opium's constipating effect led to its initial use, in the form of paregoric, in treating diarrheas and dysenteries. The main producers and exporters of opium are located in India and Turkey. About 750 tons (680 metric tons) of opium are annually needed to meet medical uses worldwide.

Opioids have been used since ancient times, both for medicinal purposes and for pleasure. Opium was taken orally, as a pill or added to beverages, for centuries in the Middle East, India, and Asia. Addiction did not become a wide problem until the practice of opium smoking was introduced by the British from India into China in the late seventeenth century (in an effort to gain a trade opening to the "closed" empire of China). China attempted to deal with the problem by restricting the cultivation and importation of opium in the nineteenth century. This led to the Opium Wars (1839–1842), since the opium trade became highly profitable to the British East India Company. Britain won over China, and opium was sold to the Chinese through treaty ports until the twentieth century.

In Europe and North America in the eighteenth century, opioids became widely used as most effective and reliable analgesics (painkillers). Heroin was developed in Germany in the 1890s and used from 1898 as a cough suppresser and analgesic with the hope that it would not lead to addiction, as did morphine (from which it was derived). From the first year or two after introduction, some clinicians agreed that it did not show addictive properties. A few even suggested that it might be useful in treating people addicted to morphine. Within a few years it became clear that, like morphine, its use could lead to addiction comparable in gravity to that of morphine.

On the street, opium is seen as a dark brown chunk of gum (from the pod of the opium poppy) or in dried powdered form. It is smoked, eaten, and drunk or injected as a solution for medicinal and recreational purposes. Indian and Chinese immigrants brought the practices with them, but the number of users is not great. During the early phases of addiction, opium produces a feeling of euphoria or well-being. With time, one may become dependent through physical and emotional factors. Tolerance develops and larger and larger doses of the drug are required to produce the same effect. If denied access to the drug, an addict will experience severe withdrawal symptoms; sudden withdrawal in a heavily dependent person has occasionally been fatal.

MESCALINE

PEYOTE, or mescal, is the common name of the small spineless cactus *Lophophora williamsii*, found in the southwestern United States and north-central Mexico. Peyote is used in Native American religious rituals, primarily for its HALLUCINOGENIC effects. At the end of the nineteenth century, Arthur Heffter demonstrated that MESCALINE (3,4,5-trimethoxyphenethylamine) was responsible for peyote's pharmacological effects. Mescaline is related to the AMPHETAMINES. When ingested, it can produce HALLUCINATIONS, frequently of a visual nature, characterized by vivid colors, designs, and a distorted space perception. It stimulates the autonomic nervous system and can cause nausea, vomiting, sweating, tachycardia (rapid heartbeat), pupillary dilation, and anxiety. The use of peyote in Native American ritual, referred to as Peyotism, was documented by Europeans in the sixteenth century. The modern practice of the peyote-based religion began in the late nineteenth century, was widely practiced by Native Americans in the southwestern United States, and was incorporated as the Native American Church in 1918. This church claimed more than 200,000 members in the 1960s. From the church member's point of view, peyote symbolizes spiritual power; the peyote "button"—the dried top of the cactus—is eaten as a sacrament to induce a hallucinogenic trance (of a few hours duration) for communion with God.

PSILOCYBIN

PSILOCYBIN is the active substance contained in the fruiting bodies of the *Psilocybe mexicana* mushroom (called the MAGIC MUSHROOM); it is a potent hallucinogen that can cause psychological disturbances. Taken orally or injected, the drug produces effects similar to those of the chemically unrelated LSD (LYSERGIC ACID DIETHYLAMIDE), and cross-tolerance has been experienced between psilocybin, LSD, and mescaline. The use of psilocybin is illegal in the United States, except for the direct consumption of mushrooms by a few religious groups as part of their ritual.

OTHER SUBSTANCES

Throughout the world, many other natural plant substances are used for mind- and mood-altering effects. These include the use of the KAVA root (*Piper methysticum*) for an intoxicating drink in the South Pacific; indole-containing snuff (distilled from indigo, genus *Indigofera*) among the Amazonian Indians of Brazil; KHAT leaves of a bush indigenous to East Africa containing an amphetamine-like drug (cathinone); BETEL NUT derived from the betel palm (*Areca catechu*) and widely used throughout the Pacific rim; and FLY AGARIC (a toxic mushroom, *Amanita muscaria*) among the Uralic-speaking tribes of Siberia.

NICK E. GOEDERS

POISON A substance that, when introduced into the body in relatively small quantities, causes destruction or malfunction of some tissues and organs. Depending on the quantity in the body (the dose), a poison can kill. The word poison usually implies that a substance has no healthful use and is to be considered dangerous even in small quantities. Most common household substances are poisonous, including bleach, ammonia, drain cleaners, paint supplies, and so on.

SUBSTANCES CAUSING DEATHS FROM ACCIDENTAL POISONING

- DRUGS
  - Analgesics and antipyretics
  - Sedatives and hypnotics
  - Tranquilizers
  - Antidepressants
  - Other psychotropic agents
  - Other drugs acting on nervous system
  - Antibiotics and other antimicrobial agents
  - Cardiovascular drugs
  - Hormones
  - Hematological agents
  - Other drugs
- OTHER SUBSTANCES
  - Alcohols
  - Cleaning and polishing agents and paint
  - Petroleum products
  - Pesticides
  - Corrosives and caustics
- GASES
  - Utility gas
  - Carbon monoxide
  - Nitrogen oxides
  - Freon
  - Other gases

In the practice of medicine, many useful DRUGS, such as antibiotics for treating infections or antihypertensive drugs for treating high blood pressure, can be poisonous or toxic in higher doses. Almost

all drugs that are abused can be poisonous or toxic; some, even at relatively low doses.

A few drugs that are commonly used in medicine in small amounts to produce important therapeutic effects are also used in other contexts as poisons. For example, the drug warfarin is used medically as an anticoagulant (to increase the time it takes blood to clot), an important effect for people who have had strokes or heart-valve replacement—but warfarin is also used as rat poison, because when rats eat it in large amounts they die soon after from massive hemorrhages. The same "mustard gas" (nitrogen mustards) that, as poison gas, caused much death and suffering in World War I, actually has medical use in the treatment of certain leukemias. Similarly, a series of extremely potent chemicals were developed during World War II as "nerve gases" for warfare, which act by flooding the body with excess acetylcholine (a body substance necessary for synaptic transmission), causing muscle paralysis and death. Consequently, close chemical relatives of some of the most potent nerve gases ever developed are being used to treat medical disorders, such as myasthenia gravis, in which there is not enough acetylcholine in nerve endings.

Treatment of someone who has been poisoned may require removal of the poison from the body (e.g., with the use of a stomach pump for ingested poisons), administration of an antidote if one exists, or simply support in repairing the damage done to the body. Many cities have a telephone "hot line" or poison-control center number where information about poisons, antidotes, and actions to take in case of poisoning can be obtained; often, they will alert emergency medical service (EMS) units to arrive in mere minutes. In case of a poisoning, including a drug overdose, it is essential to call for expert medical help as quickly as possible to minimize damage to the victim.

POISON CONTROL CENTERS *See* Appendix I, Volume 4

POLICY ALTERNATIVES This section includes two articles that introduce the reader to some of the issues surrounding public debate on the decriminalization of, or the legalization of, drugs. *Prohibition of Drugs: Pro and Con* is a short summary of the diverse opinions, expressed continually over the last 80 years, about the optimal way to deal with the reality that psychoactive drugs exist; that many people like the effects of those drugs; that some who use them do so to excess; that some are necessary for medical purposes; and that the substances themselves can be toxic not just for the user but for others who are affected by the user's behavior. The second article, *Safer Use of Drugs*, takes the view that society can reduce the toxic personal and social effects of drugs by informing potential users about how the risks of drug use can be minimized.

The argument that harm from drug use can be reduced by teaching people how to use drugs safely is viewed by many experts as counterproductive and likely to foster drug use. The *Partnership for a Drug-Free America* has developed its media campaign on the premise that the decision to try a drug is powerfully driven by two specific attitudes: perception of risk and social disapproval. This premise is supported by data emerging from the national *High School Senior Survey* (*Monitoring the Future* study) that the likelihood of drug use, especially initial experimentation, goes down as appreciation of the risks associated with drug use goes up. The more a young person feels that drugs are socially acceptable and/or not dangerous, the more she or he is likely to try them. It is difficult to imagine an educational process that can teach "ways of using drugs safely" without simultaneously communicating a message of tolerable risk and a degree of social acceptability.

Analysis of Drug Legalization Whether or not a drug should be prohibited or legalized is perhaps the most fundamental question in drug policy. It is a moderately complex question and most who write about the issue do so from an

advocacy perspective, so the debate is even more confusing than it needs to be.

It is important to start with a clear definition of what is meant by legalization vs. prohibition. There is a spectrum of policy positions. Some drugs can be used for medical but not recreational purposes (e.g., cocaine), whereas others cannot even be used for medical purposes (e.g., heroin). Some drugs cannot be used recreationally but are legal with a prescription (Valium) or when taken under medical supervision (methadone). Some drugs are legal only for adults (alcohol); others are legal for all ages (e.g., the caffeine in soda).

When a sharp line needs to be drawn between legalization and prohibition, it is useful to say that a drug is legal if it is legal for that substance to be produced and distributed for unsupervised consumption by a significant portion of the population (e.g., all adults). By this definition making marijuana available for medical use is not legalization if prescriptions are restricted to those experiencing specific, medically-diagnosed conditions (glaucoma), but it would be if any adult could write his or her own prescription. Likewise by this definition the Netherlands has legalized retail production, distribution, and use of marijuana, although wholesale (large-volume) marijuana production and distribution is still prohibited. Most other drugs in most countries are either clearly legal or clearly prohibited by this definition.

Having defined prohibition vs. legalization, the next important observation is that different people use different criteria for deciding what policy *should* be. Some people are implicitly if not explicitly consequentialists. They think the right policy is the policy that leads to the fewest problems. Others believe that there is a moral imperative to make substances legal (e.g. libertarians who believe people should be free to consume anything, even if it hurts them) or prohibited (e.g., people who believe the substance is evil for religious reasons) regardless of the consequences.

The challenge for the moral prohibitionists is defending to others why they favor prohibiting some drugs but not others. There are defensible positions predicated on consistent principles (''all intoxication is immoral'' or ''being physically dependent on a drug is idolatry''), but it is hard to articulate such a defense for US policy. Cigarettes are highly addictive, and alcohol is clearly an intoxicant, but they are both legal. In 1930 alcohol was prohibited, but marijuana was not. Ten years later, marijuana was prohibited but alcohol was not. One does not have to be very cynical to believe that the moral distinctions enshrined in public policy are just the legal formalization of arbitrary popular prejudices.

The challenge for the libertarian view is less simplistic but no less compelling (at least for those who recognize *homo economicus* as an ideal type, not a descriptively accurate model of human behavior). The basic idea is that at least some addictive, mind-altering substances may merit an exception to the general rule that a liberal society should not interfere in the private consumption decisions of its citizens. Mark Kleiman, a drug policy scholar and professor at UCLA, eloquently makes the case in his 1992 book *Against Excess*. The distinguishing characteristics are a combination of factors such as: drugs are intoxicating so consumption decisions are often made ''under the influence,'' for some drugs cessation is physically painful, drugs offer immediate pleasures and the possibility but not guarantee of delayed pain, drug initiation occurs primarily among minors, social influences play a prominent role in initiation decisions, etc. That skepticism of government regulations is healthy for a liberal democracy does not imply that prohibiting a drug is necessarily a bad idea. Liberal democracies tolerate other paternalistic infringements on freedom of behavior (such as a minimum wage, motorcycle helmet laws, and prohibitions against swimming where there are dangerous rip tides).

Furthermore, few want minors to have ready access to drugs, but legalizing use by adults inevitably makes a drug readily available to minors because every adult is a potential supplier, whether consciously (adults buying alcohol for minors) or unconsciously (minors stealing cigarettes from adults). Legalizers sometimes deny this, asserting that cocaine is more readily available to minors than alcohol is, but those assertions are contradicted by minors' self-reports (e.g., in the Monitoring the Future surveys).

The moral arguments for or against prohibition are in one sense unassailable. Every person is entitled to his or her values. But at the same time they are not very persuasive to people who do not hold those values.

For consequentialists, opinions about legalization tend to depend on how people trade off

or value the problems associated with drug use and those associated with prohibition and black markets and on predictions about how legalization would affect those outcomes. Prohibiting a drug will generally reduce but not eliminate its use. The use that persists despite prohibition supports a black market, which generates problems of its own. Indeed, the social cost per gram or per ounce consumed will typically be greater than would be the case if the drug were legally available. So prohibition typically reduces use but increases harm per unit of use.

Those who favor legalization tend to believe that a drug's legal status has little impact on its use. They also tend to be very mindful of the problems associated with black markets (stereotyped as drug dealers shooting people in battles over ''turf''), drug enforcement (e.g., racially biased enforcement tactics), and prohibition's increasing the damage per episode of use (e.g., restricting needle availability increasing spread of HIV by needle sharing). Those who favor prohibition tend to believe that prohibition substantially suppresses use (tobacco and alcohol are used far more than cocaine or heroin) and that many problems stem directly from drug use (e.g., the damage addiction can do to familial relations) not primarily from the drug's illegal status. To them, legalization is jumping out of the frying pan and into the fire. It might eliminate the black market and associated crime, but if legalization led to a ten-fold increase in the number of addicts the country could still be worse off.

Unfortunately, the public debate about the consequences of legalization is clouded with specious arguments. For example, prohibitionists argue that drugs should be illegal because they are associated with so much crime (something on the order of one-fourth of crime in the US). Legalizers counter that most of the drug-related crime is attributable to the prohibition. Only about one-sixth of drug related crime is ''psychopharmacological'' in nature (i.e., driven directly by intoxication or withdrawal). Conflicts between market participants turn violent in part because they cannot resort to the court system to resolve disputes, and one reason addicts commit robberies is to get money to buy drugs that would cost far less if they were legal. Ironically, alcohol is one of the most violence-promoting substances per se, and it is legal.

To give an example from the other side, legalizers cite statistics showing that illegal drugs such as cocaine and heroin kill only thousands of people per year, whereas alcohol and cigarettes kill hundreds of thousands. What they neglect to point out is that far more people use cigarettes and alcohol, so the death statistics per user are not so different. Furthermore, the death statistics for illicit drugs are restricted to acute effects (e.g., overdose deaths), whereas the cigarette and alcohol figures include indirect effects (e.g., deaths caused by intoxicated drivers) and delayed or chronic effects (e.g., from lung cancer). Focusing on overdose deaths would make cigarettes seem safe, whereas the expansive definition suggests that they kill more people than all other drugs combined, including alcohol.

Both sides lend a patina of scientific rigor to their arguments by citing trends in data, but the divergent trends of different indicators makes it easy to tell statistical lies. An advocate of prohibition might point out that the number of drug users fell dramatically during the 1980s when enforcement expanded rapidly. A legalizer could counter that emergency room mentions of drug use rose as fast as prevalence fell. What is lost in such bickering is the observation that the legal status of the major drugs has been stable in the US for many decades. Looking at contemporary trends might tell us about the wisdom of a more or less stringent prohibition, but we have no direct experience with legal cocaine, heroin, marijuana, or methamphetamines in recent US history. Many seek to draw lessons drawn from other times (e.g., when cocaine was legal in the US in the late 19th century) or places (e.g., Europe), but casual comparisons can be misleading and careful study of those analogies does not give definitive guidance (MacCoun and Reuter, forthcoming).

Even anecdotal evidence can be spun in different ways. Consider the periodic accounts of a mother selling her baby for crack. Some argue this proves drugs should be legalized. If they were cheap enough, addicts would not have to resort to such draconian measures. Others counter that the fundamental problem is that the drug is so powerful that it becomes more important to a mother than her own child, and we should do everything we can to protect people from the temptation to use things that so distort such societal pillars as the value of family.

The next important observation is that different drugs are different, and it may well make sense to prohibit some but not others because they have different properties (e.g., some drugs can trigger violent outbursts [PCP]; others tend to sedate [heroin]). It is by no means the case, however, that one can unambiguously rank order substances from the most to the least dangerous because a substance can be very threatening in one respect but not in others. Cigarettes are highly addictive, but they are not intoxicating. Heroin can be deadly (overdose deaths are not uncommon) but in and of itself creates almost no chronic health damage. Heroin addicts are usually in poor health because they are poor, spend money on heroin not food or shelter, and inject with dirty needles, but the heroin per does not degrade organs the way alcohol destroys the liver or smoking causes emphysema. The following table illustrates the concept.

The table divides the substances by legal status. The legalization question asks whether any substances on one side of the line should be moved to the other. It does not address changes in laws, programs, or policies that do not move a substance across the line. It might or might not be a good idea to repeal mandatory minimum sentences, cut the number of drug arrests in half, expand treatment and prevention programs, approve marijuana for medical use, eliminate profiling as an enforcement tactic, reduce the military's role in drug control, and repeal drug-related civil forfeiture statues. Doing so would blunt many of the criticisms of "prohibition," but it would not constitute legalization. Conversely, one could raise the "smoking age," require people to pass a "drinker's test" to get an alcohol consumption license, or ban smoking from all public spaces, but none of those would extend prohibition to a new substance.

There is no constituency for prohibiting caffeine, and prohibition of alcohol is perceived to have failed so badly in the last century that there is little stomach for trying it again. There is some discussion of banning tobacco use, but such proposals are probably political non-starters.

The more seriously debated proposals would legalize one or more of the currently prohibited substances. For discussion purposes, it is convenient to differentiate three groups of substances: (1) cocaine, heroin, and methamphetamines, (2) marijuana, and (3) all other illicit substances.

Cocaine, heroin, and methamphetamine are not all similar pharmacologically, but they have key commonalities. They (particularly cocaine and heroin) are expensive, are subject to stringent enforcement, can dominate the lives of an abuser, and have large, established black markets. These are the substances whose use can most confidently be predicted to rise substantially and to be problematic if they were legalized. These substances are very simple to produce, but sell for many times their weight in gold because they are prohibited and subject to severe sanctions. They are also the source of most of the corruption, violence, and disorder associated with drug markets, so legalization would bring

	Caffeine	*Tobacco*	*Alcohol*	*Marijuana*	*Heroin*	*Cocaine*
Acute health risk	None	None	High	Minimal	High	High
Chronic health risk	None	Huge	High	Some	Minimal	Some
Use affects health of others	No	Yes	Fetuses	Possibly	No	Fetuses
Problems caused by withdrawal	Minimal	Unpleasant	Physical risk	Minimal	Physical risk	Extremely unpleasant
Intoxication leads to accidents	No	No	Yes	Some	Moderate	Unclear
Intoxication leads to violence	No	No	Yes	No	No	Some
Likelihood of addiction given use [as observed in the US in last 30 years]	Minimal	High	Moderate	Moderate	High	High
Addiction disruptive to daily functioning	No	No	Yes	Somewhat	Yes	Yes

many benefits. Most observers, though, believe this would be an example of "out of the frying pan and into the fire." At a minimum, legalizing these substances is a high stakes gamble that is only partially reversible. There are other, safer alternatives to exhaust first (e.g., mending rather than ending prohibition) and more information that should be gathered about how legalization would affect use before seriously contemplating such a radical change.

Marijuana presents a quite different situation. Prohibition makes marijuana more expensive than it otherwise would be, but a daily habit is still only modestly more expensive than a two pack a day cigarette habit. Likewise, daily marijuana use is not a recipe for enhancing performance, but it does not preclude most daily functions (personal hygiene, holding down a job, etc.). So a ten-fold increase in use is a less likely outcome of legalizing marijuana than for cocaine, and even if it did happen, that outcome would be less catastrophic. On the other hand, the benefits of legalizing marijuana are far smaller than the benefits of legalizing cocaine, heroin, and methamphetamines because marijuana markets are less violent and marijuana users generally do not resort to crime to support their habit. There is no consensus about whether legalizing marijuana is wise. Some say yes. Most say no. What is clear though is that the risks, uncertainties, and potential benefits are all much smaller when considering legalizing marijuana than when considering legalizing cocaine, heroin, and methamphetamines.

The last category is diverse, so general statements are difficult. It includes drugs that can be used as a weapon in sexual assault (e.g., GHB) and drugs used not for their mind or mood altering properties but to enhance athletic performance (e.g., anabolic steroids). Two general observations are possible, however. First, prohibitions are relatively more effective and relatively less costly when preventing the spread of substances that are not commonly used than they are at reducing the use of an established drug. Second, by definition, there is more to lose in terms of increased availability and use when altering the status of drugs that are now rare. By those principles, it would be easier to make a case for legalizing XTC or LSD, for example, than for PCP, but they are not frequently the focus of legalization proposals, which typically address just marijuana or all drugs collectively.

Prohibition of Drugs: Pro and Con The history of U.S. social and legal policy in regard to psychoactive and intoxicating drug use has been characterized by periodic shifts, strong ideological presuppositions, and deep disappointment. Any analysis of current policy and the debate about drug legalization must recognize the historical roots of current policy that affect the various positions in the debate.

A brief historical note may help place the current discussion of drug policy in the United States in perspective. To borrow a phrase from Ecclesiastes, there is nothing new under the sun. Those engaged in the current, often heated, discussions about national drug policy often act as if their concerns, insights, and positions about intoxication, drug use, and society are unique to our age. A cursory review of history indicates that the debate on the meaning and effects of alcohol and other drug use on morals, public safety, productivity, and health is at least as old as written language. Some of the earliest recorded civilizations struggled with the issue and often adopted laws and policies that attempted to strictly regulate or prohibit the use of alcohol and other drugs.

Often these laws were based on a culture's perspective on the will of the divine or combined with basic civil codes. For example, the Torah appears to be very concerned with excessive alcohol use. It was seen as leading to gross immorality. The Christian New Testament holds similar views particularly on the excess use of alcohol. The theme seems to be one of avoiding all things that harm the body or one's relationship with God and moderation even in all things that are good. The Koran takes a very strong prohibition stand against alcohol and all intoxicating substances. Since much of modern Western civilization derives from these religious traditions, they continue to influence public thinking and policy. From a less theocentric perspective, many ancient civil codes also struggled with the

regulation or prohibition of intoxicating chemicals. For example, the Romans seemed especially concerned that slaves and women not use alcohol and forbade its use by them. The concern appeared to be that alcohol would make slaves less productive and more difficult to control and that it would also lead to female sexual impurity. Chinese emperors prohibited the use of opium among their subjects. In addition, during the sixteenth and seventeenth centuries when tobacco use began to spread around the world, many societies, including the Ottoman Empire, Great Britain, Russia, and Japan, initially tried prohibiting the substance.

These ancient and more recent laws and codes show that the regulation or prohibition of socially perceived harmful substances is not new to our age, nor is the range of views on the negative consequences of regulation or prohibition and what would constitute a more effective, less harmful policy.

Among the many legacies that underpin the present discussion of drug policy in contemporary society are four at times overlapping and sometimes contradicting philosophical and cultural traditions. The first is the basic American heritage of individual liberty and limited government interference with any variety of human choice, even if that choice is harmful to the individual making the decision and morally repugnant to the majority of society. This position was eloquently argued by British philosopher and economist John Stuart Mill (1806–1873) in his essay *On Liberty* (1859). It perhaps finds contemporary expression in such a social phenomenon as the pro-choice movement and in the proponents of the legalization or decriminalization of drugs.

