Preface

The idea for this *Encyclopedia of Sociology* was in gestation for a long time. Probably the notion arose when, as Sociology Advisory Editor for Rand McNally and Company, I arranged for a series of handbooks that were published in the 1960s and 1970s. This influential group of volumes covered most of sociology, especially with the *Handbook of Modern Sociology* (Robert E. L. Faris, 1964) as a key volume. Other titles in the list included: *Handbook of Marriage and the Family* (Harold T. Christensen, 1964); *Handbook of Organizations* (James G. March, 1965); *Handbook of Socialization Theory and Research* (David A. Goslin, 1968); *Handbook of Personality Theory and Research* (Edgar F. Borgatta & William W. Lambert, 1968); *Handbook on the Study of Social Problems* (Erwin O. Smigel, 1971); and *Handbook of Criminology* (Daniel Glaser, 1974). Effectively, the series functioned as an encyclopedia, especially since there was additional related coverage already provided by the *Handbook of Social Psychology* (Gardner Lindzey and Elliot Aronson, 1968). At that time Macmillan's *International Encyclopedia of the Social Sciences* (David L. Sills, ed., 1968) was also available, and a separate encyclopedia for sociology seemed superfluous.

With time, however, as social-science research and professional involvement grew, along with the proliferation of subfields, each of the social and behavioral sciences and, indeed, other specialties, such as statistics, area studies, and applied areas, developed useful encyclopedias. In the late 1970s I talked about an encyclopedia of sociology with F. E. (Ted) Peacock (F. E. Peacock Publishers, Inc.), who encouraged the development of the project.

However, since it takes time for these things, it was not until the early 1980s that I actually started reflecting actively on what would need to be done, and I sought advice on what actually would be involved in such a project. Fortunately, Raymond J. Corsini, a good friend with whom I had worked on other matters, invited me to be an Associate Editor for the *Encyclopedia of Psychology* (Corsini, 1984). I got a close look at what was involved in undertaking a project of this magnitude and I was persuaded that the task would be a feasible one for sociology.

The field of sociology had been growing and evolving rapidly in the post-World War II period. Possibly the decades of the 1960s and 1970s will be seen in retrospect as one of the periods of great change for the discipline. Of course, different people will judge past developments differently, but some of the changes that have to be recognized as important include the following:

First. Sociology, which August Comte had blessed with the title of the “Queen of the Social Sciences,” seemed to be losing much of the empire. In particular, applied fields dealing with social behavior blossomed, but as they did so, sociology seemed indifferent, uninvolved. The field of social work developed its advanced degree programs and established research interests that sociology relinquished as uninteresting because they were “applied.” The field of industrial sociology virtually disappeared as the interest in research flourished in several specialties in psychology and in schools of business and management. Interest in the key institution, the family, was largely lost to

the special applied organizations in that area. And so it went in a number of other fields. The “Queen” appeared indifferent, possibly with the exception of the field of medical sociology, in which there was considerable development.

Second. Technical training in sociology became increasingly more demanding. When I taught the first graduate course in statistics for sociology at the New York University Graduate School in 1954, it included regression analysis and factor analysis. The reception and reputation was a bit like that greeting the arrival of extraterrestrials. The title (or epithet) “Factor Analyst” was definitely not meant to be complimentary. Nevertheless, in the 1950s, the Social Science Research Council (SSRC) and others supported the idea that the formal theory and technical bases of the social sciences required attention, and programs were initiated to foster a greater appreciation of mathematics and statistics. Particularly with the support of the National Institutes of Mental Health (NIMH) graduate training grants, the University of Wisconsin, the University of Michigan, and other centers concentrated on “research methods” during and following the 1960s. The discipline reflected this focus in its journals. Sociology also became known as the leader in research training in the social sciences, with the new generation of scholars becoming conversant with statisticians, econometricians, and psychometricians, and providing service to history, political science, and anthropology. The “Queen” again had some empire.

Third. The 1960s experienced the civil-rights movement, the student movement, the feminist movement, and, implicitly or explicitly, sociologists reacted to and sometimes participated actively in these social movements. Challenges arose to the “traditional” values of objective and “value free” science in sociology. These challenges ranged from positions asserting knowledge by intuition to the posing of more serious epistemological questions. Attention was drawn to the fact that sociology apparently had little utility in solving social problems, aside from assisting in exposing them, but, further, sociologists were often accused of not studying complex problems because they were limited and hampered by their methodologies. A resurgence of interest in “qualitative” approaches developed, which also provided a stimulus for a reexamination of existing research approaches.

Fourth. At the same time, the scope of what sociologists could accomplish more generally expanded with technical development. Two of the more prohibitive cost factors in research and scholarship have progressively been reduced, since the development of computing packages made possible the elimination of computing clerks at the same time that it made possible complex numerical and statistical analyses. Additionally, this development eliminated time losses as the labor intensive aspects were eliminated. Also, the availability of word processing packages made it possible for even the most helpless scholar to by-pass the secretary or typing pool and get materials into a readable and revisable format. As these earlier “barriers” to productivity were removed, presumably the social sciences responded accordingly. In any event, there has been a proliferation of journals, and increasing collateral publication continues in various media.

Fifth. The continued development of the field of sociology can be marked by the increase of special subfields. Aside from the increases in publication, the number of specialization sections in the American Sociological Association (ASA) continues to grow, as do the Research Committees in the International Sociological Association (ISA). A reflection of this may be seen by glancing at the topical coverage of *Contemporary Sociology*, the ASA journal of book reviews.

This broadening of the field of sociology affected the way topics were chosen for the *Encyclopedia of Sociology*. In the early stages, a broad set of topics was used to accumulate the important concepts and subfields included in sociology. Initially, the objective was to be as inclusive as possible and to avoid errors of omission. A constant problem in the process was that topics did not fit neatly into only one broad category. Often they could fit as easily into two, three, or four. In fact, the number of broad categories became increasingly elastic, but eventually these were reduced to seventeen, corresponding to no known system of organization other than expedience. The broad categories did not have any obvious theoretical basis of division, which was disconcerting, but represented the pragmatic result of many revisions. Our Advisory and Associate Editors participated in reviews of the total set of categories or of selected subsets for a few of the broad categories. It is fair to report that while we often saw consensus in the process,

sometimes we felt that there was no effective way to manage the procedure for selection of topics or to satisfy every piece of advice, sound as it might seem. At one point we had more than 1,700 potential entry titles. These eventually were consolidated into about 400 titles with notations of how overlapping concepts were handled, how related concepts were to be combined, and so forth. In making the arrangements with authors, further consolidation brought the final number of entries to the 370 in this 4-volume set.

The process of defining topics, thus, while driven by theoretical interests and strategic representations of the field, ultimately resulted in a pragmatic and eclectic product. Thus some topics became very comprehensive while others have more specific content. In areas where there is intensive attention by sociologists, such as social stratification, race and ethnic studies, gender, medical sociology, and aging, coverage by authors may overlap in a way that provides emphasis.

Other factors that guided the formulation of entry topics included defining the audience for whom the encyclopedia was intended. It was expected that sociologists would read about areas with which they were not familiar, but we wanted the materials to be useful to other scholars and professionals who need information about topics in sociology. Further, encyclopedias are gold mines for students, and so a central concern was that articles could be read and understood by younger and uninitiated persons looking for a first introduction to a sociological topic. This latter message was communicated to authors, and in large part it has been possible to provide presentations that

will reach a broad range of literate audiences. There are some obvious exceptions. In some technical areas the presentations, while self-contained and elegantly presented, do require a preexisting knowledge base in order to be fully understood by the readers.

Preface for Second Edition

After the *Encyclopedia of Sociology* had been in print only three years, we began to receive inquiries about when there would be a revised edition. This was surprising given that the *Encyclopedia* was so well received, that its distribution had been much broader than even optimistic supporters of the project had anticipated, and that the articles were largely broad reviews and summaries of areas of knowledge in sociology. However, some areas in sociology changed quickly during the last decade as we approached the Millennium so that interest in a recapitulation and updating did not seem inappropriate. In addition, the social sciences appear to have softened their borders, and thus we realized that a substantial and thoughtful addition of titles would add breadth and depth to the *Encyclopedia*.

August Comte's description of sociology as the "queen" of the social sciences seems to have been awakened in a new generation, and the relevance of sociology to the social and behavioral sciences has been renewed. We took seriously our obligation to improve the representation of the areas of sociology in this edition of the *Encyclopedia*. The *Encyclopedia* was greatly improved through the input of Advisory Editors and authors who identified new content areas and titles that should be included and indicated which titles could be eliminated or consolidated. Some provided comprehensive reviews of the *Encyclopedia's* scope and coverage, as well as reviews of the content of many individual articles. Suggestions for additional titles for the revised *Encyclopedia* accumulated to a list of over 80 concepts and themes, resulting in the

addition of 66 new titles, but in addition some of the revised articles also included substantially new and expanded topics.

With the help of the Advisory Editors and quite a few authors, we reviewed articles and sectors of coverage to determine what changes would be important in a new edition. We distilled the major points of emphasis provided by reviews and user comments, and incorporated them into the guidelines for revision provide to authors.

Reflecting the kind of question that comes up so often in sociology doctoral exams, reviewers repeatedly asked us why a particular article was included in an encyclopedia of sociology. Authors who are expert in a particular subject area assume too frequently that readers will know their topic's relevance for sociology. To guard against this we asked authors to note the sociological relevance of the topic and to show how it fit into not only the scheme of sociological knowledge but also social and behavioral knowledge in general. As a consequence, most articles have been expanded.

Authors, experts in their fields, often concentrate on the knowledge and the issues within their field but do not give sufficient attention to the *practical value* of that knowledge, particularly how it is important for policy formation and in applications to everyday life. Of course, this is a comment often made about academic scholars in general, namely, that they sometimes forget that an important reason for research and the accumulation of knowledge is to provide bases for useful and informed applications.

Reviewers raised another theme. Articles often did a wonderful job of summarizing knowledge but did not indicate what to expect from future endeavors in the field. In other words, what areas need more attention in scholarship and research to expand the knowledge in a given field? While this kind of presentation is speculative, we reminded authors of the need to give direction for future work.

An additional theme for the revised edition is one that is temporally controlled. There is no way that references can provide more information than what already has been published. Updating content is important, but equally important is providing information about easily accessible general resources for those who want to go beyond the relatively brief discussions in the *Encyclopedia*. We reminded authors that the purpose of the reference section is to provide users with an opportunity to explore the area further. Academic scholars can too easily become exhaustive bibliographers. Thus, we asked authors to give special attention to providing direction rather than overwhelming the reader, and we are impressed that most authors have been extremely successful in this task. In addition to the work of the authors, the professional sociological staff of the *Encyclopedia* prepared for some article a short list of additional references to broaden the scope of coverage and

provide additional transitions to related concepts. We updated and provided new references for 20 articles from the earlier edition of the *Encyclopedia*.

Finally, reviewers commented that some of the presentations in the first edition were too brief, and some topics were too narrowly drawn. Thus, some topics have been combined, some topics have been eliminated and the content incorporated into related broader articles, and many articles have been expanded to cover neglected aspects of a topic and to provide greater detail for a more well-rounded presentation. Thirty-nine titles were eliminated and incorporated into more substantial articles, but some additional titles were changed when the original topic was expanded. In summary, there were 370 articles in the original edition, 39 were eliminated and 66 new articles were added, resulting in 397 in this revised edition.

In short, we have greatly improved the breadth and depth of coverage in the *Encyclopedia*, and we have paid particular attention to those articles that relate to other social and behavioral sciences. We have substantially increased the content of the *Encyclopedia* in this edition, and we have made every effort to ensure that the content is current, accurate, and representative of the field.

EDGAR F. BORGATTA, *EDITOR-IN-CHIEF*

Acknowledgments

The revision of the *Encyclopedia of Sociology* began with the optimistic hope that following reasonably on the original edition it would turn out to be easier to do. It did not turn out that way, but for good reasons. With the support and encouragement of Elly Dickason, Macmillan Reference USA's Publisher, the research and development for the project was more extensive than anticipated. On this score, our debt to the Advisory Editors in providing broad reviews and suggestions can hardly be emphasized enough. Further, as we proceeded in inviting old and new authors it became apparent that the Encyclopedia was getting a great deal of use and authors provided guidance from their experience on directions for development. Our authors are, of course, truly responsible for the Encyclopedia, but in addition through much interaction they provided support that was both welcome and of enormous value.

Marie L. Borgatta was the managing editor for the original publication, and for this edition she requested a less demanding role as a consulting editor. It was a nice idea, but she inevitably became involved and delivered support in quantities and quality that can only be described as exploitation.

Many ideas and innovations are due to her participation in the project. As Managing Editor for the revision, Rhonda J. V. Montgomery provided a work and intellectual partnership for the project that contributed enormously to the breadth and quality of the Revised Edition. Her initiatives kept the progress of the project smooth and on a reasonable schedule in spite of often unanticipated demands.

During the preparation of this Revised Edition, the Gale Group acquired Macmillan Reference USA, and production moved from New York to Michigan. This was done with only minimal loss of time and effort because of the planning and management of Elly Dickason, the Publisher, but also because in the New York office Timothy Prairie generated a very effective program for copyediting manuscripts and managing the records of progress. Of course, the shift to Michigan was obviously not effortless, but Linda Hubbard guided the project into the capable hands of Pamela Proffitt, who took on the mammoth task of making the Revised Edition of the *Encyclopedia of Sociology* a reality. The devoted efforts of the publisher's staff are greatly appreciated.

ADOLESCENCE

Recognition of the life stage between childhood and adulthood as a subject of modern scientific inquiry began in the early twentieth century with the publication of Antonio Marro's *La Puberta* (1898) and G. Stanley Hall's highly influential compendium *Adolescence* (1904). Although Hall's book represented an initial effort to describe adolescence, it nevertheless resonated with themes already familiar among scholars and the public. In Europe, romantic conceptions of a sexually charged, troubled youth (e.g., in Rousseau's *Émile*) circulated among the socially concerned. In America, an established tradition of cautionary literature emphasized the impressionable nature of young people and their vulnerability to sin (e.g., in the essays and sermons of Cotton Mather). Hall incorporated many of these ideas into a Darwinian framework to conjure an "adolescence" recognizable to

his readers (Ross 1972). Although the work is viewed as a curious and difficult amalgam today, it nevertheless emphasized themes that continue to shape the study of youth.

Hall viewed adolescence through the lens of Ernst Haeckel's biogenetic principle, which holds that the human life span recapitulates the phases of human biological and social evolution (Gould 1977). Hall maintained that late childhood corresponds to a period of peaceful savagery in the distant past, whereas adolescence represents a "neo-atavistic" period of migration into a challenging environment, which prompted physical, social, and psychological conflict and growth. This characterization of the adolescent, as troubled by all-encompassing turmoil, was contested early in the twentieth century by prominent behavioral scientists such as Edwin Thorndike (1917) and has been repeatedly challenged since then, perhaps most famously by Margaret Mead's *Coming of Age in Samoa* (1928) (but see Freeman 1983; Côté 1994). Likewise, sociologists such as Robert and Helen Lynd (1929) and August Hollingshead (1949) found little evidence of pervasive trouble among the youth of Middletown or Elmtown. Contemporary behavioral scientists take a more moderate view than Hall's, depicting adolescence as a time of both change and continuity (e.g., Douvan and Adelson 1966). Nevertheless, the study of adolescence has been indelibly marked by the "storm and stress" motif.

Hall also maintained that adolescents are highly responsive to adult guidance. Drawing on work by

Edward Cope, a leading American proponent of the biogenetic principle, he believed that the influence of the environment in producing acquired characteristics that were then transmissible by heredity was greatest during adolescence. The implication of this Lamarckian view was momentous: The future development of the human race depended on improvements in the adolescent (Hall 1904, v. 1, p. 50). Indeed, as a leader of the Child Study Movement, Hall forcefully argued for collaborative efforts between pedagogy and the emerging discipline of psychology, creating schools that push adolescents to their physical and mental limits, and effect the “moral rejuvenation” of youth, society, and indeed the human race. A view of adolescence as a source of manifold revitalization was especially appealing to Hall’s readership, a Gilded Age middle class weary from concern over urbanization and the perceived cultural and eugenic threats posed by large-scale immigration into the United States (Kett 1977; Ross 1972). The view that adults can constructively regulate the socialization of youth is reflected in continuing scientific and public interest in the settings of youth (e.g., the workplace) and their implications for development.

Hall’s *Adolescence* was an interdisciplinary work, and drew from a wide range of sources, including writings by early sociologists such as Auguste Comte, Herbert Spencer, Gustave Le Bon, and Adolphe Quételet. The interdisciplinary study of youth remains an important theme, with many fields recognizing adolescence as a significant area of inquiry, including psychology (Petersen 1988), history (Modell and Goodman 1990), and anthropology (Schlegel and Barry 1991). Yet each discipline has its unique presuppositions and focal points. Psychologists tend to focus on adolescents’ cognitive, motivational, and emotional capacities; their maturation (often along universalistic lines, as one finds in the work of Piaget and Erikson), their interrelationships, and how they are shaped by experiences in proximal settings, including the family, peer group, school, and workplace. Anthropologists and historians focus on the range of experiences that adolescence encompasses across cultures and through historical time: the existence

of the adolescent life phase, its distinctive social and cultural traditions, and interrelationships among youth, other age groups, and social institutions.

Sociological studies of adolescence often overlap with these concerns, reflecting interests in the social settings of youth and their implications for the self, as well as variability in this stage of life across societies and through historical time. Yet sociologists have also maintained a unique view by drawing on the life course paradigm as an analytic framework. The life course focuses on age-graded roles, opportunities, and constraints; how these differ through historical time, and how they shape the biography. The analytic focus is on the structural complexity and diversity of social settings through time and place, as well as the plasticity of humans in these settings (Dannefer 1984).

The remainder of this entry will focus on three distinctive features of adolescence as viewed from a life-course perspective (see Table 1). The first feature concerns adolescence as a life phase in historical perspective: Has adolescence been a recognized part of the life course through historical time? And how have the factors that mark the transition both into and out of adolescence changed? Implicit in the concept of markers that distinguish adolescence from childhood and adulthood is the rate of movement from one phase to the next. Accordingly, the second feature concerns how quickly young people move through the adolescent role set and the social circumstances that promote an accelerated life course.

The third feature focuses on the central role of institutionalized pathways through adolescence. In this context, pathways refer to routes from childlike dependence on the family of origin to the autonomies of adulthood. At the same time, individuals actively construct their lives. Within the structured pathways from childhood to adulthood, how do adolescents actively shape their biographies? Throughout this essay, social historical accounts are presented to underscore the highly variable nature of adolescence in the last two centuries; in turn, these accounts are juxtaposed with current sociological efforts to understand the social worlds of youth. The entry concludes by considering the dual role of sociologists in the study of adolescence: To contribute to substantive debates about the place of youth in society, but

Adolescence As a Phase of the Life Course

Features of Adolescence	Core Idea
1. Adolescence in social historical perspective	Variability in the adolescent experience can be studied through the social history of youth.
A. Historical permanence of adolescence	Adolescence is a semi-autonomous phase of life that is not of modern origin. Adolescence is always changing in response to social forces.
B. The boundaries of adolescence	Adolescence is differentiated from childhood and adulthood by transition markers and roles.
(1) From childhood to adolescence	The pubertal transition was not always a critical marker between childhood and adolescence.
(2) From adolescence to adulthood	The transition markers have been compressed and their sequence has become more complex.
2. Pace of movement through adolescent roles	Social stressors may promote rapid movement into, through, and out of adolescent roles.
3. Pathways through adolescence	Pathways direct youth through social positions in organizations.
A. Pathways in the school	This pathway is defined by the transition to 8th grade, tracks, and transitions out of high school.
B. Pathways in the workplace	This pathway is defined by the adolescent work career: extent of work involvement, quality of work, and fit with other roles and life goals.
C. Agency in pathways	Adolescent planfulness is a critical resource with which to actively negotiate the life course.