A second major social tradition is rooted in the moral utilitarian view of government that is also a part of the nation's heritage. The utilitarian perspective, also argued by Mill in his book *Utilitarianism* (1863), emphasized that government had a legitimate right to prohibit the behaviors that actually caused real harm to others. From this viewpoint, government had the right and responsibility to protect the common welfare by legally prohibiting individuals from engaging in behavior that was demonstrably harmful, not to themselves (which would have been an interference with liberty), but to other citizens.

The moral utilitarian perspective was an important underlying element in many of the late nineteenth- and early twentieth-century social-reform movements that culminated in the many state laws prohibiting narcotics and other drug use and the national HARRISON NARCOTICS ACT OF 1914 and the Volstead Alcohol PROHIBITION Act of 1920. The utilitarian perspective was that narcotics and alcohol use caused real harm to others and society in general in the form of family poverty, crime, violence, and health-care costs.

A third social tradition that has influenced U.S. drug policy is commercialism. There is ample evidence that through the nineteenth century, U.S. society had a strong commercial attitude toward alcohol use and the use of a variety of powerful drugs. As has been documented by historians, merchandise catalogs, as well as a variety of traveling entrepreneurs, legally distributed OPIUM, BARBITURATES, and COCAINE as wonderful cure-alls for the ills of the human condition. These merchants were an organized, respected part of the commercial establishment. Perhaps based on British narcotics commercialism, there has always been a commercial attitude toward alcohol and drug distribution in the United States. From the commercial perspective, alcohol and drugs are a wonderful commodity. They are often rapidly metabolized, highly addictive, and easily distributed, However, by the end of the nineteenth century, this rather freewheeling distribution of drugs caused a widespread public reaction that became incorporated into a variety of health- and social-reform movements.

A fourth significant element in the development of national alcohol and drug policy is a public-health perspective. As was noted, at the turn of the twentieth century, the United States was in the midst of major social and health reforms. After the passage of the 1906 Pure Food and Drug Act, a host of public-health-based government bureaus and regulations emerged, focusing on improving the quality of meats and other foods and requiring the accurate labeling of drugs. In addition, the American Medical Association initiated major reforms in the medical profession, eliminating over-the-counter narcotic drug advertisements in their journal and supporting the licensing of physicians as the only legitimate prescriber of many drugs. The public-health reform movements attempted to decommercialize drug distribution and make drug use a medical, not commercial, decision. The passage of the Harrison and Volstead acts probably

represented a significant triumph of the moral utilitarian and public-health perspectives.

Following the Harrison Act and further legislation, the U.S. government instituted various bureaus and departments to carry out law enforcement and antidrug educational programs. Any review of the education programs of the Bureau of Narcotics would tend to conclude that they primarily constituted a heavy dose of propaganda with little basis in scientific fact. The federal proclivity for restricting the availability of drugs and arresting users and dealers continued strongly through the 1960s. During the decades following the Harrison Act and until the 1960s, the media and government were fairly united in their opposition to drug use, and there were few questions about the efficacy of drug laws or the social policy on which those laws were based.

In the 1960s, U.S. society experienced the coming of age of the first of the baby boomers—those born between 1946 and 1958. By their sheer numbers, a proportion of this generation challenged the traditional socialization mechanisms of society and significantly questioned traditional assumptions, rationales, explanations, and authority. In a drive for generational self-discovery, drug use, particularly as a means to alter consciousness, became a part of the youth movement of the late 1960s and the 70s. Most of the baby boomers who used drugs explored the use of MARIJUANA and HALLUCINOGENS, but over the same years HEROIN use was increasing in inner cities across the country; crime, too, was increasing. Despite the declaration of a "war on drugs" by the Nixon administration in 1970 through 1971, national surveys conducted during the 1970s and early 80s showed annual increases in almost all types of drug use among high school seniors, household residents, and criminal justice populations. The one exception was heroin, the major target of the Nixon drug war. Heroin use levels declined and then remained stable, but COCAINE use rose dramatically during the 1970s and early 1980s, as did marijuana use among young people. By 1985, more than 20 percent of U.S. adults had taken drugs illegally, and for persons aged 18 to 34 more than 50 percent had done so.

Perhaps because of the fundamental changes in national drug-using behavior that occurred during this period, the modern movement to legalize drugs began. The basis of the argument was that (1) many of the drugs that were then illegal were not as harmful as government and media propaganda portrayed them to be; (2) drugs such as marijuana were relatively less harmful than alcohol and tobacco; and (3) the use of marijuana was a generational choice. In fact, the 1978 NATIONAL HIGH SCHOOL SENIOR SURVEY showed that in the prior thirty days, a higher proportion of seniors had smoked marijuana than had smoked tobacco. By 1979, the media and American households were holding serious discussion about the legalization of marijuana, moving toward the BRITISH SYSTEM of heroin maintenance, and considering the legalization of cocaine as a nonaddictive stimulant. Social political movements such as NORML were organized to achieve passage of laws decriminalizing marijuana use. With the tacit support of the Carter administration, there were eleven states, including Alaska, that decriminalized the possession of small amounts of marijuana for personal use. Even the director of the National Institute on Drug Abuse in the late 1970s, Robert Dupont, appeared to accept the likelihood that marijuana would be decriminalized. However, in 1977, in reaction to growing marijuana use by young people and a perception that government itself was being tolerant of drug use, groups of parents organized a grassroots campaign to buttress the resistance to drug law liberalization. By 1978, the PARENTS MOVEMENT had become a force to be considered, and their views had ready access to the White House policy office. The apparently about-to-be-successful national movement to legalize many drugs in the 1970s came to an abrupt end with the 1980 election of President Ronald W. Reagan.

Corresponding with the election of President Reagan, there was a general conservative shift in national consciousness. First Lady Nancy Reagan, who made drug use among young people one of her prime topics of concern, was a welcome speaker at annual national meetings of the parents groups. The public debate on legalization during the early 1980s was also affected by increasing evidence of the physical and psychological consequences of drug use, declining illegal drug use among high school students, decreasing use among household members, and, maybe, the initiation of maturation among the baby boomers. During the 1980s, U.S. policy was characterized by the increasing intolerance of drug addiction or even recreational drug

use. On an official level, this came to be called ZERO TOLERANCE.

According to the official federal policy of the 1980s, the assumption was that to a large extent drug use was an individual choice that could be affected by raising the cost of drug use to the users. It was believed that if enforcement reduced the availability of drugs, thus raising their prices, and increased the consequences of use by increasing the severity and certainty of punishment, individuals would choose to say no to illegal drug use. During the 1980s, funding shifted from a balance between demand reduction (treatment) and supply reduction (enforcement), to one primarily focusing on enforcement. The federal government became disengaged from a primary responsibility for treatment, while at the same time it increased its involvement in enforcement. The change in support was not dramatic at first. The total federal budget for all demand-side and supply-control activities was about $1.5 billion in 1981, with about two-thirds allocated to law enforcement and supply control. This amount escalated sharply, starting in 1986, when President Reagan redeclared a "war on drugs." By 1989, the total had reached $6.7 billion, with two-thirds allocated to controlling drug supply. The resources escalated still further during the Bush administration, reaching $12.2 billion in fiscal year 1993.

By the end of the 1980s, the national drug-abuse policy of zero tolerance with a heavy focus on enforcement without any comparable increase in support for treatment began receiving critical reviews from policymakers, public administrators, clinicians, and academic researchers. These critical reviews were generally based on civil libertarian and public health harm-reduction perspectives. The key points made by national policy critics were:

1. About two-thirds of all felony arrestees in major metropolitan areas were currently using cocaine.
2. A large proportion of all criminal charges were drug charges. This had resulted in a significant expansion of prisons and the proportion of the population incarcerated. All this had occurred at a very high economic cost.
3. The high profits from the drug trade were funding international terrorism and resulting in a rapidly increasing rate of violence in American urban areas.
4. Because of the vast amount of cash generated in the drug trade, there was corruption at every level of each branch of government.
5. In an attempt to reduce illegal drug use, draconian laws focusing on search and property seizures had been passed that undermined hard-won civil rights.
6. Treatment availability for the poor had been reduced, with many cities reporting month-long waiting lists for publicly funded treatment slots.

All these real consequences have resulted in a major reinvigoration of the interest in legalizing or decriminalizing drug use. Those who argue for legalization come from a wide variety of professions and ideological positions, but they all essentially believe that U.S. society has reached the point where it can no longer afford to enforce existing law. There simply are not enough police, courts, prosecutors, or jail cells, nor is there the sense of justice that will allow U.S. society to enforce laws that have been broken by more than 20 percent of U.S. citizens.

In summary, the zero-tolerance just-say-no policy of the 1980s had come to be viewed by critics as resulitng in a virtual saturation of the criminal justice and prison system with drug law offenders, the undermining of crucial civil rights, and the decreasing availability of drug treatment for the poor accompanied by increasing violence in high drug-trafficking areas and large-scale public corruption. Many critics came to view drug laws as contrary to the very basis of a libertarian civil government. These critics saw the war on drugs declared in the 1980s and continued to the present as inimical to civil liberty. In addition to the civil libertarian perspective, there are many critics of current drug-prohibition policy that focus on a public-health harm-reduction perspective. From this perspective, current policy is not reducing the public-health harm caused by drug use. Strict law enforcement and reduction in treatment availability have resulted in denying treatment to those being personally harmed by drug abuse. The public-health-reduction model emphasizes that drug abuse and addiction are the product of a complex set of psychological, sociological, and economic variables that are very little affected by the threat of prison. This perspective argues that the best way

to reduce the personal and public-health harm of drug use would be to increase drug education and prevention, increase drug-treatment availability, and reduce the harm caused by drug abuse by providing clean needles and, perhaps, decriminalizing use—thus significantly reducing the cost of drugs and the associated CRIME.

Although there are very few detailed legalization proposals, those who advocate decriminalization generally argue that national policy should move toward an approach in which the distribution of drugs such as marijuana, cocaine, and heroin would not be governed by criminal law but by governmental regulations that controlled the manufacture, distribution, and use of these substances so that they would go only to those already addicted or be dispensed under very regulated conditions. Advocates of this policy believe that the movement of drug policy from criminal law to regulatory restrictions would result in the relatively easy availability of drugs and inexpensive access to them for those who are addicted, thus resulting in a significant reduction in corruption and violence as well as an increasing willingness on the part of addicts to enter treatment. This, it is asserted, would relieve the severe overcrowding of the criminal justice system. At the same time, it is argued, because of strict regulation, this policy change would more effectively protect young people as well as public health and safety than the current policy (see Nadelmann, 1988; Wisotsky, 1991).

Critics of the legalization perspective do not question many of the basic judgments of the consequences of the 1980s national policy, but they do severely question the assumptions on which legalization is based. Those who are opposed to drug legalization often draw on the moral utilitarian and public-health perspectives. They make the following arguments:

1. During the 1980s and continuing into the early 90s, drug use, by all measures, significantly decreased among high school and college students as well as in the general population.
2. It is naive to assume that increasing availability, lowering cost, and reducing legal consequences will have no effect on the incidence and prevalence of marijuana, cocaine, and heroin use. From this perspective, it is argued that once these drugs are legalized, even though regulated, they will enter the arena of advocacy through free speech and thus the realm of market creation and expansion through advertising. Alcohol use, which is severely regulated and illegal for those under 21 years of age, is initiated in junior high school. In addition, about a third of high school seniors report being drunk each month. In most states, tobacco cannot be sold to minors, but smoking among junior high school students is common. These facts imply that regulation to make a drug available to one age group actually makes it available to all age groups.
3. The resulting increase in use in society and broadening of the societal base of use will result in detrimental health, behavioral, and economic consequences that will far outweigh any proposed benefit of legalization.
4. There is no broad societal base for legalizing drugs. Surveys among high school seniors clearly show that a large majority oppose the legalization of drugs—even the legalization of marijuana. Traditionally liberal countries such as Switzerland and SWEDEN have tried relaxing drug laws and were forced to modify their positions by their citizens, who daily had to experience the consequences of wide drug availability. Additionally, in a referendum in November 1991, Alaskans voted to rescind a marijuana legalization law passed in the 1970s and recriminalized marijuana possession. In a democracy, governmental policy cannot ignore the voice of the public. Finally, in the first presidential debate of the 1992 election, one of the few things that all three candidates agreed on was that drugs absolutely should not be legalized and that the criminal justice system plays a useful role in forcing users into treatment. Dr. Joycelyn Elders, the first Surgeon General in the Clinton Administration, was criticized for merely suggesting that the issue of legalization should be debated.
5. In these times of concern with HIV infection and AIDS, it may be hard to conceive of popular or governmental support for any policy that may increase intravenous-drug use.
6. Although the costs of drug law enforcement and incarceration of offenders may seem high, it is a misconception to assume that those incarcerated are all petty first-time violators of the drug laws. DiIulio (1993) asserts that "... in 1991 more than 93 percent of all state prisoners were

violent offenders, repeat offenders (one or more prior felony convictions) or violent repeat offenders.'' He suggests that the vast majority of ''drug'' criminals were not arrested of simple possession, but of sale or manufacture. In short, most people would probably want to have these offenders behind bars even if the antidrug laws did not exist.

Many of those opposed to legalizing drugs, such as former Secretary of Health, Education and Welfare Joseph A. Califano, Jr., and Mathea Falco, a former Carter administration official, argue that the existing policy should be drastically modified to increase the availability of treatment and educational and economic opportunities in societal groups with high drug-use rates. Specifically, what is called for is an increase in treatment availability in the criminal justice system, either through diversion or probation to treatment or through the provision of therapeutic services in jails and prisons, as well as a major increase in the availability of publicly funded treatment slots in the United States. It is argued that every dollar invested in treatment results in several dollars saved in terms of other social costs, including crime.

Some who oppose drug legalization believe that the current discussion has subtly eroded the public's will to fight illegal drug use. From this perspective, the only way to retain the *reduction* in general societal drug use that occurred during the 1980s is to retain a vigorous enforcement of drug laws. The advocates of strict law enforcement have taken note of the most recent high school surveys and other studies that indicate an increase in drug use among students, and they believe that this increase reflects the weakening of the war on drugs in the current administration and a kind of backdoor legitimization, a demoralizing discussion of the failure of drug policy. Previous drug policy leaders such as William J. Bennett argue that national drug policy during the 1980s was effective in reducing drug use in the general youth and adult population by making use morally, socially, and legally unacceptable and that the current discussion is making drug use more acceptable, resulting in recent increases in use (Bennett & Walters, 1995a, 1995b; Rosenthal, 1995). Bennett and Walters do not believe that support of treatment programs is a useful investment, and they would leave it to state governments to decide to exactly what degree treatment should be supported.

Although it may be very difficult to reconcile the extremes of the drug legalization debate, there is some common ground that could emerge into a broadly acceptable public policy. Many involved in the current drug policy debate share a common belief that there is a need for increasing drug education, prevention, and treatment availability, as well as expanding economic opportunities.

Some of those on both sides have strongly endorsed the need to restore the balance between interdiction and treatment in favor of treatment. Ignoring federal responsibility for treatment has been disastrous. Both sides would probably agree that a crucial priority for the federal administration would be to provide treatment availability for all those who seek it and to incorporate drug-abuse treatment into national health-care policy. In addition, many on both sides of the debate would probably also agree as to the convincing need of addressing basic questions of educational and economic opportunity, as well as that of institutionalized racism, which may function as societal underpinnings of drug-use epidemics.

REVISED BY JONATHAN CAULKINS

Safer Use of Drugs People commonly use drugs in safe ways, that is, nonabusively. Safe use means that drug use does not significantly impair health or interfere with social or economic functioning. For example, most users of alcohol consume that drug in moderation, not to the point of extreme intoxication, during specified hours, and for specified purposes, such as relaxation after daily work or promotion of social interchange.

Any drug can be used or abused, although some drugs and some ways of introducing them into the body may favor safe use. In general, less potent forms of drugs taken by mouth are more likely to be associated with safe use, whereas more potent forms taken parenterally (that is, introduced other than by way of the intestinal track) are less likely to be associated with safe use.

It is difficult to discuss the safe use of illegal drugs, because foes of those substances regard them as "drugs of abuse" that cannot possibly be consumed in nonabusive ways. This attitude is unhelpful. Whether a drug is used or abused has little to do with whether a drug is legal or illegal; it depends, rather, on the relationship an individual forms with it. One can as easily find examples of abusive use of legal drugs (TOBACCO, ALCOHOL, and OVER-THE-COUNTER medications) as of safe use of illegal ones. Take for example, the majority of coffee drinkers in our society who are addicted to the CAFFEINE in coffee (meaning they will have a withdrawal reaction on sudden cessation of intake). Many of these people also experience adverse effects on health as a result of their coffee addiction (cardiac arrhythmias, stomach and intestinal problems, irritation of the urogenital tract, tremors, insomnia, mood swings, and more). Many users of MARIJUANA, however, consume that drug moderately and occasionally, without suffering ill effects on health or behavior.

By observing safe use of drugs throughout the world—from Native Americans who use HALLUCINOGENIC PLANTS ritually to the many people who have figured out how to enjoy alcohol, tobacco, and caffeine nonaddictively and nonabusively—one can draw up a list of suggestions for users to increase the likelihood of safe use.

1. Know that the substance you are using is a drug or contains a drug.
2. Know how it affects your mind and body and what the risks are of moderate to excessive use.
3. Use lower potency (dilute) forms of drugs rather than higher potency (concentrated, refined) forms.
4. It is always safer to take drugs by mouth rather than by other routes of administration.
5. If the substances are illegal, it is important to know your sources in order to avoid adulterated, toxic, or misrepresented products.
6. Limit frequency of use by defining appropriate occasions and purposes for use. Regular, especially daily, use of any psychoactive drug com-

monly leads to loss of desired effects (tolerance) and to dependence.
7. Do not use any drug without good reason or just to go along with the crowd.
8. Seek advice about drugs from books and from people who know from experience what their real benefits and risks may be.
9. Reactions to drugs are strongly shaped by dose, mind set (expectations) and setting. Pay attention to these variables to reduce the risk of bad reactions.

Clearly, it is in society's interest to discourage the unsafe use of drugs. It is also in society's interest to foster the safe use of drugs by those who are inclined to use them. Of course, abstinence is a sure way to avoid problems, but there is no reason to think that most people will choose it in regard to drugs any more than they choose it in regard to sex. Therefore, providing good education about ways of using drugs safely should be a priority along with encouraging abstinence.

In addition, government drug policy should not work against safe use. Strongly prohibitionist policies may drive out of circulation dilute, natural forms of drugs, while encouraging the growth of black markets in concentrated, refined, and adulterated forms. This has certainly been the case with coca leaf and COCAINE. Coca leaf, with a low abuse potential and significant medical usefulness, has disappeared from our world, as powder and CRACK-cocaine have become more available—a change that has favored unsafe use rather than safe use. It would therefore be in society's interest to make dilute, low-potency forms of natural drugs more available.

ANDREW T. WEIL

POLYDRUG ABUSE This term refers to the common observation that individuals who are considered drug abusers often abuse more than one type of drug. Almost all drug abusers smoke NICOTINE cigarettes and a large proportion consume alcoholic beverages, but many of them do not consider the co-occurrence of these two forms of drug use as an instance of polydrug abuse.

There are several types of polydrug abusers. They include those who abuse two or more substances but with a definite preference for one; only when they are not able to get supplies of their preferred drug do they abuse other types of drugs. These other types of drugs may either be from the same pharmacological class (e.g., HEROIN abusers may abuse other NARCOTICS as CODEINE or Demerol) or from different pharmacological classes (e.g., STIMULANT abusers—such as COCAINE abusers—may also use heroin, a narcotic). Some polydrug abusers do not necessarily have a favorite drug but instead may select different drugs for consumption at different times (e.g., stimulants in the morning, SEDATIVES at night) or under different conditions.

Polydrug abuse can also refer to the consumption of a drug to counteract an unpleasant effect produced by another drug or by withdrawal from another drug. For example, individuals who take enough stimulants to become highly agitated and aroused may take a tranquilizer to counteract the unpleasant side effects. Finally, polydrug abuse can refer to the consumption of different drugs simultaneously (e.g., speedballs). The assumption is that the different drugs in combination constitute more than the sum of their individual parts, producing a unique, highly reinforcing effect.

POVERTY AND DRUG USE One of the most popular stereotypes about drug use is that it is more prevalent among the poor. In fact, a lack of money—in itself—does not seem to be associated with drug use. Empirical research has found, however, that in the United States, a number of attitudes, behaviors, and conditions linked to drug use

also are linked to poverty, thus creating a situation that encompasses more than a lack of money. The study of poverty and drugs in the United States is complicated by the complexity of poverty as a conceptual category and by methodological problems in the measurement of drug use.

Merriam-Webster's Collegiate Dictionary, Tenth Edition defines poverty as "the state of one who lacks a usual or socially acceptable amount of money or material possessions." The sociological definition focuses on the relational aspect of poverty: Poor people are those who are at the bottom of a hierarchy of social stratification. Such a system is marked by unequal distribution of resources and income and also by differences in prestige, lifestyle, and values. In one review of the literature about poverty, authors listed the "critical features" of poverty—attitudes, behaviors, or conditions that are believed to distinguish poor from people who are not poor. Poor people often are categorized by unemployment or intermittent employment, low-status and low-skill jobs, unstable family and interpersonal relationships, low involvement in the community, alienation from the larger society, low aspirations, and individual feelings of helplessness. Poverty was also correlated with divorce and unhappy marriage, illegitimacy, low rates of voting, dropping out of school, high arrest rates and incidence of mental disorders, poor physical health, and high mortality rates. The literature concluded that poor people differed quantitatively, but not qualitatively, from people who were not poor; that is, the differences in their attitudes, their behaviors, and their conditions were differences of degree, not kind. Interestingly, however, extreme poverty is not necessarily linked to a lack of education. Some research has shown that drug users with little education were less likely to be homeless than those with considerably more education, perhaps because those with less education look for and easily find unskilled labor jobs, and they earn enough to keep them in stable housing.

When studying the relationship of poverty to drug use, some of the literature is devoid of attempts to use the multidimensional conception of poverty. Instead, researchers have tended to choose one critical feature and look at its relationship to the use of specific drugs. Such studies have examined the association of U.S. drug use with income; educational attainment; educational success; employment; mental health; HOMELESSNESS; and neighborhood. The results of these studies are largely inconclusive, thereby pointing not to a simple correlation between poverty (or poverty-linked attitudes, behaviors, and conditions) and drug use, but to more subtle pathways of direct and indirect effects.

Some of the sociological literature on poverty since the 1980s has focused on the concept of an American underclass—a population caught in an intergenerational cycle of poverty, isolated from mainstream society, living in an urban ghetto, and at risk for a number of social ills, including drug use. It should be noted that only a small proportion of poor people lead lives fitting this description. Many poor people are poor for only a short time. Poor people are also a highly heterogeneous group. They live in all regions of the United States, in both rural and urban areas, and they are represented in all age and ethnic groups.

Collecting valid information about poverty and drug use has proved to be methodologically problematic. For example, for various reasons, some individuals misrepresent the severity of their drug use or their level of poverty. In addition, some surveys of drug use are based on household samples. Those who are poor are less likely to live in stable households and more likely to live in extended or amorphous households—both situations that would result in their being excluded from such a survey. Some reporting of drug use also comes from testing of arrestees, and this may introduce a bias in the estimation of the amount of drug use by people who are poor. Some statistical information on the drug-using population also comes from treatment programs or outreach services and not all individuals with drug abuse problems seek such programs or services. A number of individuals avoid treatment programs because problems with mental health interfere with their ability to desire or seek treatment. Finally, many studies focus on certain drugs (e.g., crack-cocaine, HEROIN) and not others (e.g., MARIJUANA, COCAINE), and this may tend to misrepresent the extent of drug use among poor people as compared to its extent among people of the middle and upper classes.

Regardless of these many obstacles, researchers have reached some conclusions about drug use among the poor, especially the extreme poor—the homeless. The homeless do appear to be at higher risk for drug abuse, and some findings suggest that drugs may have displaced alcohol as an important

precursor of homelessness for many people. Researchers have also found that the homeless population is no longer primarily older, white males, but that women now make up a large portion of the homeless and that among them are many drug users.

One area in the study of drug use among the poor that has recently received much attention is the prevalence of mental health problems among the drug-using, homeless population. Researchers have found that this is a heterogeneous population in which not all individuals have the same health problems or severities of drug abuse, but studies have found a high incidence of mental health problems among homeless substance abusers. Some of the disorders seen in connection with this population include mood disorders, conduct and antisocial personality disorders, and anxiety disorders. Researchers have speculated that individuals with mental health problems use drugs as a means of self-medicating. Studies have also suggested that dealing with the mental health of drug-abusing homeless individuals may take first priority in the treatment of these individuals because mental health problems can prevent people from finding stable housing situations, getting a job, connecting with family, and staying with a drug-treatment program.

The risk of HIV infection among impoverished drug users is also an issue of increasing concern. Youths with mental illness are at particular risk for HIV infection as they have been found more likely to engage in such risky behavior as prostitution and unprotected sex, drug dealing, and drug use by injection.

Perhaps the greatest impact of poverty on the life of a drug user is how it can make prevention and treatment efforts inaccessible to that person. With private inpatient and outpatient treatment costing thousands of dollars and the long waiting lists for admission to publicly funded programs, impoverished drug users are less likely to obtain access to treatment. The heterogeneity of the poor and the lack of an empirical association between income level and drug use imply that making the poor the object of a targeted prevention and treatment effort might not be successful. Instead, the extant research on poverty and drug use suggests that policy efforts be directed at ensuring that lack of money does not become a barrier to participation in prevention and treatment programs.

Researchers have also suggested that special efforts must be made to target homeless youths due to their high risk of drug abuse. The range of services needed included outreach and sheltering services, substance abuse treatment, counseling, and HIV prevention programs. Unfortunately, many youths who engage in risky behavior do not seek traditional services or programs, and consequently those most in need may be underserved.

NORA JACOBSON
MARGARET E. ENSMINGER
REVISED BY PATRICIA OHLENROTH

PREGNANCY AND DRUG DEPENDENCE: OPIOIDS AND COCAINE During the 1980s, increasing numbers of pregnant drug-dependent women went to medical facilities—some to receive ongoing prenatal care, but others only to deliver their babies without the benefit of any prenatal care. Such women fear the threat of confrontation with legal authorities. The general lack of women-oriented drug-treatment programs contributes to this major health problem—addiction in pregnancy. It has also contributed to increased medical and social maladies and mortality in such mothers and their infants.

The 1990 NATIONAL HOUSEHOLD SURVEY ON DRUG ABUSE estimated that almost 50 percent, approximately 29 million of the 60 million women of child-bearing age, used an illicit drug at least once in their lifetimes. In 1988, one study reported for the United States an annual occurrence rate (prevalence) of 11 percent, resulting in an estimated 375,000 drug-exposed births; these data cannot be applied to the entire country, since they were collected from a limited number of mainly urban hospitals—and the frequency, amount, type, and duration of drugs used were unavailable. The basis is also unclear for the reported estimates of 50,000 to 100,000 cocaine-exposed babies born each year. The occurrence of drug abuse among pregnant women varies widely in local studies—from 7.5 percent in Rhode Island, to 14.8 percent in Pinellas County, Florida, to 17 to 31 percent in a Boston hospital. These local rates cannot be used to estimate the prevalence of drug abuse among pregnant women in the United States; they can only provide data for averages.

As a result of the uncertainty among data sources, in 1992, the NATIONAL INSTITUTE ON DRUG ABUSE (NIDA) began a national hospital-based study known as the *National Pregnancy and Health Survey*. This survey collected data on the prevalence of licit and illicit drug use by pregnant women, limited data on infant birth weight, and the duration of hospital stay. The results were released in late 1994 and the summary tables are included here. Additional surveys in progress include the *National Maternal and Health Survey* conducted by the National Center for Health Statistics, which will collect data on drug-abusing women who had a live birth, stillbirth, or an infant who died before one year of age, and the *National Longitudinal Survey*, which collects data on the frequency of marijuana and cocaine use during pregnancy by women who have given birth to a child since 1986.

OPIOIDS

Due to preexisting conditions and ongoing active drug use, the opioid-dependent woman frequently suffers from chronic ANXIETY and DEPRESSION. Social problems, such as POVERTY, HOMELESSNESS, involvement in an abusive or battering relationship, and ALCOHOLISM, may overwhelm her ability to cope with life activities. She usually lacks confidence and hope for the future and has extreme difficulty with interpersonal relationships, especially with men. One study found that 83 percent of addicted women were raised in households marked by parental drug or alcohol abuse, 67 percent of those women had been sexually assaulted, 60 percent had been physically assaulted, and almost 100 percent of the women wished that they were someone else as they were growing up. In addition to these problems, the treatment and resolution of their addiction is a complex biopsychosocial matter which requires understanding and patience. Addiction is a chronic, progressive, relapsing disease, and one cannot expect a smooth and rapid recovery. It should not be surprising, therefore, that the lifestyle of the pregnant addict has a profound influ-

ence on her psychological, social, and physiological well-being.

She may have several other children who are currently not living with her, but instead with a relative or in placement. Drug-dependent women are frequently intelligent, although the average level of high school achievement is usually at the tenth-grade level. Housing situations are frequently chaotic, and plans for the impending birth of the child may not have been considered.

It is well known that medical complications impact many drug-involved pregnancies; the most frequently encountered complications include anemia, various infections such as pneumonia, hepatitis, urinary tract infections, and sexually transmitted diseases. The women are at risk for human immunodeficiency virus (HIV) disease culminating in acquired immmunodeficiency syndrome (AIDS).

The HIV disease has been increasingly linked to drug usage. The practice of sharing contaminated needles to inject HEROIN or COCAINE, the practice of prostitution to buy drugs, or the direct sex-for-drugs transaction associated with "crack" smoking have all contributed to this serious international health crisis. Currently, the spread of HIV is less linked to homosexual spread and more to hetero-

sexual transmission and intravenous drug abuse. Although the exact risk of an infected mother passing the disease to her offspring is not precisely known, it is estimated that approximately 25 to 30 percent of infants exposed in this fashion will actually contract AIDS. Counseling in an effort to prevent HIV infection, therefore, forms an essential part of services that must be offered to pregnant substance-abusing women or women involved in relationships with addicted men.

Nutritional deficiencies associated with drug addiction are due largely to the lack of proper food intake, which may result in iron and folic-acid deficiency anemias. Toxic responses to narcotics may contribute to malnutrition by interfering with the body's ability to absorb or utilize nutrients. Abnormalities result because of the high incidence of altered function of the intestine, liver, and pancreas; malnutrition is often related to the presence of liver disease (since nausea causes addicts to eat infrequently or to vomit). Low sugar levels in the bloodstream or certain vitamin (B_6, thiamine) and

mineral (magnesium) deficiencies may cause seizures in both alcoholics and drug addicts. Hepatitis, a viral infection of the liver, often accompanies the abuse of injectable drugs; it causes addicts to eat infrequently—due to fatigue, swollen liver, nausea, and vomiting—which in turn diminishes the intake of nutrients, vitamins, minerals, and trace elements. Consequently, intensive diet therapy is needed in correcting drug and alcohol addiction—to balance fluids, electrolytes, trace elements, minerals, and vitamins—especially in acutely ill patients.

In addition to many potential medical problems, the lifestyle of some pregnant addicts becomes bur-

densome. To meet the high cost of maintaining a drug habit, she may often indulge in robbery, forgery, the sale of drugs, and/or prostitution. Because most of her day may be consumed by the activities of either obtaining drugs or using drugs, she spends most of her time unable to function in society's usual activities. She may have intermittent periods of normal alertness and well-being, but for most of the day, she will be either "high" or "sick." The high (euphoric) state will keep her sedated or tranquilized, absorbed in herself, and incapable of fulfilling familial responsibility. The sick (withdrawal) state is generally characterized by craving for more drugs, malaise, nausea, tearing, perspira-

tion, tremors, vomiting, diarrhea, and cramps. Since hormonal changes in pregnancy manifest some of these symptoms in nondrug users, the sick state may be more frequent or intensified for addicts.

IMPACT OF MATERNAL OPIOID USE ON FETAL WELFARE

Opioid dependence in the pregnant woman is not only overwhelming to her own physical condition but also dangerous to that of the fetus (and eventually to the newborn infant). Because of her lifestyle, and because she may fear calling attention to her drug habit, the pregnant addict often does not seek prenatal care. Obstetrical complications associated with heroin addiction include miscarriages, premature separation of the placenta, infection of the membranes surrounding the FETUS, stillbirth, retardation of the growth of the fetus, and premature labor.

Because no quality control exists for street drugs, doses and substances used to stretch the dose may cause repeated episodes of underdose, withdrawal, and/or overdose. Maternal narcotic withdrawal has been associated with the occurrence of stillbirth. Severe withdrawal is associated with increased muscular activity, thereby increasing the rates of metabolism and oxygen consumption; during maternal withdrawal, fetal activity also increases, as does the oxygen need of the fetus. The oxygen reserve in the placenta may not be able to supply the extra oxygen needed by the fetus. During labor, contractions further inhibit the blood flow through the uterus. If labor coincides with withdrawal symptoms in the mother, the fetus will also withdraw. Since uterine blood flow will vary at this time, and less oxygen will be delivered to the fetus, fetal death may occur.

COCAINE

Cocaine is known to cause many medical complications in adult users, including heart attacks, irregular heart beats, rupture of major blood vessels, strokes, fevers, seizures, infections, as well as a range of psychiatric disorders. The medical impact of cocaine on human pregnancy must consider all associated variables such as poverty, homelessness, inadequate prenatal and postpartum care, deficient nutrition, varying types of cocaine usage, multiple drug use, sexually transmitted diseases, and the possible presence of toxic chemicals that are mixed with or used to process cocaine.

Suppression of maternal appetite with inadequate nutritional intake is well recognized in cocaine "binging." Many cocaine users admitted for treatment may have at least one vitamin deficiency (B_1, B_6, C). Correction of these vitamin deficiencies is important during pregnancy so that essential chemicals (neurotransmitters) that transmit messages in the brain can be replenished.

Cocaine's chemical properties (low molecular weight and high solubility) allow it to cross the placenta easily and enter the fetus. The passage from maternal circulation to the fetus is enhanced by the injection or smoking of cocaine. In addition, because of acid/base balance issues and low levels of certain enzymes, which usually metabolize the drug, accumulation of cocaine in the fetus occurs. Furthermore, the "binge" pattern commonly associated with cocaine use may lead to even higher levels of cocaine in the fetus. Transfer of cocaine appears to be greatest in the first and third trimesters of pregnancy. Cocaine has a very potent ability to constrict blood vessels. A deleterious effect of this blood vessel constriction is fetal deprivation of essential nutrients and decreases in the amount of fetal oxygen. In addition to an acute oxygen deprivation, long time use of cocaine may produce a chronic decrease in nutrients and oxygen, leading to diminished growth of the fetus.

The use of cocaine by the mother may also affect the course of labor. CRACK (smokable cocaine in its base form) also appears to increase directly contractions of the uterus and may thus precipitate the onset of premature labor. Higher rates of early pregnancy loss and third-trimester separations of the placenta appear to be major complications of maternal cocaine use. Increased blood pressure and increased body temperature caused by cocaine may be responsible for early fetal loss and later separation of the placenta. The latter is hazardous to the fetus and the mother because of bleeding, shock, and the chance of death for both, if an emergency cesarean section is not performed.

The major fetal effect of cocaine is retardation of growth, resulting in smaller than normal babies at the time of birth. Although animal studies suggest that cocaine may cause malformations of the fetus, data from studies in humans are contradictory. Some reports have shown an increased chance of

abnormalities of the heart, limbs, and urinary tract, but others show no differences; studies in humans have not included large populations, and good scientific methods have not been utilized to control for many other factors that may contribute to abnormalities. Studies like these are very difficult to design for human populations.

It is currently thought that the incidence of malformations in infants as a result of cocaine taken by pregnant women is very low and that those that do occur are the result of disruption in the fetal blood vessels due to the constriction that occurs. This vessel constriction diminishes blood supply, which causes organs to malform at varying stages of fetal development. Abnormalities have been observed in the intestines, the kidneys, and the extremities.

RECOMMENDATIONS TO AMELIORATE THE EFFECTS OF DRUGS ON WOMEN AND THEIR CHILDREN

Despite the increased use of other drugs of abuse, such as cocaine, opioid abuse continues to be a major problem in the United States. Numerous investigators have reported the extremely high incidence of obstetrical and medical complications among street addicts, as well as the increase in medical conditions and death among their newborn infants.

Insufficient data exist for measuring the long-term effects of maternal drug usage. Controversy exists on how best to prevent anti treat the adverse effects of addiction. It now seems clear, however, that providing comprehensive multidisciplinary drug-treatment services and prenatal care for addicts will significantly reduce the medical and psychological conditions and the death rate in both mothers and infants. Recommendations for treatment for drug-dependent women are multifaceted. The pregnant woman who abuses drugs must be designated as high risk; she warrants specialized care in a perinatal center where she can be provided with comprehensive addictive and obstetrical care and psychosocial counseling. Care must be provided in a supportive, proactive, and nonjudgmental fashion. The women must know that sharing of confidential information with healthcare providers will *not* render them liable to criminal prosecution under state law statutes that define drug addiction in pregnancy as a form of fetal abuse.

Treatment of addiction in pregnancy may involve voluntary drug-free THERAPEUTIC COMMUNITIES, outpatient or day treatment, and, in narcotic-dependent women, METHADONE MAINTENANCE. The pregnant drug-dependent woman should be evaluated in a hospital setting where a complete history and physical examination may be performed and targeted laboratory tests carried out to evaluate her overall health status. Opioid dependent women should receive appropriate methadone maintenance, with support from an extensive medical and psychosocial network. Psychosocial counseling should be provided by experienced social workers who are aware of the medical needs, as well as the social and psychological needs, of these women. The pregnant woman addicted to BARBITURATES or major tranquilizers along with opioids should be medically withdrawn during her second trimester in a setting that furnishes appropriate monitoring of fetal well-being.

Maternal-infant attachment should have special emphasis. Parenting skills of these women need to be strengthened in an effort to nullify the anticipated (assumed) increase in child neglect and abuse that occurs in this population. Social and medical support should not end with the hospitalization. An outreach program, incorporating public health nurses and community workers, should be established. The ability of the mother to care for the infant after discharge from the hospital should be assessed by frequent observations in the home and clinic settings. Mechanisms by which to follow and supervise the infant's course after discharge from the hospital must be developed.

The major impact of comprehensive care, coupled with methadone maintenance for opioid-dependent women, has been the reduction of perinatal illness and mortality and the reduction of rates of low birthweight in offspring. Increases in birthweights, in themselves, have dramatically reduced illness and mortality for drug-exposed infants and children (mortality rates for low-birthweight newborns are forty times that of the full-term infants of normal weight).

Moreover, it is known that low-birthweight infants contribute greatly to the population of infants who test as mentally retarded (IQ of 70 or below), as well as those who will have great difficulty in school because they are "poor learners." These

handicapped individuals will be unable to compete fully in our increasingly complex society. In addition, the incidence of cerebral palsy and lethal malformations are increased in low-birthweight infants. Emotional disturbances, social maladjustments, and visual and hearing deficits are also increased. With the increasing number of addicted women, custodial facilities for their mentally and neurologically deficient infants may be necessary if programs do not deal with prevention and treatment during pregnancy.

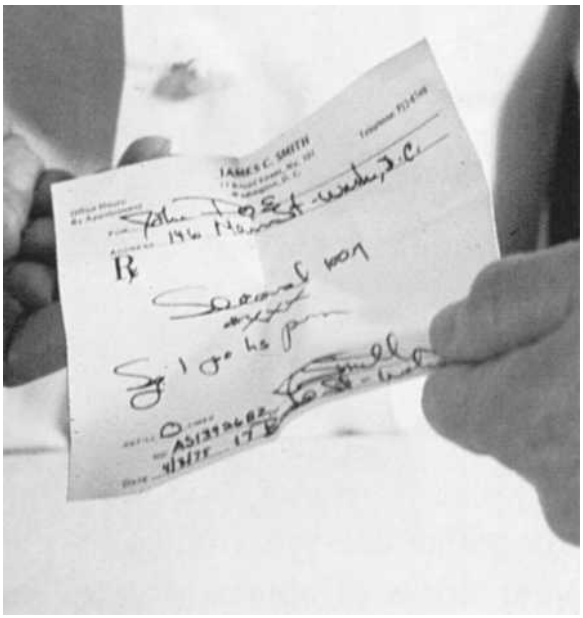
PRESCRIPTION DRUG ABUSE Unfavorable responses to medical treatments—addiction to prescribed drugs or to those used in treatments—is termed *iatrogenic*. A wide array of medicines can be associated with addiction or abuse in some people. Such drugs include the OPIOIDS, antihistamines, anticholinergies, and steroids, among others—but the most common are those prescribed for psychological problems.



Some prescription drugs, such as barbiturates and amphetamines, have a high potential for abuse and dependence when taken in non-prescribed doses or combinations. (Drug Enforcement Administration)

Some drugs acting on the mind have a low potential for abuse and dependence, for example, the ANTIPSYCHOTICS, antidepressants, and lithium salts. Others, such as the BARBITURATES and AMPHETAMINES, have a high potential.

BARBITURATES

Although barbiturates are more or less obsolete as tranquilizers and sleeping tablets, addiction to them is still encountered. TOLERANCE AND PHYSICAL DEPENDENCE can rapidly occur during therapy—and abrupt withdrawal can result in a severe and life-threatening withdrawal state. Studies in abusers show them to greatly prefer barbiturates to BENZODIAZEPINES, which have replaced them pharmacologically and are discussed below. MEPROBAMATE, a carbonate used as a tranquilizer, is similar in many ways to the barbiturates, including its abuse potential.

Clinically, patterns of nonmedical use of nonopioids vary greatly; large quantities can be injected into a vein or muscle, often producing abscess formation. Other users take large amounts by mouth, on a binge or spree basis, the most popular

being pentobarbital, amylbarbital, quinalbarbital, and Tuinal—the amylbarbital/quinalbarbital combination. Some users become permanently intoxicated and totally engrossed in maintaining their supply, licit or illicit. POLYDRUG use in combination with amphetamines or opioids is common.

Withdrawal can be hazardous, with the risk of SEIZURES or psychotic features, when discontinuing chronic usage of 500 milligrams a day or more. Withdrawal DELIRIUM (similar to DELIRIUM TREMENS, DTs) is common and often difficult to treat; a chronic state with HALLUCINATIONS may ensue.

BENZODIAZEPINES

The benzodiazepines supplanted the barbiturates because they seemed to be at least as effective, with few side effects and less likelihood of producing addiction. Benzodiazepines are preferred to placebo by drug abusers but vary in this regard; for example, diazepam (Valium) and lorazepam (Ativan) seem more likely to be taken than is oxazepam (Serax or Serehid). Benzodiazepines have been abused in various countries at various times. They have been injected as the main drug of abuse or as part of a polydrug-abuse pattern. Abusers of alcohol may also abuse benzodiazepines, finding that with drug interaction a potentiation occurs, that is, the combination is particularly powerful. Most benzodiazepine abuse is with drugs obtained legally from a number of complaisant prescribers, but the very heavy user may have to resort to illicit sources of supply. About 50 percent of abusers of benzodiazepines were introduced to the drug within the medical context.

Within polydrug abuse, the benzodiazepine is used to eke out the supply of opioid or to ease the crash from the high euphoria of COCAINE use. Patterns of usage and beliefs about the possible effects of benzodiazepine use vary widely among hard-drug abusers, but, generally speaking, benzodiazepines are viewed as potential drugs of dependence in their own right and not as relatively innocuous adjuncts.

It is fairly uncommon for patients started on benzodiazepines for therapeutic purposes to increase their dosage steadily. Nevertheless, since benzodiazepine use is widespread, high-dose users are seen fairly often. It is unclear why some patients escalate their dosage, whereas most remain at therapeutic levels indefinitely.

AMPHETAMINES

Amphetamines are stimulants, which raise mood, increase the sense of well-being, energy, and alertness, and decrease appetite. Some few users, paradoxically, become the opposite—drowsy, anxious, and irritable.

Normal-dose usage was typically prescribed; an obese, middle-aged, mildly depressed housewife might have taken two or three doses every day as a pick-me-up, a mild stimulant and appetite suppressant. (Some weak physical dependence ensued from such use, mainly seen as sleep changes on withdrawal.) With the discouragement of such indications, usage by physicians and patients has fallen off. Another obsolete use was as a vigilance-enhancer in those who felt the need to keep awake for excessively long periods, such as medical interns or long-distance truck drivers. Few people progressed from iatrogenic oral misuse to intravenous abuse.

Intravenous amphetamine produces euphoria, similar to but more sustained than that following the use of cocaine. Alter a few hours, the effects wear off, leaving the abuser feeling exhausted, drowsy, and depressed. Clandestine laboratories manufacturing amphetamine are still at work. Their preferred substance is METHAMPHETAMINE, which can be synthesized easily. Since intravenous use of methamphetamine is usual, and tolerance quickly occurs, larger and more frequent doses become required to achieve the desired effect. Toxic effects supervene, with repetitive face and hand movements and stereotyped behavior—for example, the user assembling and dismantling mechanical objects. A full-blown paranoid type of psychosis may develop, with loss of reality and delusions of persecution. Individual susceptibility to these toxic effects varies greatly. Polydrug abuse of amphetamines is common; co-administration of amphetamine with heroin (“speedball”) or a barbiturate is believed to optimize the pleasurable effects while minimizing the toxic ones.

APPETITE SUPPRESSANTS

Appetite suppressants cover a range of compounds, from the decongestant phenylpropanolamine (often available without prescription), to powerful amphetamine analogues (chemical variants). Most are stimulant, although

one, fenfluramine, is quite sedative. As with the amphetamines, patterns of use and abuse vary a great deal, from chronic daily ingestion of a therapeutic dose to binge or spree use of large quantities. As a general rule, the more amphetamine- like the appetite suppressant, the more likely it is to be abused.