Table 1

also to identify how the contours of these debates are themselves the products of social forces.

Two additional features of adolescence are not covered in this entry. One involves the social relationships of youth, a subject that has been examined from several vantage points. Considerable attention has been devoted to the “sociometric” properties of peer relationships, mapping out affiliations among young people in high schools (see Hallinan and Smith, 1989 for a contribution to this tradition). Relatedly, sociologists have also examined the typical personalities, behavioral patterns, and group identities of youth as they reflect responses to the social organization of the high school and this phase of life (e.g., Matza 1964). Sociologists have also focused on youth and their intergenerational relationships: How youth are integrated into adult society (for example, see Coleman 1994), how they and their parents interrelate (for a useful review, see Dornbusch 1989), and how youth serve as agents of social change (for

a classic statement, see Mannheim 1928/1952). The second feature is juvenile delinquency (see *JUVENILE DELINQUENCY*).

ADOLESCENCE AS A LIFE PHASE

Each phase of life reflects social norms and institutional constraints and serves as a principal source of identity for the individual by specifying appropriate behaviors and roles (Elder 1980). The study of adolescence as a life phase requires that it be situated in the life course, that its distinctive features be identified in comparison to both childhood and adulthood. Indeed, adolescence is frequently depicted as a transitional period of semiautonomy, reflecting movement from the complete dependence of children on their parents to the establishment of one’s own livelihood and family in adulthood (e.g., Kett 1974; Katz 1979; Gillis 1974). Yet the study of adolescence as a life phase also requires that it be situated in history,

that the changing norms and institutions that shape adolescence be identified, and correspondingly, that the changing nature of adolescent semiautonomy be recognized. Within this frame of life-stage analysis, social scientists have studied the historical permanence of adolescence and the factors that have circumscribed this phase of life, marking its beginning and end.

“Adolescence” in historical time. Initial efforts to interpret the social history of youth concluded that adolescence did not exist before the modernization of societies (modernization refers to a constellation of societal changes thought to mark a break with previous forms of social organization: rapid technological changes, the emergence of market economies, urbanization, industrialization, the decline of agricultural life, secularization, broad-based political participation, the use of currency, and the spread of science [Kleiman 1998]). Norbert Elias (1994) suggested that children and adults became increasingly distinct in their behaviors as etiquette became more widespread and refined, particularly with the collapse of feudal societies. Indeed, Elias implied that the life span recapitulates the history of manners, an instance of Haeckel’s biogenetic law.

More focused on youth was Philippe Ariés’s path-setting *Centuries of Childhood* (1962). Drawing on a diverse array of evidence—including art history, linguistics, and literature—Ariés argued that in medieval times children merged directly into adult roles starting at around seven years of age. Medieval society distinguished between adults and nonadults, but, in the latter category, distinctions were not maintained between children and adolescents. Most medieval and premodern children did not attend school, but were incorporated into adult life as quickly as possible by way of daily interactions with their elders in tightly knit communities. The few youth who did attend school remained integrated in adult society by way of a vocational curriculum designed largely to train lawyers and the clergy. According to Ariés, beginning as early as the sixteenth century, a wide range of factors—from Cartesianism to technological advancements—led to the prolongation of childhood and the emergence of adolescence as a life phase. Youth were to be educated in age-segregated settings according to curricula that were less concerned with vocational training. With this prolongation of education and segregation from the

adult world, adolescence emerged as a distinct age-graded identity.

Like Hall’s *Adolescence*, Ariés’s work was read by a receptive audience (Ben-Amos 1995). The prominent functionalist Kingsley Davis (1944) had already argued that the transmission of adult norms and values took less time in “simpler” societies. Similarly, in his highly influential *The Lonely Crowd*, David Riesman (1950) argued that children could assume adult roles in tradition-directed societies (see also Eisenstadt 1956). But Ariés was unique in his use of the historical record, and his work was a point of departure for the social history of children and adolescence that subsequently emerged in the 1970s (e.g., Demos 1970; Gillis 1974). Accordingly, some commentators maintained that adolescence was “discovered” or “invented” in the eighteenth century, as shown in part by more precise distinctions among words like “child,” “adolescent,” and “youth” (e.g., Musgrove 1964). Yet a linguistic analysis says little about the historical permanence of adolescence as a set of transitional experiences marked by semiautonomy between childhood and adulthood. Indeed, many of Ariés’s arguments have been seriously contested, including his description of education in medieval and Renaissance Europe and his lack of appreciation for the semiautonomous roles youth often played in these societies as servants or apprentices (e.g., Davis 1975).

The guiding principle of most contemporary social historical research is that adolescence reflects ever-changing values and societal structures, encompassing demographic, political, economic, and social realities. For example, Kett (1977) views American adolescence as a set of behaviors imposed on youth beginning in the late nineteenth century. This imposition was justified by “psychological laws” (e.g., the necessity of religious decision during adolescence) freighted with middle-class concerns over the dangers of cities, immigrants, bureaucracies, and the pace of social change. Not surprisingly, social historians have detected “different adolescences” in diverse settings defined by historical time and place.

Reflecting a continuing engagement with Ariés, a focal point of social historical research has been the experience of adolescence before, during, and after the emergence of industrialism. An overview

of research on England highlights the contingent nature of adolescence as a social category. Two realities were prominent in defining adolescence in premodern England (Gillis 1974). First, children of all social classes were often sent out of their household of origin to become servants for another family at about age seven. "Binding out" coincided with the adoption of adult dress and codes of behavior, although the young person was viewed as neither fully adult nor child. Rather, this practice marked a form of semiautonomy: they participated in the labor market and resided outside their parents' home, but they did not marry and they were not financially independent.

Second, marriage was often linked with the establishment of an independent household. The timing of this transition, which marked full adulthood, was in turn determined by when the father conveyed dowries for daughters and annuities or land to sons. Although the specifics of inheritance were often far more complex than the rule of primogeniture would suggest (Stone 1979), the net result was that marriage was typically postponed among the poor and lower-middle classes (that is, most of society) until young people were in their late twenties, with males marrying about two years later than females. For the proportion of the population that never married (about one in five), the commencement of adulthood hinged on occupational achievements and financial independence, which probably took place in the late twenties as well.

The coming of industrialism changed the adolescent experience dramatically. Reactions to industrialism differed greatly by class and were complicated by a wide array of factors. For many strata of society, however, economic livelihood was often enhanced by encouraging several wage laborers within the family (Gillis 1974). In turn, wage labor was a strong force in creating new and popular pathways into marriage. Concerns over inheritance were less common than in the earlier period, and kin ties were defined along more pragmatic lines that allowed youth greater freedom to marry and to establish a household. The absence of strong patriarchal control and new-found pocket money led many youth to courting and consumption patterns that shocked their elders. A new adolescence had emerged.

This broad-brush view varied in important ways from place to place, among social classes, and

by gender (for related accounts of the English experience, see Anderson 1971; Musgrove 1964; Smelser 1959; for the Continental experience, see Mitterauer and Sieder 1982; for the American experience see Demos 1970; Handlin and Handlin 1971; Hareven 1982; Kett 1977; Prude 1983). Yet it is instructive for two reasons. First, most scholars now agree that as a transitional stage of semiautonomy, adolescence existed before the emergence of modern societies, although it had distinctive "premodern" characteristics. For example, premodern adolescence was typically not a period of identity formation, as Erik Erikson's (1963) putatively universal model of psychosocial development maintains (Mitterauer 1992). Young people knew their occupational and educational futures, their parents arranged both their marriages and home-leaving, and the realities of inheritance, fecundity, and infant mortality dictated their reproductive behaviors. Furthermore, for most youth, few real political or religious options presented themselves. Although there are recorded instances of youth riots in urban areas and many adolescents and young adults were active in the Protestant Reformation, political and religious beliefs generally reflected the traditions and customs of the locale.

Second, although adolescence existed in preindustrial times, historians such as Ariés maintain too sharp a distinction between premodern and modern phases of the life course (Ben-Amos 1995). The adolescences of both the preindustrial and contemporary West are not entirely dissimilar, suggesting that there are distinctly "modern" features of preindustrial adolescence and "traditional" features of contemporary adolescence. For example, many adolescents of both periods lack a parent. In seventeenth-century England, life expectancy was approximately thirty-two years, so that many youth, born when the mother was in her early to mid-twenties, lacked at least one parent. In contemporary society, parental separation is not uncommon through the early life course. For example, among cohorts born between 1967 and 1973, about 20 percent of white males and 60 percent of black males have lived in a mother-only family between birth and age 15 (Hill et al. 1999). Parental separation and absence today is a substitute for the parental mortality of the premodern period.

Similarly, the adolescence of both historical eras was a drawn-out process. Because of early home-leaving and late marriage, preindustrial adolescence in England spanned two decades. In contemporary times, it is commonly asserted that the span between puberty and the transition to adulthood is excessive because of delays in school completion, marriage, and home-leaving. Indeed, some sociologists have suggested adding a “postadolescence” stage to the life course (e.g., Hurrelmann 1989). Although the duration of adolescence today appears extended against the backdrop of the early to mid-twentieth century, it is nevertheless brief when compared to preindustrial adolescence (about twelve versus twenty years).

In short, adolescence traces back to at least the High Middle Ages in the West, but its form and content have been remarkably responsive to social setting (Mitterauer 1992). Furthermore, one often observes both similarities and differences among the “adolescences” defined by historical time and place.

The transition from childhood to adolescence. Sociologists have not studied the transition to adolescence extensively, perhaps because it is typically equated with the onset of puberty, which strongly reflects individual differences in genetics, nutrition, and physical exertion (Tanner 1978). This lack of interest is unfortunate, as the effects of these factors on pubertal timing have always been conditioned by social circumstances (e.g., improvements in nutrition diffused through many societies on the basis of class and urban-rural distinctions; see Mitterauer 1992).

In any event, historical analyses suggest that puberty was not always the primary marker of the transition to adolescence. By today’s standards, physical changes associated with puberty occurred notably later in the premodern and early modern periods. For example, the average age of menarche was about fifteen for girls in early eighteenth-century America and final height was not attained among men until around age twenty-five (Kett 1977). Sources from mid-sixteenth century Europe suggest even later dates and a much more gradual progression of physical changes than is observed today (for a review of earlier sources and their critical evaluation, see Tanner 1981).

In the premodern period, young people were probably viewed as semi-autonomous when they

were sent to other households as servants or apprentices (often between ages seven and ten). Other local customs (such as religious confirmation and conversion, and membership in a wide array of village groups) also marked the end of childhood, and these frequently occurred before the pubertal transition. Thus historical evidence suggests that physical changes associated with puberty were not prominent factors that distinguished children from adolescents, and this generalization may be valid into the mid-nineteenth century, when improvements in nutrition began to take hold for large segments of society. Indeed, the pubertal transition often represented an important step into adult roles. Before the mid-nineteenth century, puberty in America was associated with a sense of rising power and energy and the ability to assume adult work responsibilities. It was largely after the Civil War that puberty came to represent a vulnerable and awkward stage closely associated with the adolescence of today (Kett 1977).

The transition from adolescence to young adulthood. A range of “transition markers” are typically used to indicate movement out of adolescence and into adulthood. These include leaving school, starting a full-time job, leaving the home of origin, getting married, and becoming a parent. These markers can not be used uncritically, however, because their relevance in defining stages of the life course changes through historical periods (Mitterauer 1992). Furthermore, although young people in the contemporary West rely on these markers to distinguish between adolescence and adulthood, they also draw on other criteria, including cognitive self-sufficiency, emotional self-reliance, and behavioral self-control (Arnett and Taber 1994). Nevertheless, most sociological research has focused on these transition markers and has generated valuable insights about the changing life course. Paradoxically, many commentators argue that markers of the transition from adolescence to adulthood have become both more standardized and variable.

Standardization: The compression of transition markers. Standardization reflects the increasing importance of age-grading and is seen in the increasing “compactness” of transition markers, particularly the ages of school completion, first job, and marriage. Theorists argue that the organization of public services, transfer payments, and

employment opportunities according to age renders the life course more orderly and calculable (Beck 1992; Kohli 1986). Also, as the state increased the number of rights that an individual could claim on a universalistic, standardized basis, it also restricted the individual's right to organize many aspects of life (e.g., with respect to education and entry into, and exit from, the labor market) (Buchmann 1989).

Evidence from historical demography suggests that the transition to adulthood has indeed become more standardized. Examining the prevalence of different female life-course patterns (e.g., spinster, dying mother, widowed mother) among cohorts of women born between 1830 and 1920, Uhlenberg (1969) observes a convergence on the "typical" pattern, involving marriage, having children, and surviving with husband until age 55. Among women born in 1830, about 21 percent experienced this "typical" pattern in contrast to about 57 percent of women born in 1920. In addition, the age range in which women typically married and had children narrowed. The primary factor promoting standardization of the life course was improvement in mortality due to the management of contagious and infectious diseases such as smallpox, typhoid and scarlet fever, diphtheria, and measles. Similarly, the time it took 80 percent of both men and women to leave the household of origin, marry, and establish their own households decreased markedly between 1880 and 1970 among those who experienced these transitions (Modell et al. 1976). A considerable body of evidence suggests that the transition to adulthood was standardized between about 1830 and 1960, as measured by a constriction of the time in which most people pass through a range of transition markers (for further discussion, see Shanahan forthcoming).

Theoreticians have emphasized the critical role of "modernity" in explaining this long-term pattern, but this formulation, with its connotation of a monotonic pace and continuous process, has not been supported by empirical study. Instead, age standardization has been affected by historically specific conditions, including improvements in health (Uhlenberg 1969) and age-grading in the school system (Hogan 1981). And as historians have noted, legal reforms, public debates about the rights and responsibilities of age groups, and cultural innovations have come into play at different times and with varying degrees of import (Kett

1977; Modell 1989; Zelizer 1994). Evidence thus points to a long-term trend of compression of the transition markers, but that trend reflects manifold factors proceeding at an uneven pace.

Variability: The complex sequencing of transition markers. Variability is found in the increasing complexity of role overlap and sequencing during the transition to adulthood. Theorists of modernity maintain that as individuals were freed from the traditional constraints of family and locale, they were able to exercise more agency in the construction of their biographies (e.g., Beck 1992; Giddens 1991). Consistent with these arguments, Modell, Furstenberg, and Hershberg (1976) observe that as transition markers occurred in briefer periods of time, they exhibited greater diversity in their sequencing. Between 1880 and 1970, the familial and nonfamilial transition markers increasingly overlapped, creating variability in the transition to adulthood in the form of more sequence patterns of school completion, leaving home, starting a family and career, and becoming a parent.

Hogan (1981) provides important empirical evidence for variability in the sequencing of markers among cohorts born between 1907 and 1946. The percentage of men experiencing an "intermediate nonnormative" order of transition markers (beginning work before completing school or marriage before beginning work but after school completion) increased from about 20 percent in the cohorts born between 1907 and 1912 to about 30 percent for men born in 1951. The prevalence of "extreme nonnormative" ordering (marriage before school completion) increased from less than 10 percent among cohorts born between 1907 and 1911 to over 20 percent for cohorts born between 1924 and 1947. "Modernity" has a large negative effect on the prevalence of the normative pattern, but a large positive effect on the prevalence of the extreme nonnormative pattern. That is, in historical times marked by greater educational attainment, lower infant mortality, greater longevity, and fewer youth in the adult labor market, men are more likely to make extremely nonnormative transitions to adulthood. Evidence thus suggests a trend toward individualization of the life course as found in the increased variability in the sequencing and overlap of transitions (for further discussion, see Shanahan forthcoming).

THE ACCELERATED LIFE COURSE AND ADOLESCENCE

A conception of adolescence as bounded by markers implies a normative rate of movement through roles that indicate childhood, adolescence, and adulthood. Accordingly, influential accounts of youth view adolescence as a transitory period, marking normatively paced movement from childlike to adult roles (e.g., Linton 1942). The individual is construed as more or less adultlike depending on the acquisition of symbols, the provision of opportunities, and demands for responsibility that indicate adulthood. With respect to the second decade of life, behavioral scientists recognize three forms of an accelerated life course, reflecting the nonnormatively rapid (1) transition into adolescence, (2) movement through adolescence, and (3) transition into adulthood. These manifestations of the accelerated life course are frequently linked to stressors operating on the parents and the young person.

Precocious youth represent an early form of accelerated life course in American history. Since at least the mid-eighteenth century, some young people have been portrayed as astonishingly adultlike in their intellectual, moral, physical, and social capacities. Early American history is replete with admiration for youth who grew up in log cabins only to rise to high levels of prominence while still young, a rise often linked to exceptional talents exhibited in childhood. Yet precocity was also viewed as an inconvenience. Thus, the father of an eleven-year-old graduate from Yale at the end of the eighteenth century lamented that his son was "in no way equipped to do much of anything" (Graff 1995, p. 47). Instances such as these became rare as the social institutions of youth became age-graded, beginning in the mid-nineteenth century.

In contemporary times, an accelerated life course may reflect an early transition to adolescence. For example, Belsky and his colleagues (1991) have proposed a sociobiological model of early menarche and sexual activity. According to this model, high levels of stress during childhood—reflecting marital discord, inconsistent and harsh parenting, and inadequate financial resources—lead to aggression and depression in late childhood, which in turn foster early puberty and sexual activity. In contrast, children whose families

enjoy spousal harmony, adequate financial resources, and sensitive, supportive parenting tend to experience a later onset of puberty and sexual activity. That is, depending on environmental cues about the availability and predictability of resources (broadly defined), development follows one of two distinct reproductive strategies.

Empirical studies provide partial support for this model. Menarche occurs earlier among girls who live in mother-only households or with stepfathers. Conflict in parent-child relationships or low levels of warmth are also associated with earlier menarche (Ellis and Graber forthcoming; Graber, Brooks-Gunn, and Warren 1995; Surbey 1990). Drawing on longitudinal data, Moffitt and her colleagues (1992) report that family conflict and the absence of a father in childhood lead to earlier menarche, although this relationship is not mediated by any psychological factors examined in their study. Research findings to date, however, are open to genetic interpretation. It may be that early-maturing mothers transmit a genetic predisposition toward early puberty and the same genes produce traits in the mother that affect parenting (Rowe forthcoming) finds some support for both models. Maccoby (1991) suggests an additional class of explanations, namely that these findings reflect social psychological processes (e.g., the adolescent's imitation of the mother's permissiveness).

The accelerated life course may also involve the rapid assumption of autonomy not typically associated with adolescent roles. This form may appear in the adoption of the parent role by adolescents in their family of origin, what Minuchin (1974) refers to as the "parental child." Children and adolescents may respond to the family's emotional and practical needs through activities such as serving as a confidant to a parent, mediating family disputes, and the extensive parenting of younger siblings. Young people may assume responsibilities such as these in single, working-parent homes, which can have positive consequences for adolescents but detrimental effects for younger children (Weiss 1979). The contextual and interpersonal factors that promote "parentification," however, are potentially numerous and complex, perhaps encompassing family structure, sibship size, marital dysfunction, and the employment status of the parents (Jurkovic 1997).