Trying to stop the use of appetite suppressants may be difficult for abusers, because of withdrawal symptoms such as tiredness, dysphoria (discomfort), or frank depression. These problems and growing doubts about sustained effectiveness (for their original dietary purposes) have led many doctors to cease prescribing them.

In the early to mid-1990's, two prescription diet drugs, fenfluramine (often taken with phentermine and popularly known as fen-phen) and dexfenfluramine (Redux), grew in popularity. These drugs stimulated production of the brain chemical serotonin, creating a feeling of satiety. Stories in the news media hailed fen-phen and Redux as a miracle cure for obesity. By 1996, millions of prescriptions had been written for the diet pills.

In 1997, reports of heart valve disease in women taking fen-phen or Redux began to surface. *The New England Journal of Medicine* published a study by doctors at the Mayo Clinic that reported twenty-four women taking fen-phen developed symptomatic heart valve disorders. At the same time, the Food and Drug Administration issued a Public Health Advisory reporting the Mayo Clinic findings and reporting that it had received reports of thirty-six cases of unusual heart valve abnormalities in women ages 30 to 72 taking fenfluramine or dexfenfluramine.

By September 1997, the drugs dexfenfluramine and fenfluramine were withdrawn from the U.S. market by their manufacturer, American Home Products. In December 1999, the company agreed to compensate thousands of people who took either drug in a $3.75 billion dollar settlement of a nationwide class action suit.

Since 1997, subsequent studies have confirmed a causal link between fenfluramines and valve disorders. There is also persuasive evidence of a significant duration effect. In a 1998 study of more than 17,000 obese patients in the United Kingdom, 92 percent of the patients with symptomatic valve disorders had used fenfluramines for more than 3 months. For those who took fen-phen or Redux for less than 3 months, the risk of heart valve disorders appears to be minimal.

MALCOLM H. LADER
REVISED BY JILL LECTKA

PREVENTION By the 1980s, many urban neighborhoods in the United States became seriously debilitated by the departure of middle-class residents to the suburbs, the influx of illegal immigrants, growing unemployment rates, weak family structures, and a host of other under-class problems. In the mid-1980s, the proliferation of cheap CRACK cocaine, used mainly by inner-city adolescents and young adults, transformed a bad situa-

tion into a desperate one. For some residents, this new upsurge in drug use was the last straw, they got angry and began looking for ways to reclaim their neighborhoods and their children.

The Citizens' Drug Prevention Movement The drug-prevention movement led by private citizens and nonprofit organizations began in the mid–1970s with parents who were concerned about the health and safety of their children. During this decade, drug use among American adolescents escalated from relatively low levels to the highest levels in the history of the world. Some young drug users were addicted and needed treatment. Others were in trouble with drugs but had not yet become addicted. Some were dying of drug overdoses and many were being killed in alcohol– and drug–related automobile crashes.

Many social and environmental factors appeared to contribute to the escalation in the use of alcohol and other drugs among the young. Parents organized to address these factors in order to prevent drug use among young people. In many cases, youth groups also formed to help parents prevent substance abuse among their peers.

Media groups soon organized in response to parents' concerns about the glamorization of drug use on television, in films and in song lyrics, and, more recently, on the Internet that influenced young people. A few years later, the advertising community initiated a campaign to design and air commercials with strong anti-drug messages targeted to children and adolescents.

A drug-related tragedy on the aircraft carrier Nimitz, in which many young servicemen were killed during routine practice maneuvers, brought the military into the prevention movement. It instituted universal drug testing to ensure that such an event would never happen again. The business community adopted drug–testing policies similar to those initiated by the military to prevent drug use in the workplace, particularly in jobs that involved public safety.

Educators and researchers concerned about drug use in primary and secondary schools and on college campuses developed school-based approaches to drug prevention. The law–enforcement community added its voice to the prevention effort through community–policing programs. It also joined forces with the education community through efforts such as DARE (Drug Abuse Resistance Education), in which police officers teach DARE's drug–education curriculum to students in elementary, middle and high schools, and to their parents.

Local, state, and national political leaders created policies and allocated resources to stem the flow of drugs into the country and to help people prevent substance abuse in their families and communities.

Specific ethnic and cultural groups created prevention groups as well. They focused on strengthening their communities through a renewed appreciation of their respective heritages and building on the resiliency that had enabled them to survive the long-term, debilitating effects of racism and poverty.

Seeing the opportunity to contribute its considerable strength and human resources, the faith community also initiated drug-prevention programs. When researchers established the links between substance abuse and the transmission of HIV/AIDS, the AIDS-prevention community joined hands with the substance-abuse prevention community.

Community partnerships and coalitions formed to bring all parts of the local community together to develop and implement substance-abuse-prevention strategies collaboratively.

The citizens' drug-prevention movement continues to expand at this writing. Each component that joins it seeks to create communities in which individuals and families can live healthy lives free of drug abuse and addiction and the problems they generate.

THE PARENT MOVEMENT

Parents initiated the prevention movement in response to the escalation of drug use among teenagers throughout the 1970s. Surveys conducted by the government indicate that in 1962, just seventeen years before drug use peaked at the highest levels in history, less than 2 percent of the entire U.S. population, and less than 1 percent of adolescents, had tried any illicit drug. By 1979, when the use of most drugs peaked, twenty-four million Americans used drugs regularly. Seventy percent of young adults (ages 18–25), 65 percent of high school seniors, and 34 percent of youth (ages 12–17) had tried an illicit drug. Even higher rates of

use occurred with alcohol and tobacco. Ninety-five percent of young adults, 93 percent of seniors, and 70 percent of youth had tried alcohol, while 83 percent of young adults, 74 percent of seniors, and 54 percent of youth had tried cigarettes. One in nine seniors smoked marijuana daily.

Several social and environmental factors appeared to be contributing to this escalation in drug use among young people.

Between 1972 and 1978, eleven states decriminalized marijuana. The political rhetoric that accompanied the decriminalization effort tended to deny or minimize the harmful effects of marijuana and other drugs. State governmental action that equated penalties for marijuana possession with that of a traffic violation tended to reinforce this denial. Most people thought that state legislatures would not make marijuana more available through decriminalization if it were truly harmful.

Prevention research in the early 1970s persuaded some that drug education did not reduce drug use, and government funding for drug education materials ceased. This created a vacuum that was filled by decriminalization advocates and those who stood to profit from increased illicit drug sales. A great deal of the educational materials available throughout the 1970s taught people how to "use drugs responsibly," rather than teaching them what scientists were learning about the harmful effects of drugs. These materials tended to promote drug use rather than prevent it.

As states decriminalized marijuana, an industry emerged to assist people in their drug-taking. This industry manufactured drug paraphernalia—toys and gadgets designed to enhance drug use—and sold it in "head shops," places where so–called "pot heads," "acid heads," "coke heads," and other drug users could go to buy implements to help them take drugs. Head shops also sold promotional materials and "starter kits" targeted to young aspiring drug users. By 1977, some 30,000 head shops were conducting business across the nation.

Each of these factors helped drive drug use up among children and teenagers. Parents organized to help young people who were using drugs stop using them through education, prevention, counseling, or treatment. They also sought to prevent nonusers from starting in the first place, and to reinforce those who decided not to use drugs by emphasizing the desirability of living drug-free lives. Groups that led this effort included the Parents Resource Institute on Drug Education (PRIDE), National Families in Action, the National Federation of Parents for Drug-Free Youth, the American Council on Drug Education and Committees of Correspondence, as well as state groups, such as Texans War on Drugs, Florida Informed Parents, Tennessee Families in Action, and Alaskans for Drug-Free Youth, to name a few, and thousands of local groups in cities, towns, and counties across the country.

Parent groups targeted the social and environmental factors they felt were contributing to the escalation in drug use among young people and developed strategies to address those factors. They did this by first establishing clear definitions. They defined drug abuse to include all illegal drugs and all legal drugs and substances used illegally. These latter included alcohol and tobacco for those under the legal purchasing age, as well as medicines, glue, gasoline, and other substances people abused. Then, parent groups set clear goals: To prevent use before it started, to persuade users to stop and to help those who couldn't stop, find treatment. For alcohol, the goals were slightly different: To prevent use before the legal drinking age, to persuade those who chose to drink when they reached the legal drinking age to follow low-risk drinking guidelines, and to help those who were addicted to alcohol find treatment.

To achieve these goals, parent groups developed several strategies. They mounted an intensive effort to obtain laws to ban the sale of drug paraphernalia. Over a four-year period they succeeded in getting such laws passed in several communities and states. By 2000, nearly every state had such laws. Challenges to the paraphernalia laws were brought by the National Organization for the Reform of Marijuana Laws (NORML), which argued that they were unconstitutional. Many of NORML's board members were also members of the drug-paraphernalia industry. However, in the early 1980s after several conflicting rulings issued by federal district and appeals courts across the nation, the United States Supreme Court upheld these laws as constitutional. This ended the joint effort between NORML and the paraphernalia industry to defeat the paraphernalia laws.

NORML also led the marijuana decriminalization movement. Between 1972 and 1978, the organization persuaded eleven states to

decriminalize marijuana. The parent prevention movement stopped this effort: Parents prevented additional states from decriminalizing after 1978, and defeated a federal effort to decriminalize marijuana nationwide. In some decrim states, such as Alaska, parents worked to re–criminalize the drug, after surveys showed that marijuana use among young people was considerably higher in decrim states than in non–decrim states.

Parent groups placed primary focus on ensuring that drug-education materials convey a no-use message, rather than recommending the "responsible use" of drugs that were both illegal and harmful. They did this by going to the medical and scientific literature and insisting that drug-education materials reflect what was reported in that literature about drug effects.

These strategies seemed to have contributed to the peak and then steady decline in drug use among adolescents, young adults, and the entire population since parents first initiated the prevention movement. The Monitoring the Future Survey, conducted by the government annually since 1975, shows a direct correlation between rates of use and young people's belief that drugs are harmful. The more students who believe a specific drug will hurt them, the fewer students use that drug. Sadly, for reasons not yet fully understood, the steady rise of high school students who perceived drugs to be harmful leveled off and began to decline in the early 1990s. As a result, the steady decline in drug use over fourteen years reversed shortly after. Starting in 1993 student drug use once again began rising and doubled throughout the decade.

A re–emergence of calls for drug decriminalization and legalization worries prevention advocates. This effort was being led once again by NORML and by other organizations that emerged from NORML, including the Drug Policy Foundation and The Lindesmith Center. Many leaders of these organizations were once active in NORML. The glamorization of drug use in song lyrics and films was also reappearing, as were claims by legalization proponents that people can use highly addictive drugs "safely." Whether these shifts in environmental conditions were contributing to the turnaround in drug use was not yet clear. Nor was it clear whether the rise in drug use among high school students was a temporary aberration or a permanent trend. Nonetheless, the prevention community has redoubled its efforts to ensure that drug abuse resumes and sustains it downward trend.

THE ANTI–DRUNK–DRIVING MOVEMENT

At the same time the parent drug-prevention movement was targeting illicit drug use and the problems it generated among young people, another group of parents and families took aim at the problem of drunk driving and the devastation it was creating on the highways, particularly among young people. At the time, deaths from alcohol-related crashes were so prevalent that drunk-driving crashes had become the leading cause of death among adolescents. Families of many young people whom drunk-driving crashes had killed organized groups such as Mothers Against Drunk Driving (MADD), Remove Intoxicated Drivers (RID), and Students Against Drunk Driving (SADD) (now Students Against Destructive Decisions) to stop the carnage on the highways. As with the parent-led, drug-free movement, parents who led the anti-drunk-driving movement first raised the nation's awareness about the problem and then developed strategies to address it.

Among the many contributions this movement has made, perhaps the most significant deals with the age at which young people may legally purchase and consume alcohol. For many years the legal drinking age in every state was twenty-one. During the Vietnamese War, however, when young men aged 18 and over were drafted into the military, most states lowered their legal drinking ages to eighteen in the belief that if young men were old enough to fight for their country, they ought to be old enough to drink. The unanticipated consequence of this action, however, was to further drive down the age at which young teenagers and even pre-adolescents were able to purchase alcohol, albeit it illegally. This led to the appalling rise in the number of young people who were killed in drunk–driving crashes.

As anti–drunk–driving groups tried to persuade state legislatures to return the legal drinking age to twenty-one, their efforts were consistently defeated, year after year, by the alcohol industry, which had considerably more dollars to spend lobbying against such an action. In many states, drug–free parents groups joined forces with MADD, RID and other parent–led, anti-drunk-driving groups,

but to no avail. What broke the log jam was MADD's strategy of advocating for a federal bill that would deny federal highway funds to states that refused to increase the drinking age to 21. Although the alcohol industry also succeeded in defeating the federal effort for several years in a row, the anti-drunk-driving forces finally overwhelmed the industry, and Congress passed the federal bill.

Faced with the loss of federal highway funds, nearly all states have raised the drinking age to twenty-one. The U.S. Department of Transportation estimates changes to the drinking age laws have saved some 13,000 teenage lives to date. Furthermore, when MADD, RID, and similar groups first organized, some 52,000 Americans were killed on the highway each year. About half of those deaths, 26,000, were due to alcohol–related crashes. By the year 2000, both highway deaths and those caused by drunk–driving had been reduced considerably.

These groups continue to work to reduce drunk–driving and the problems it generates by advocating for better enforcement of existing laws, passage of new laws, and effective methods to mandate repeat DUI offenders into treatment.

THE MEDIA

In response to parental concerns about the glamorization of drug and alcohol use in films and on television, several groups organized to address these concerns. The family of actor Paul Newman founded the Scott Newman Center in memory of Mr. Newman's only son, Scott, who died of an overdose of alcohol and drugs. The Center bestowed awards to producers and writers who created television programs and films that contained strong no-use messages and that enhanced the public's understanding of substance-abuse issues and ways to deal with them successfully. The Entertainment Industries Council has advanced this strategy with its PRISM Awards, conducted in partnership with the National Institute on Drug Abuse. The Council also developed programs to work with film makers to educate them about the issue of substance abuse and to encourage them to de-glamorize drug use in movies. The National Academy of Television Arts and Sciences implemented strategies to enhance the industry's awareness of the impact it could have in reducing substance abuse through the power and reach of the mass media.

In the mid-1980s, advertising and public–relations agencies formed the Partnership for a Drug-Free America. These agencies volunteer their talent and time to create and produce anti-drug commercials targeted to young people. The Partnership originally solicited free air time and space in the electronic and print media in which to place these commercials and ads, securing several billion dollars worth of media placement for the anti-drug messages it created. In the late 1990s, after media interest in drug abuse waned and coverage of the issue plummeted, the Partnership and the federal government joined forces. Congress appropriated $195 million over five years to purchase time and space in the media to conduct a public–education campaign to prevent drug use among young people. The campaign appeared to be working, driving drug use down 21 percent among adolescents between 1997 and 1999.

ETHNIC AND CULTURAL GROUPS

The introduction of crack in the mid-1980s made cocaine cheap and plentiful and brought illicit drug use and addiction into poverty-stricken communities that had heretofore succeeded in avoiding massive use of illicit drugs. Members of African American, Hispanic and Latino, native American, and Asian American communities organized to prevent drug use, drug addiction, and drug-related crime in their communities. The passage of the first Anti-Drug Abuse Act of 1986 assisted this effort. With it, Congress made demonstration grants available to local groups to prevent substance abuse among youth at high risk of becoming involved with illicit drugs.

The resulting movement mounted intensive efforts to confront the consequences of poverty and racism. One consequence was to have made poor communities more vulnerable to drug use and the health and social problems it created. Ethnic and cultural groups organized to confront these problems, helping addicts find treatment and reclaiming their communities from drug dealers. They also address other environmental factors, taking aim at the tobacco and alcohol industries' efforts to target ethnic communities for increased consumption of their products. They have defeated the introduction of new brands of cigarettes and alcoholic beverages

targeted to African Americans and Hispanics and Latinos. Campaigns to eliminate the disproportionately high numbers of alcohol and tobacco billboards located near schools and churches in inner-city neighborhoods have resulted in outright bans of such advertising in at least two American cities, Baltimore and Cincinnati.

COMMUNITY PARTNERSHIPS

In 1989, the Robert Wood Johnson Foundation invited communities to submit proposals to establish Community Partnerships, bringing together all segments of the community—parents, young people, schools, ethnic and cultural groups, religious institutions, businesses, local governing bodies, and social and civic organizations—to reduce substance abuse. So many communities responded to the foundation's invitation that the government arranged for $100 million in assets seized from drug smugglers to make even more funds available to communities to establish partnerships to prevent substance abuse and related problems.

As the community coalition movement grew, the Foundation funded Community Anti-Drug Coalitions of America (CADCA) to lead it and join together, to provide technical assistance to coalitions and others. The Foundation also funded the Center on addiction and Substance Abuse at Columbia University to conduct research on substance-abuse issues.

Most authorities credit the activities of this sustained grass-roots, drug–prevention effort, as well as strategies implemented by federal, state, and local governments, with contributing to the reduction in drug abuse, drug addiction, and drug- and alcohol–related deaths that have occurred since the late 1970s. While drug use has increased since 1992, these increases in most cases are still below the levels of 1979. Reductions since then include the following:

- The number of Americans who are current users of illicit drugs was cut in half, from 24.0 million in 1979 to 11.0 million in 1992. The 1999 National Household Survey on Drug Abuse shows that current drug use rose to 14.8

TABLE 1

Drug	*Age Group*	*1979*	*1992*	*1999*
Any Illicit Drug	Young Adults	38.0%	13.1%	18.8%
	Seniors	38.9%	14.4%	25.9%
	Youth	16.3%	5.3%	9.0%
Marijuana	Young Adults	35.6%	10.9%	16.4%
	Seniors	36.5%	11.9%	23.1%
	Youth	14.2%	3.4%	7.0%
Cocaine	Young Adults	9.9%	2.0%	1.9%
	Seniors	5.7%	1.3%	2.6%
	Youth	1.5%	0.3%	0.7%
Alcohol	Young Adults	75.1%	58.6%	60.2%
	Seniors	71.8%	51.3%	51.0%
	Youth	49.6%	20.9%	19.0%
Cigarettes	Young Adults	42.6%*	41.5%	41.0%
	Seniors	34.4%	27.8%	34.6%
	Youth	12.1%*	18.4%	15.9%

The significant reductions in drug abuse, drug addiction, and in drug-related deaths that have occurred over two decades suggest that prevention efforts should be continued and expanded and that private sector prevention efforts should be funded to increase positive gains.

*These figures are taken from the *Overview of the 1991 National Household Survey on Drug Abuse.* Final data were eliminated from later versions of the survey, and no information about cigarette use is available for youth or young adults for 1979.

million by the end of the decade. Current cocaine use, which peaked in 1985, dropped from 5.8 to 1.3 million in 1992, and rose to 1.5 million in 1999. Daily marijuana use by high school seniors dropped 500 percent: from 10.7 percent in 1979 to 1.9 percent in 1992, and rose to 6.0 in 1998. Alcohol-related traffic deaths have been reduced from 26,000 to 15,935 per year.

- Table 1 shows drug use among young adults (18–25), high school seniors, and adolescents (12–17) in the peak year (1979), the lowest year (1992), and in 1999.

SUE RUSCHE

Community Drug Resistance The fear and anger fueled by COCAINE use had already breathed new life into the community anticrime movement of the 1970s. Social scientists and policymakers had concluded that community anticrime programs were unlikely to arise spontaneously in poor, crime-ridden neighborhoods where they were most needed—and, indeed, could not even be implemented successfully by professional organizers (Rosenbaum, 1986). But research on citizen antidrug programs has found that, actually, they are most likely to arise in poor neighborhoods, where drug activity is most common (Davis et al., 1991).

TYPES OF COMMUNITY ANTIDRUG PROGRAMS

Weingart (1992) proposed a typology for understanding citizen antidrug organizations. He defines four types of programs: (1) Law-enforcement enhancement, (2) civil justice, (3) treatment and prevention, and (4) community building. Weingart argues that community antidrug efforts are overwhelmingly dominated by the first category of program—those that aim to complement the activities of law-enforcement agencies.

Law-Enforcement Enhancement. Block-watch programs train participants to observe drug activity from their homes and to report it—usually to a designated member of the block-watch organization—in as much detail as possible (descriptions of suspects, locations of drug caches, license numbers of buyers). That person relays the information periodically to a designated police-liaison officer and, in return, the police-liaison officer reports back to the organization on the form of action taken as a result of the complaints.

Citizen patrols are commonly used programs that enhance law-enforcement efforts. Patrols vary in the degree of confrontation they use with drug dealers. Some simply observe and call their base or the police when drug sales are spotted; others have gone as far as obviously photographing or otherwise harassing drug dealers. Experience suggests that just a few individuals patrolling can be effective in removing drug activity from a neighborhood, although it has proven difficult to maintain residents' commitments to participation over extended periods of time.

Civil-Justice Efforts. These involve bringing suits against drug dealers in civil court for actionable nuisances (the noise and violence that accompany drug activity) and bringing suits against property owners, demanding abatement of a nuisance (drug selling) at a particular location. These are by far the most common type of civil action, and many major cities have made enforcement of nuisance-abatement laws a priority of the city attorney's office. Civil actions against property owners seem to be highly effective in abating drug sales at the targeted location, usually through eviction of drug sellers (and other occupants of their apartments). Questions remain about whether these actions simply displace the problem to another locale and whether they violate the rights of property owners and (at times) innocent tenants (Smith, Davis, & Hillenbrand, 1992).

Treatment and Prevention Programs. Such programs often rely on the voluntary efforts of drug abusers, their families, and their neighbors to help one another. Community-treatment programs range in size from those that are part of national organizations-like COCAINE ANONYMOUS and NARCOTICS ANONYMOUS—to small grass-roots programs, which are often church affiliated. Local drug-education efforts are usually citywide rather than neighborhood based, and they often work through the schools. Other prevention programs offer neighborhood youths supervised recreational activities for self enhancement and as an alternative to the drug culture.

Operation Weed and Seed is a community based program designed to combat drugs, violence and gang activity in high-crime neighborhoods. First launched by the Department of Justice in 1991, the

program is administered by the Executive Office for Weed and Seed within the DOJ's Office of Justice Programs. It combines law enforcement efforts to target, apprehend and incapacitate violent street criminals (weed) with community policing, prevention and treatment, and neighborhood revitalization efforts (seed). Weed and Seed grew from three grant sites in 1991 to 200 sites across the United States in 1999. Approved sites receive an annual stipend which ranges from $35,000 to $500,000. In June, 1999, The National Institute of Justice published an impact evaluation of Operation Weed and Seed. The evaluation reported that the effectiveness of weeding and seeding varied across the eight sites surveyed. The most successful sites featured established community-based organizations, active community leaders and programs that concentrated on smaller population groups. Several evaluation sites encountered early community resistance to the program because residents were concerned about aggressive enforcement measures and targeted harassment. The 1999 report emphasized the importance of involving local residents early in the process to encourage interaction and trust between law enforcement personnel and community members.