Likewise some critics of youth employment suggest that extensive involvement in the workplace during the high school years can promote “pseudomaturity,” the appearance of adult status that nevertheless lacks the full set of rights and responsibilities that accompany adulthood. (Psychologists have also expressed concern about “pseudomaturity” among contemporary youth, although they define it as a disjunction between the apparent ability to play adult roles and a lack of “commensurate psychological differentiation” [e.g., Erikson 1959].) For example, although youth may earn considerable amounts of money during high school, they spend a relatively high percentage of their income on entertainment because they lack the financial responsibilities of true adults (e.g., insurance, housing). In turn, this “premature affluence” may interfere with the development of realistic financial values (Bachman 1983; Bachman and Schulenberg 1993). However, studies show that youth spend their earnings on a wide range of things, not all of which are concerned with leisure, including savings for future education, car insurance, and even loans and contributions to parents (Shanahan et al. 1996). Moreover, studies of families during the Great Depression suggest that economic hardship can lead to the assumption of more adultlike work responsibilities among children and adolescents, which can benefit the latter group (Elder 1974).

Finally, the accelerated life course may reflect a rapid transition to adulthood. For example, because young black men have markedly shorter life expectancies than white men, they often accelerate their transition behaviors (Burton et al. 1996). There may also be an important element of intentionality in the “search for role exit” from adolescence (Hagan and Wheaton 1993). Although the desire to leave home, marry, and have children may be normative, the intent to exit the adolescent role set too early is nonnormative and often associated with deviant acts. Indeed, the search for adolescent role exits significantly predicts frequency of dating and the timing of first marriage and parenthood. That is, some adolescents may seek rapid transition to adulthood because they are substantially dissatisfied with their experience of adolescence as a life phase. In any event, sociologists have offered numerous explanations for adolescent parenthood including, for example, the lack of role models and opportunities that would

otherwise encourage postponing intercourse and pregnancy (Brewster 1994).

PATHWAYS AND AGENCY THROUGH ADOLESCENCE

The preceding discussion highlights the variable meanings of adolescence in the life course; a related issue is the structured pathways that constitute likely sequences of social positions through which the adolescent moves. Pathways reflect institutional arrangements that both provide and restrict opportunities, channeling youth from one social position to another. Pathways are a prominent feature in the school and workplace—and between these institutions (see *ADULTHOOD*)—where social forces match individuals to social opportunities and limitations. Pathways are also evident in the family, as a sequence of roles that the child assumes and that offer progressively greater autonomy.

Before the mid-nineteenth century in America, the immediate environments of youth were casual and unstructured; mortality and frequent moves from the home placed limits on the direct and sustained application of parental discipline, and schools were decidedly unstructured settings marked by violence and informality (Kett 1977). Between 1840 and 1880, a different viewpoint emerged in both Britain and the United States, a viewpoint that emphasized character formation in planned, “engineered” environments. For example, Horace Bushnell’s influential *Christian Nurture* (1848) argued for carefully controlled settings that would promote in youth qualities necessary to succeed in a world threatened by urbanization and non-Protestant immigrants. By the end of the nineteenth century, efforts to standardize the settings of youth—particularly schools—led to the emergence of recognized tracks of educational and occupational experiences for young men entering the medical and legal professions. Educational and occupational pathways from adolescence to adulthood were becoming standardized.

Although pathways sort individuals and assign them to various positions in social systems, people are also active agents who attempt to shape their biographies. In life-course perspective, agency at the level of the person can be defined as the ability

to formulate and pursue life plans. Young people are constrained and enabled by opportunity structures of school and work, but they also construct their life course through their active efforts. This section provides a set of examples that highlight structured pathways that describe likely sequences of social positions in terms of education and work. It also discusses sociological efforts to understand the active efforts of adolescents to shape their biographies in these structured settings.

Educational pathways through adolescence.

At the turn of the nineteenth century, youth fortunate enough to attend school typically started their educations late and attended class sporadically. Academies of education, not uncommonly a single room in a private residence, were eager to accommodate the seasonal demands of agriculture. Consequently student bodies encompassed a wide range of pupils, whose ages often said little about their academic accomplishments. This situation was more pronounced in district schools, where attendance was said to fluctuate from hour to hour. Furthermore, teaching was not yet an occupation that required credentials, and teachers frequently resorted to violence to impart lessons or to maintain order, as did the students in response to frequent humiliation.

At the college level, the violence was pronounced. There were riots at Harvard, Yale, and Princeton, nightly stoning of the president's house at Brown through the 1820s, and frequent beating of blacks, servants, fellow students, and professors (Kett 1977). During the early years of the republic, little in the educational system was standardized. Beginning in the mid-nineteenth century, the educational system changed as Horace Mann, Henry Barnard, and Calvin Stowe led the common school revival, aimed at creating regulated, controlled school settings. In addition to the efforts of early reformers, many social, economic, political, and cultural forces contributed to the standardization of schools, particularly in the late nineteenth century (Tyack 1974; Tyack, James, and Benavot 1987).

Today, the educational system is highly standardized and adolescent pathways through school are readily identifiable: Adolescent pathways through the educational system can be described in terms of the transition to the seventh grade and tracking through the high school years. A considerable

body of sociological research also examines the many structured connections among secondary education, tertiary institutions such as colleges and vocational schools, and the workplace.

At the transition to seventh grade, children may remain in the same school (a "K-8" system) or change to a junior high school. The latter structure is thought to be more stressful by sociologists, as it typically brings with it a disruption in social networks and the student's first exposure to a bureaucratic setting with a high degree of specialization. Students in K-8 systems continue to have one teacher and one set of classmates for all subjects, while students attending junior high school often have a different teacher and classmates for each subject. In fact, students in K-8 systems are more influenced by peers, date more, and prefer to be with close friends more than students making the transition to junior high school. The latter report higher levels of anonymity. Further, girls who make the transition to junior high school appear especially vulnerable to low levels of self-esteem when compared with girls in a K-8 system and boys in either system (Blyth et al. 1978; Simmons and Blyth 1987; Simmons et al. 1979).

It may be that the negative effects of the transition to junior high school are amplified as the number of transitions experienced by a young person increases. A "focal theory of change" maintains that young people are better able to cope with significant life events serially rather than simultaneously (Coleman 1974). Some evidence supports this view: As the number of transitions—including school change, pubertal change, early dating, geographic mobility, and major family disruptions such as death—that students must cope with concurrently increase, their grades, extracurricular involvements, and self-esteem decrease (Simmons et al. 1987). These associations are particularly deleterious for girls. How the transition to seventh grade is organized can thus have pervasive implications for the well-being of youth.

Within secondary schools students are frequently assigned to "tracks," different curricula for students of differing talents and interests. Sociologists have identified several noteworthy features of tracks, including selectivity (the extent of homogeneity within tracks), electivity (the extent to which students choose their tracks), inclusiveness (the extent to which tracks leave open options

for future education), and scope (the extent to which students are assigned to the same track across subjects and through time). Scope—particularly the extent to which students are in the same track across grade levels—predicts math and verbal achievement, when earlier scores of achievement are controlled. (Gamoran 1992).

In turn, these differences in educational achievement largely reflect socialization and allocation processes (for a useful review, see Gamoran 1996). Socialization refers to systematically different educational experiences across tracks. Allocation refers to the decisions made by teachers to assign students to tracks, assignments that provide information to students about their abilities and that elicit differential responses from others. That is, students of differing ability are assigned to different educational opportunities, which in turn creates inequalities in outcomes, even if initial differences in ability are taken into account. Unfortunately, tracking systems are often unfair in the sense that students of similar ability are assigned to different tracks, and assignments may be based on factors other than intellectual talents and interests (see Entwisle and Alexander 1993). Furthermore, status allocations from primary through tertiary school and to the labor force are remarkably consistent (Kerckhoff 1993). The advantages or disadvantages of one's position in the educational and occupational systems cumulate as individuals increasingly diverge in their educational and labor market attainments. Thus, educational tracks can exert substantial influence on socioeconomic achievements throughout the life course.

Pathways in the workplace. Work responsibilities have always indicated one's status in the life course. Through the early nineteenth century in America, young people began performing chores as early as possible in childhood and often assumed considerable work responsibilities by age seven, either on the farm or as a servant in another household. Many youth were fully incorporated into the workforce with the onset of physical maturity, in the mid- to late teens (Kett 1977). During this same period, however, agricultural opportunities waned in the Northeast while expansions in commerce, manufacturing, and construction provided new employment for youth in and around cities. Many families adopted economic strategies whereby parents and children were involved in

complex combinations of farming, work in factories, and other sources of wage labor (Prude 1983) or whereby entire families were recruited into factory work (Hareven 1982; for the case of England, see Anderson 1971; Smelser 1959).

The second Industrial Revolution, commencing after the Civil War and extending to World War I, led in part to less reliance on children as factory workers (Osterman 1979). Technological innovations in the workplace—the use of internal combustion engines, electric power, and continuous-processing techniques—created an economic context conducive to the consolidation of primary schools in the life course as many youth jobs were eliminated by mechanization (Troen 1985) and manufacturers required more highly skilled employees (Minge-Kalman 1978). These economic factors operated in concert with progressive political movements, as well as cultural, demographic, social, and legal changes (Hogan 1981; Zelizer 1985), all of which fueled debates about the appropriate role of youth in the workplace. These debates continue to the present, particularly focusing on the work involvements of high school students (for useful overviews, see Institute of Medicine/National Research Council 1998; Mortimer and Finch 1996). Today, almost all adolescents work in paid jobs and time commitments to the workplace can be substantial (Bachman and Schulenberg 1993; Manning 1990). Whereas youth work at the beginning of the twentieth century often centered around agriculture and involved family, kin, and neighbors, today's adolescent is more frequently employed in “entry-level” jobs among unrelated adults in the retail and restaurant sectors. These changes have prompted arguments that contemporary adolescent work interferes significantly with the basic developmental tasks of youth.

Yet the transition to paid work represents a large step toward autonomy and can promote a sense of contribution, of egalitarianism, and of being “grown up” among youth. Although very little research has examined the adolescent work career, several generalizations are currently plausible. First, adolescents have work careers in that they typically progress from informal work (e.g., babysitting and yard work for neighbors) to a surprisingly diverse set of occupations as seniors in high school, a trend that is accompanied by an

increase in earnings. That is, work tends to become more complex and to produce more earnings through the high school years (Mortimer et al. 1994).

Second, adolescent work can have positive or negative consequences, depending on the extent and the quality of the experience, as well as its meaning. For example, work of high intensity (that is, exceeding twenty hours of work on average across all weeks employed) curtails postsecondary education among boys and increases alcohol use and smoking among high school girls (Mortimer and Johnson 1998). But adolescents engaged in low-intensity work during high school have favorable outcomes with respect to schooling (for boys) and part-time work (for both boys and girls).

Third, the quality of work matters. For example, several studies show that jobs that draw on or confer skills deemed useful in the workplace are associated with feelings of efficacy during the high school years as well as success in the job market three years after high school (Finch et al. 1991; Stern and Nakata 1989). Similarly, adolescent work experiences can have positive implications for development depending on how they fit into the adolescent's life. Thus, when earnings are saved for college, working actually has a positive effect on grades (Marsh 1991), and nonleisure spending (e.g., spending devoted to education or savings) may enhance relationships with parents (Shanahan et al. 1996). In short, the adolescent work career can pose positive or negative implications for subsequent attainment and adjustment.

Life course agency in adolescence. Whereas the concept of pathways reflects an interest in how organizations and institutions allocate youth to social positions and their attendant opportunities and limitations, young people are also active agents attempting to realize goals and ambitions. It is unlikely that most youth were agents in this sense before or during the founding of the republic. In a detailed study of autobiographical life histories between 1740 and 1920, Graff (1995) observes that lives marked by conscious choice and self-direction, a search for opportunities including social mobility, the instrumental use of further education, and risk-taking in the commercial marketplace, were atypical before the nineteenth century. In some accounts this emerging orientation

was expressed in explicit emulation of the widely circulated autobiography of Benjamin Franklin, who emphasized planning, thrift, decision making, and independence. Before this period, the major features of the life course—including education, occupation, and family life—were largely determined by family circumstances. (The notable exception to a lack of decision making about one's life was religious “rebirth.” Departing from Catholic and Lutheran doctrine, religious sects such as the Anabaptists emphasized the adolescent's conscious decision to be baptized and then lead an appropriately Christian life [Mitterauer 1992].)

This active orientation toward the life course gained currency as “conduct-of-life” books in the first decades of the nineteenth century departed from Puritan hostility to assertiveness in order to emphasize the building of a decisive character marked by “a strenuous will” (e.g., as found in John Foster's popular essay “Decision of Character” of 1805). The message was especially appealing to the large number of young men leaving rural areas for the city in search of jobs. Since that time, themes such as self-reliance, decisiveness, willpower, and ambition have recurred in popular advice books and social commentaries directed to adolescents and their parents (Kett 1977). Indeed, a view of “youth as shapers of youth” has become prominent among social historians of the twentieth century (for a superb example, see Modell 1989).

In contemporary times, a conception of life as shaped through decision-making, planning, and persistent effort is common. A particularly useful concept to study this phenomenon is *planful competence*, the thoughtful, assertive, and self-controlled processes that underlie selection into social institutions and interpersonal relationships (Clausen 1991a). Although these traits can be found in approaches to personality (e.g., conscientiousness), planful competence is uniquely concerned with the ability to select social settings that best match a person's goals, values, and strengths. That is, planful competence describes the self's ability to negotiate the life course as it represents a socially structured set of age-graded opportunities and limitations. Clausen (1991b, 1993) maintains that a planful orientation in mid-adolescence (about ages 14 and 15) is especially relevant to the life course because it promotes realistic decision-making about the roles and relationships of adulthood. That is, one's self-reflexivity, confidence, and self-regulation at

mid-adolescence lead to better choices during the transition to adulthood, choices that in turn have implications for later life. Clausen reasons that children are not capable of planful competence, but most adults possess at least some; therefore interindividual differences at mid-adolescence are most likely to differentiate people during the transition to adulthood and through later life. Adolescents who are planfully competent “better prepare themselves for adult roles and will select, and be selected for, opportunities that give them a head start” (1993, p. 21).

Drawing on extensive longitudinal archives from the Berkeley and Oakland samples at the Institute of Child Welfare, Clausen (1991b, 1993) demonstrated that planful competence in high school (age 15 to 18 years) had pervasive effects on functioning in later life. Planfulness significantly predicted marital stability, educational attainment for both males and females, occupational attainment and career stability for males, and life satisfaction in later adulthood. Satisfaction with marriage was often associated with adolescent planfulness among men and women, especially among men who were capable of interpersonal warmth. Men who were more planful earlier in life reported greater satisfaction with their careers, more job security, and better relationships with their coworkers.

Some research suggests that the effects of planfulness are conditioned by historical experience, an insight that joins the concepts of pathways and agency. Drawing on the Terman Sample of Gifted Children, Shanahan and his colleagues (1997) examined the lifetime educational achievement of two cohorts of men who grew up during the Great Depression. The older cohort, those born between 1900 and 1910, often were in college or had just begun their careers when the Great Depression hit. The younger cohort, those born between 1910 and 1920, typically attended college after the Depression and began their careers in the post-World War II economic boom. For the older cohort, it was hypothesized that adolescent planful competence would not predict adult educational attainment. Rather, very high levels of unemployment during the Depression would support a prolonged education for this cohort—through continuity in or return to school—regardless of their planfulness. In contrast, planful competence in adolescence was expected to predict adult educational attainment in the younger

cohort, which was presented with practical choices involving employment opportunities and further education.

As expected, planfulness at age fourteen positively predicted educational attainment, but only for the men born between 1910 and 1920, who often finished school during the postwar economic boom. Planful competence did not predict educational attainment for men from the older cohort, who typically remained in school or returned to school after their nascent careers floundered. Thus, for the older cohort, the lack of economic opportunity precluded entry into the workplace and under these circumstances, personal agency did not predict level of schooling. In short, the Terman men’s lives reflect “bounded agency,” the active efforts of individuals within structured settings of opportunity.

ADOLESCENCE IN RETROSPECT AND PROSPECT

A historically sensitive inquiry into the sociology of adolescence reveals several prominent features of this life phase. First, although adolescence as a state of semiautonomy between childhood and adulthood has long been part of the Western life course, it has nevertheless been highly responsive to social, political, economic, and cultural forces. Indeed, adolescence acts like a “canary in the coal mine.” As successive generations of youth encounter adult society for the first time, their reactions tell us much about the desirability of social arrangements. These reactions have ranged from enthusiastic acceptance to large-scale revolt and have often led to the emergence of new social orders.

Second, the many “adolescences” revealed through historical time and place are both different and similar in significant ways. Many supposedly universalistic accounts of social and psychological development would not describe adolescent experiences and interpretive frames in the past (Mitterauer 1992). On the other hand, few, if any, aspects of the adolescent experience are without precedent. Statistics on adolescent sexual behavior are met with great alarm today, and yet alarm was already sounded in pre-Colonial times: Leaving England for America in the 1630s, the Puritans hoped to establish an “age-relations utopia” between young people and their elders, which had

not been possible in the Old World because of the “licentiousness of youth” (Moran 1991; for the related problem of adolescent pregnancy, see Smith and Hindus 1975; Vinovskis 1988). Likewise, contemporary debates about whether adolescents should be allowed to engage in paid work echo exchanges over child labor laws a century ago (Zelizer 1985). Analogous observations could be made about drug abuse, violence in schools, gangs, and troubled urban youth with diminished prospects.

Yet each generation of adults insists that its adolescence is uniquely vulnerable to social change and the problems that come with it. Indeed, this orientation has spawned a large and often alarmist and contradictory literature about the American adolescent (see Graff 1995, especially Chap. 6). Although many strands of scientific evidence show that adolescence as a state of semiautonomy has lengthened over the past several decades, a torrent of books nonetheless warn of “the end of adolescence.” And although many studies show that adolescence is not a period of sudden and pervasive distress, scientific journals devoted to adolescence are filled with contributions examining psychological disorder, substance use, antisocial behavior, sexually transmitted disease, delinquency, troubled relationships with parents, and poor academic performance. Denials of “storm and stress” frequently accompany implicit statements of “doom and gloom.”

Unfortunately, these negative images run the risk of defining adolescence (Graff 1995). Studies and social commentaries that highlight the troubled nature of youth may alert the public to social problems in need of redress, but they may also create dominant cultural images that ultimately define what it means to be an adolescent in negative terms, breeding intergenerational mistrust and, among youth, alienation (Adelson 1986).

In this context of research and representation, sociology has much to contribute to an understanding of adolescence. What is needed are balanced accounts of their lived experiences and how these vary by social class, race, gender, and other indicators of inequality. These descriptions need to be situated in both place and time. Place refers to the many contexts of youth, encompassing families and neighborhoods, urban and rural distinctions, ideologies, modes of production, and national and international trends. Time refers to the

history of youth, with its many continuities and discontinuities, but it also refers to the life course, how adolescence fits into the patterned sequence of life’s phases. Through such efforts, sociologists can contribute to public discourse about youth and comprehend this discourse as being itself a product of social forces.