Community Building. Finally, some community-building efforts try to unite local residents against drugs through vigils, rallies, and marches. These kinds of activities are common in major U.S. cities. Other community groups have fought back against drugs by eliminating signs of disorder—such as uncollected trash and graffiti; by enhancing the appearance and safety of the neighborhood—installing better street lighting or clearing refuse and planting flowers; or by demanding that local officials raze the abandoned buildings and clear the refuse-filled empty lots used by drug abusers and drug dealers.

LINKS TO POLICE ORGANIZATIONS

Some community antidrug efforts (most notably Black Muslim patrols in Washington, D.C., in Brooklyn, N.Y., and elsewhere) have been mounted without the involvement of the police. Such efforts are relatively rare, however. In the vast majority of programs, potential activists have found a willing ally in the police. At the time that citizens were attempting to organize against drugs, many local police departments were in the process of undergoing a conversion to a community-oriented approach to law enforcement, which invited citizen participation (Skogan, 1990).

Davis et al. (1991) report that the police played a critical role in the maintenance, and sometimes the formation, of community antidrug programs. Although police administrators are normally the first to state that they cannot mobilize a neighborhood against drugs, they often facilitate incipient organizations by donating space and speakers for meetings, by acting as advocates with other city agencies (sanitation, building inspection, etc.), by providing training and backup for patrols, and by bringing together leaders from different neighborhoods to cross-pollinate ideas.

RISKS OF VIGILANTISM

The same war on drugs that promotes the vigorous enforcement and prosecution of drug cases may also have adverse consequences, including the erosion of personal freedoms and the promotion of vigilantism. Since about 1980, the Supreme Court has responded to public outcries for tougher action against drug dealers by upholding cases that permit broader latitude in surveillance and search activities. Furthermore, very aggressive citizen efforts (such as the Black Muslim patrols and the Guardian Angels) have been criticized for harassment and violent assaults against drug dealers.

PROGRAM EVALUATION

Because community antidrug programs are new, the media have been the main source of information about their activities; however, a handful of studies have been undertaken to explore the implementation and impact of community antidrug programs. Davis et al. (1991) examined the kinds of communities that have spawned antidrug efforts and the effects the programs have had on residents' perceptions of crime and disorder. Contrary to extant theories of community organizing—which suggest that resident programs against crime can only be mounted successfully in middle-class areas—the investigators found that antidrug initiatives were more common in low-income neighborhoods, even after taking into account the fact that such neighborhoods had more drug activity. In addition, the study looked closely at four of these initiatives. Residents in neighborhoods served by

the programs reported lower fear of crime and greater neighborhood satisfaction than residents of comparable nearby areas without programs.

Rosenbaum and his colleagues studied the initiation of a national demonstration program called Community Responses to Drug Abuse (CRDA). Using federal funds, ten communities in nine U.S. cities implemented a variety of antidrug projects, including closing drug houses and creating drug-free zones. The researchers interviewed participants, observed program activities, and analyzed records at the ten sites. Rosenbaum et al. (1992) report that the local community organizations accomplished a great deal with limited funds. A crucial lesson learned by the organizations was that enforcement activities provide only a limited solution to the drug problem. The most effective strategies involved broader partnerships with other agencies and institutions, such as churches and schools.

Finally, the federal Community Partnership Demonstration Program, funded by the Office for Substance Abuse Prevention, provides assistance to more than 250 programs for the prevention of substance abuse and now the CENTER FOR SUBSTANCE ABUSE PREVENTION (CSAP) allows local organizations considerable discretion to shape their own initiatives in combating drug and alcohol abuse.

A 48-community study of the Community Partnership Program, released in December, 1999 by CSAP, reported a statistically significant reduction in drug and alcohol use among males in partnership-communities. The study selected a representative sample of 24 communities from the 251 funded by CSAP and compared substance abuse rates to 24 non-partnership communities over a period of 18 months. The researchers collected surveys from 83,473 randomly selected adults, 10th graders, and 8th graders in the 48 communities. The study found that community partnerships can be effective in decreasing alcohol and illicit drug use in males, but were less effective in decreasing alcohol and illicit drug use among females. The study also found that adults reporting less illicit drug use were more likely to live in a partnership community, be involved in substance abuse prevention activities, and live in a neighborhood perceived to have minimal illicit drug trading.

REVISED BY JILL LECTKA

Prevention of Alcoholism: The Ledermann Model of Consumption The Ledermann model of alcohol consumption is an important concept for anyone who wishes to understand the underpinnings of modern policy efforts to prevent heavy drinking and alcoholism. The point of departure for this concept is a set of observations about how alcohol consumption is distributed in human societies.

Many have thought of this distribution as occurring in two parts. First, there is the great mass of "normal" drinkers; their drinking might be plotted as a bell-shaped curve, with a few people drinking no more than a sip in a year, an increasing number drinking greater amounts than a sip but less than the average amount, and then a declining number drinking more than the average amount, until the graph reaches the normal drinkers who drink much more than the average—and these are relatively few in number. Second, there is a much smaller number of "abnormal" drinkers; their drinking distribution also might be plotted as a bell-shaped curve, but this curve is shifted to the right of the distribution for normal drinkers. Figure 1 shows this two-distribution concept of normal and abnormal drinking, with the number of drinkers on the y axis and the amount consumed on the x axis.

Sully Ledermann, a French demographer, thought of this problem in relation to a single distribution that was not bell shaped or normal in its distribution. He imagined that drinking ought to be plotted in relation to a single curve, with a shape that is known as "lognormal" and without a categorical distinction between normal and abnormal drinkers. The shape is known as lognormal because the natural logarithms of individual consumption, rather than actual consumption values, are normally distributed. Assuming Ledermann is correct, the majority of individuals within a society will drink relatively modest amount of alcohol, and a small proportion will drink large quantities, but this will appear in an asymmetric or "skewed" distribution curve with a longer tail to the right of the average alcohol-consumption level (see Figure 2). To the right of the curve there should be no bump, which would be caused by the presence of an abnormal-drinkers category, distinct from the category of normal drinkers.

Perhaps the most important implication of Ledermann's thinking about alcohol consumption has to do with the prevention and the reduction of heavy drinking. Categorical distinctions between normal and abnormal drinkers make it possible to focus prevention and intervention efforts on the abnormal drinkers. In contrast, the Ledermann model suggests that efforts can be focused on the great mass of people who drink modestly as well as on the heavier drinkers: In so doing, reductions in the average amount of alcohol consumed should also result in significant reductions in the proportion of people who are very heavy drinkers. This difference in approach is part of an important ongoing debate about how societies can best organize to reduce the hazards of alcohol use.

BACKGROUND

Ledermann (1915–1967) first proposed his single-distribution hypothesis in a French publication entitled, *Alcool, Alcoolisme, Alcoolisation* (1956). In a second report published in 1964, he attempted to test and confirm the validity of his theory by using empirical data on drinking behavior from multiple studies. Born in Algeria, Ledermann spent most of his career in Paris, at the National Institute of Demographic Studies (INED) and the University of Paris. A prolific researcher, his interest in the distribution of alcohol consumption within societies developed out of a broader effort to identify the reasons for the lower average longevity of the people in France, in comparison to that of the people in other European countries. Increasingly, he came to believe that a close connection existed between the average, or per capita, level of alcohol consumption within a society and the prevalence of excessive drinkers at risk for alcohol-related injury or death, and that this relationship could be described mathematically.

Ledermann argued that the lognormal distribution of alcohol consumption resulted from the tendency of individuals to develop and change their drinking habits according to a "boule de neige" (snowball) mechanism driven by social pressures. The Norwegian scientist Ole-Jorgen Skog noted that, in general, lognormal distributions tended to result from the exponential (multiplicative) combination of behaviors (1985). On an individual level, this means that persons will tend to increase or decrease their frequency of a behavior by an amount proportional to the initial frequency with which they perform it. For example, we might expect that a person currently consuming 30 liters of

alcohol per year would perceive an increase of 6 liters as being comparable to an increase of 1 liter by an individual who currently consumes 5 liters. Such phenomena grow exponentially, in snowball fashion, and tend to distribute according to a lognormal function within populations. Ledermann believed that the snowball effect was caused by the operation of social pressures within drinking environments. This notion implies that the drinking behaviors of individuals within a particular social environment or "drinking culture" are tightly interrelated, such that changes in the alcohol consumption level of some individuals are very likely to induce changes in the consumption level of others. Skog and other scholars have elaborated upon this rudimentary social-interaction hypothesis in an effort to understand how shifts in the drinking habits of one sector may rapidly diffuse throughout the entire population.

The Ledermann model provides a simple formula for estimating the distribution of alcohol use in any homogenous population of drinkers (that is, any population in which the average consumption level does not vary significantly across subgroups). In addition to assuming lognormality with his model, Ledermann also hypothesized that the proportion of drinkers consuming more than 365 liters of absolute alcohol (ethanol) annually was small and invariant across populations, because such high consumption levels (1 liter per day) would quickly have lethal effects. With this constant determined, he could establish mathematically the full distribution of alcohol consumption within a population, knowing only the per capita or average consumption level. Knowledge of the distribution of alcohol consumption yields three important additional insights. First, one can estimate the proportion of heavy or excessive alcohol users in the population. This value is frequently defined as the percentage of drinkers consuming 10 centiliters or more of absolute alcohol per day. Second, the total amount of alcohol consumed by heavy users can be estimated. Third, and most important, the effect of changes in average consumption on the proportion of excessive drinkers in the population can be predicted. This final corollary of the model is perhaps the most controversial, because it indicates that the prevalence of excessive alcohol use within a society can be manipulated by restrictions on alcohol availability or other preventive efforts designed to reduce the general level of consumption in the population. The implications of the Ledermann model for alcohol-control policy and other public health efforts were carefully elucidated in a monograph by Finnish scholar Kettil Bruun and an international body of colleagues (1975).

Ledermann's hypotheses have been the object of intense scrutiny and debate in the half century since they were first proposed. Many researchers have examined the "fit" between the lognormal distribution and data obtained from actual populations of drinkers, with mixed results. Significant deviations from expectations of the model have been demonstrated in some cases; in other populations, the distribution closely approximated lognormality. Ledermann's assumption of constancy across populations of the proportion of heavy drinkers who consume 365 liters or more of alcohol annually has been severely challenged. In general, these critiques have weakened the deterministic character of Ledermann's original formulation, without challenging the basic assertion that there is a close connection between average alcohol consumption in the population and the prevalence of excessive or "at risk" drinkers. The debate over these issues is unresolved, but it is clear that Ledermann's ideas have served as a major stimulus in the effort to understand the relationship between the "drinking culture" of a society and the prevalence of excessive alcohol use.

Ledermann's thinking directly or indirectly underlies many current alcohol policies, especially those that control where, when, and how alcohol is consumed, and how much we pay for it. However, in the half century since his single distribution theory was first proposed, alcohol problem prevention research has continued to grow in sophistication, and modern efforts reflect a greater appreciation of the complexity of societal drinking patterns (Holder et al., 1999; Toomey and Wagenaar, 1999). The assumption of societal homogeneity in drinking behavior was a major tenet of Ledermann's first conceptualization of the single distribution theory. We now have a much greater understanding of the magnitude and significance of variation in drinking behavior, both within and between societies, based on age, gender, ethnicity, locale, and other aspects of culture (Holder and Reynolds, 1998). In addition to level of consumption, alcohol problem prevention efforts also focus on the pattern of drinking and the physical environments where alcohol is consumed. Particular at-

tention in both alcohol and drug abuse prevention studies has centered on such "harm reduction" efforts. This approach focuses on the promotion of safer use patterns rather than limitations on availability (Giesbrecht, 1999; Mosher, 1999). Alcohol server intervention programs, other alcohol education efforts, and early problem identification and intervention programs are examples of this targeted prevention approach. Ledermann's stature and influence in the field of alcohol problem prevention research are still marked, but modern alcohol problem prevention efforts are highly diverse and include a mix of individual and group-based strategies, recognizing that some approaches are appropriately directed at the societal level, but special populations and settings may require focused, specific efforts.

PREVENTION PROGRAM DIRECTORY

See Appendix, Volume 4.

PREVENTION PROGRAMS Prior to the 1980s, most schools around the country had courses in health education, tobacco education, alcohol education, or drug education. In these courses, students typically were taught that using tobacco, alcohol, MARIJUANA, or other drugs was bad for their health, and they may have found out how or why they were dangerous. Sometimes students were given detailed information about how these substances affected the body, how long the effects lasted, and even how people used them. Many tobacco-, alcohol-, and drug-education programs had tried deliberately to scare students by pointing out how many people die each year from drug abuse. It was widely believed that if students really knew how harmful smoking, drinking, or using drugs is, they would not do it. However, numerous studies found that teaching facts or using scare tactics often does not work. Therefore, programs designed to go beyond merely providing students with facts about the harmful effects of using drugs were implemented.

Many prevention programs did not work because they did not deal with the real causes of drug abuse (U.S. Public Health Service, 1986). Although we still need to learn more about what leads to drug abuse and how it develops, much is already known. This knowledge about the causes of drug abuse and the theories that researchers have developed to explain it provide the foundation upon which successful prevention programs are based. At this point, most drug-prevention experts agree that drug abuse does not have a single cause. Many different factors cause individuals to first try one or more drugs, and then they gradually become both

physically and psychologically dependent on them (Schinke, Botvin, & Orlandi, 1991).

Most people start using drugs during their early teenage years or slightly before (Schinke, Botvin, & Orlandi, 1991). This is the time when they are experimenting with a wide range of behaviors and life-style patterns as part of the natural process of growing up, becoming more independent, and discovering their own identity. Contrary to what some adults might think, more than half of all adolescents try one or more of these substances. Most individuals who try drugs do not use them more than a few times, but those who do run the very real risk of developing a compulsive pattern of use characterized by increases in both the frequency and amount of drug use and possibly development of drug dependence.

Many specific programs have been and are being carried out in schools and communities throughout the United States in the continuing effort to prevent experimentation with and use of alcohol and drugs. Included here is information on *"Here's looking at You"; Life Skills Training; Napa Project, Revisited; Ombudsman Program; PRIDE; Project SMART; Talking with Your Students about Alcohol; and the Waterloo Smoking Prevention Project.*

The overview entries on the *Parents Movement* and the *Prevention Movement* and the individual articles in the section entitled *Prevention* provide a framework for the articles in this section. For an extensive listing of other organizations engaged in similar efforts and of other programs now being used, see also *Education and Prevention* and the directory in the Appendix, Volume 4.

Prevention programs have undergone many physical changes throughout the years, from lecture-based to participation-based and from scare tactics to skill development, yet the programs do not always have positive effects. However, the outlook was becoming brighter in the late 1990s. According to Steven Schinke and Gilbert Botvin, writing in *Contemporary Pediatrics*, "Adolescents' penchant for risky behavior is no longer an impenetrable mystery, and there is now a body of scientific research on how attitudes and behavior can be changed. That research is beginning to pay off, yielding solid and empirically tested programs for preventing problems with tobacco, alcohol, and drugs among youth."

An early 1990s study evaluated the content and teaching strategies of ten school-based prevention programs: D.A.R.E., Health Skills for Living, Project Alert, Here's Looking at You 2000, Project I-STAR, Life Skills Training, Stanford Decide, QUEST, That's Life, and Teenage Health Teaching Modules. It was found that programs were becoming more similar, yet more training was necessary for the teachers.

Further studies are being done on some of these programs to see if they are still producing the desired results. For example, Drug Abuse Resistance Education (D.A.R.E.), an elementary and junior high school program, is the most widely-used prevention program in the nation (as of March 2000). Between 1999-2001, students receiving the curriculum and students receiving an addition of peer, parent, and community involvement will be evaluated and compared in the Minnesota D.A.R.E. PLUS Project.

"HERE'S LOOKING AT YOU"

The "Here's Looking at You" (HLAY) program grew out of the work done by Clay Roberts and Douglas Goodlett for their master's degrees in the 1970s. By 1978, Mr. Roberts and other health-education specialists at Seattle's Educational Service District No. 121 (ESD-121) had created a full alcohol-education curriculum for kindergarten through twelfth grades, designed mainly for delivery in fifteen to twenty class presentations each year, complete with multimedia support materials.

From the beginning, HLAY has been based on an educational theory involving both cognitive and affective elements: knowledge (information), attitudes, self-esteem, decision-making skills, and other social skills (Mooney et al., 1979). In subsequent versions of the program (HLAY-2 and HLAY-2000, with updates of the latter), strenuous efforts have been made to improve the educational strategy in light of ongoing psychosocial research and program evaluations. The program components fall into three basic categories: information, social skills, and "bonding." A two-pronged "inoculation" strategy—stressing both "risk factors" and "protective factors"—runs through these three categories. In both design and delivery, HLAY is one of the most thorough and sophisticated school-based programs in the United States, as well as one of the most widely used.

The underlying theoretical basis that has evolved for this program is recognizable by social

scientists as combining elements of both "rational choice" and "control" theories. In layman's terms, the program rests on the assumption that schoolchildren will be far less likely to use alcohol or other drugs if they are (1) given full and reliable information about the properties of chemical substances and the consequences of using them; (2) trained in self-control, decision making, and other social skills (including refusal); and (3) assisted in feeling positive about themselves and in bonding with friends, families, schools, and communities. Many of these outcomes would obviously be desirable in other arenas of youth and health as well.

One evaluation of HLAY-2000 has measured positive program impact on reported actual *use* of alcohol or other drugs (DuBois et al., 1989). This evaluation, covering grades 1 to 6, found evidence of positive impact on knowledge, self-esteem, and refusal skills but no evidence of impact on actual substance *use*, except in the case of chewing tobacco in grades 1 to 3. Other unpublished evaluations of HLAY-2000 (Bubl, 1988; Barrett, 1989) have not measured program impact on actual use of drugs or alcohol but have shown some evidence of impact at various grade levels on knowledge, self-esteem, coping, decision-making and refusal skills, and making friends.

LIFE SKILLS TRAINING

Toward the end of the 1970s, an approach to drug-abuse prevention called Life Skills Training (LST) was initiated. This approach differed from the type of information programs conducted by many schools until that time. Instead of students being taught a collection of facts about drugs and the dangers of using them, they were taught general skills for living happier and healthier lives. Studies testing the LST approach have been conducted since 1980, and they provide evidence that teaching life skills can help adolescents avoid becoming involved with drugs.

The main objectives of the LST program are: (1) to provide students with the information and skills they need to resist social pressures to use drugs; (2) to decrease potential motivations for using drugs by helping students develop greater autonomy, self-esteem, self-mastery, and self-confidence; (3) to enable students to cope effectively with anxiety, particularly anxiety induced by social situations; (4) to increase students' knowledge of the immediate negative consequences of drug use and provide them with accurate information concerning the prevalence rates of tobacco, alcohol, and marijuana use; and (5) to promote the development of attitudes and beliefs supportive of a lifestyle that excludes drug use.

The LST curriculum is a three-year program. It consists of fifteen class periods during the first year, ten booster sessions in the second year, and five booster sessions in the third year. The booster sessions, which are intended to reinforce the material taught in the first year of the program, focus on the demonstration and practice of the life skills that form the foundation of this prevention approach. The LST program contains the following five components, each of which consists of two to six sessions: Knowledge and Information (Four Sessions); Decision Making and Independent Thinking (Four Sessions); Self-directed Behavior Change (Two Sessions); Coping with Anxiety (Two Sessions) and Social Skills (Six Sessions).

During the 1980s, LST was tested by Botvin and his colleagues in eight separate studies that involved more than 25,000 students from over 150 schools in New York and New Jersey. Most of the studies focused on cigarette smoking, but several also examined the impact of LST on alcohol and marijuana use. The LST approach typically produced reductions of 50 percent to 80 percent in new smoking, drinking, and marijuana use after the first year of the program (Botvin & Tortu, 1988), but booster sessions appear to be necessary to maintain these initial prevention effects. Studies have demonstrated that the LST program can be effectively implemented by adult providers and peer leaders. Not surprisingly, it was found that the effectiveness of the LST program was related to how thoroughly it was implemented. Students whose teachers conducted the program carefully and completely demonstrated lower rates of drug use than did students whose teachers either deviated from the program or taught only part of it.

Research is currently under way to determine the extent to which the LST approach is effective in reducing risk for HIV infection. Studies are also being conducted to investigate the long-term effectiveness of this type of prevention strategy with tobacco, alcohol, and marijuana, as well as to determine the extent to which it is effective with other illicit drugs. In May 1999, students who had been through the LST program had approximately 50

percent lower incidences of drug abuse than students who had not been through any program.

NAPA PROJECT, REVISITED

The Napa Project was designed to demonstrate the promise of school-based affective and alternatives programs. It was oriented toward exemplary strategies for elementary and junior high school students because interventions in senior high seemed to be too late. The hope was to see each strategy implemented in high-quality fashion and in fertile circumstances, for periods measured in semesters and years, not days or weeks. The goal was to assess the strategies' effects on a range of student outcomes. Further, in addition to implementing and evaluating the strategies individually, there was reason to assess them in several combinations and sequences, in recognition that significant effects might not be attainable with any one strategy alone.

The Napa Project was conducted between 1978 and 1983, in close collaboration with the Napa Unified School District in northern California. All the studies were done in the Napa schools, which served a largely white, middle- and working-class community on the periphery of the San Francisco Bay area. The intervention and evaluation costs of the project were supported by a large, multiyear grant from the NATIONAL INSTITUTE ON DRUG ABUSE (NIDA).

Underlying the selection of seven total prevention strategies for the Napa Project was a theoretical model linking them to improvements in classroom and school environments, and then to positive changes in students' competencies, values, and attitudes (see Figure 1). Derived from the work of the Jessors (Jessor & Jessor, 1975) and Fishbein (Ajzen & Fishbein, 1977; Schlegel et al., 1977), the causal model held that as students' satisfaction with self, peers, and school increased, and as they perceived their peers to have more positive attitudes toward school, their own attitudes toward drug use would become less accepting and they would perceive the norms of their peers to be similarly antidrug. This was intended to decrease both intentions to use drugs and actual drug use.

The four strategies and the grade levels at which they were implemented are listed below.

- Magic Circle—teachers were trained to lead structured class meetings designed to build a sense of connection and community, as well as to foster social and academic development (grades 3–4).
- Effective Classroom Management (ECM)-Elementary—teachers were taught communication skills, discipline techniques, and self-concept enhancement techniques for use throughout the school day (grades 4–6).
- Effective Classroom Management (ECM)-Junior High—communication, discipline, and self-concept enhancement skills were adapted for teaching in the junior high environment (grades 7–9).
- Jigsaw—teachers were taught to organize classrooms into cooperative learning groups of five or six students, in which each student was given the responsibility of teaching an essential piece of the regular curriculum to the other group members (grades 4–6).

Two alternatives strategies were offered as elective academic courses to junior high students. In these courses, students were taught skills and provided with opportunities for helping peers or younger children. The courses did not address the topic of drug use; instead, they sought to teach social competencies and to enhance self-esteem. The alternatives strategies were the following:

- Cross-age tutoring—students regularly tutored younger children in reading or other academic subjects (grades 8–9).
- Operating a school store—students ran a school store on their campus, selling school supplies and snacks, while learning relevant business skills in a related academic course (grades 8–9).

The final strategy was a drug education course that taught social competencies and drug information to seventh graders. In the course, students were taught Maslow's (1980) framework for understanding motivation; learned a systematic decision-making process; analyzed techniques used in commercial advertising; learned assertiveness skills for dealing with peer pressure; and practiced setting personal goals. Toward the end of the course, students were provided with information about tobacco, alcohol, and marijuana, in response to their

written questions. They also applied the social skills in considering drug-use issues.

The seven strategies were evaluated individually and in certain combinations in twelve separate studies. All studies assessed the implementation of the strategies, as well as their effects on students. Process and outcome evaluations were conducted by the project's full-time four-person research staff. General information about the studies can be found in Schaps et al. (1984), which lists twenty-eight publications describing the various studies.

None of the strategies was shown to be effective. The four in-service strategies and the two alternatives strategies had no systematic effects on students' perceptions of classroom climate; attitudes toward self, peers, or school; attendance; academic achievement; perceptions of peer group norms; or drug-related attitudes, intentions, or behaviors. Moreover, this lack of effects could not be readily explained by poor implementation of the strategies. Implementation of the alternatives strategies was generally satisfactory. Although implementation of the in-service strategies did vary greatly from teacher to teacher, and was found to be inadequate in many classrooms, no effects were found even for the subgroups of students had who the greatest exposure to the strategies, or who were in classrooms where the strategies were best implemented, or who received combinations of strategies over two or three years.

Nevertheless, the failings of Napa's strategies and theory may well have been inadequacies of scope and depth, not of direction. That is, Napa may well have been on a potentially fruitful track in seeking to promote socially constructive norms, attitudes, and competencies—and reduce substance abuse—by fundamentally altering students' experience of schooling. But those who designed Napa may have grossly underestimated the scope and substance of the needed changes, and also the resources and processes needed to enact those changes. Even the classrooms in which the best implementation of Napa's strategies was observed may not have differed much from "ordinary" ones.

In providing twelve workshops over a period of several months, supplemented by one or two individualized consultations with a trainer, Napa offered teachers more support than most prevention programs of its time. However, it is recognized that to change in meaningful ways, most teachers need several years of focused staff development; regular opportunities for planning, reflection, and problem solving with peers; congruent instructional and curricular materials; encouragement from school and central office administrators; supportive assessment practices; and protection from conflicting demands for change.

NATIONAL FAMILIES IN ACTION

In November 1977 a group of concerned citizens in Atlanta, Georgia, troubled by the emergence of commercial and environmental pressures that seemed to encourage people to use addictive drugs, formed National Families in Action (NFIA). These commercial and environmental pressures coincided with an escalation in drug use among children and young adults to the highest levels in the history of the world. The organization's founders—parents, doctors, law-enforcement officials, political leaders, educators, business leaders, and others—sought to replace the glamorization of drug use with accurate, reliable information based on scientific research about drug effects.

Initially, National Families in Action targeted the drug PARAPHERNALIA industry. If drugs such as MARIJUANA and COCAINE were illegal, the group reasoned, it made no sense to allow the sale of implements to enhance their use. Three months after its founding, National Families in Action got the Georgia legislature to pass the nation's first laws prohibiting the sale of drug paraphernalia. Publicity surrounding this event brought calls from people across the United States who wanted to organize similar groups to ban drug-paraphernalia sales in their communities. They also wanted to educate their families and communities about the harmful effects of drugs, to prevent drug use before it started, to help users stop, and to find treatment for those who couldn't stop using drugs. The organization published a manual, *How to Form a Families in Action Group in Your Community*, which helped many thousands of groups organize. In addition, members traveled throughout the United States to help families organize community-based, substance abuse prevention groups.

National Families in Action established a drug information center, collecting articles from medical and scientific journals about all aspects of substance abuse, including research about drug effects, prevention of use, intervention, and treatment. It also collects articles from newspapers and maga-

zines about drug policy and the emergence and growth of the grass-roots prevention movement in the United States (and, increasingly, abroad). In addition, the collection houses publications of the drug paraphernalia industry and organizations that advocate drug legalization. National Families in Action's drug information center contains more than 500,000 documents on substance abuse. The center answers questions from people throughout the world who call or write for information.

In 1982, National Families in Action began publishing *Drug Abuse Update*, a quarterly digest containing abstracts of articles collected at the center. In 1990, the organization introduced *Drug Abuse Update for Kids*, written for children in elementary and middle schools. It publishes other drug-education materials as well, including a curriculum about drugs and the brain titled *You Have the Right to Know*. From 1984 to 1990, National Families in Action's executive director, Sue Rusche, wrote a twice-weekly column on substance abuse that was syndicated by King Features to more than 100 newspapers throughout the nation.

In 1990, National Families in Action received a demonstration grant from the CENTER FOR SUBSTANCE ABUSE PREVENTION to help families who lived in two Atlanta public housing developments prevent substance abuse in their communities. Called Inner City Families in Action, this project was named one of eleven exemplary programs in the United States in 1993. The program trains parents to teach *You Have the Right to Know* to neighbors, friends, and children. It helps parents obtain needed skills to complete their education and enter the work force. It also helps parents form Families in Action groups to seek treatment for loved ones who are addicted to drugs, to engage children in productive activities, and to prevent substance abuse in their communities.

National Families in Action recently agreed to help support International Students in Action (ISIA), which was founded in 1999. ISIA's board members include students from educational institutions like the University of California, Berkeley, and Harvard, as well as international students from the United Kingdom and other countries. The group's goals include involving students in the drug prevention dialogue and creating a drug-education curriculum on campuses all over the world.

National Families in Action also developed an after-school program, Club HERO (Helping Everyone Reach Out), which provides a positive environment for youths and rewards them for school performance and good behavior. NFIA introduced the *You Have A Right to Know* course into the program, and gives youths the chance to listen to and interact with local community role models.

NFIA has always been a leader in the fight against the drug-legalization movement. They stepped up these efforts in 1999 when they joined two other organizations in condemning a reality-based drug education program that teaches children that it is possible to have "positive relationships" with marijuana, cocaine, and other illicit drugs. A proposed conference in October 1999 called *Just Say Know: New Directions in Drug Education*, sponsored by The Lindesmith Center-West, aimed to instruct parents and students that drug use among some kids is inevitable and something that should not be stopped or prevented. The director of The Lindesmith Center-West suggested that "successful" drug users be sent into classrooms to serve as good examples for children.

Sue Rusche, NFIA executive director, condemned the conference and said its major goal was to use children as pawns in the drug-legalization crusade. "In the 1970s," she remarked, "this approach to drug education helped drive adolescent drug use to the highest levels in history."

The Lindesmith Center and its supporters believe that the "Just Say No" policies of the 1980s have not worked and a new approach to drug education is necessary. Drug prevention advocates such as NFIA believe that parents who teach and discipline their children can make a difference. They suggest keeping a continuous dialogue with kids, setting limits, and enforcing consequences if rules are broken. Recent data has suggests that kids whose parent instruct them about the dangers of drug use are 36 percent less likely to use marijuana and 56 percent less likely to use cocaine (Office of National Drug Policy, 1998). NFIA continues to fight numerous organization and movements whose major goal is the legalization of drugs or reality-based drug education.

Throughout its history, National Families in Action has developed numerous networks and national coalitions to advance the field of substance abuse prevention. These include the Prevention, Intervention and Treatment Coalition for Health (PITCH), an association of community-based prevention organizations that serve many different

ethnic and cultural groups throughout the nation. Through its advocacy efforts, PITCH helped bring about the creation of a new federal agency, the Substance Abuse and Mental Health Services Administration, to further develop the prevention field. National Families in Action is increasingly called upon to help citizens from other nations develop prevention groups.

Along with other national prevention organizations, National Families in Action has played a pivotal role in driving drug use down since 1979.

NATIONAL FEDERATION OF PARENTS FOR DRUG-FREE YOUTH/NATIONAL FAMILY PARTNERSHIP (NFP)

A large number of parent-group leaders, who had previously organized drug-prevention groups in their states and local communities, formed the National Federation of Parents for Drug-Free Youth in the spring of 1979. With the assistance of national organizations in Atlanta, Massachusetts, and elsewhere, these leaders had organized prevention groups of parents in response to the greatest escalation in drug use by American adolescents in the history of the world. They organized to protect children by striving to prevent drug use before it began, by helping young drug users to stop, and by obtaining treatment for those who couldn't stop by themselves.

During the 1970s, legislatures in eleven states decriminalized MARIJUANA. During this same period, an explosion of head shops proliferated throughout the United States. These places, which sold PARAPHERNALIA to enhance drug use, targeted their products to children and teenagers. The national decriminalization discussion produced rhetoric that ignored or played down the harmful effects of drugs, and this rhetoric spilled over into drug-education materials, which counseled the "responsible use" of drugs that were both dangerous and illegal. Song lyrics and films in the adolescent culture tended to reinforce the popularity and acceptance of drug use. These factors appeared to contribute to, if not actually drive, the astonishing escalation in adolescent drug use throughout the 1970s.

Parent groups organized to prevent children from entering the drug culture and to rescue those who already had, taking aim at the drug-paraphernalia industry and fighting decriminalization. By 1979, however, it had become clear that action at local and state levels was not enough. Representation at the national level was critical particularly in light of the fact that a federal bill to decriminalize marijuana was gaining support from members of Congress. Parent-group leaders formed the National Federation of Parents for Drug-Free Youth to represent their interests in Washington.

The first order of business was to defeat the pending federal decriminalization bill, which would have removed criminal penalties for the possession of up to an ounce of marijuana. Federation volunteers bought 1-ounce jars of parsley to demonstrate that an ounce was not an insignificant amount, and to reinforce the fact that an ounce of marijuana can yield from forty to sixty "joints." They delivered these jars to each member of Congress, educating senators and representatives about the high levels of marijuana and other drug use that decriminalization in some states appeared to have produced among young people, and asking them to vote against the federal decriminalization bill. The Federation succeeded in this effort. Congress voted the bill down and rejected decriminalization for good.

Shortly afterward, the Federation led a letter-writing campaign to newly elected President Reagan, asking him to place leaders sympathetic to parent-groups' concerns in important drug-policy roles in his administration. In addition, the Federation brought parent-group leaders from communities across the United States to Washington to brief First Lady Nancy Reagan about their efforts. As a result, Mrs. Reagan became an informal spokesperson for the Federation and its work.

When Drug Enforcement Administration agent Enrique Camarena was brutally murdered while on duty in MEXICO, the Federation's Virginia chapter conceived a Red Ribbon campaign to honor the slain agent. The chapter wanted to express support for law-enforcement officers nationwide who put their lives on the line every day to enforce the nation's drug trafficking laws. The initial campaign developed into Red Ribbon Week, held annually each October. During this week, schools and communities across the nation celebrate the Red Ribbon campaign for drug-free communities.

In 1993, the Federation refocused its mission and scope, reincorporating under the name of National Family Partnership (NFP).

The NFP conducts training for parents, youth. and community leaders to help them organize prevention groups. Along with other national prevention organizations, the NFP has contributed to the reduction in drug use that has occurred since 1979.

OMBUDSMAN PROGRAM

Ombudsman is a word of Swedish origin that can be loosely translated as "a helping person." The Ombudsman program is a drug-abuse prevention program geared to students in grades five through nine. The program was developed by the Drug Education Center, located in Charlotte, North Carolina, and is based on the assumption that the most effective way to prevent adolescent alcohol and other drug (AOD) abuse is through the promotion of individual personal growth. This is attempted via enhancements of self-esteem, social skills, and the empowerment of students in a group project that seeks to help others. Students meet once or twice per week (depending on the course module chosen) during regular classroom hours. In addition, the program activities are designed to be integrated into academic subject areas. Either a trained facilitator or a classroom teacher who has been trained by a certified Ombudsman trainer directs the program.

The Ombudsman program was one of the first drug-abuse prevention programs in the United States to be funded by the NATIONAL INSTITUTE ON DRUG ABUSE (NIDA) in 1977. The purpose of the NIDA grant was to fully develop and evaluate the outcome of this program.

The program has three phases. The first, Self-Awareness, involves a series of exercises that encompass activities for building self-esteem. The purpose of these activities is to foster the development of self-worth and respect for others. The second phase, Group Skills, gives students an opportunity to foster communication, positive group interaction, and refusal/resistance decision-making skills. Information on the effects of drugs is taught in this phase. During the third and last phase, students apply the knowledge and skills they have gained in the program by planning and carrying out a project that helps others within their own community or at school. Ombudsman program activities are experiential, utilize cooperative learning techniques, and appeal to a variety of learning styles.

Ombudsman program outcomes have been evaluated by using the Student Attitudinal Inventory (Kim, 1981c). Short-term evaluation results indicate that the program can affect seven high-risk student attitudinal factors closely related to adolescent drug-using behavior: negative social attitude, rebelliousness, low valuing of school, poor student-teacher relationship, perception of incohesive family relationship, low self-esteem, and attitudes favoring drug use. It has also been learned that the program is more effective among younger than among older students. Finally, data from one long-term evaluation suggest that there is a greater proportion of students who no longer use drugs (i.e., who gave up experimenting with drugs) among the students trained in the Ombudsman program than among those who have not participated in the program.

PRIDE (NATIONAL PARENTS RESOURCE INSTITUTE FOR DRUG EDUCATION)

Thomas "Buddy" Gleaton, Ed.D., and Marsha Keith Manatt Schuchard, Ph.D., founded PRIDE in Atlanta, Georgia, in 1978. PRIDE's purpose is to help parents form groups to protect their children from becoming involved with MARIJUANA and other drugs. The organization is based on the following fundamental principles: (1) drug abuse is a health issue; (2) the family is the greatest bulwark against adolescent drug use; (3) families need help from the rest of the community to steer young people safely through the many temptations and dangers that confront them every day.

Initially, PRIDE based its group model on parent peer groups initiated by Dr. Schuchard and her family. A parent peer group encourages parents to get to know and link up with the parents of their children's friends. They establish social guidelines for their children to which they all agree to adhere, and they try to create positive alternatives for young people to prevent them from engaging in unhealthy and destructive behaviors during adolescence. Dr. Schuchard's handbook, *Parents, Peers and Pot*, published and distributed by the National Institute on Drug Abuse, outlines how to form parent peer groups.

PRIDE later expanded its parent peer-group model to include larger groups of parents who wanted to work for change throughout their com-

munities to prevent drug abuse among young people. The organization offers training to parents across the nation. PRIDE also added a youth component, training junior high and high school students and encouraging them to take a stand against drug use. In both cases, the essence of the PRIDE philosophy is to help parents and young people reverse adolescent peer pressure that encourages negative behaviors, and use it as a force to persuade young people to adopt positive behaviors.

The PRIDE Drug Use Survey has helped thousands of local school systems determine the extent of ALCOHOL, marijuana, and other drug use among students in elementary, middle, and high school. A large data base allows PRIDE to spot early trends in the rise or fall of various drugs used by students. A systemwide survey of Atlanta public school students in 1994 demonstrated a shocking correlation between drug use and possession of guns and other weapons. The more involved a student is with drugs, the more likely he or she is to possess a weapon. If this early indicator holds true for students in other school systems, it will provide even more reason to intensify efforts to prevent drug use among students, in order to free them from violence as well as drug abuse and addiction.

As the United States devoted more resources to developing the discipline of substance-abuse prevention, and as grass-roots organizations such as PRIDE and others increasingly demonstrated that PREVENTION reduces drug use and abuse, European and other nations became intensely interested in learning about the American prevention experience. PRIDE has done much to foster this interest, and the PRIDE conference increasingly draws participants from other nations to learn about American grass-roots prevention techniques and processes.

PROJECT SMART

Project SMART was started in 1981 in Los Angeles by Drs. C. Anderson Johnson, Brian R. Flay, William B. Hansen, and John W. Graham as a pioneering effort to scientifically test programs for preventing experimental and habitual use of multiple substances. Originally the name stood for Self-Management and Resistance Training, but since then, it has come to stand more generally for the programs created by this University of Southern California research team, and for the programs used in many of their projects.

It was the goal of Project SMART researchers to interrupt the usual pattern of experimentation and habituation by presenting innovative programs that provided students with skills for overcoming situations that might promote use. Project SMART provides instructions for classroom teachers on how to prevent experimentation with and regular use of alcohol, tobacco, marijuana, and other drugs. Originally, there were two sets of Project SMART materials. One set focused on teaching students self-management skills. The other set provided students with social pressure resistance skills for dealing with peer pressure to use substances as well as skills for avoiding pressure from television, movies, music, adults, and ADVERTISING that might make substance use attractive. Both sets of materials included information about the consequences of alcohol, tobacco, and marijuana use.

These two curricula represented two different ways of thinking about what causes young people to experiment with substances. Self-management training came from the idea that young people use drugs to help them handle the challenges of growing up. This approach was based on the hypothesis that young people who lack the ability to manage their lives may experiment with alcohol or drugs as an alternative to handling difficult situations. The goal was to increase the skills that are important to being successful so that substance use would not be seen as a practical alternative. The training was applied to making decisions, handling STRESS, improving self-esteem, and increasing a person's ability to set and achieve goals. Students were taught how to identify and manage their stress through relaxation training; how to increase their self-esteem through finding positive qualities about themselves and others; and how to make well-thought-out decisions by mastering a process for identifying problems, thinking of alternatives, and weighing consequences. They learned how to set and achieve goals through practicing personal goal setting.

Training in resistance skills came from the idea that experimentation with alcohol, tobacco, and other drugs was related to social pressure. It was hypothesized that young people had to deal with offers, threats, and dares to use drugs and that they experimented with alcohol and other drugs in order to fit in with their peer group. Thus young people who had the skills necessary for refusing offers in a

way that allowed them to still be accepted were thought to be able to avoid experimentation. In this program, students learned to identify different types of peer pressure to use drugs; they were then taught some simple but effective strategies for refusing offers and resisting pressure, such as saying "No, thanks." Students practiced these techniques in role plays. The program also informed students about the real rates of use among their peers, which were nearly always lower than what students originally expected.

Both programs included a session in which students were videotaped making a personal commitment to use the skills they had been taught in order to remain drug-free. Students who had been trained in self-management skills described what they would do instead of using drugs, while students who had received resistance training described how they would respond if someone offered them a drug. Finally, in both programs, admired and respected classmates were used as peer facilitators. The peer facilitators helped conduct both programs' small-group activities and were trained to demonstrate the skills that students needed to master.

In 1982 and 1983, the two programs were presented to two groups of students in the Los Angeles Unified School District (Hansen et al., 1988). A third group of students received no special Project SMART program. Students who participated in the project filled out surveys that asked them to report on their use of alcohol, tobacco, and marijuana. After being pretested, students were given the program in the seventh grade and then completed surveys in the eighth and ninth grades. The students who had not been given any special program also completed surveys at the same time. At the end of this project, it was found that students who had received training in how to resist pressure were less likely to use all three substances.

The program materials for Project SMART have continued to evolve. Numerous research projects have added variations to what students are taught, and the actual methods for teaching the resistance skills have been revised and refined as the people who created and delivered the programs learned more about how young people think and found better ways to get the message of the program across.

In 1985, Drs. William B. Hansen and John W. Graham started a new project that emphasized a new strategy for prevention termed normative education. This program component was designed to establish a social norm that was intolerant of alcohol, tobacco, and other drug use. Normative education was based on that part of the original Project SMART that gave young people feedback about the rates of substance use among their peer group. In addition, the program encouraged young people to discuss openly with their parents and their friends the appropriateness of drinking in a number of situations.

A test was conducted that compared students who had participated in the normative-education program with students who had participated in the program that taught resistance to peer pressure. The two groups had received their program in the seventh grade and results tallied in the eighth grade were analyzed and published (Hansen & Graham, 1991). The results showed that each group of students had benefited from the program it received. Students who were given normative education expected greater intolerance of alcohol and drug use among their peers than did the other group. Students who had been taught how to resist pressure were much more capable than the students of the other group of refusing when tested in a situation in which a fellow student pretended to offer them a can of beer. However, the students who had established conservative group norms were less likely to drink alcohol, get drunk (see Figure 1), develop problem behaviors in relation to alcohol, use marijuana (see Figure 2), and/or smoke tobacco.

Ultimately, Project SMART became a curriculum guide that included the best components of all the research projects that contributed to it. The program now consists of two parts: the basic program that is delivered to students in the first year of middle or junior high school and a booster program that is given the following year. Some Project SMART program materials have been given different names, such as Project STAR and Project I-STAR. Except for being based on the most up-to-date versions of the curriculum, these programs are identical to Project SMART. The success of the curriculum was reproduced in a large study conducted in the greater Kansas City area. In this region, students from schools that received the program exhibited reduced rates of alcohol, tobacco, and marijuana use compared to students from schools that received no special program (Pentz et al., 1989).

TALKING WITH YOUR STUDENTS ABOUT ALCOHOL (TWYSAA)

TWYSAA is concerned with influencing the students' drinking behavior not just in the present (during childhood and adolescence) but throughout their entire lives. The authors realized that, once children are no longer in school, their opportunities to receive in-depth education about alcohol would be very limited. TWYSAA teaches children how to estimate their own personal biological risk of developing ALCOHOLISM—based on their family history and individual physiological factors. Students also learn how factors such as age, gender, fatigue, illness, pregnancy, menstrual period, and medication must be considered in making drinking choices. Safety issues, such as DRUNK DRIVING are discussed, and information is given about alcohol's negative effects on the cognitive skills needed for success in school. Students are encouraged to honor the parental and religious values of their households as well as the legal prohibition (in the U.S.) against purchasing alcohol or drinking before age 21.

This curriculum has three levels available: Level One for grades five and six; Level Two for grades seven and eight; and Level Three for grades nine and ten. TWYSAA is designed to be presented once at each level, so students receive instruction every other year. The major goals of the program are to increase the number of students who choose to abstain from drinking ALCOHOL, to delay the age at which students begin to drink alcohol (if they do begin drinking), and to reduce high-risk drinking.

TWYSAA is part of a series of alcohol-education programs designed by the Prevention Research Institute in Lexington, Kentucky. The original program, Talking With Your Kids About Alcohol, was a ten-hour course for parents—aimed at educating them about how to make low-risk drinking choices for themselves and giving them guidance on how to teach their children about alcohol. TWYSAA was the second program developed for the series; it is meant to be used as a complement to the course for parents. Schools that wish to implement the TWYSAA curriculum are first required to make Talking With Your Kids About Alcohol available to parents.

The TWYSAA course is usually taught as a part of the school's health-education curriculum. Teachers prepare for course instruction by attending a three- or four-day training program. The Prevention Research Institute provides these training sessions at various locations; it will also bring the training program to a location if a sufficient number of teachers want to be trained. At the training session, teachers receive all the course materials including slides to use in classroom presentations, a detailed teacher's guide with lesson plans, and printed materials that may be reproduced for students.

An evaluation of the curriculum was conducted by the Prevention Research Institute over a three-year period in nine schools in Kentucky and Ohio. Drinking behaviors and attitudes were measured before students took the TWYSAA course, immediately after the course, then one and two years later. A group of students (a control group) who did not take the course were also studied for comparison. The findings from this study indicated that TWYSAA had successfully achieved each of its major goals. Compared to students who had not taken the course, more of the TWYSAA students chose to abstain from alcohol; those who began drinking started later; and fewer TWYSAA students drank heavily.