MICHAEL J. SHANAHAN

ADULT EDUCATION

Most basically defined, adult education is the intentional, systematic process of teaching and learning by which persons who occupy adult roles acquire new values, attitudes, knowledge, skills, and disciplines. As a concept, “adult education” demarcates a subfield of education that is distinct from the latter’s historical and still general identification with the formal schooling of youth in primary and secondary schools, colleges, and universities. Once lacking the central social significance long recognized for this formal schooling, adult education expanded rapidly after 1950. Changing social, economic, and demographic forces occasioned new educational forms and organizations and new levels of adult participation in existing forms. Adult education is now so widespread and important a feature of societies worldwide that it increasingly occupies the attention of social scientists, policy makers, businesses, and the public.

TYPES OF ADULT EDUCATION

Adult education now permeates modern societies. It does not do so, however, with the kind of public funding, legislative sanction, organizational cohesion, and standardization of practice that have made universal schooling a highly visible and central institution. Precise substantive definition and classification of adult education is frustrated by the great and changing variety that characterizes the field (Courtney 1989). The complex circumstances of adult life and development lead to the informal, nonformal, and formal pursuit of education for many different purposes. In response to an intricate array of social, economic, and political conditions, formal and nonformal organizations—from multi-state international agencies to corporations to local recreational clubs—support and develop adult education programs. In consequence, an eclectic set of professions, occupations, disciplines, and practices forms the division of adult education labor.

Adults seek a wide variety of educational goals. These include basic literacy and work readiness skills; knowledge and technical competencies required for entering and improving performance of occupational, avocational, and recreational roles; credentials for status attainment; information for the improvement of family life, health, and psychological well-being; knowledge, values, and disciplines for spiritual growth and intellectual enrichment; and tools for addressing community problems and advancing political and social-action agendas. An equally diverse set of organizations and groups provides such education. Publishers and producers of print and electronic educational media serve a growing market for informal adult education with products that range from golf tutorials to taped lectures on the history of philosophy. A large and rapidly expanding nonformal sector (i.e., educational organizations that are not a part of the formal school and college system), now mobilizes very considerable resources to educate adults. Businesses, government agencies, and non-profit organizations train employees to enhance productivity, organizational effectiveness, and client satisfaction, to spur innovation in products and services, and as an employment benefit to attract workers. Proprietary schools and training companies seek profits by providing similar training to both businesses and individuals. National, regional, and local governments fund adult education programs to reduce welfare dependency and promote economic development. Political parties and special-interest groups deliver adult education designed to foster either dominant or insurgent civic values, knowledge, and action. Professional associations sponsor and certify continuing education to maintain and enhance member competence, ensure the value of their credentials, and maintain market advantages for their members.

Other major providers of nonformal education programs that expressly target adults include unions; churches; libraries, and museums; the armed forces; prison systems; charitable, fraternal, service, and cultural associations; and the health care industry. The formal educational system itself no longer serves only the young. Community school adjuncts to primary and secondary schools teach basic literacy, prepare adults for high school equivalency exams, and offer classes in subjects ranging from the latest computer software to traditional arts and crafts. Colleges and

universities now educate almost as many adults as youth; in the United States almost half of all college students are adults above twenty-five years of age. With increasing frequency, these students study in divisions of colleges and universities specifically dedicated to adults.

The functional and organizational diversity of adult education is mirrored in its professions and occupations. Those working in the field include the administrators, researchers, and professors in university graduate programs that train adult educators and maintain adult education as an academic discipline. Teachers and student-service personnel in university, governmental, and proprietary organizations deliver graduate, undergraduate, and continuing education to adults. Managers, trainers, and associated marketing and support personnel staff the employee, technical, and professional training industry. Adult literacy and basic education practitioners form a specialization of their own. Professional activists, organizers, and volunteers consciously include adult education in the portfolio of skills that they apply to pursuits ranging across the full spectrum of ideologies and interests. Policy analysts, planners, researchers, and administrators staff the adult education divisions of international organizations, national and regional governments, and independent foundations and development agencies.

While those who occupy these professional statuses and roles are clearly doing adult education, not all identify themselves as adult educators or, even when sharing this identity, see themselves as engaged in similar practice. The field is conceptually, theoretically, and pedagogically heterogeneous both within and among its many sectors. Role identity and performance differences based in organizational setting and population served are compounded by differences in fundamental aims and methods. One of the sharpest divides is between many in the “training and development” industry and those in academia and elsewhere who identify with “adult education” as a discipline, as a profession and, sometimes, as a social movement.

Training and development specialists tend to define their task as cultivating human resources and capital that can be used productively for the purposes of businesses, armed forces, government agencies, and other formal organizations. For training line employees, and all employees in technical

areas, they tend to emphasize teaching and learning methodologies that maximize the efficiency and effectiveness of individual acquisition of skill sets that can be easily and usefully applied to well-established performance objectives. For executive and managerial development, they tend to emphasize leadership, team, problem-solving, strategy, and change management competencies in the context of developing general organizational learning, effectiveness, and continuous quality improvement (Craig 1996).

Those who identify themselves as adult educators, on the other hand, tend to emphasize theories and methods designed to “facilitate” individual transformation and development. Variants of the facilitation model advocated by the adult education profession include the following: one perspective focuses on the special characteristics of learning in adulthood, and on “andragogy” as a new type of specifically adult teaching and learning distinct from pedagogy, as critical to successful adult education (Knowles 1980); another emphasizes adult life circumstances and experiences as key variables (Knox 1986); a third sees facilitating new critical and alternative thinking as the key to successful adult transformation (Brookfield 1987); and yet another sees adult education as active, consciousness-transforming engagement with social conditions to produce individual liberation and progressive social change (Coben, Kincheloe, and Cohen 1998). Common to all of the facilitation approaches is the ideal of adult education as a democratic, participatory process wherein adult educators facilitate active learning and critical reflection for which adult learners themselves assume a large measure of responsibility and direction.

Theoretical and ideological differences among adult education practitioners draw sharper lines than does their actual practice. Active learning techniques through which concepts, information, and skills are acquired in the course of real or simulated practical problem solving, strongly advocated by professional adult educators, have been embraced by the corporate training and development industry. Educational technology tools such as interactive, computer-based learning modules and Web-based tutorials, tools most robustly developed by the training industry, enable precisely the kind of independent, self-directed learning celebrated by the adult education profession. In

most of its settings and branches, adult educators of all types deploy the entire array of pedagogies from rote memorization to classic lecture-recitation to the creation of self-sustaining “learning communities.” Few central methodological tendencies demarcate distinct factions within the field, or the field itself from other types of education. Visible variants, such as the training and facilitation models, serve only partially to distinguish different segments of the field; and even these differences stem more from the particular histories, conditions, aims, and clients of those segments than from distinct disciplines, theories, or methods. Other methodological tendencies, such as widespread reliance on adult experience and self-direction as foundational for instructional design and delivery, reflect differences between adult and childhood learning more than a distinctly adult pedagogy (Merriam and Cafferella 1991).

Adult learning has several well-established characteristics that distinguish it from learning earlier in the life cycle: greater importance of clear practical relevance for learning, even of higher-order reasoning skills; the relatively rich stock of experience and knowledge to which adults relate new learning; “learner” or “student” as a role secondary to and embedded in adult familial, occupational and social roles; and the application of adult levels of responsibility and self-direction to the learning process. Indeed, at the level of practice, the learning characteristics of those being educated (i.e., adults) serve to distinguish adult education as a distinct field much more clearly than do distinctively adult educators, organizations, or methods.

DEVELOPMENT OF ADULT EDUCATION

The remarkable variety of contemporary adult education directly reflects complexity in the social environment and the necessities and rewards associated with mastering that complexity. Like schooling, adult education emerged and developed in response to the social, economic, political, cultural, and demographic forces that produced increasing structural and functional differentiation as one of the few clear trends in human social evolution. As social roles and practices proliferated, conveying the skills, knowledge, and disciplines that they embodied required the intentional and

organized teaching and learning that is education. As productivity, wealth, power, and status became more dependent on the mastery and application of knowledge, education to acquire it increasingly occupied the interest and resources of individuals and groups.

The long and discontinuous trajectory of increasing social complexity within and among human societies yielded very little formal and nonformal adult education before the advent of industrialism. Prior to the Neolithic revolution, education of any type was rare; informal socialization without conscious, systematic intent to train or study sufficed for most cultural transmission and role acquisition. Agrarian, state-organized societies, especially the early and late classical civilizations of the Middle East, Asia, and Europe, developed the first formal and nonformal schooling in response to the increasing complexity of knowledge, administration, social control, and production. This schooling was delivered by professional tutors and early versions of primary and secondary schools to educate the children of political, military, and religious aristocracies for their rulership roles; in schools and colleges to train bureaucratic and religious functionaries, professionals in law and medicine, and the elite in the liberal arts; and by nonformal systems of apprenticeship, such as the medieval guilds, for specialized crafts and trades. Although there are many examples of adults seeking informal education from adepts in the arts, religion, and natural philosophy, the educational systems of agrarian societies were devoted mostly to preparation for adult roles.

The widespread and diverse adult education of the present era emerged in response to the development of modern, urban, scientifically and technologically complex societies. Education became an important and dynamic institutional sector, one that gradually extended its territory from basic schooling for the literacy, numeracy, and general knowledge necessary to market relationships, industrial production, and democratic politics to adult continuing education for advanced professional workers in the theoretical and applied sciences. With some exceptions, the pattern of extension was from earlier to later stages of the life cycle (finally yielding education for learning that is “lifelong”) from the upper to the lower reaches of class and status hierarchies (yielding

“universal education”) and from informal education occurring in avocational and domestic contexts, to nonformal education conducted by voluntary organizations to increasingly institutionalized formal systems.

Prior to industrialization, informal and nonformal adult education was relatively widespread in Europe, especially in England and North America, and especially among the growing urban middle class of artisans and merchants. As this new middle class sought to acquire its share of the growing stock of culture, and as literacy spread and became intrinsic to social and economic participation, adults increasingly engaged in self-directed study (aided by a publishing explosion that included a growing number of “how-to” handbooks) participated in informal study groups, and established cultural institutes and lyceums that delivered public lectures and evening courses of study.

Systematic efforts to spread adult education to the working class and the general population emerged during the process of industrialization. Until the last decades of the nineteenth century, these were almost entirely voluntary efforts devoted to democratization, social amelioration, and social movement goals. In both Britain and the United States, mechanics’ institutes, some with libraries, museums, and laboratories, delivered education in applied science, taught mechanical skills, and conducted public lectures on contemporary issues. In Scandinavia, “folk high schools” performed similar functions. Religious groups conducted literacy campaigns among the new urban masses and established adult educational forums in organizations such as the Young Men’s Christian Association (YMCA). Women’s suffrage groups, labor unions, abolitionists, socialists, and many others developed educational programs both to develop their members and as an organizing tool. After 1860 and until World War I, efforts to popularize education among adults continued in various ways: in an extensive network of lyceums, rural and urban Chautauquas and settlement homes; in educational efforts to aid and acculturate immigrants to the burgeoning industrial cities; and in post-slavery self-improvement efforts of African Americans. These middle- and working-class adult education activities received considerable support and extension from the spread of public libraries.

In most societies, state support for and sponsorship of adult education has always been scant in comparison to that for schooling children and adolescents. Late nineteenth- and twentieth-century imperialism included modest adult educational efforts designed to selectively spread literacy and educate indigenous peoples as functionaries for colonial administrations. Some higher-level adult education of the type delivered by the mechanics’ and folk institutes received public funding, especially in Nordic societies where leisure time and adult continuing education were well provisioned by the state. With the Hatch Act of 1887 and enabling legislation in 1914, American land-grant universities were charged with developing “extension” services to deliver a wide range of educational and technical assistance to farmers and rural populations. The agricultural extension model later expanded to include technical training and assistance for industry, and night schools and continuing education for adults. Public funding for these developments was minimal; extension services beyond the land-grant mandate, to the present, have usually been expected to operate as fiscally self-supporting units.

Robust state support for adult education occurred only in the socialist societies that emerged after the Russian Revolution of 1917. Beginning with the mass literacy campaign initiated by the Bolsheviks, adult education was an important priority of the Soviet regime (Lee 1998). It established a large and wide-ranging formal adult continuing education system, with branches in virtually all institutional sectors of Soviet life. It was intended to foster ideological allegiance to the Soviet system, develop the Soviet workforce, spread socialist culture, and foster progress in sports and the arts. A nonformal, decentralized system of “people’s universities” paralleled and reinforced the formal system. After World War II, Soviet-style adult education was transplanted to most of its Eastern European satellites and, usually in severely truncated form, to the developing societies of Asia, Africa, and Latin America that followed the Soviet model. After the communist victory in 1949, China began its own mass literacy campaign for adults. Later it developed a near-universal system of “spare-time” and other adult schools that trained students for very specific political, economic, and cultural roles in the new society, and for political and ideological conformity to the tenets and goals

of the revolution. In the decade following 1966, China conducted one of the largest and most disastrous adult education programs in history. The Cultural Revolution spawned a severe and mandatory form of experiential learning that replaced much of higher education by sending professionals and officials with suspect class pedigrees, intellectuals, professors, and students into agricultural villages and factories to be reeducated by proletarian labor and incessant exposure to Mao-sanctioned communist propaganda.

In spite of the social control service to the dominant regime that it was designed to deliver, socialist adult education played a very significant role in the rapid industrialization and modernization of agrarian Russia and China. In the market societies of the West, the unplanned and longer-term realization of such development did not entail centralized efforts to transform adults for new roles. The systems of political and social control did not generally require the systematic and continuous indoctrination of adults. Thus, until the second half of the twentieth century, adult education in the West remained largely a function of individual and small group informal education, voluntary and philanthropic organizations, relatively small government efforts, specialty units of the system of formal schooling, and small training programs in proprietary schools and businesses.

CONTEMPORARY STRUCTURES AND PARTICIPATION

After 1950, adult education grew in scale and organization. The pattern of this growth involved a shift from adult education delivered by community-based organizations to that provided by formal educational institutions and the training industry. Demand for education among adults grew because of increasing rates of technological innovation, professional specialization, organizational complexity, knowledge intensiveness in goods-and-services production, and rising credential requirements for employment. Adults returned to secondary and postsecondary education in steadily increasing numbers. In the United States, the GI Bill sent the first large wave of these new students into colleges and universities after World War II (Olson 1974). In the 1960s and 1970s new or expanded units of formal education were organized to accommodate and recruit adult students in

both Europe and the United States: college adult degree programs, open universities, evening colleges, programs for accrediting experientially based adult learning, and government and school-district sponsored adult high school completion programs.

Higher education attendance among adults continued to accelerate in the 1980s and 1990s as a result of several factors: multiple stop-in, stop-out college career paths; rapid obsolescence of knowledge and associated multiple career changes throughout a lengthening cycle of life and work; increased requirements and rewards for specialized graduate, certificate, and technical education; and, most significantly, the large returning student population among Baby Boom adults. In turn, the growing market of adult students spawned new forms of higher education. In the 1990s, the for-profit, fully accredited University of Phoenix became the largest private university in the United States, with over 65,000 adult graduate and undergraduate students (Winston 1999). Phoenix provides a library that is entirely electronic, uses both branch campuses in strip malls and office buildings and Internet-delivered courses to provide education nationwide, and employs only forty-five full-time faculty and more than 4,500 adjuncts. Internationally, “mega-universities,” such as Britain’s Open University and China’s TV University—100,000 and 500,000 students respectively—deliver education to adults through diffuse networks of distance education technologies and part-time local mentors. Collectively, the new virtual (i.e. based entirely on the Internet), distance, for-profit, and mega-universities, all oriented primarily to adults, are beginning to significantly alter the structure and practice of higher education worldwide.

Training and development programs witnessed similar growth after World War II under the impact of a combination of forces. New technologies, especially those associated with information technology production and use, and increased rates of innovation, required education for entirely new skill sets and for continuous upgrading of existing knowledge. Increased job mobility required more new worker training. More intense, global economic competition and new understandings of the contribution of training to productivity and profitability led to greater training investments by firms, agencies, and individuals.

The growing volume of adult training is delivered in many forms and sectors of society and has important consequences. In the advanced industrial societies of Europe and Asia, training and development systems, usually involving employers, unions, and governments, provide training in a substantial majority of firms and to most workers (Lynch 1994). Yearly participation rates by both firms and individuals are highest in the European and Japanese systems and may be an important factor in their high rates of productivity growth. Even in the more diffuse U.S. system with lower participation, over 60 percent of adults between twenty-eight and fifty years of age had participated in some variety of part-time adult education or training by the early 1990s (Hight 1998). Workplace training alone became a \$60-billion a year industry with 53,000 providers (Martin 1998). Some firms supply most of their own training through another new institutional form of adult education, the "corporate university." With curricula ranging from basic employee orientation to the most advanced technical and business subjects, several of these universities are now fully accredited to grant baccalaureate and graduate degrees. As the U.S. military's reliance on technologically complex strategies, tactics, logistics and equipment grew, it became the largest single provider of training in the United States. Even with post-Cold War downsizing, the military's adult training activities remain significant contributors to labor-force development, especially in computer, electronics, and mechanical specialties (Barley 1998). Higher education institutions are also major training providers. Collectively, college and university adult continuing and professional education now rivals or surpasses the volume of military training (Gose 1999). Harvard serves over 60,000 adults each year in continuing education classes. New York University's School of Continuing and Professional Studies offers more than one hundred certificate programs and has revenues of over \$90-million a year. The involvement of universities in the expansion of training presents something of a paradox. In many instances, the new training complex is endowing its adult students with professional and industry certifications that are beginning to rival standard degrees as the credentials of both individual and employer choice. This training may also be working significant changes in the social structure. Considerable evidence suggests that a large

measure of the growing income inequality characteristic of advanced industrial societies is a function of technological change and associated wage premiums paid for workers with the kind of technical credentials and competencies that much of the new training is designed to deliver (Bassie 1999).

Contemporary developing societies of Africa, Asia, and Latin America contain all of the forms of adult education found in the West, as well as forms of popular adult education now only minimally present there. While virtually all of the less developed societies have succeeded in establishing systems of primary, secondary, and higher education for youth, participation rates vary widely among and within them. Some Latin American countries, for example, have higher college attendance rates than their European counterparts while many poor children never enter or complete primary school (Arnové et al. 1996). In such contexts, adult education is often bifurcated (Torres 1990). The poor are served by literacy programs, popular education efforts developed by local nongovernmental organizations, and the health and technical education programs of international agencies. Middle and upper classes participate in corporate training, government-sponsored adult higher education, and professional continuing education programs that are little different from and, in the case of training delivered distance education technologies and global firms, exactly the same as those found in the most advanced societies. However, under the impact of globalization, the distinctions among higher education, human resource training, and popular education are softening. There is a growing recognition among education professionals and policy makers that widespread and inclusive lifelong learning is a critical common good (Walters 1997).