WATERLOO SMOKING PREVENTION PROJECT

In 1979, the Waterloo Smoking Prevention Project represented one of the first rigorous efforts to evaluate a "social influences" approach to smoking prevention. Based in Waterloo, Canada, this project made use of a school-based curriculum to help students become aware of the social pressures to smoke and to practice ways of resisting those pressures.

The first curriculum component of the Waterloo Project consisted of two sessions in Grade 6 that were intended to provide information on the consequences of SMOKING. This was done with a method pioneered by the ancient Greek philosopher Socrates, who posed questions and then used the answers and discussion to shed light on difficult problems. In the Waterloo sessions, the Socratic method was used to stimulate the development in students of beliefs, attitudes, and intentions regarding smoking. Information obtained during the discussion was repeated in later work by the instructors and also via videotapes, poster making, and class

discussions, so as to increase students' understanding and recall of the material.

The second and probably most important component of the project was the focus on the social influences that cause one to smoke (e.g., family, media, peers) and the development of skills to resist such pressures. Ideas were again elicited from students and repeated in a variety of ways. Students then practiced using the skills by role-playing what they could do when someone wanted them to smoke.

The third component of the program concerned decision making and public commitment. Students were asked to pull together the information learned earlier and to consider the social consequences of smoking in their own social environment. Each student then made a decision about smoking and announced it to the rest of the class, along with the reasons for the decision. "Booster" sessions were used to strengthen the students' skills. After the sixth-grade curriculum, students in Waterloo schools were given two booster sessions in Grade 7 and one booster session in Grade 8. All curriculum sessions were delivered by advanced graduate-school students who were on the research staff.

The Waterloo Project research team completed a very rigorous experiment to evaluate the short-term and long-term impact of this smoking-prevention curriculum and its booster sessions in grades six to eight. Out of twenty-two participating schools, eleven were designated at random to receive the Waterloo Project curriculum; the other eleven schools did not use any social-influences curriculum.

After tracking virtually all of the students in the participating schools, the research team used questionnaires to ask them whether and when they had started to smoke tobacco. There seemed to be a beneficial impact of the program before students reached Grade 9: Students who had received the curriculum were less likely to have started smoking. These early effects were not maintained during the high school years, however: The smoking levels of students who had received the curriculum were just as high as those of students who had not received it.

The value of the social-influences approach in preventing the onset of regular smoking by the end of high school needs further study. Results from the Waterloo Project and from other studies suggest that program effects obtained in junior high school might gradually decay during the following years and totally disappear by Grade 12. This kind of outcome may mean that high school booster sessions are necessary.

The apparent lack of effects of social-influence programs in preventing students from smoking by the time they reach Grade 12 should not be overinterpreted. First, it is possible that boosters in early high school years might help to maintain substantial early effects. Second, there is a much better understanding in 2000 than there was in the late 1970s and early 1980s of the essential components of effective prevention programs (Glynn, 1989). These improvements might well mean that current versions of social-influence programs might produce more durable effects. Third, society at large has changed since 1979, and social values are now more supportive of nonsmoking.

OVERALL SIGNIFICANCE

Youth drug prevention programs are seen as a vital, though often needing improvement, resource in the attempt to help today's society. Continuing evaluation of such programs is crucial since the programs need funding and are expensive. In May 2000, House and Senate subcommittees proposed further cuts (as compared to the cuts of 1999) to the substance abuse prevention budget for development and application grants. [paa]It is inherently difficult, of course, to prevent or change undesirable behavior through any classroom curriculum—given the wider and emotionally powerful influences of home, peers, and community—which create a countervailing mode, especially in the case of alcohol. Even where classroom programs might have a beneficial impact, it is difficult to measure with much sensitivity, given the present stage of evaluation technology and especially when such measurement depends on the self-reports of children.

Efforts are being made, however. For example, The Bureau for At Risk Youth published a booklet in 2000 with research-based information on establishing prevention programs. Another report in 2000 was prepared by the National Association of State Alcohol and Drug Abuse Directors detailing successful prevention program models. If continuing studies can concretely show essential and effective program elements, it is likely that ineffective programs could be enhanced to further help youth.

PRISONS AND JAILS Prisons serve as a principal form of punishment in the United States. In 1997, federal prison facilities held 99,000 inmates, while state prisons held just over one million inmates. Local jails held another 567,000 prisoners. These figures represent a constant and dramatic rise in prison population since the early 1990s, when federal prisons held 56,000 inmates and state prisons held 533,000 inmates. (Lipton,

Falkin, & Wexler, 1992). These increases in prison population are largely due to the public outcry against drug-related crimes and the resultant tougher sentencing practices that have been enacted against the committers of these crimes and against repeat offenders (Wexler et al., 1992). State and federal sentencing guidelines impose mandatory minimum sentences for drug crimes and these sentences are often lengthy. Repeat offenders in some jurisdictions, including New York, can be sentenced to life imprisonment. Most states have chosen to respond to prison crowding by accelerating the construction of new prisons rather than by diverting offenders into community treatment programs and increasing the emphasis on preventative measures.

The costs of incarceration in the United States are high. In 1997, the Federal Bureau of Prisons calculated the average yearly cost to incarcerate an inmate at $23,542. The average yearly cost for a state prisoner was $19,800 and the cost for those housed in local jails was $20,225. In light of these costs, states have begun to establish drug courts that use drug treatment programs rather than incarceration as the preferred remedy. States have also tried boot-camp prisons as a way to reduce the recidivism rates—the rate of repeat criminal activity—of juvenile and adult offenders, yet by 2000 states began to abandon or scale back such approaches because they proved no more effective than traditional forms of incarceration.

Especially since the advent of CRACK use in the mid-1980s, drug-dependent offenders have been responsible for a disproportionate amount of crime as compared to nonusers. In 1995, drug offenders constituted 23 percent of state prison population and 60 percent of the federal population. Many persons arrested were actively engaged in the use of drugs around the time of their arrests. Current urinalysis surveys of persons arrested in twenty-two major U.S. cities indicated that roughly two-thirds of adult arrestees and more than half of juvenile arrestees tested positive for at least one illicit drug. One-third of state prisoners and about 20 percent of federal prisoners said that they committed their offenses while under the influence of drugs. Therefore, it is clear that drug-related behavior takes up a significant part of corrections budgets.

It has become imperative to find ways of keeping offenders from reverting to crime, thereby reducing the amount of money devoted to new jails. Intensive substance-abuse treatment programs have become an important part of the corrections approach in prisons because of accumulating evidence that treatment is capable of reducing recidivism rates (Wexler, 1994). Although drug and alcohol counseling is available in nearly 90 percent of state and federal prisons, only 10 to 20 percent of prison inmates participate in treatment during their incarceration. The failure of inmates to take advantage of treatment options is troubling, especially when state corrections officials have estimated that from 70 to 85 percent of inmates need some type of substance abuse treatment.

The majority of jails also provide some form of drug treatment or counseling. Of local jails that offered drug programs in 1997, 50 percent provided detoxification, 78 percent provided drug education, 68 percent had individual counseling, 85 percent had group counseling and 87 percent provided community referrals.

PRISONS AND JAILS: DRUG TREATMENT IN Several public policies converged with, and the completion of important research documenting the efficacy of drug-abuse treatment for incarcerated offenders, to make the 1990s a significant decade for treatment in jail and prison settings. In regard to policy, the crack cocaine epidemic that began in the mid-1980s led state legislatures and Congress to pass drug laws which attempted to reduce crack distribution at the street level. As a consequence the arrests, convictions, and incarceration of drug offenders increased dramatically. Determinate and mandatory minimum sentences for drug-related offense resulted in overcrowded jails and prisons. More jails and prisons were built to address this growing inmate population crisis, and the composition of jail and prison inmates changed. The percent of Hispanic and African-American inmates, particularly those from the inner city, increased dramatically; late in the late 1990s, there was a substantial increase in the number of African-American women entering jails and prisons. Most inmates were seriously involved in drug use, particularly cocaine, and relatively few had received previous treatment. There was increased urgency to develop interventions that would reduce the swelling inmate population as in state and federal jails, detention centers, and prisions, as well as the related escalating costs. Interest in effective drug-abuse treatment grew.

Based on the results of federally funded efforts in the 1980s and Early 1990s, data showed that drug-abuse treatment was effective in reducing drug abuse and crime among incarcerated offenders. Among the treatment modalities that had been tried (e.g. Alcoholics Anonymous or other twelve step programs), the most comprehensive data on treatment impact existed for therapeutic communities (TCs). TCs are self-help, group-based residential treatment programs that through repetition and reinforcement try to aid addicts in developing a drug free life style. Drug abuse and crime are seen as reflecting a disorder of the whole person, not just a result of using drugs. By committing oneself to the values and activities of the TC, with its emphasis on work ethic, social productivity, and responsibility to the community, clients develop better values and the skills for right living (DeLeon, 1999; Pearson & Lipton, 1999).

PRISON BASED DRUG TREATMENT PROGRAMS

The 1990s witnessed the growth of prison TCs throughout the United States. The spread of these programs was fueled by the results of evaluation studies in New York State, Delaware, California, and Texas, which confirmed the effectiveness of this modality. These studies also emphasized that TC treatment needs to be of sufficient duration (9 to 12 months) to be maximally effective, with inmates recruited within 12 to 15 months of release eligibility. Further, a continuum of TC treatment linked to the inmate's changing correctional status (prison→work release→parole/other community supervision) was found most likely to lead to long-term success (Martin et al., 1999).

JAIL BASED DRUG TREATMENT PROGRAMS

Drug-abuse treatment in jails setting has a more limited history, and evaluation studies generally reflect a lower level of methodological rigor, than prison studies. Jail treatment outcome studies completed in Chicago and Hillsborough County, Florida nonetheless arrived at some related positive conclusions (Peters & Matthews, in press; Swartz & Lurigio, 1999). Mirroring the experience of prison studies, they indicate that length of treatment and aftercare services increased greatly the chances of long-term success. The Chicago jail program used a modified TC lasting 6 months, whereas the Florida program involved a number of treatment components (e.g., relapse prevention, stress manage-

ment). Jail-based treatment programs face a number of unique challenges:

1. devising effective programming of shorter duration than prison programs,
2. logistical problems relating to controlling client flow through the program's phases,
3. coordination with the courts to permit (wherever possible) a client to remain in program for a sufficient period to benefit from its services and follow-up.

PRISONS AND JAILS: DRUG USE AND HIV/AIDS IN From the beginning of the epidemic in the early 1980s, HIV/AIDS has seriously affected correctional inmate populations. The first AIDS cases among inmates were reported in New York State in 1983. As the overall face of the epidemic has changed, with the virus first infecting mostly white homosexuals, to increasing predominance among African American and Hispanic intravenous drug users and their sexual partners, prisons and jails have become epicenters for HIV/AIDS, STDs, tuberculosis, and hepatitis. Nevertheless, the prevalence of HIV among inmates, although disproportionate to rates found in the total U.S. population, has probably declined in recent years.

In 1997, the most recent year for which data are available, there were about 9,200 U.S. prison and jail inmates with AIDS, representing a prevalence rate of 0.5 percent or five times that found in the total U.S. population. In addition, there were between 26,000 and 36,000 inmates with HIV infection (non-AIDS), representing a prevalence of 1.45 to 2.03 percent or five to seven times the rate in the total population. Perhaps more significantly for the public health, somewhere between 151,000 and 197,000 people with HIV infection and AIDS passed through a U.S. correctional facility and were released to the community during 1997, between 20 and 26 percent of all people in the country living with HIV and AIDS in that year (Hammett et al., 2000).

HIV prevalence rates among inmates vary widely by geographic region, with the highest rates found in the Northeast, particularly in New York State and New York City (about 10-13 percent among men and 18-20 percent among women). More than half of all HIV-infected inmates are found in correctional facilities in the Northeast. HIV prevalence rates are also typically higher among women inmates than among male inmates. The higher rates among women are generally thought to result from female inmates' generally higher rates of drug involvement, either through their own drug use or sexual relations with drug users, as well as prostitution (Hammett et al., 1999).

There is a very close relationship between substance use and HIV/AIDS among inmates. In New York State, it is consistently estimated that over 90 percent of inmate cases of HIV/AIDS are related to drug use. Although HIV transmission among inmates has been documented, it has been at quite low rates. The vast majority of inmates with HIV disease are believed to have been infected while in the community (Hammett et al., 1999).

The vast majority of correctional inmates have at least some history of substance abuse. The National Center on Addiction and Substance Abuse estimates that 81 percent of State inmates, 80 percent of Federal inmates, and 77 percent of city/county jail inmates are "substance-involved". This is defined as having one or more of the following characteristics: used an illegal drug regularly; incarcerated for a drug offense, driven under the in-

fluence, or another alcohol-related offense; under the influence when committing a crime; committed a crime to obtain money for drugs; or has a history of alcohol abuse. Despite these high rates of substance abuse among inmates, the availability of substance abuse treatment in correctional facilities is falling farther and farther short of the need (CASA, 1998). In 1997, the U.S. government's Substance Abuse and Mental Health Services Administration estimated that there were more than 865,000 state and federal inmates in need of drug treatment, but only about 111,5000 (or 13%) receiving treatment (SAMHSA, 2000).

In general, prisons and jails offer tremendous opportunities to provide substance abuse treatment, medical and mental health care services, and public health interventions such as HIV prevention programs to an extremely high-risk and underserved population. To date, however, the opportunity has by no means been fully explored.

PROBATION *See* Coerced Treatment for Substance Offenders

PROBLEM DRINKING *See* Addiction: Concepts and Definitions

PROCESSES OF CHANGE MODEL Historically, changing an addictive behavior was assumed to be the same as taking action. People with addictions were viewed as changing when they quit drinking, smoking, or abusing other substances. Action-oriented therapies were readily available but only a small percentage of addicted individuals entered therapy, only about 50 percent completed therapy and only 25 to 35 percent were successful in overcoming their addiction following therapy. Action-oriented therapies impacted on a small percentage of addiction problems on a population basis.

In the late 1970s one-thousand ordinary people attempting to stop smoking taught us that change is a process which unfolds over time and involves progress through six stages of change: precontemplation, contemplation, preparation, action, maintenance, and termination. Creating therapies that match the needs of people at each stage of change has permitted us to reach, retain, and impact on more people than we ever imagined possible. How can therapy help people progress across the stages?

In precontemplation, people to not intend to take action in the foreseeable future. Individuals in this stage may be unaware or under-aware of their problems. Families, friends, or employers, however, are often well aware that precontemplators have problems. When precontemplators present for psychotherapy, they often do so because of pressure. Often, they feel coerced into counseling by spouses, employers, parents, or courts that threaten to punish them.

These clients are at risk of dropping out of therapy quickly and prematurely. So the first therapeutic strategy is drop-out prevention: "How can I help you to stay in therapy long enough to have it make a significant difference in your life?" Fortunately, if therapists match interventions to the client's stage, precontemplators will complete therapy at the same rate as those in preparation.

Stage matching begins by setting realistic goals. If therapists pressure precontemplators into immediate action, they will keep clients away or drive them away from counseling. Historically, thera-

pists labeled such clients as unmotivated, noncompliant, resistant, or not ready for therapy. But, it was therapists who were not ready for them, nor motivated to match clients' needs, and were resistant to changing their paradigms and practices.

The goal is to help precontemplators progress to contemplation. This initial goal produces success early in treatment. Consciousness-raising is used to help clients become aware of how they defend against pressures to quit when they are not ready. "How do you react when someone tries to pressure you to quit drinking or smoking?" Common responses include, "I get angry," "I withdraw," "I tell them to mind their own business," "I change the topic," or "I minimize the problem."

As precontemplators become aware of their defenses and start to drop them, they can process more of the pros of therapy. "We're not here just to help you understand your substance use. Therapy can help you be less defensive and happier, raise your esteem, improve your relationships, and help you make more money." As the pros of changing increase, we know that clients are progressing into contemplation.

Contemplators intend to take action in the next 6 months. Awareness of the pros of changing increase, but the cons also increase. Once clients intend to stop substance abuse, they confront the costs or cons. "Am I ready to give up my substance of choice that has been a good friend? Am I prepared to pay the price of time, effort, emotion and the risk of failure?"

A delicate balance between the pros and cons produces a profound ambivalence that causes some people to procrastinate. The love–hate relationship with their "good friend" can fool therapists into assuming that these clients are ready for immediate action. In fact, their rule of thumb is, "When in doubt, don't act!"

The goal for these clients is to progress to preparation. Their perception of the cons of quitting must change. They may need anticipatory grief counseling during which they mourn the loss of a good friend. They need to reevaluate how they think and feel about themselves as an addict and how they imagine themselves free from addiction.

Their cons have to decrease only about half as much as their pros increase, so in stage-matched treatments we place twice as much emphasis on the benefits of changing. Typically, there are more than forty scientific benefits to becoming free from an addiction. One way to enhance motivation is to become aware of how much of one's body, self, social relations, and society benefit from such major changes.

People in preparation are convinced the pros of changing outweigh the cons. They are ready to take immediate action. But, they need to be prepared for how long action will last. Many clients think the worst will be over in a matter of days or weeks. Biologically, the worst is over that quickly as they go through withdrawal. Behaviorally, however, people have to be prepared to work the hardest for about 6 months.

Clients are encouraged to think of such action as the behavioral equivalent of a life-saving surgery: "Would you inform people that recovery has to be your top priority for 6 months; that you can't be at your best and that you will need their support to get through this toughest of times?"

After 6 months, clients progress into the maintenance stage where they do not have to work nearly as hard but they still have to work to prevent relapse. How long does maintenance last? Some people believe it is a lifetime: Addicts are always in recovery and never recovered. Evidence suggests maintenance lasts 4 to 5 years. With smoking, for example, the national data in the 1990 Surgeon General's Report indicated that after 12 months of not a single puff, the percent of smokers who resume regular smoking is about 40 percent. After 5 years of total abstinence the relapse rate drops to 5 percent. When is cancer cured? Cures are counted after 5 years of no symptoms or remission. Some of the most common cases of cancer, and chronic diseases take five years to be cured.

Therapy will not continue indefinitely. But, clients will need to be prepared to cope with the most common causes of relapse. Across addictions, the most common cause is emotional distress: times of anxiety, anger, depression, boredom, loneliness, and stress. How do average Americans cope with such distress? They drink more, smoke more, eat more, and take more over-the-counter drugs and illicit drugs.

What are healthy alternatives during times of temptation? Three choices are:

(1) talking or social support;
(2) relaxing via yoga, meditation, prayer, or some other form of releasing stress or distress; and

(3) exercise or physical activity as an excellent way to manage moods, stress, and distress.

Clients need to develop a plan for how they will cope in the face of inevitable distress that will hit when therapy has stopped.

JAMES O. PROCHASKA

PRODUCTIVITY: EFFECTS OF ALCOHOL ON ALCOHOL is the most commonly used and abused drug in the United States. In 1991, approximately 50 percent of all 125 million employed workers in the United States had taken at least one drink, and about 6 percent reported they had been drinking heavily (five or more drinks on five or more occasions) during the past month. Heavy drinking is more than four times as prevalent among male workers than it is among female workers, and it is most prevalent in male-dominated, semiskilled, transient occupations such as construction and transportation.

Alcohol can affect productivity in various ways. The relevant physiological effects of alcohol include intoxication, hangovers, WITHDRAWAL (abstinence syndrome) after long-term heavy use, and residual physical, mental, or social disabilities due to abuse or chronic dependence. The most important effects of intoxication—clumsiness, sleepiness, difficulty in processing new information or communicating ideas—impair physical safety and cognitive capability. Both effects can lead to poor performance, absenteeism, and job loss. Hangovers or periods of withdrawal can have similar results. Liver and heart damage, stroke, and irreparable injuries are the most common physical and mental disabilities. The most common social disability is withdrawal of trust by associates.

The consequences for economic productivity are measured not by taking them individually but by statistically estimating the overall loss of wage-earning capacity attributable to alcohol abuse and dependence. These losses are computed in two forms. *Morbidity cost* is the annual loss of earnings by individuals who are impaired by alcohol compared to the earnings of unimpaired people with similar demographic characteristics. According to the most recent estimate of this loss in the United States, one fourth of working-age men and one twentieth of working-age women were so impaired, thus averaging a 4 percent loss of earnings potential, or a total of a 35-billion dollar loss in income reduction in 1993. *Mortality cost* is the present value of the lost lifetime earnings of the nearly 100,000 individuals (two thirds of them male) who are estimated to die annually because of alcohol use—one fourth in traffic crashes, one fifth from liver disease, one eighth from homicide or suicide, one tenth from other accidents, and the remainder from esophageal cancer and a wide variety of other toxic effects. The average expected value of future earnings lost was about 33 billion dollars in 1993.

Morbidity and mortality costs account for well over half the estimated economic burden of alcohol-related illness. However, morbidity and mortality cost estimates involve complex econometric modeling procedures and use survey data from many sources. Model results have differed by as much as 200 percent for morbidity costs and 25 percent for mortality costs.

DEAN R. GERSTEIN

PRODUCTIVITY: EFFECTS OF DRUGS ON Concern about drug use in the U.S. workforce has focused on the most common illicit drugs—COCAINE and MARIJUANA—although also common is the nonmedical use of TRANQUILIZERS, SEDATIVES, and STIMULANTS. In 1990, about 7 percent of employed workers had used an illicit drug in the past month, according to national surveys. Illicit drugs are used at higher rates by men than by

women and also at higher rates by low-paid workers in transient occupations than by other workers.

Laboratory studies show that typical single doses of marijuana effect small temporary impairments in performing complex tasks, whereas typical single doses of cocaine may effect small temporary enhancements—especially when the performance of subjects is impaired by fatigue. To the extent that generalization is possible, sedatives and tranquilizers are similar in their effects to marijuana. Using illicit drugs during off hours is much more common than doing so while on the job. The effects of hangovers, post intoxication fatigue, or withdrawal from a chronic run of use may be significant for productivity, as may also be the potential accumulation of longer term disabilities, including social mistrust.

Productivity loss due to drugs is estimated by comparing the earnings of problem users with those of other people with similar demographic characteristics. The total income losses are now estimated at about 10 billion dollars annually, with a large fraction of this estimate being attributable to the nonmedical use of sedatives and tranquilizers. Productivity losses account for about one sixth of the total estimated economic burden of drug problems.

DEAN R. GERSTEIN

PROFESSIONAL CREDENTIALING A host of health-care professionals provide treatment for substance-abuse disorders. They include, but are not limited to, physicians, psychologists, social workers, nurses, pastors, and addiction or drug-abuse counselors. Institutions and programs that train these professionals are accredited, and the individuals, after undergoing the training, may obtain credentials from a professional or state body. In this context, one must define the terms *accreditation* and *credential* and examine the role of each in protecting the interests of the consumer of substance-abuse treatment.

In the United States, there are two forms of educational accreditation—institutional accreditation, which began in the late 1790s in New York State, and professional accreditation, which began in the first years of the twentieth century. Accreditation is a voluntary, self-regulating process designed to evaluate the strengths and weaknesses of an educational institution. Institutional accreditation and professional accreditation have a pattern in common. It involves: (1) preparation of a detailed and objective self-study by the institution or professional program that outlines and evaluates objectives, activities, and achievements; (2) an on-site visit by a team of peers that provides expert evaluation and offers suggestions for improvement; and (3) a subsequent review and decision by a central governing commission or board to award or deny accreditation. The location of the institution determines which one of the six regional accreditation organizations will accredit it. An exception to this regional pattern is made for institutions with programs of a specialized nature, such as trade and technical education, rabbinical and Talmudic education, and the like. National accreditation bodies accredit these programs.