Lifelong learning and adult education that is on a par with schooling are increasingly articulated goals of social policy. The United Nations concluded its fifth Conference on Adult Education in 1997 with a call for worldwide lifelong learning to promote social and economic development, empower women, support cultural diversity, and incorporate new information technologies. Adult education and training is now a central focus of the United Nations Education Scientific and Cultural Organization's (UNESCO) development policy, planning, and programs. The European Union

designated 1996 the “European Year of Lifelong Learning” and established the European Lifelong Learning Initiative to research, coordinate, and develop lifelong learning policies and programs throughout Europe. In 1997, the Commission for a Nation of Lifelong Learners, representing U.S. business, labor, government, and education interests, called for policies that would ensure equity of access to lifelong learning, optimize the use of new technologies, reorganize the education and training system into one providing comprehensive lifelong learning, and commit private and public resources sufficient to these ends. The federal administration established a yearly summit on lifelong learning to pursue implementation of these goals. Similar policy formation and advocacy is now widespread at the local level, and cities recognize the importance of lifelong learning to workforce development and urban economic viability in the new “knowledge economy.” It remains to be seen whether the new focus on adult education policy will result in the kind of resource deployment or accessible, comprehensive system for lifelong learning recommended by most analysis.

SOCIOLOGY OF ADULT EDUCATION

The sociology of education has traditionally focused on the processes, structures, and effects of schooling, with very little attention to adult education. Thus, there is no scholarly or applied field, no distinct body of theory or research that can be properly labeled “the sociology of adult education.” Expositions of a sociology of adult education that do exist tend to be general characterizations of the field in terms drawn from general sociological and schooling literature (e.g., Rubenson 1989; Jarvis 1985). Certainly much of this is applicable. Adult education presents many opportunities for sociological interpretation in terms of the functionalist, conflict, reproductive, or postmodernist educational models applied to schooling; in terms of adult education’s impact on social mobility, status attainment, and distributional equity; or in terms of its contribution to organizational effectiveness, social welfare, or economic development. The small body of sociological research in the area takes just such an approach, focusing on issues such as: the patterns and causes of adult enrollment in higher education (e.g., Jacobs and Stoner-Eby 1998); the consequences of women’s return to

higher education (e.g., Felmlee 1988); and the patterns of access to and provision of employer-provided training (e.g., Jacobs, Lukens, and Useem 1996). However, neither the extent nor the depth of sociological study in the area matches its potential importance.

Adult education is clearly no longer a social activity marginal to schooling. The information-technology revolution, the knowledge society, the learning organization, and the increasingly critical concern of individuals and organizations with the development and control of human and knowledge capital are representative of trends that are bringing adult education into the mainstream of social interest, analysis, and policy. Responses to these trends for which adult education is central include new and powerful forms of higher education, new determinants of the structure and process of social inequality, new bases for economic and social development, and new conceptions of the relationship of education to the human life cycle. Many opportunities for the application of sociological theory, research, and practice to adult education await realization.

JOHN HOUGHTON

ADULTHOOD

Becoming an adult is a life-cycle transition signified by multiple markers (Hogan and Astone 1986). These include the completion of education, the establishment of an independent residence, the attainment of economic self-sufficiency, marriage, parenthood, permission to vote and serve in the military, and the entry into full-time work. These multifaceted, objective markers of adult status, variability in the ages at which they occur, and differences in both preadult and adult roles, make the character of this transition variable across societies, historically relative, and subject to diverse interpretations and subjective meanings. Each new generation's experience of transition to adulthood is somewhat unique, dependent on the particular economic, political and social currents of the time (Mannheim 1952). Institutional contexts (cultural, social, educational, economic) determine the pathways through which the transition to adulthood occurs, as well as the competencies that enable successful adaptation to adult roles.

In addition to the formal markers of transition, there are clearly recognized prerogatives of adult status (e.g., smoking, alcohol use, and sexuality) that are widely frowned upon or legally prohibited when engaged in by minors. Youth's engagement in these "problem behaviors" can be attempts to affirm maturity, gain acceptance by peers, or to negotiate adult status (Jessor and Jessor 1977, p. 206; Maggs 1997). Finally, there are even more subtle, subjective indicators of adulthood—for example, the development of "adult-like" psychological orientations or the acquisition of an adult identity. Considering oneself as an adult may or may not coincide with the formal markers of transition.

There has been a trend in the United States and Western Europe toward earlier assumption of full adult civil rights (e.g., the age at which it is legal to vote or to marry without parental consent) from the age of twenty-one to eighteen (Coleman and Husen 1985). Youth must be age eighteen to vote in France, Germany, Great Britain, and the United States, but must be twenty to vote in Japan (The World Factbook 1998).

Within countries, legal restrictions on the age at which certain events can occur, signifying adulthood to a greater or lesser degree, vary depending

on the marker in question. For example, in the United States, a person has the right to vote and serve in the military at the age of eighteen, but must be twenty-one to purchase alcoholic beverages. At age sixteen, a young person can leave school and work in paid jobs without federal restriction on hours of work. (However, restrictions on work hours of sixteen and seventeen year olds exist in many states; see Committee on the Health and Safety Implications of Child Labor 1998). The legal age of marriage varies widely across U.S. states, from none to twenty-one (The World Factbook 1998), but the age of consent is sixteen to eighteen in most states (www.ageofconsent.com).

However, many eighteen, and even twenty-one year olds in the United States and other modern countries would not be socially recognized as “adults,” since they have not yet accomplished other key markers of transition. The law only sets minimum standards, and may have little relation to the age at which young people actually make the various transitions in question. Despite prohibitions on the use and purchase of alcohol until the age of twenty-one, “it is more normative to drink during adolescence than it is not to drink” (Maggs 1997, p. 349). The majority of young people in the United States stay in school beyond the age of sixteen; they graduate from high school and receive at least some postsecondary education. With the extension of formal education, contemporary youth in modern countries delay the acquisition of full-time employment, and remain economically dependent for longer periods of time. Moreover, the legal age of marriage hardly reflects the average age of first marriage. Since the 1950s, it has been increasing (from 20.3 for women and 22.8 for men in 1950 to 24.4 for women and 26.5 for men in 1992; Spain and Bianchi 1996).

HISTORICAL AND SOCIETAL VARIATION IN THE TRANSITION TO ADULTHOOD

Neither the timing nor the process of becoming adult are universalistic or biologically determined. Throughout Western history, there has been increasing differentiation of early life stages, postponement of entry to adulthood, and change in the status positions from which adulthood is launched (Klein 1990). Some scholars argue that in medieval times persons moved directly from a

period of infancy, when small size and limited strength precluded productive work, to adulthood, at which time younger persons began to work alongside their elders (Ariés 1962).

A new stage of childhood, between infancy and adulthood, arose with the emergence of schools. As economic production shifted from agriculture to trade and industry, persons increasingly entered adulthood after a stage of apprenticeship or “child labor.” By the beginning of the twentieth century, with schooling extended and child labor curtailed, adolescence gained recognition as the life stage preceding adulthood (Hall 1904). The adolescent, though at the peak of most biological and physiological capacities, remained free of adult responsibilities.

With more than 60 percent of contemporary young people obtaining some postsecondary education (Halperin 1998), a new phase of “youth” or “postadolescence” has emerged, allowing youth in their mid-to-late twenties, and even older youth, to extend the preadult “moratorium” of continued exploration. This youth phase is characterized by limited autonomy but continued economic dependence and concern about the establishment of adult identity (Keniston 1970; Coleman and Husen 1985; Buchmann 1989).

Various forms of independent residence are now common in the United States before marriage (Goldscheider and Goldscheider 1993). Youth’s residence in dormitories (or, less commonly, military barracks) allows independence from familial monitoring, while a formal institution assumes some control (Klein 1990). Even greater freedom from supervision occurs when young people, still economically dependent on parents, live in their own apartments. For contemporary young people in the United States who enter the labor force after high school, a continuing period of “moratorium” (Osterman 1989) lasts several years. During this time, youth hold jobs in the secondary sector of the economy to satisfy immediate consumption needs. They experience high unemployment and job instability (Borman 1991). At the same time, employers express preference for low-wage workers who do not require fringe benefits and are not likely to unionize. When filling adultlike “primary” jobs, such employers seek evidence of stability or “settling down.”

But youth “irresponsibility” and employer reluctance to offer desirable jobs to youthful recruits are not universal in modern societies. Instead, they derive from particular institutional arrangements. In the United States, the absence of clear channels of mobility from education to the occupational sector, and youths’ lack of occupation-specific educational credentials, fosters a prolonged period of trial and instability in the early career (Kerckhoff 1996). In contrast, the highly developed institution of apprenticeship in Germany implies the full acceptance of young workers as adults, and encourages employers to invest in their human capital (Hamilton 1990, 1999; Mortimer and Kruger forthcoming).

The onset of adulthood has thus been delayed through historical time by the emergence of successive preadult life stages. This historical progression of preadult phases refers to the normative, legitimate pathways to adulthood. A highly problematic, but increasingly prevalent way station in the transition is supervision by the criminal justice system; indeed, it is estimated that a full ten percent of U.S. males, aged twenty to twenty-nine, is in jail, in prison, on parole, or on probation on any one day (Halperin 1998).

Obstacles to “growing up” are sometimes presented when assuming adultlike statuses threatens adult interests and values. The extension of required schooling was motivated, at least in part, by a desire to curb competition for jobs with older workers (Osterman 1980). “Warehousing” the young in secondary and tertiary education has reduced adolescent unemployment during times of economic contraction; earlier movement out of school into the workforce is promoted by economic expansion (Shanahan et al. 1998).

Societal wealth may also encourage postponement of adulthood and the extension of “youthful” values and life styles to older ages. Japanese young people, traditionally oriented to the extended family, obedience, educational achievement, and hard work, seem to be becoming more rebellious and interested in immediate enjoyment as delayed gratification becomes more difficult to sustain in a more affluent society (Connor and De Vos 1989; White 1993).

Although age-related increases from birth through the second decade of life—in strength,

cognitive capacity, and autonomy (Shanahan, this volume)—are probably recognized in some form in all human societies, the social construction of the early life course clearly reflects societal diversity and institutional change. Processes of modernization, encompassing changes in education, the labor force, and the emergence of the welfare state, produce age standardization of the early life course (Shanahan forthcoming). For example, the social differentiation of children and adolescents was less pronounced in the educational system in nineteenth- and early twentieth-century America than in the contemporary period (Graff 1995). Secondary school students have become increasingly homogeneous in age; this more pronounced age grading promotes “adolescent” life styles and orientations. Similarly, the extension of postsecondary schooling promotes the perpetuation of “youth.” However, during the past century in the United States the changes marking the transition have taken place first in quicker, and then in more lengthy, succession (Shanahan forthcoming; Modell et al. 1976).

As a result of technological and economic change and increasing educational requirements (Hogan and Mochizuki 1988; Arnett and Taber 1994; Côté and Allahaar 1994), as well as family instability (Buchmann 1989), the entry to adulthood has been characterized as increasingly extended, diversified, individualized (Buchmann 1989; Shanahan forthcoming), “disorderly” (Rindfuss et al. 1987), variable (Shanahan forthcoming), and less well defined (Buchmann 1989). For example, while the acquisition of full-time work is widely considered to mark the transition to adulthood, distinctions between “youth work” and “adult work” blur as young people increasingly combine, and alternate, student and occupational roles, in various forms and levels of intensity through a lengthy period of adolescence and youth (Mortimer and Johnson 1998, 1999; Mortimer et al. 1999; Morris and Bernhardt 1998; Arum and Hout 1998). Markers of family formation likewise become less clear as young people move in and out of cohabiting and marital unions (Spain and Bianchi 1996).

Orderly sequences of transition events have become less common (Shanahan forthcoming). For example, many youth return to their parental homes after leaving for college or other destinations (Cooney 1994). Divergence from normative

timing or sequencing sometimes generates public alarm, becomes defined as a social problem, and leads to difficulties for the young people whose lives exhibit such patterns. Whereas parenting is becoming more common outside of marriage (approximately one-third of births in the United States occur to unmarried women; Spain and Bianchi 1996), it is widely thought that nonmarital birth in the teenage years marks a too-early transition to adulthood. Adolescent parenting is linked to school dropout, difficulties in the job market, restricted income and marital instability (Furstenberg, et al. 1987). (However, Furstenberg and colleagues' 1987 study of a panel of black adolescent mothers sixteen to seventeen years after their children were born actually showed considerable diversity in maternal socioeconomic outcomes.)

Still, assertions that the transition to adulthood is especially indeterminate, or becoming more difficult, in contemporary Western societies remain controversial. Graff (1995) documents the extended and equivocal nature of this transition in eighteenth- to twentieth-century America. Foner and Kertzer (1978) noted ambiguity even in premodern contexts, where elders and the rising adult generation often struggled over the timing of age-set transitions and corresponding transfers of power, wealth, and privilege. It is certain, however, that the transition to adulthood assumes a quite different character historically and across national contexts, and may be more clear in some than in others.

THE SUBJECTIVE TRANSITION TO ADULTHOOD

A series of psychological, or subjective, changes are expected to occur as young people move into adulthood. The adolescent is said to be oriented to fun, sports, popular music, and peers; receptive to change; and ready to experiment with alternative identities and sometimes, mood-altering substances (Hall 1904). Youth are encouraged to enjoy themselves as they continue to explore their interests and potentials. Osterman (1989) describes out-of-school employed youth as lacking career orientation; instead, they emphasize peer relationships, travel, adventure, and short-term jobs.

Young adults, in contrast, are expected to relinquish such dependent, playful, experimental,

carefree, and even reckless stances of adolescence and youth, so that they can address the "serious business" of life. Those who become financially and emotionally independent, productive, hard-working, and responsible are considered "adult" (Klein 1990). Moreover, they themselves are expected to "feel like" adults (Aronson 1998).

The concept of "maturity" is integrally tied to adulthood. Most generally, it refers to the psychological competencies deemed necessary to adapt to the roles and responsibilities of adulthood (Galambos and Ehrenberg 1997). For Greenberger and Sorenson (1974), the term signifies autonomy, the capacity to make decisions on the basis of life goals and to function independently in work and other spheres; skills in communicating and relating to others; and social responsibility, the motivation and ability to contribute to the wider society. Greenberger and Steinberg (1986) worry that teenagers who have paid jobs become "pseudomature," as they take on adult identities and behavioral prerogatives without being psychologically equipped for them. Such pseudomaturity can precipitate disengagement from more beneficial, albeit dependent and childlike, roles (especially the role of student). Bachman and Schulenberg (1993) similarly note syndromes of adultlike roles, activities, and identities that promote premature entry to adult family and occupational roles.

But like the objective markers of transition, beliefs about the specific attributes that define maturity, and how these competencies may be fostered and recognized, vary across time and social space (Burton et al. 1996). The extent to which youth feel that they possess such capacities, and the likelihood that adults will attribute these qualities to them, may be highly variable across social situations. Furthermore, in postmaterialist societies and especially in the more highly educated and affluent social niches within them, orientations promoting success in the economic sphere may recede in importance as criteria of maturity, in favor of continued "youthful" emphases on freedom and self-actualization throughout adulthood (Vinken and Ester 1992; Inglehart 1990).

Meanings and interpretations of the various transitions signifying acquisition of adult status, such as those linked to family formation (Modell

1989), also exhibit historical and cross-societal variability. In contemporary modern societies, structural differences in the link between school and work (Shavit and Muller 1998) are reflected in the phenomenal experience of the transition into the labor force. Variation in the institutional connection between school and work in the United States and Germany influences the ages at which young people begin to actively prepare for the highly consequential decisions (especially regarding postsecondary schooling and career) that lie ahead of them, and the degree of stress and uncertainty they encounter in doing so (Mortimer and Kruger forthcoming).

It is widely believed that age norms, specifying the timing and order of key life events, influence the subjective passage, as well as the objective trajectory, through the life course (Neugarten et al. 1965; Neugarten and Danan 1973). "On-time" transitions are "culturally prepared" by socialization and institutional arrangements (Model 1989, p. 13), and are thereby rendered psychologically salutary. Those who are "off-time," too early or too late, are thought to be the target of negative social sanctions and to experience psychological strain (Rossi 1980). National polls on the ideal age to marry and become a parent yield age distributions that cluster around the modal ages at which these changes generally occur. But consistency in expectations, "ideal ages," or even in the actual timing of transitions, may have more to do with institutionally determined pathways and other structural constraints than personal norms.

The notion that norms control timing behavior is contradicted by evidence that age preferences ("ideal" ages for marker events) lag behind behavioral change (Modell 1980; McLaughlin et al. 1988, ch. 9). Marini (1984) notes that there is little direct evidence regarding the existence or content of social norms governing the timing of life events. She asserts that if norms (and associated sanctions) do exist, they probably vary by population subgroup (e.g., by socioeconomic status, gender, and ethnicity), and encompass such a wide range of acceptable ages that they lack causal import. In one study, college students' expectations about the ages at which they would most likely traverse various markers of transition were found to be more variable than those of high school students (Greene 1990).

Older ages of marriage and finishing school, coupled with the increasing reversibility of status changes (serial marriages and cohabiting unions, adult education, etc.) could erode age norms, to the extent that they do exist, since such passages are "no longer viewed in a linear way as transitions passed at a given point and left behind permanently" (Arnett 1997, p. 20). Historically, as objective markers of adulthood have become increasingly variable in their timing and sequencing, age norms may have lost whatever force they once had. But in fact, we do not know whether the failure to make particular transitions at an age when one's contemporaries have mostly done so engenders a subjective sense of being "too early" or "too late" and creates stress, either for earlier cohorts or for contemporary young people.

Arnett (1997) found that youth themselves were more likely to choose psychological traits indicative of individualism and responsibility as necessary for a person to be considered an adult; as criteria for adult status, youth reject role transitions or "objective markers" of adulthood, such as finishing school, marriage, or parenthood. Rituals, such as marriage and graduation, have traditionally allowed public recognition of successful passage to adulthood. If such objective markers of transition have less psychological salience than in the past, they may be less important in signifying and reinforcing adult status.

However, in Arnett's study, two such transitions were endorsed by the majority: living outside the parental household and becoming financially independent of parents. These linked changes, signifying autonomy from parents, may have important symbolic meaning for young people as they contemplate becoming adults. So too, three-fourths of the participants endorsed "decide on personal beliefs and values independently of parents or other influences" (p. 11) as criteria of adulthood.

Consistent with Arnett's research, there is apparently no clear correspondence between particular objective markers (e.g. graduating from college, beginning a full-time job) and young people's subjective identification of themselves as "adults." Aronson (1999b) found that some contemporary young women in their mid-twenties do not "feel like" adults, even when occupying roles

widely considered to be indicative of adulthood. Interviews revealed a great deal of ambiguity about adult identity, as well as career uncertainty, despite having already graduated from college and begun full-time work linked to postsecondary areas of study.

Asynchronies in the age-grading systems of different societal institutions generate status inconsistencies (Buchmann 1989) with important psychological implications. If adultlike identities are confirmed in some contexts, such as the workplace, but not in others, such as the family, this discrepancy could produce strain. Moreover, the "loosening" of age-grading and structured sequencing in transitional activities decreases the ability to predict the future from current circumstances (Buchmann 1989), and may thereby engender both stressful situations and depressive reactions (Seligman 1988).

It is widely believed that adolescence and youth are stressful life stages, and that problems diminish with successful acquisition of adult roles (Modell et al. 1976). Consistent with this supposition, youth have been found to exhibit less depressed mood from late adolescence to early adulthood, as they move from high school into postsecondary education and, especially, into full-time work roles (Gore et al. 1997). Moreover, there is evidence that men's self-perceptions of personal well-being and competence decline during college, but rise during the following decade (Mortimer et al. 1982).

However, women's morale may follow a less sanguine trajectory from adolescence through midlife (Cohler et al. 1995). Contemporary women are more likely than those in the historical past to take on multiple and conflicting roles. Difficulties in balancing work and family may be particularly acute and stressful during the transition to adulthood (Aronson 1999a), as increasing numbers of young women attempt to balance the conflicting demands of single motherhood, work, and postsecondary education.

Though the literature tends to focus on problematic outcomes of historical change and the loosening of age-graded social roles, greater diversity in the sequencing and combination of roles (schooling and work, parenting and employment) have promoted more diversified, and autonomous,

courses of action. Indeed, the allowance of more diverse sequences of transitions enables some youth to escape from dissatisfying circumstances in adolescence, for example, by leaving home (Cooney and Mortimer 1999).

The greater individualization and lengthening of the adult transition and early life course in recent times may increase the potential for freedom, and the effective exercise of choice, as well as stress. The extension of formal education allows more time for the exploration of vocational and other life-style alternatives (Maggs 1997). Although change in occupational choice in the years after high school (Rindfuss et al. 1990) may be seen as indicative of a kind of "floundering" and instability, it also may reflect youth's increasing capacity to assess alternatives before making a firm vocational commitment. Modell's (1989) social history of the transition to adulthood in twentieth-century America finds youth increasingly taking charge of their heterosexual relationships and the formation of new families, becoming ever freer of adult surveillance and control. Aronson (1998) found that contemporary young women appreciate their life-course flexibility (Aronson 1998).

THE TRANSITION TO ADULTHOOD AS A CRITICAL PERIOD OF HUMAN DEVELOPMENT

The transition to adulthood is a highly formative period for the crystallization of psychological orientations relating to work, leisure (Inglehart 1990), and politics (Glenn 1980). Alwin and colleagues' (1991) study of a panel of Bennington college women from the 1930s to the 1980s reports extraordinary persistence of political attitudes formed while in college over an approximately fifty-year period (a stability coefficient of .781). Work orientations also become more stable following early adulthood (Lorence and Mortimer 1985; Mortimer et al. 1988). Three explanations have been put forward to account for this pattern: The first implicates the environment; the second, features of the person; the third combines both elements. According to the first line of reasoning, the relatively dense spacing of major life events during the transition to adulthood generates external pressures to form new attitudes or to change previous

views (Glenn 1980). While similar events can occur later in life (e.g., a job or career change, remarriage, or entry into an adult education program), they are usually spaced more widely and are like those experienced previously, rather than wholly new circumstances requiring adaptation. Similarly, experiences at work generally assume greater constancy after an initial period of job instability (Osterman 1980). Primary relationships that provide support for attitudes are often in flux during the transition to adulthood; thereafter, stable primary groups may provide continuing support for previously crystallized attitudinal positions (Sears 1981; Backman 1981; Alwin et al. 1991). According to this perspective, there may be continuing capacity to change throughout life (Baltes et al. 1980), but if environments become more stable after the adult transition, there will be less impetus for such change (Moss and Susman 1980).

A second explanation links the “aging stability” pattern to intrapersonal processes that increasingly support the maintenance of existing personality traits, and resistance to change. Mannheim’s (1952) classic concept of generation implies that the young are especially receptive to influences generated by the key historical changes of their time (economic upheaval, war, or political revolution). Analysis of data from the European Values Survey shows that younger cohorts are less religiously traditional, are more sexually and morally permissive, and value personal development more highly than older cohorts (Vinken and Ester 1992).

Alwin and colleagues (1991) find evidence for a “generational/persistence model,” which similarly combines notions of vulnerability in youth and persistence thereafter. Before role and character identities are formed, the person may be quite malleable. However, preserving a consistent, stable sense of self is a major motivational goal (Rosenberg 1979); and once self-identities are linked to key attitudes and values, the person’s self may become inextricably tied to those views (Sears 1981). Moreover, feelings of dissonance (Festinger 1957) arise when attitudes and beliefs that provide a sense of understanding are threatened (Glenn 1980). Consistent with the notion that young adults may be more ready to change, occupational experiences (i.e., related to autonomy) have stronger influences on the work orientations of younger

workers (ages sixteen to twenty-nine) than of those who are older (Lorence and Mortimer 1985; Mortimer et al. 1988).

According to a third point of view, an interaction between the young person and the environment fosters a process of “accentuation” of preexisting traits. While early experiences provide initial impetus for personal development, attitudes and values formed in childhood or adolescence are later strengthened through the individual’s selection, production, and/or maintenance of environmental circumstances that support earlier dispositions. According to this view, youth making the transition to adulthood select and/or mold their environments (Lerner and Busch-Rossnagel 1981) often so as to maintain (or to reinforce) initial psychological states. This process typically results in an “increase in emphasis of already prominent characteristics during social transitions in the life course” (Elder and Caspi 1990, p. 218; see also Elder and O’Rand 1995).

Such processes of accentuation take many forms. For example, students choosing particular college majors become increasingly similar in interests and values over time (Feldman and Weiler 1976). Mortimer and colleagues’ (1986) study of a panel of young men showed that competence measured in the senior year of college predicted work autonomy ten years later, which in turn, fostered an increasing sense of competence. Similarly, intrinsic, extrinsic and people-oriented values prior to adult entry to the workforce led to the selection of occupational experiences that served to strengthen these value preferences. A similar pattern was found among high school students seeking part-time jobs; intrinsic values predicted opportunities to acquire skills and to help others at work, and further opportunities for skill development strengthened intrinsic values (Mortimer et al. 1996). Alwin and colleagues’ (1991) follow-up study of women who attended Bennington College in the 1930s indicated that the choice of associates and the formation of supportive reference groups—e.g., spouses, friends, and children—played a substantial part in maintaining the women’s political values.

Elder’s longitudinal study of young people growing up during the Great Depression amassed considerable evidence that successful encounters

with problems in adolescence can build confidence and resources that promote effective coping with events later in life, fostering personality continuity (Elder 1974; Elder et al. 1984). Thus, early achievements and difficulties can give rise to “spiralling” success and failure. For members of the Oakland cohort, early economic deprivation provided opportunity to help the family in a time of crisis; the consequent increase in self-efficacy, motivation, and capacity to mobilize effort fostered adult work and family security. Elder and Caspi (1990) similarly find that adolescents with more resilient personalities reacted more positively as young adults to combat in World War II. Such reciprocities are also evident among women in the National Longitudinal Survey of Youth; early self-esteem predicted educational attainment and more substantively complex employment, which, in turn, further enhanced their sense of worth (Menahgan 1997).

In contrast, negative early events may set in motion processes that accentuate problems. Early failures can produce psychological reactions and cognitive attributes that perpetuate poor outcomes. There is evidence from several studies that early unemployment fosters distress, self-blame, and negative orientations toward work in general, engendering continued failure in the labor market (Mortimer 1994). Traumatic war experiences in early adulthood can threaten marriage and thereby reinforce a cycle of irritability (Elder and Caspi 1990, p. 235).

Whereas sociologists emphasize the social determination of early adult outcomes, and social psychologists have noted enduring personality traits that influence the process of transition to adulthood, changes in both socioeconomic and personal trajectories do occur, frequently at times of life-course transition. Change can occur as a result of “fortuitous events” that intervene in the developmental process rather than reinforcing patterns of preadult behavior (Elder and Caspi 1988, p. 102). For example, marriage to a nondeviant spouse, the quality of a first marriage, or of economic self-sufficiency from a full-time job may lead to change in direction of a previously “disorderly” or otherwise problematic early life course (Rutter and Quinton 1984; Sampson and Laub 1993; Gore et al. 1997). “Identity transformations” (Wells and

Stryker 1988) can also result when “turning points” (Strauss 1959) in personal history intersect with a rapidly changing historical context to alter a previously held worldview (Aronson forthcoming).

FACTORS INFLUENCING SUCCESSFUL ACQUISITION AND ADAPTATION TO ADULT ROLES

Social scientists are giving increasing attention to processes of individual agency, including goal setting, choice among alternative lines of action, and the mobilization of effort, which influence trajectories of attainment throughout the life course. Early orientations toward, and expectancies about, competent action are critical for later adult success (Mainquist and Eichorn 1989). Jordaan and Super (1974) report that adolescents’ planfulness, responsibility, and future orientation predicted their level of occupational attainment at the age of twenty-five. The more explorative adolescents, who were actively engaging of the environment, had more positive early adult outcomes. “Planful competence,” denoting ambition, productivity, and dependability in adolescence, has also been linked to men’s adult occupational status and marital stability (Clausen 1991, 1993). These attributes imply planfulness, delayed gratification, an intellectual orientation, and a sense of control over goal attainment. Planfully competent adolescents actively explore future options and opportunities, and select those that match their developing proclivities and potentialities. This process gives rise to a better fit between the person and the environment, fostering satisfaction and stability in adult social roles (see Shanahan and Elder 1999).

However, the institutional structure, and the individual’s place within hierarchies establishing unequal resources and opportunities, may either facilitate or limit the effective exercise of agency. Shanahan (forthcoming) speaks of “limited strategic action,” resulting from “the dynamic tension between selection and assignment.” Because the relation between courses of study and higher educational outcomes is often obscure, students may have limited ability to alter negative educational trajectories (Dornbusch 1994). The consequences of planfulness may also be historically variable, depending on the degree of opportunity available

to a cohort at critical phases of its life course (Shanahan and Elder 1999).

As the process of acquiring adultlike markers of transition becomes more complex and ambiguous, a wide variety of psychological orientations—including aspirations, values, goals, life plans, self-concepts, and identities—may become increasingly determinative of subsequent outcomes (Mortimer 1996). In fact, both general (Bandura 1996) and facet-specific (Grabowski et al. 1998) dimensions of efficacy are predictive of goal-directed behavior and achievement. Fact-specific orientations include expectations relevant to particular spheres, such as school and work.

The social structural conditions and circumstances that enable some young people to continue to pursue their goals despite obstacles, and others to relinquish them, deserve further study. However, in some circumstances, more favorable outcomes will accrue to those who are more flexible. Kerckhoff and Bell (1988) find that the achievement of postsecondary educational credentials in the form of some vocational certificates yield higher earnings than attaining only some college. The relative merit of tenacious goal pursuit (e.g. a baccalaureate degree) versus the substitution of new, more realistic, alternative objectives (“assimilation” and “accommodation” in Brandtstadter’s [1998] terminology) may be determined by structurally constrained resources as well as opportunities.

The character and outcomes of the transition to adulthood are clearly dependent on diverse resources that are differentially distributed among young people (Shanahan forthcoming). There are social class differences in the age at which adult roles are acquired, in the character of marking events, and even in the availability of opportunities to assume adult-status positions (Meijers 1992). The socioeconomic background of the family of origin sets the level of available resources, fostering intergenerational continuity in attainment (Blau and Duncan 1967; Sewell and Hauser 1976; Kerckhoff 1995). Relative advantage or disadvantage can derive from placement in familial and other networks that provide information (Granovetter 1974; Osterman 1989), for example, about higher educational opportunities, jobs (Lin 1992), or even prospective marital partners. A lack of resources, as well as instability (McLanahan and Sandefur 1994),

in the family of origin is associated with disadvantaged transitions to adulthood. Moreover, structural sources of cumulative advantage, such as advantageous placement in ability groups, high school tracks or secondary schools, increase the likelihood of higher education (Kerckhoff 1993; Garmoran 1996).

Personal resources facilitating the educational and occupational attainment process have been linked to social class background. Adolescents’ educational and occupational aspirations, and their educational attainments, are important mediators of the effects of occupational origins on destinations (Featherman 1980; Featherman and Spenner 1988). The transmission of self-directed values may also constitute a mechanism through which socioeconomic status is perpetuated across generations (Kohn and Schooler 1983; Kohn et al. 1986). Close father-son relationships in late adolescence engender continuity in paternal occupations and values, and sons’ work values and early adult-occupational destinations (Mortimer and Kumka 1982; Ryu and Mortimer 1996). Parents of higher socioeconomic level typically engage in more supportive child-rearing behavior (Gecas 1979), which fosters the development of personality traits such as competence, work involvement, and positive work values, that facilitate early adult socioeconomic attainments (Mortimer et al. 1986).

Gender differences in future orientations can foster differences in achievement. For example, if young women view their futures as contingent on the needs of future spouses, children, and others, this will diminish their propensity to make firm plans (Hagestad 1992), thereby diminishing their attainment. Despite dramatic changes in adult women’s employment (McLaughlin et al. 1988; Moen 1992), and in contrast to young men’s occupational aspirations, many young women are “talking career but thinking job” (Machung 1989, pp. 52–53).

Geissler and Kruger (1992) have identified different patterns of contemporary “biographical continuity” among young German women, each having important implications for career achievement. Traditionally-oriented women expect to have limited labor force participation and to be economically dependent on a husband. Career-oriented young women emphasize the acquisition of professional qualifications and delay marriage. Still

others are actively concerned with both work and family spheres. Such divergence in future orientations and planning influences the intensity of striving for achievement and attainment during the transition to adulthood.

Moreover, to the extent that young women are aware of the difficulties adult women face, resulting from employer discrimination and the unequal division of family work, this would likely depress expectations for labor market success. Ambivalence about work could exacerbate the detrimental consequences of other psychological differences (relative to males) for socioeconomic attainment, such as lower self-efficacy, lower self-esteem, and higher levels of depressive affect (Simmons and Blyth 1987; Gecas 1989; Finch et al. 1991; Shanahan et al. 1991; Mortimer 1994). It is therefore not surprising that although women have narrowed the historical gap in educational attainment (McLaughlin et al. 1988), they often get “diverted” from their initial plans, emphasizing romance over academics (Holland and Eisenhart 1990). For today’s women, taking on adult work and family roles is more likely than for men to result in the termination of schooling (Pallas 1993).

If the family is an important institutional context for the acquisition of economic and other resources for the adult transition, family poverty or disintegration may be expected to have negative consequences. Experiences in youth may thus set in motion a train of events that have a profound impact on the early life course. Disruption and single parenthood in the family of origin, and the economic loss and emotional turmoil that frequently ensue, may jeopardize parental investment in children and youth. However, Coleman (1994) argues that declining investments in the next generation may occur even in more favorable and affluent circumstances. As the functions of the family are transferred to other agencies in welfare states (e.g., as the government takes over education, welfare, support of the aged, and other functions), there is a declining economic dependence of family members on one another. As the multigenerational organization and functions of the family weaken, parental motivation to invest attention, time, and effort in the younger generation may also decrease throughout the population.

However, Shanahan (forthcoming) speaks of “knifing off” experiences during the transition

to adulthood, which can enable some youth to escape from poverty, familial conflict, stigmatization, and other debilitating circumstances of their childhood and teen years. For example, service in the military enabled many men from disadvantaged backgrounds to extricate themselves from the stressful circumstances of their families, mature psychologically, and therefore be in a better position to take advantage of educational benefits for veterans after World War II (Elder and Caspi 1990).

The availability of opportunities for anticipatory socialization or practice of adult roles may also affect adaptation to them. Contemporary youth spend much of their time in schools, cut off from meaningful contact with adult workers (excepting their teachers). Some have expressed concern that this isolation from adult work settings reduces opportunities for career exploration and encourages identification with the youth subculture (Panel on Youth 1974). Many parents encourage adolescent children to work, believing that this experience will help them to become responsible and independent, to learn to handle money, and to effectively manage their time (Phillips and Sandstrom 1990). However, “youth jobs” are quite different from adult work, involving relatively simple tasks and little expectation of continuity.

The impacts of part-time employment during adolescence for the transition to adulthood is the subject of much controversy (Committee on the Health and Safety Implications of Child Labor 1998, ch. 4). While the full impact of employment in adolescence is not known, there is evidence that increasing investment in paid work (as indicated by the number of hours spent working per week) is associated with reduced educational attainment (Marsh 1991; Chaplin and Hannaway 1996; Carr et al. 1996). However, several studies have shown that employment during high school also predicts more stable work histories and higher earnings in the years immediately following (Mortimer and Finch 1986; Marsh 1991; Ruhm 1995, 1997; Mortimer and Johnson 1998). Stern and Nakata (1989), using data from noncollege youth in the National Longitudinal Survey of Youth, report that more complex work activity in adolescence is associated with lower incidence of unemployment and higher earnings three years after high school.

The meaning of adolescent work also influences subsequent educational and occupational

outcomes. For example, employment has been found to have a positive effect on high school students' grades when the workers are saving their earnings to go to college (Marsh 1991; Ruscoe et al. 1996). Consistently, youth who effectively balance their part-time jobs with school, working near continuously during high school but restricting the intensity of their employment to twenty hours a week or fewer, were found to have high early-achievement orientations and obtained more months of post-secondary education (Mortimer and Johnson 1998).

There is further evidence that the quality of adolescent work experience matters for psychological outcomes that are likely to influence adult attainment (Mortimer and Finch 1996). For example, adolescent boys who felt that they were obtaining useful skills and who perceived opportunities for advancement in their jobs exhibited increased mastery (internal control) over time; girls who thought that they were being paid well for their work manifested increasing levels of self-efficacy (Finch et al. 1991). Exposure to job stressors, in contrast, heightened depressive affect (Shanahan et al. 1991).

For the most disadvantaged segments of society there is concern that poor educational opportunities and a rapidly deteriorating economic base in the inner cities preclude access to youth jobs as well as to viable adult work roles (Wilson 1987), irrespective of personal efficacy, ambition, or other traits. The shift from an industrial- to a service-based economy has lessened the availability of entry-level employment in manufacturing. Economic and technological change has created a class of "hard-core unemployed"; those whose limited education and skills place them at a severe disadvantage in the labor market (Lichter 1988; Halperin 1998). Black males' lack of stable employment in U.S. inner cities limits their ability to assume the adult family role (as male provider) and fosters the increasing prevalence and legitimacy of female-headed families.

Research on African-American adolescents suggests that the transition to adulthood may differ significantly from that of non-minority teens. Ogbu (1989) implicates beliefs about success as critical to understanding the paradox of high aspirations among black adolescents and low subsequent

achievement. The "folk culture of success," fostered by a history of discrimination and reinforced by everyday experience (e.g., the observation of black career ceilings, inflated job qualifications, housing discrimination, and poor occupational achievement despite success in school), convinces some young blacks that desired occupational outcomes will not be assured by educational attainment. Given the belief that external forces controlled by whites determine success, alternative strategies for achievement may be endorsed—hustling, collective action, or dependency on a more powerful white person. These, in turn, may diminish the effort in school that is necessary to obtain good grades and educational credentials.

In the context of urban poverty and violence, youth expectations for a truncated life expectancy (an "accelerated life course"), may lessen the salience of adolescence as a distinct life stage (Burton et al. 1996). With few employment and educational opportunities available, these youth often focus on alternative positive markers of adulthood, such as becoming a parent, obtaining material goods, or becoming involved in religious activities. Under such conditions, even a menial job can engender and reinforce "mainstream" identities and "possible selves" as economically productive working adults (Newman 1996). However, structural opportunities pervasively influence achievement orientations and outcomes throughout the social class hierarchy; such processes are clearly not limited to any particular societal stratum (Kerckhoff 1995).

Supportive families and other social bonds are predictive of successful adjustment in the face of poverty and other disadvantages (Ensminger and Juon 1998). Families who are successful in these circumstances place great emphasis on connecting their adolescent children with persons and agencies outside the immediate household, in their neighborhoods and beyond, thereby enhancing their social networks and social capital, invaluable resources in the transition to adulthood (Furstenberg et al. 1999; Sullivan 1989).