The U.S. Secretary of Education and the Commission on Recognition of Post-Secondary Accreditation (CORPA) recognize both regional and national accreditation organizations—that is, they accredit the accreditors. Professional accreditation is carried out, in the main, by organizations formed by members of the profession. For example, the American Psychological Association accredits doctoral programs in psychology. These specialized accreditation bodies operate nationally. Within each field, one accrediting agency is recognized by the Committee on Post-Secondary Education. These recognized agencies come together to form the Assembly of Specialized Accrediting Bodies, which works on issues of common interest to those involved in professional education. The counseling function is recognized within several professions that undergo accreditation, but the subspecialty of substance-abuse or addictions counseling is not at present independently recognized within this framework (as of 1995).

Although accreditation applies to programs or institutions and does not cover substance-abuse counseling, *credentials* apply to individuals and do cover this subspecialty. Institutions that offer training in substance-abuse counseling design their programs to meet the requirements outlined by the state or by potential employers so that graduates can obtain *certification*. Graduates must then pass tests certifying that they have a specific level of

proficiency in the theoretical and practical aspects of substance-abuse treatment. For example, in Michigan the Department of Public Health and other interested organizations initiated a program for the professional development of counselors that is based on education, experience, supervised practical training, professional recommendation, testing and review, ethics, and residence. Michigan requires that persons undergo a three-tier testing process covering the theoretical and practical aspects of substance-abuse treatment to become certified addictions counselors (CACs). The first test covers fundamental knowledge of substance-abuse counseling; the second, applications to specific populations; and the third, the oral presentation of a case. Certification is for a specific term and renewal requires additional education. Once certified, a person may provide addiction treatment in states other than the one that awarded certification, through a reciprocity agreement that covers states with membership in the International Certification Reciprocity Consortium.

In addition to certification by the state, certification may also be obtained through professional organizations. For example, the American Society of Addiction Medicine, under the auspices of the American Medical Association, certifies physicians who wish to treat substance abuse. The association offers courses that review topics in addiction theory and practice, examines candidates who wish to obtain credentials, and certifies their advanced knowledge and skills in this area. Other professional associations such as the American Psychological Association are currently developing procedures and mechanisms for providing substance-abuse-treatment credentials to their members who supply mental health services in this area.

Both accreditation and certification work to improve the quality of the education and specialty training that individuals receive and to assure the quality of the services provided. As a safeguard, consumers of substance-abuse services may determine whether the professional delivering the services was trained in a program accredited by the appropriate professional organization in a university or college accredited by the appropriate regional accrediting board. Consumers may also determine whether the professional holds credentials as a substance-abuse counselor, since these credentials certify that a person has met certain educational requirements and displayed the level of knowledge and skill deemed necessary in the profession.

AMY L. STIRLING

PROHIBITION OF ALCOHOL The Eighteenth Amendment to the Constitution of the United States prohibited the "manufacture, sale and transportation of intoxicating liquors." The amendment, passed by Congress in 1917, was written to become effective one year after its ratification by the states. The amendment outlawed only the manufacture, transport, and sale of liquor; it did not criminalize the possession of ALCOHOL for personal use, nor did it make purchase of liquor from bootleggers a criminal offense, nor did it define what was meant by "intoxicating" liquors. To implement the amendment, Congress passed the National Prohibition Act, better known as the Volstead Act. The Volstead Act was crafted to allow supplies of alcohol to be produced and transported for scientific and other commercial purposes. It also defined an intoxicating liquor as any beverage containing more than 0.5 percent alcohol. It could have set the permissible level higher and allowed, for example, the production, transportation, and sale of BEER, but it did not. Prohibition became effective in 1920. A Prohibition Bureau was established within the Treasury Department to carry out the provisions of the law. Under the Volstead Act, Treasury agents could obtain a search warrant only if they could prove that alcohol was being sold, thus precluding searches of individual homes no matter how much liquor might be there. Some wealthy people, given the ample notice that Prohibition was coming, laid in enough alcoholic beverages to last them through most of the following decade. The law also had the effect of allowing manufacture for personal use. Such home production sometimes became part of a cottage industry contributing to the supplies distributed by bootleggers. Even committed Prohibitionists appeared to believe that the public would not tolerate any effort to criminalize the act of drinking itself. The Volstead Act, unlike some state laws, permitted the manufacture of beer

as long as the beer contained no more than 0.5 percent alcohol (near beer).

Given the common belief that Prohibition failed utterly to alter the consumption of alcohol or its adverse effects on health, it is appropriate to ask, To what extent did the law reduce alcohol use in the United States? First, there is no question that it succeeded in eliminating 170,000 saloons, even if it did not change the attitudes of most Americans about the morality of drinking. And, while some writers have asserted that drunkenness actually increased during Prohibition, most available records point to the opposite conclusion (Aaron & Musto, 1981; Lender & Martin, 1987). The most consistent findings on the impact of Prohibition come from statistics on medical problems known to be linked to alcohol consumption, especially excessive alcohol consumption. Among these problems were hospital admissions for alcoholism and admissions to state mental institutions for alcoholic dementia and alcoholic psychosis. Striking decreases were observed in New York and Massachusetts, two states that did not have restrictions on alcohol consumption prior to 1920. Massachusetts state mental hospital admissions for alcoholic psychosis fell from 14.6 per 100,000 in 1910, to 6.4 in 1922, and were 7.7 in 1929; in New York, such admissions fell from 11.5 in 1910, to 3.0 in 1920, rising again to 6.5 in 1931 (Aaron & Musto). Deaths from alcohol-related diseases also fell. National statistics showed that the number of deaths from cirrhosis, about 14.8 per 100,000 in 1907, were only 7.9 in 1919, 7.1 in 1920, and did not rise above 7.5 during the 1920s. There were decreases in arrests for drunkenness and in the costs of jailing public inebriates. Commander Evangeline Booth of the Salvation Army asserted that not only had drinking fallen off sharply, especially among the poor, but there were fewer broken homes because of wages lost to drinking or violence related to drinking.

Aaron and Musto state, "Observers . . . have been unanimous in concluding that the greatest decreases in consumption occurred in the working class. . . . In large measure, intoxicants priced themselves out of the market" (Aaron & Musto 1981, p. 165). A quart of beer or a quart of gin were five to six times more expensive in 1930 than they were prior to Prohibition. Prohibition defenders asserted that instead of purchasing liquor in saloons, workers were putting their earnings into cars and refrigerators. Admittedly, the impact on alcohol consumption was greatest in the early years of Prohibition. As bootlegging increased in the late 1920s, medical problems linked to alcohol use began to rise again, but they did not reach the high levels experienced before 1920. Other data on per capita alcohol consumption immediately after repeal in 1934 indicated that there must have been a drastic decline in average alcohol consumption during the Prohibition years. Undoubtedly, crime associated with bootlegging increased. Many bootleggers became quite wealthy. Some who were involved in illegal activities prior to Prohibition used the wealth flowing from bootlegging to extend and further develop organized criminal enterprises, some of which later became involved with trafficking in illicit drugs. One of the most notorious of the figures associated with organized crime was Al Capone, who came to national attention as a result of his Chicago-based criminal activities. Aaron and Musto point out, however, that organized rackets existed in large cities before Prohibition and that the homicide rate increased most sharply between 1900 and 1910.

Unquestioned, also, is the unreliable quality of bootlegged liquor, much of which was produced by diverting or hijacking industrial alcohol. Some industrial alcohol could simply be flavored and sold as scotch, gin, or bourbon. Much of it, however, had been mixed with METHANOL (methyl alcohol) or other chemicals to render it undrinkable—denatured. Bootleggers hired chemists to remove the denaturants by redistillation ("washing"). Inadequate processing, which was not uncommon, produced a liquor that could be toxic or even lethal. The liquor produced in England and Canada and smuggled in by ship or truck was of a higher quality. One smuggler who brought in such quality liquor, Bill McCoy, has given us a term still used to describe an authentic product—the "real McCoy."

The continued criticism of Prohibition and the frustration of enforcing the Volstead Act led many of their advocates to become increasingly defensive and hostile to those not seen as supporters. Concern for the drunkard sharply diminished. According to Lender and Martin, "Many crusaders began labelling rehabilitation as nothing more than a waste of time and energy; prohibition, they promised would make such work unnecessary" (Lender & Martin 1987). Groups interested in treatment declined. The Association for the Study of Inebriety dissolved in the mid-1920s. Volstead Act advocates became more hostile toward alcoholics as criticism of Prohibition increased. Some suggested amending the Act to make drinking itself a criminal offense. One such suggestion came from an official in the Prohibition Unit of the Treasury Department, Harry J. ANSLINGER, then the Assistant Commissioner of Prohibition. Thus the nineteenth-century concerns of the TEMPERANCE MOVEMENT for the physical and spiritual health of alcoholics turned, in the 1920s, to calls for stiffer jail terms, or even exile, for chronic alcoholics. In the context of these attitudes, the harsh penalties that were then being meted out under the leadership of the Treasury Department for mere possession of illicit drugs become somewhat more comprehensible.

The enforcement of the Volstead Act had been vested in the Treasury Department's Prohibition Unit within the Internal Revenue Bureau. The first National Prohibition Administrator, the head of the Prohibition Unit, was John F. Kramer. The Narcotics Division, headed by Levi G. Nutt, a pharmacist by training, was part of the Prohibition Unit. The Narcotics Division became an independent unit in the Treasury Department in 1930 when the Prohibition Unit was transferred to the Department of Justice. Harry J. Anslinger was appointed first Commissioner of Narcotics.

Despite growing criticism, Prohibition, according to Aaron and Musto, was still alive and well when Herbert C. Hoover was elected president by a large margin in 1928. An overwhelming majority of both houses of Congress and nearly all the state governors supported the Eighteenth Amendment. Even opponents of Prohibition did not realistically expect to see it repealed. But the onset of the Great Depression in 1929 dramatically changed the situation. Opponents of Prohibition no longer argued for its repeal because of its demoralizing effects on civil liberty but argued instead that the revival of the liquor industry would provide jobs and tax revenue. In the 1932 campaign for the presidency, Franklin D. Roosevelt promised to repeal Prohibition. Almost immediately after his inauguration, he had changes introduced in the Volstead Act to legalize the sale of beer.

In 1933, the Twenty-First Amendment to the Constitution was ratified. It was brief and to the point: "Section 1. The Eighteenth Article of Amendment to the Constitution of the United States is hereby repealed." The federal government, however, retained responsibility to regulate and tax beverage alcohol and to prevent its illegal production. Section 2 of the Amendment allowed the states to continue Prohibition under state laws if they so desired. Some states did so; many states adopted alcohol beverage control laws (ABC laws). These were intended to curb the abuses that had characterized the production and sale of alcohol prior to prohibition. Among other provisions, ABC laws restricted the hours when alcohol could be sold (to make taverns and bars less attractive) and banned liquor sales on Sundays and election days. Some ABC laws created state-operated monopolies for the sale of packaged beverages. The various federal laws dealing with control of alcohol remained the responsibility of various federal agencies. It was not until 1972 that they were brought together and responsibility lot overseeing them was assigned to a single agency—the Bureau of Alcohol, Tobacco, and Firearms (BATF) in the Department of the Treasury.

PROPOXYPHENE *d*-Propoxyphene (Darvon®) is an OPIOID drug that is structurally related to METHADONE. It is used clinically to produce analgesia when the level of PAIN is not severe. Its popularity rests largely on the belief that propoxyphene is less likely to cause addiction than CODEINE, a drug that is also used for relief of moderate levels of pain. Propoxyphene is typically used in combination with aspirin or acetaminophen. Its ANALGESIC effects are synergistic with those of aspirin and other nonsteroidal anti-inflammatory agents.

When it was introduced into clinical medicine in the early 1960s, propoxyphene was not subject to special narcotic regulatory control. This fact may explain its early popularity, which was probably due to clinicians' unrealistic fears about the addictive potential of codeine and to the inconvenience of prescribing it under the narcotic regulations that were in effect before the the CONTROLLED SUBSTANCES ACT of 1970 was passed.

Although propoxyphene has only one-half to two-thirds the potency of codeine, it has been used to control symptoms of the opioid WITHDRAWAL syndrome. It is not commonly abused because it produces unpleasant toxic effects at high doses.

PSILOCYBIN This is an indole-type HALLUCINOGEN, found naturally with another hallucinogen in a variety of mushrooms—the most publicized being the Mexican or MAGIC MUSHROOM, *Psilocybe mexicana*, as well as other *Psilocybe* and *Conocybe* species. These mushrooms have long been consumed by Native Americans, especially in Mexico and the southwestern United States, as part of religious rites.

Psilocybin produces effects similar to LYSERGIC ACID DIETHYLAMIDE (LSD), but it is less potent and is metabolized in the body to form psilocin, another hallucinogenic compound. Both of these compounds have been synthesized in clandestine laboratories and made available on the streets.

PSYCHEDELICS *See* Hallucinogens; Lysergic Acid Diethylamide (LSD) and Psychedelics

PSYCHOACTIVE *Psychoactive* is a general term that came into use about 1961. It describes a substance that affects the central nervous system, producing changes in mental activity and/or behavior. A psychoactive substance or process may affect the way an individual thinks or the manner in which the environment is perceived or experienced; it may change the behavior of an individual in a given situation.

NICK E. GOEDERS
REVISED BY NICHOLAS DEMARTINIS

PSYCHOACTIVE DRUG Any of a group of drugs (also called psychotropic drugs) that act upon the central nervous system, producing changes in mental activity and/or behavior. Psychoactive drugs are among the most widely used group of pharmacologically active agents, with extremely important clinical applications, including anesthesia for surgery and analgesia for relief of pain. They are also used for nomedical purposes, such as to alter consciousness, improve performance, and as elements in cultural and religious rituals (alcohol and peyote are examples). Some psychoactive drugs produce an effect in those who suffer from a mental or medical disorder, but no effect on normal individuals. The antidepressants, fo example, have little or no effect on normal individuals other than side effects. Other psychoactive drugs, such as the sedative-hypnotics, produce effects in all individuals.

Psychoactive drugs are used to suppress disorders of movement and to treat anxiety disorders, depression, bipolar disorder (manic-depression), and schizophrenia, among other mental illnesses. In addition, drugs used primarily to treat disorders in peripheral organs can also affect the central nervous system (e.g., beta-blocking agents, used to treat high blood pressure or disorders of heart rhythm, or steroid hormones used to control inflammation). The psychoactive effects of these drugs are generally considered side effects, although some are used for their psychoactive properties as well.

Culturally approved non-medical psychoactive drugs include alcohol, nicotine (tobacco), and caffeine. Psychoactive drugs that have been determined to have a high potential for harm and little medical benefit include heroin, hallucinogens, and some older sedative-hypnotics such as methaqualone. Marijuana has traditionally been placed in this category, but recent research has demonstrated potential effectiveness for medical problems including glaucoma, nausea, and weight loss associated with cancer or AIDS.

PSYCHOANALYSIS Psychoanalysis is an analytic technique originated by Sigmund Freud (1856–1939), an Austrian neurologist. It has been altered by his students and their students, in turn, throughout the twentieth century. Psychoanalysis is a theory of the way the mind works: (1) Sequences of thoughts are determined—they do not occur by chance; (2) Much of our thinking takes place out of awareness—it is unconscious and not easily recovered; (3) The experiences of early childhood, particularly those with important caretakers, continue to have an impact (often uncon-

sciously) on our daily lives; (4) Feelings, both sexual and aggressive, are present at birth and affect behavior. The theory helps us understand something of the addicts' complex motivations and of their inner experience and behaviors.

Psychoanalysis is also a method: It attempts to understand mental processes by free association (following thoughts wherever they lead without selection or censoring) and by the analysis of dreams, fantasies, and behaviors. Psychoanalysts apply this method as a therapy or treatment for certain forms of mental disability.

PSYCHOLOGICAL DEPENDENCE *See* Addiction: Concepts and Definitions

PSYCHOLOGICAL TREATMENT FOR SUBSTANCE ABUSE *See* Treatment; Treatment Types

PSYCHOMOTOR EFFECTS OF ALCOHOL AND DRUGS Alcohol and other drugs of abuse can alter normal behavior in a deleterious way. Epidemiological studies have shown that 50 percent or more of all single-vehicle traffic fatalities in the United States are associated with the use of ALCOHOL. The risk of a driver causing an accident increases progressively the more that BLOOD ALCOHOL CONTENT (BAC) increases past 0.4 grams per liter (g/l). At BACs of 1.0 g/l, the risk is tenfold, and with BACs of 1.5 g/l, the risk is almost thirtyfold compared to nonalcohol conditions. The same phenomenon applies to accidents in which pedestrians are killed by drunk drivers.

PSYCHOMOTOR PERFORMANCE

Most behavioral tasks are complex processes in which information sampling and its processing, motor responses, and sensorimotor coordination are involved. A decrement in any part of this system leads to impaired performance. Numerous studies describe techniques used to assess the psychomotor functions of people under the influence of chemicals with the potential for impairing performance. The vastness of the range of behavioral activities, however, makes it unlikely that any one, or even a small number, of tests could completely describe the impairing properties of alcohol and other drugs under all conceivable circumstances.

A way to approach this problem is to isolate the main variables of performance into smaller entities and measure the effects separately with a set of relevant tests. Since psychomotor behavior consists of external stimuli and a rational response to them, a simplified chain of events can be divided into a sensory part (detection of stimulus), a central part (complex processing of the sensory information), and a motor part (overt behavior or motor reaction to the stimulus).

It is sometimes difficult to select the most sensitive, accurate psychomotor test for various agents that impair performance. Sets of tests have been used—for example, in studies on the likelihood of bus drivers to have traffic accidents. The capabilities that best characterized the drivers with low accident records were constant and keen attention, adequate information processing, and the absence of hasty reactions. Eye-to-hand coordination was less important, and simple reaction times represented the poorest correlation to safe driving. Although it is logical to choose a set of tests that cover the most important variables, in most tests there is an overlap among several skills. Alcohol, drugs, and their combinations, moreover, may impair these integrated variables to a varying extent in different individuals. Because of this, one cannot predict or give exact numerical data for the amount of impairment associated with a single variable of the system affected. Nor does impairment in one sensitive test mean that the overall performance is severely impaired. In practice, it may not be important to know whether the accident of a drunken driver resulted from impaired attention rather than from poor motor coordination or slowed reactions, when all these skills were more or less affected.

CONFOUNDING FACTORS IN PSYCHOMOTOR TESTING

Substance abuse is commonly, but not necessarily, associated with an acquired TOLERANCE; this means that after repeated administration, a given dose of a drug produces a decreased effect and larger doses become needed to obtain the effects observed with the original dose. Deleterious psychomotor effects are usually easy to detect when large single doses are taken by people who have not yet acquired tolerance to the effects of drugs. The question becomes more complex when the user who takes small doses acquires significant tolerance to them because of regular use.

For any skilled performance, a large variation is observable among individuals. Thus some people may, by nature, have slower reactions or poorer information-processing capacities, and their best performance in the respective tests may be clearly worse compared with that of more capable subjects—even when the more capable are under the influence of performance-impairing drugs. The decremental drug effect can be similar in both cases, but the more capable subjects can afford it because of their better reserves. It is consequently difficult to define safe and unsafe doses of any agent.

Other factors that may influence psychomotor behavior include motivation, learning, adaptation to the task, and drowsiness. Paying the subjects according to how well they perform might improve motivation and performance, and this might skew the test results. (Such a motivational enhancer is not always mentioned in the research reports.) Impairment of performance may not be detected in tasks of short duration in a stimulating environment, whereas deleterious effects can be documented in monotonous tasks of long duration. Transposed to normal life situations, this observation may explain why an inebriated driver can get through a difficult driving test without any significant errors but cannot handle a surprising event after several hours of monotonous driving on a highway.

ALCOHOL

An alcohol dose affects the central nervous system (CNS)—the predominant effect being a depression of central functions. This means that the higher the dose of alcohol, the more the CNS is depressed. The most highly integrated brain functions are involved first; when the brain cortex is released from its functions of integrating and control, processes related to judgment and behavior occur in a disorganized fashion and the proper operation of behavioral tasks becomes disrupted.

The effects of alcohol are biphasic, and the phases depend on the dose and the rate of administration. With higher alcohol concentrations, central depressant effects dominate. Low concentrations seem to stimulate various functions by inhibiting the control mechanisms. This is seen in animal studies as decreased motor activity with large doses of alcohol and increased activity with small doses. In humans, very small doses of alcohol do not necessarily impair performance, and the tension-relieving effects of alcohol can sometimes be seen in some tests of short duration. However, there is no reason to overestimate this occasionally observed pseudostimulant effect of alcohol; in actuality, alcohol impairs various skills that are needed to cope with everyday routines.

Several investigators have demonstrated that alcohol does induce a larger decrease in test performances requiring hand-eye coordination, whereas simple tests of cognitive ability show less of a decrease. When more complex cognitive functions are studied, however, low to moderate BACs (0.3–1 g/l) impair sensory tasks and sensorimotor skills less than they do complex cognitive behavior, such as performing two tasks simultaneously (“divided attention”). It thus seems that alcohol impairs the rate of information processing by slowing the ability to switch attention from one to another sensory input to motor control, without significantly impairing sensory motor functions as such. In fact, moderate BACs (less than 1 g/l) are not associated with dramatic changes in such basic neurophysiological mechanisms as neuromuscular transmission or the conduction velocity of motor nerves. Alcohol effects are thus better seen in situations where the information load is increased and highly integrated functions are needed for the task.

It is well known that the muscles of the eye and eye movements often easily reflect the CNS depression caused by alcohol. One of the most sensitive signs is the appearance of lateral nystagmus; small twitches or vibration in the position of the eye are seen when the person looks to the side. The angle of the gaze at which the nystagmus appears correlates

with the alcohol dose: On average, a BAC of 0.5 g/l induces nystagmus at a 45-degree angle of deviation, whereas a BAC of 1 g/l produces nystagmus even at the 35-degree angle. Also, saccadic eye movements (from one fixation point to another) become slower with BACs of 0.8 g/l to 1 g/l. All this indicates that people who are drunk have a narrower sector of intact vision than people who are sober. Visual information becomes disrupted if eyes must be turned to the side to detect stimuli, or if eyes must be moved quickly from one point to another.

Several types of tests measure skilled performance in tasks related to driving behavior. *Tracking tasks* involve hand-to-eye coordination, and the task is to keep an object on a prescribed path by controlling its position through turning a steering wheel. Impairment of performance is seen at BACs of as little as 0.7 milligrams per milliliter (mg/ml). *Choice reaction task* refers to a situation where aural or visual stimuli (or both) need response according to rules that necessitate mental processing before giving the answer. In traffic, driving requires a division of attention between a tracking task and surveillance of the environment. When a driver must process information from more than one source concomitantly—by adding sudden reaction tasks to the tracking task—very low BACs are sufficient to produce significant impairment of performance.