In summary, becoming an adult involves changes in objective status positions and in subjective orientations. The transition to adulthood has changed through historical time as a result of economic, political, and social trends. Contemporary young people face increasingly extended and

individualized paths in the timing and sequencing of their movement into adult roles. The transition to adulthood is found to be a critical period for the crystallization of key orientations and values. Adult status placement and adjustment are influenced by socioeconomic background and poverty, gender, early employment experiences, and psychological resources.

The multiplicity of transition markers, the variety of macrostructural and personal influences, and the little-studied subjective component give rise to important challenges and complexities in the study of this phase of life.

PAMELA ARONSON

AFFECT CONTROL THEORY AND IMPRESSION FORMATION

Sociologist Erving Goffman (1969) argued that people conduct themselves so as to generate impressions that maintain the identities, or "faces," that they have in social situations. Human action—aside from accomplishing tasks—functions expressively in reflecting actors' social positions and in preserving social order. Affect control theory (Heise 1979; Smith-Lovin and Heise 1988; MacKinnon 1994) continues Goffman's thesis, providing a mathematized and empirically grounded model for explaining and predicting expressive aspects of action.

AFFECTIVE MEANING

Cross-cultural research among people speaking diverse languages in more than twenty-five nations around the world (Osgood, May, and Miron 1975) revealed that any person, behavior, object, setting, or property of persons evokes an affective response consisting of three components. One component consists of approval or disapproval of the entity—an evaluation based on morality (good versus bad), aesthetics (beautiful versus ugly), functionality (useful versus useless), hedonism (pleasant versus unpleasant), or some other criterion. Whatever the primary basis of evaluation, it tends to generalize to other bases, so, for example, something that is useful tends also to seem good, beautiful, and pleasant.

Another component of affective responses is a potency assessment made in terms of physical proportions (large versus small, deep versus shallow), strength (strong versus weak), influence (powerful versus powerless), or other criteria. Again, judgments on the basis of one criterion tend to generalize to other criteria, so, for example, a powerful person seems large, deep (in a metaphorical sense), and strong.

The third component of affective responses—an appraisal of activity—may depend on speed (fast versus slow), perceptual stimulation (noisy versus quiet, bright versus dim), age (young versus old), keenness (sharp versus dull), or other criteria. These criteria also generalize to some degree so, for example, a young person often seems metaphorically fast, noisy, bright, and sharp.

The evaluation, potency, and activity (EPA) structure in subjective responses is one of the best-documented facts in social science, and an elaborate technology has developed for measuring EPA responses on “semantic differential scales” (Heise 1969). The scales consist of adjectives separated by a number of check positions. For example, a standard scale has Good–Nice at one end and Bad–Awful at the other end, and intervening positions on the scale allow respondents to record the direction and intensity of their evaluations of a stimulus. The middle rating position on such scales represents neutrality and is coded 0.0. Positions moving outward are labeled “slightly,” “quite,” “extremely,” and “infinitely,” and they are coded 1.0, 2.0, 3.0, and 4.3 respectively—positive on the good, potent, and active sides of the scales; and

negative on the bad, impotent, and inactive sides (Heise 1978).

EPA responses tend to be socially shared within a population (Heise 1966, 1999), so a group’s average EPA response to an entity indexes the group sentiment about the entity. Group sentiments can be computed from as few as thirty ratings since each rater’s transient response originates from a single shared sentiment rather than a separately held position (Romney, Weller, and Batchelder 1986). Sentiments vary across cultures. For example, potent authorities such as an employer are evaluated positively in U.S. and Canadian college populations, but German students evaluate authorities negatively; small children are evaluated positively in Western nations but neutrally in Japan.

IMPRESSION FORMATION

Combinations of cognitive elements bring affective meanings together and create outcome impressions through psychological processes that are complex, subtle, and yet highly predictable (Gollob 1974; Heise 1979; Anderson 1996).

One kind of impression formation amalgamates a personal attribute with a social identity resulting in a sense of how a person is different from similar others (Averett and Heise 1987). For example, among U.S. college students (the population of raters for examples henceforth), someone who is rich is evaluatively neutral, very powerful, and a little on the quiet side. Meanwhile, a professor is fairly good, fairly powerful, and a bit quiet. The notion of a “rich professor” combines these sentiments and yields a different outcome. A rich professor is evaluated somewhat negatively, mainly because the personalized power of wealth generates an uneasiness that is not overcome by esteem for academic status. A rich professor seems very powerful because the average potency of wealth and of professors is high, and the mind adds an extra increment of potency because of the personalized power deriving from wealth. A rich professor seems even quieter than the component statuses because activity connotations do not merely average, they summate to some degree.

The processes that are involved in combining a social identity with a status characteristic like “rich” also are involved in combining a social

identity with personal traits. Thus, an authoritarian professor evokes an impression roughly similar to a rich professor since the affective association for authoritarian is similar to that for rich.

Another example involving emotion illustrates additional processes involved in combining personal characteristics with social identities (Heise and Thomas 1989). Being outraged implies that one is feeling quite bad, somewhat potent, and somewhat lively. A child is felt to be quite good, quite impotent, and very active. The combination "outraged child," seems fairly bad, partly because the child is flaunting personalized power deriving from an emotion and partly because the mind discounts customary esteem for a person if there is a personal basis for evaluating the person negatively: The child's negative emotion undercuts the regard one usually has for a child. The child's impotency is reduced because of a bad and potent emotional state. And the child's activity is greater than usual because the activity of the emotion and the activity of the identity combine additively.

The combining of attributions and identities involves somewhat different processes in different domains. For example, North American males and females process attributions in the same way, though both make attributions about females that are more governed by morality considerations than attributions about males (Heise 1999). Meanwhile, Japanese males are socialized to be more concerned than Japanese females with evaluative consistency in attributions and with matching goodness and weakness, so Japanese males process attributions about everything with more concern for morality than do Japanese females (Smith, Matsuno, and Ike 1999).

Events are another basis for impression formation. A social event—an actor behaving on an object or person within some setting—amalgamates EPA impressions of the elements comprising the event and generates a new impression of each element. For example, when an athlete strangles a coach, the athlete seems bad, and the coach seems cowardly because the coach loses both goodness and potency as a result of the event. The complex equations for predicting outcome impressions from input impressions have been found to be similar in different cultures (Heise 1979; Smith-Lovin 1987a; Smith-Lovin 1987b; Smith, Matsuno, and Umino 1994).

To a degree, the character of a behavior diffuses to the actor who performs the behavior. For example, an admired person who engages in a violent act seems less good, more potent, and more active than usual. Impressions of the actor also are influenced by complex interplays between the nature of the behavior and the nature of the object. For example, violence toward an enemy does not stigmatize an actor nearly so much as violence toward a child. That is because bad, forceful behaviors toward bad, potent objects seem justified while such behaviors toward good, weak objects seem ruthless. Moreover, the degree of justification or of ruthlessness depends on how good the actor was in the first place; for example, a person who acts violently toward a child loses more respect if initially esteemed than if already stigmatized.

Similarly, diffusions of feeling from one event element to another and complex interplays between event elements generate impressions of behaviors, objects, and settings. The general principle is that initial affective meanings of event elements combine and thereby produce new impressions that reflect the meaning of the event. Those impressions are transient because they, in turn, are the meanings that are transformed by later events.

IMPRESSION MANAGEMENT

Normal events produce transient impressions that match sentiments, whereas events that generate impressions deviating widely from sentiments seem abnormal (Heise and MacKinnon 1987). For example, "a parent assisting a child" creates impressions of parent, child, and assisting that are close to sentiments provided by our culture, and the event seems normal. On the other hand, "a parent harming a child" seems abnormal because the event produces negative impressions of parent and child that are far different than the culturally-given notions that parents and children are good.

According to affect control theory, people manage events so as to match transient impressions with sentiments and thereby maintain normality in their experience. Expressive shaping of events occurs within orderly rational action, and ordinarily the expressive and the rational components of action complement each other because

cultural sentiments incite the very events that are required by the logic of social institutions like the family, law, religion, etc.

Having adopted an appropriate identity at a scene and having cast others in complementary identities, a person intuitively behaves that will create normal impressions. For example, if a person in the role of judge is to act on someone who is a proven crook, then she must do something that confirms a judge's power and that confirms the badness of a crook, and behaviors like "convict" and "sentence" produce the right impressions. Fitting behaviors may change in the wake of prior events. For example, a father who is fulfilling his role in a mediocre manner because his child has disobeyed him strives to regain goodness and power by controlling the child or by dramatizing forgiveness. Other people's identities may serve as resources for restoring a compromised identity (Wiggins and Heise 1987); for example, a father shaken by a child's disobedience might recover his poise by supporting and defending mother.

Behaviors that confirm sentiments are the intrinsically motivated behaviors in a situation. Actors sometimes comply to the demands of others and thereby forego intrinsically motivated behaviors. Yet compliance also reflects the basic principle since compliant behavior is normal in one relationship even though it may be abnormal in another relationship. For example, a child acts normally when calling on a playmate though also abnormally if his mother has ordered him not to do so and he disobeys her. The actor maintains the relationship that is most salient.

Sometimes other people produce events that do not confirm sentiments evoked by one's own definition of a situation. Affect control theory suggests several routes for restoring consistency between impressions and sentiments in such cases. First, people may try to reinterpret other's actions so as to optimize expressive coherence. For example, an actor's movement away from another person can be viewed as departing, leaving, escaping, fleeing, deserting—and one chooses the interpretation that seems most normal, given participants' identities and prior events (Heise 1979). Of course, interpretations of a behavior are bound by determinable facts about the behavior and its consequences, so some behaviors cannot be interpreted in a way that completely normalizes an event.

Another response to disturbing events is construction of new events that transform abnormal impressions back to normality. Restorative events with the self as actor might be feasible and enacted, as in the example of a father controlling a disobedient child. Restorative events that require others to act might be elicited by suggesting what the other should do. For example, after a child has disobeyed his mother, a father might tell the child to apologize.

Intractable disturbances in interaction that cannot be handled by reinterpreting others' actions or by instigating new events lead to changes in how people are viewed, such as attributing character traits to people in order to form complex identities that account for participation in certain kinds of anomalous events. For example, a father who has ignored his child might be viewed as an inconsiderate person.

Changing base identities also can produce the kind of person who would participate in certain events. For example, an employee cheating an employer would be expressively coherent were the employee known to be a lawbreaker, and a cheating incident may instigate legal actions that apply a lawbreaker label and that withdraw the employee identity. The criminal justice system changes actors in deviant events into the kinds of people who routinely engage in deviant actions, thereby allowing the rest of us to feel that we understand why bad things happen.

Trait attributions and labels that normalize particular incidents are added to conceptions of people, and thereafter the special identities may be invoked in order to set expectations for a person's behavior in other scenes or to understand other incidents. Everyone who interacts with a person builds up knowledge about the person's capacities in this way, and a person builds up knowledge about the self in this way as well.

EMOTION

Affect control theory is a central framework in the sociology of emotions (Thoits 1989; Smith-Lovin 1994), and its predictions about emotions in various situations match well with the predictions of real people who imagine themselves in those situations (Heise and Weir 1999). According to affect control theory, spontaneous emotion reflects the

state a person has reached as a result of events and also how that state compares to the ideal experience of a person with a particular social identity. For example, if events make a person seem neutral on goodness, potency, and activity, then the tendency is to feel emotionally neutral, but someone in the sweetheart role ends up feeling blue because he or she is experiencing so much less than one expects in a romantic relationship.

Because emotions reflect the impressions that events have generated, they are a way of directly sensing the consequences of social interaction. Because emotions simultaneously reflect what kinds of identities people are taking, emotions also are a way of sensing the operative social structure in a situation. Moreover, because displays of emotion broadcast a person's subjective appraisals to others, emotions contribute to intersubjective sharing of views about social matters.

People sometimes mask their emotions or display emotions other than those that they feel spontaneously in order to hide their appraisal of events from others or to conceal personal definitions of a situation. For example, an actor caught in misconduct might display guilt and remorse beyond what is felt in order to convince others that he believes his behavior is wrong and that he is not the type who engages in such activity. Such a display of negative emotion after a deviant act makes the actor less vulnerable to a deviant label—an hypothesis derived from the mathematics of affect control theory (Heise 1989).

APPLICATIONS

Affect control theory provides a comprehensive social-psychological framework relating to roles, impression formation, behavior, emotion, attribution, labeling, and other issues (Stryker and Statham 1985). Consequently it is applicable to a variety of social-psychological problems. For example:

- Smith-Lovin and Douglass (1992) showed that sentiments about relevant identities and behaviors are positive in a deviant subculture, and therefore subcultural interactions are happier than outsiders believe.
- MacKinnon and Langford (1994) found that moral evaluations determine the prestige of occupations with low and middle

but not high levels of education and income; and they found that income affects occupational prestige partly by adjusting feelings about the potency of the occupation.

- Robinson and Smith-Lovin (1992) found that people with low self-esteem prefer to associate with their critics rather than their flatterers. Robinson (1996) showed that networks can emerge from self-identities, with cliques reflecting differing levels of self-esteem, and dominance structures reflecting differing levels of self-potency.
- Francis (1997a, 1997b) showed that therapists often promote emotional healing by embedding clients in a social structure where key identities have particular EPA profiles; the identities are associated with different functions in different therapeutic ideologies.
- Studies of courtroom scenarios (Robinson, Smith-Lovin, and Tsoudis 1994; Tsoudis and Smith-Lovin 1998) showed that people (such as jurors) deal more leniently with convicted criminals who show remorse and guilt over their crimes, as predicted by affect control theory. In a related study, Scher and Heise (1993) suggested that perceptions of injustice follow justice-related emotions of anger or guilt, so social interactional structures that keep people happy can prevent mobilization regarding unjust reward structures.
- Heise (1998) suggested that solidarity comes easier when a group identity is good, potent, and lively so that group members engage in helpful actions with each other and experience emotions in parallel. Britt and Heise (forthcoming) showed that successful social movements instigate a sequence of member emotions, culminating in pride, which reflect a good, potent, and lively group identity.

Affect control theory's mathematical model is implemented in a computer program that simulates social interactions and predicts the emotions and interpretations of interactants during expected or unexpected interpersonal events. Simulations can be conducted with EPA measurements

obtained in a variety of nations—Northern Ireland, Canada, Germany, Japan, and the United States. The computer program, the datasets, and other materials are available at the affect control theory web site at: www.indiana.edu/~socpsy/ACT.

CONCLUSION

Goffman (1967, p. 9) called attention to the expressive order in social relations:

By entering a situation in which he is given a face to maintain, a person takes on the responsibility of standing guard over the flow of events as they pass before him. He must ensure that a particular expressive order is sustained—an order that regulates the flow of events, large or small, so that anything that appears to be expressed by them will be consistent with his face.

Affect control theory's empirically based mathematical model offers a rich and productive foundation for studying the expressive order.

DAVID R. HEISE

AFFIRMATIVE ACTION

The term *affirmative action* has been used in the United States since the late 1960s to refer to policies that go beyond the simple prohibition of discrimination on grounds of race, national origin, and sex in employment practices and educational programs. These policies require some further action, "affirmative action," to make jobs and promotions and admissions to educational programs available to individuals from groups that have historically suffered from discrimination in gaining these opportunities or are, whether discriminated against or not by formal policies and informal practices, infrequently found in certain occupations or educational institutions and programs.

Affirmative action policies may be policies of governments or governmental units, affecting their own procedures in employment or in granting contracts; or they may be policies of governments, affecting the employment procedures of companies or nonprofit agencies and organizations over whom the governments have power or with whom they deal; or they may be the policies of profit and nonprofit employers, adopted voluntarily or under varying degrees of public or private pressure. Affirmative action policies may include the policies of philanthropic foundations, when they affect the employment policies of their grantees, or educational accrediting agencies, when they affect the employment or admissions policies of the institutions they accredit.

The range of policies that can be called affirmative action is wide, but the term also has a specific legal meaning. It was first used in a legal context in the United States in an executive order of President John F. Kennedy. Subsequent presidential executive orders and other administrative requirements have expanded its scope and meaning, and since 1971 affirmative action so defined has set employment practice standards for contractors of the United States, that is, companies, colleges, universities, hospitals, or other institutions that have business with the U.S. government. These standards are enforced by an office of the Department of Labor, the Office of Federal Contract Compliance Programs. Because of the wide sweep of the executive order and its reach into the employment practices of almost every large employer, affirmative action policies have become extremely controversial.

Affirmative action, under other names, is also to be found in other countries to help groups, whether majority or minority, that have not fared as well as others in gaining employment in higher status occupations or admissions to advanced educational programs.

Affirmative action has been controversial because it appears to contradict a central objective of traditional liberalism and the U.S. civil rights movement, that is, the treatment of individuals on the basis of their individual talents and not on the basis of their color, race, national origin, or sex. Affirmative action, as it has developed, requires surveys by employers of the race, national origin,

and sex of their employees to uncover patterns of “underutilization” and to develop programs to overcome this underutilization and thus to take account of the race, national origin, and sex of applicants for employment and of candidates for promotion. To many advocates of expanded civil rights, this is seen as only the next and a most necessary step in achieving equality for groups that have in the past faced discrimination. To others, who may also deem themselves advocates of civil rights and of the interests of minority groups, affirmative action, in the form in which it has developed, is seen as a violation of the first requirement for a society that promises equal opportunity, that is, to treat individuals as individuals independent of race, national origin, or sex.

This apparent contradiction between civil rights and affirmative action may be glimpsed in the very language of the Civil Rights Act of 1964, the central piece of legislation that banned discrimination in government programs, public facilities, and employment. In the debate over that act, fears were expressed that the prohibition of discrimination in employment, as codified in Title VII, would be implemented by requiring certain numbers of employees to be of a given race. This fear was dealt with by placing language in the act that was understood at the time specifically to forbid the practices that are required under affirmative action since the late 1960s and early 1970s. Title 703 (j) reads:

Nothing contained in this title shall be interpreted to require any employer . . . to grant preferential treatment to any individual or to any group because of the race, color, religion, sex, or national origin of such individual or group on account of an imbalance which may exist with respect to the total number or percentage of persons of any race, color, religion, sex, or national origin employed by any employer.

However, federal executive orders governing how the federal government does its business may set their own standards, independent of statutory law. The first executive order using the term *affirmative action* was issued by President John F. Kennedy in 1961. It created a President’s Committee on Equal Employment Opportunity to monitor the obligations contractors undertook to extend affirmative action. At this time, the general understanding of affirmative action was that it

required such things as giving public notice that the employer did not discriminate, making the availability of positions and promotions widely known, advertising in minority media, and the like. With the Civil Rights Act of 1964—which not only prohibited discrimination on grounds of race, color, and national origin but also on grounds of sex—a new executive order, no. 11,246, was formulated by President Lyndon B. Johnson and came into effect. It replaced the President’s Committee on Equal Employment Opportunity with an Office of Federal Contract Compliance Programs (which still operates). Subsequent federal regulations of the late 1960s and early 1970s specified what was meant by affirmative action in the executive order, and the meaning of affirmative action was considerably expanded into the full-fledged program that has existed since 1971. Revised order no. 4 of that year, which is part of the *Code of Federal Regulations* and is still in effect, reads in part:

An affirmative action program is a set of specific and result-oriented procedures to which a contractor commits itself to apply every good effort. The objective of those procedures plus such efforts is equal employment opportunity. Procedures without efforts to make them work are meaningless; and effort, undirected by specific and meaningful procedures, is inadequate. An effective affirmative action program must include an analysis of areas within which the contractor is deficient in the utilization of minority groups and women, and further, goals and timetables to which the contractor’s good faith efforts must be directed to correct the deficiencies and, [sic] thus to achieve prompt and full utilization of minorities and women, at all levels and in all segments of its work force where deficiencies exist. (Code of Federal Regulations 1990, pp. 121–122)

Much of the controversy over affirmative action is over the term *goals and timetables*: Are these “quotas”? Supporters of affirmative action say not—only good faith efforts are required, and if they fail the contractor is not penalized. Further controversy exists over the term *utilization*: What is the basis on which a group is found “underutilized,” and to what extent is this evidence of discrimination? Similarly, there is considerable dispute over how to label these programs. “Affirmative action”

has a positive air, and in public opinion polls will receive considerable support. Label the same programs “racial preference”—which indeed is specifically what they are—and public support drops radically. In the 1990s, as campaigns were launched to ban affirmative action programs by popular referendum, just what language could or should be used in these referenda became hotly disputed.

Controversy also arises over the categories of employees that contractors must report on and over whose utilization they must be concerned. The executive order lists four categories: blacks, Spanish-surnamed Americans, American Indians, and Orientals. (These are the terms in the order as of 1971 and are still used in the *Code of Federal Regulations*.) The preferred names of these groups have changed since then to Afro- or African Americans, Hispanics or Latinos, Native Americans, and Asians. While the original executive order and the Civil Rights Act was a response to the political action of black civil rights groups, and it was the plight of blacks that motivated both the executive order and the Civil Rights Act, it was apparently deemed unwise in the mid-1960s to limit affirmative action requirements to blacks alone. The Civil Rights Act bans discrimination against any person on grounds of race, national origin, and sex and specifies no group in particular for protection; but the Equal Employment Opportunity Commission, set up by the Civil Rights Act to monitor discrimination in employment, from the beginning required reports on the four groups listed above, despite the fact that even in the 1960s it could be argued that discrimination against Asians was far less acute and much less of a problem than discrimination against blacks, that discrimination against American Indians also differed in severity and character from discrimination against blacks, and that discrimination against Spanish-surnamed Americans ranged from the nonexistent or hardly existent (Spaniards from Spain? Cubans? Sephardic Jews?) to the possibly significant. Nevertheless, these four categories set up in the mid-1960s are still the groups that governmental programs of affirmative action target for special attention (Glazer 1987).

Since affirmative action is a governmental program operated by government agencies that grant contracts and is overseen by the Office of

Federal Contract Compliance Programs, one major issue of controversy has been over the degree to which these programs are really enforced. It is generally believed that enforcement is more severe under Democratic administrations than under Republican administrations, even though the program was first fully developed under the Republican administration of President Richard Nixon. President Ronald Reagan was an avowed opponent of affirmative action, but despite his eight-year administration no modification of the program took place. Changes were proposed by some parts of the Republican administration but opposed by others. Business, in particular big business, had learned to live with affirmative action and was not eager to upset the apple cart (Belz 1990).

One of the most controversial areas in which affirmative action is applied is in the employment and promotion of police, firefighting and sanitation personnel, and teachers and other local government employees. Here strict racial quotas often do apply. They are strongly resented by many employees when new employees are hired by race and even more when promotions are given out by race and layoffs are determined by race. The basis of these quotas is not the presidential executive order but rather consent decrees entered into by local government on the basis of charges of discrimination brought by the federal government. These charges are brought on the basis of the Civil Rights Act; under this act, if discrimination is found, quotas can be required by courts as a remedy. Since local government employment is generally on the basis of tests, one very controversial aspect of such cases is the role of civil service examinations. Blacks and Hispanics characteristically do worse than white applicants. Are these poorer results to be taken as evidence of discrimination? A complex body of law has been built up on the basis of various cases determining when a test should be considered discriminatory. In the Civil Rights Act of 1964, one provision read “it shall not be an unlawful employment practice . . . for an employer to give and act upon the results of any professionally developed ability test provided that such test . . . is not designed, intended, or used to discriminate.” But the courts decide whether the test is “designed, intended, or used to discriminate.” Because of the frequency with which courts have found tests for the police, fire, or

sanitation force discriminatory, and because state and local governments believe they will lose such cases, many have entered into “consent decrees” in which they agree to hire and promote on the basis of racial and sex criteria.

Affirmative action is also used in the granting of government contracts on the basis of either statutes (federal, state, or local) or administrative procedures. It is in this area that the edifice of affirmative action was first effectively attacked in the 1980s and 1990s, in the wake of the failure of Republican administrations to take any action limiting affirmative action. The first major crack came in the U.S. Supreme Court’s decision in *City of Richmond v. Croson*, in which the Court ruled against a Richmond, Virginia, city program to set aside 30 percent of city contracts for minority-owned businesses. The Court ruled that such programs could only stand, under the judicial “strict scrutiny” standard triggered by apparent government discrimination, if it could be demonstrated there had been discrimination against these groups by the city in the past. The response of cities to this judicial limitation on their minority “set-aside” programs was often to commission studies to demonstrate they had indeed discriminated, in order to save the set-aside programs (LaNoue 1993). In a later decision, *Adarand v. Peña* (1995), the Court ruled against a federal statute requiring that 10 percent of public works contracts be set aside for minorities. While these programs still continue in many jurisdictions, including the federal government, they are all legally threatened.

One issue in minority contract set-asides has been that of possible fraud, as various contractors find it to their advantage to take on black partners so as to present themselves as minority contractors and thus to get whatever advantages in bidding that status provides. In this area, as in other areas where advantage might follow from minority status, there have been debates over what groups may be included as minorities. It was unclear, for example, whether Asian Indians—immigrants and American citizens of Indian origin—were to be considered Asian. Asian Indian Americans were divided among themselves on this question, but during the Reagan administration they were reclassified as Asian, presumably in part for the modest political advantage this gave the Republican administration.

Affirmative action also governs the employment practices of colleges and universities, whether public or private, because they all make use of federal grants and loans for their students, and many have government research contracts. Colleges and universities therefore must also survey their faculties and other staffs for underutilization, and they develop elaborate affirmative action programs. Affirmative action applies to women as well as to racial and ethnic minority groups. There has been, perhaps in part because of affirmative action programs, a substantial increase in female faculty. But there has been little increase in black faculty during the 1980s. The numbers of blacks taking doctorates in arts and sciences has been small and has not increased. The higher rewards of law, business, and medicine have attracted into those fields black students who could prepare themselves for an academic career. Many campuses have been shaken by controversies over the small number of black faculty, with administrators arguing that few were available and protestors, often black students, arguing that greater effort would change the situation.

In the 1990s, the most controversial area of affirmative action became admissions to selective colleges and universities and professional schools. Affirmative action in admissions is not required by government regulations, as in the case of employment, except in the special case of southern public higher education institutions. There parallel and separate black and white institutions existed, and while all of these institutions have been open to both white and black students since at least the early 1970s, an extended lawsuit has charged that they still preserve their identity as traditionally black and traditionally white institutions. As a result of this litigation, many of these institutions must recruit a certain number of black students. But the major pressure on many other institutions to increase the number of black students has come from goals voluntarily accepted by administrators or as a result of black student demands. (In one case, that of the University of California, the state legislature has called on the institution to mirror in its racial-ethnic composition the graduating classes of California high schools.) Voluntary affirmative action programs for admission of students, targeted on black, Hispanic, and Native American students, became widespread in the late

1960s and early 1970s, particularly after the assassination of Martin Luther King.

The first affirmative action cases to reach the Supreme Court challenged such programs of preference for black and other minority students. A rejected Jewish applicant for admission to the University of Washington Law School, which had set a quota to increase the number of its minority students, sued for admission, and his case reached the Supreme Court. It did not rule on it. The Court did rule on a subsequent case, in 1978, that of Allan Bakke, a rejected applicant to the University of California, Davis, Medical School, which also had set a quota. The Court, splitting into a number of factions, rejected fixed numerical quotas but asserted race was a factor that could be taken into account in admissions decisions for purposes of promoting academic diversity. Under the protection offered by this complex decision, most colleges and universities and professional schools do grant preferences to black and Hispanic students. Asian Americans, also considered a minority, did not receive preference, but this was hardly necessary since their academic achievement is high. Indeed, by the 1980s, Asian American students were protesting that it was more difficult for them than whites to gain admission to selective institutions (Bunzel and Au 1987).

Matters turned around in the mid-1990s. In 1995, the regents of the University of California banned any consideration of race or ethnicity in admission to the university. In 1996 the voters of California approved the California Civil Rights Initiative, which banned the use of race or ethnic criteria in state government action, in employment and contracts as well as college admissions. This initiative, launched by one academic and one former academic, became the basis of a movement to extend the ban on affirmative action. In 1998 the State of Washington became the second state to pass such an initiative. In Texas, the assault on affirmative action in admissions led to a wide-ranging decision by the Fifth Circuit Court of Appeals in 1996 banning the use of race and ethnicity in admissions to the University of Texas Law School. This decision affects all institutions of higher education in the states covered by the fifth circuit. Massive changes have followed in the admissions procedures of the University of California, the peak institution in the system of public

higher education in California, and the University of Texas, which holds a similar position in Texas.

Initially, there were substantial drops in enrollment of black and Hispanic students, but energetic action by the university administrations has stemmed this fall-off, and the decline statistically is not as drastic as originally projected or feared. The commitment by university administrators to maintain a substantial representation of black and Hispanic students is so strong that they have devised new admissions practices and procedures designed to keep the number up, and have had some success in doing so. Further, the Texas legislature has voted that the top 10 percent of every high school graduating class be eligible for admission to the University of Texas, and the Board of Regents of the University of California has similarly voted that the top 4 percent of California high school graduating classes should be eligible for enrollment in the University of California. The effect of such actions, in view of the high concentration of black and Hispanic students in low-achieving high schools, which ordinarily send few students to the selective state institutions, is to keep up the number of black and Hispanic students.

Affirmative action in admissions has become perhaps the best-researched area of affirmative action as a result of these controversies. An important study by William Bowen and Derek Bok of admissions procedures in selective institutions has argued effectively that "race-sensitive" admissions have been good for the students, good for the institutions, and good for the country. Their conclusions, however, have been sharply disputed by critics of affirmative action. (Bowen and Bok 1998; Trow 1999). At this writing (Fall, 1999) the Supreme Court has not yet ruled on the issue of the degree to which public colleges and universities may take race into account. In view of the fact that neither Congress nor state legislatures will take decisive action on race preference owing to the political sensitivity of the issue, it is clear the key decisions in this area will have to be taken by the Supreme Court. It is possible that the age of affirmative action in American race relations and race policy is coming to an end.

Affirmative action has been a divisive issue in American political life and has sometimes been raised effectively in political campaigns. It has

divided former allies on civil rights issues, in particular American Jews, normally liberal, from blacks. Jews oppose quotas in admissions to medical and law schools because they were in the past victims of very low quotas imposed by American universities.

Affirmative action under various names and legal arrangements is found in many countries: in India, to provide opportunities to scheduled castes, scheduled tribes, and other backward classes, where different requirements operate at the national level and within the states and where some degree of preference has existed in some areas and for some purposes as far back as the 1920s (Galanter 1984); in Malaysia, to protect the native Malay population; in Sri Lanka, to benefit the majority Sri Lankan population (Sowell 1990); and in Australia and Canada, where milder forms of affirmative action than those found in the United States operate. It is now being raised in the countries of Western Europe, which have received since World War II large numbers of immigrants who now form distinctive communities who lag behind the native populations in education and occupational status. The policies called affirmative action in the United States are called "reservations" in India, and "positive discrimination" in some other countries.

There is considerable debate as to the effects of affirmative action policies and how weighty these can be as against other factors affecting employment, promotion, and educational achievement (Leonard 1984a; 1984b). A summary judgment is difficult to make. Black leaders generally consider affirmative action an essential foundation for black progress, but some black intellectuals and publicists have been skeptical. Black leaders often denounce opponents of affirmative action as racists, hidden or otherwise, yet it is clear that many opponents simply find the use, required or otherwise, of racial and sexual characteristics to determine job and promotion opportunities and admission to selective college programs in contradiction with the basic liberal principles of treating individuals without regard to race, national origin, color, and sex. Affirmative action has undoubtedly increased the number of blacks who hold good jobs and gain admission to selective programs. But it has also had other costs in the form of increased racial tensions. It has coincided with a period in which a pattern of black advancement occupationally and educationally since World War II has been

surprisingly slowed. The defenders of affirmative action argue that this is because it has not yet been applied vigorously enough. The opponents argue that the concentration on affirmative action encourages the neglect of the key factors that promote educational and occupational progress, which are basically the acquisition of qualifications for better jobs and superior educational programs. NATHAN GLAZER

AFRICAN-AMERICAN STUDIES

Research on African Americans covers many important areas, only a few of which will be discussed here: theories of white-black relations; the enslavement of African Americans; the development of an antiblack ideology; the creation of white wealth with black labor; the idea of whiteness; racial discrimination today; and possibilities for social change.

THEORIES OF WHITE-BLACK RELATIONS

Explanatory theories of U.S. racial relations can be roughly classified into *order-deficit theories* and *power-conflict theories*. Order-deficit theories accent the gradual inclusion and assimilation of an outgroup such as African Americans into the dominant society and emphasize the barriers to progress that lie within the outgroup. Power-conflict theories, in contrast, emphasize past and present structural barriers preventing the full integration of African Americans into the society's institutions, such as the huge power and resource imbalance between white and black Americans. They also raise larger questions about the society's historically racist foundations.

Milton Gordon (1964) is an order-deficit scholar who distinguishes several types of initial encounters between racial and ethnic groups and an array of subsequent assimilation outcomes ranging from acculturation to intermarriage. In his view the trend of immigrant adaptation in the United States has been in the direction of substantial conformity—of immigrants giving up much of their heritage for the Anglo-Protestant core culture. Gordon and other scholars apply this scheme to African Americans, whom they see as substantially assimilated at the cultural level (for example, in regard to language), with some cultural differences remaining because of "lower class subculture" among

black Americans. This order-deficit model and the accent on defects in culture have been popular among many contemporary analysts who often seek to downplay discrimination and accent instead problems internal to black Americans or their communities. For example, Jim Sleeper (1990) has argued that there is no institutionalized racism of consequence left in United States. Instead, he adopts cultural explanations—for example, blacks need to work harder—for present-day difficulties in black communities.

In contrast, power-conflict analysts reject the assimilationist view of black inclusion and eventual assimilation and the inclination to focus on deficits within African-American individuals or communities as the major barriers to racial integration. From this perspective, the current condition of African Americans is more oppressive than that of any other U.S. racial or ethnic group because of its roots in centuries-long enslavement and in the subsequent semislavery of legal segregation, with the consequent low-wage jobs and poor living conditions. Once a system of extreme racial subordination is established historically, those in the superior position in the hierarchy continue to inherit and monopolize disproportionate socioeconomic resources over many generations. One important power-conflict analyst was Oliver C. Cox. His review of history indicated that from the 1500s onward white-on-black oppression in North America arose out of the European imperialistic system with its profit-oriented capitalism. The African slave trade was the European colonists' "Way of recruiting labor for the purpose of exploiting the great natural resources of America" (Cox 1948, p. 342). African Americans provided much hard labor to build the new society—first as slaves, then as sharecroppers and tenant farmers, and later as low-wage laborers and service workers in cities.

In the late 1960s civil rights activist Stokely Carmichael (later renamed Kwame Ture) and historian Charles Hamilton (1967) documented contemporary patterns of racial discrimination and contrasted their power-conflict perspective, which accented institutional racism, with an older approach focusing only on individual whites. They were among the first to use the terms "internal colonialism" and "institutional racism" to describe discrimination by whites as a group against African Americans as a group. Adopting a similar

power-conflict perspective, sociologist Bob Blauner (1972) argued that there are major differences between black Americans and the white immigrant groups at the center of assimilationist analysis. Africans brought across the ocean became part of an internally subordinated colony; white slaveowners incorporated them against their will. Black labor built up white wealth. European immigrants, in contrast, came more or less voluntarily.

More recently, sociologist Molefi Kete Asante (1988) has broken new ground in the development of a new power-conflict perspective, termed *afrocentricity*, that analyzes the Eurocentric bias in U.S. culture and rejects the use of the concepts such as “ethnicity,” “minority,” and “ghetto” as antithetical to developing a clear understanding of racism and to building antiracist movements. Similarly, anthropologist Marimba Ani (1994) has shown how from the beginning European colonialism was supported by a well-developed theory of white supremacy, a worldview that attempted to destroy the cultures of other non-European peoples. Yet other analysts (Feagin 2000) have argued for a power-conflict framework that understands white oppression of black Americans—with its racist ideology—as the foundation of U.S. society from the beginning. From this perspective much in the unfolding drama of U.S. history is viewed as a continuing reflection of that foundation of systemic racism.

THE ENSLAVEMENT OF AFRICAN AMERICANS

Research on slavery emphasizes the importance of the power-conflict perspective for understanding the history and conditions of African Americans. Manning Marable (1985, p. 5) demonstrates that before the African slave trade began, Europeans were predisposed to accept slavery. Western intellectuals from Aristotle to Sir Thomas More defended slavery.

Research by sociologists, historians, and legal scholars emphasizes the point that slavery is the foundation of African-American subordination. Legal scholar Patricia Williams has documented the dramatic difference between the conditions faced by enslaved Africans and by European immigrants: “The black slave experience was that of lost

languages, cultures, tribal ties, kinship bonds, and even of the power to procreate in the image of oneself and not that of an alien master” (Williams 1987, p. 415). Williams, an African American, discusses Austin Miller, her great-great grandfather, a white lawyer who bought and enslaved her great-great-grandmother, Sophie, and Sophie’s parents. Miller forced the thirteen-year-old Sophie to become the mother of Williams’s great grandmother Mary. Williams’s white great-great grandfather was thus a rapist and child molester. African Americans constitute the only U.S. racial group whose heritage involves the forced mixing of its African ancestors with members of the dominant white group.

Eugene Genovese (1974) has demonstrated that the enslavement of African Americans could produce both servile accommodation and open resistance. Even in the extremely oppressive slave plantations of the United States, many peoples from Africa—Yorubas, Akans, Ibos, and others—came together to create one African-American people. They created a culture of survival and resistance by drawing on African religion and values (Stuckey 1987, pp. 42–46). This oppositional culture provided the foundation for many revolts and conspiracies to revolt among those enslaved, as well as for later protests against oppression.

In all regions many whites were implicated in the slavery system. Northern whites built colonies in part on slave labor or the slave trade. In 1641, Massachusetts was the first colony to make slavery legal; and the state’s merchants and shippers played important roles in the slave trade. Not until the 1780s did public opinion and court cases force an end to New England slavery. In 1786 slaves made up 7 percent of the New York population; not until the 1850s were all slaves freed there. Moreover, an intense political and economic subordination of free African Americans followed abolition (Higginbotham 1978, pp. 63–65, 144–149). As Benjamin Ringer (1983, p. 533) puts it, “despite the early emancipation of slaves in the North it remained there, not merely as fossilized remains but as a deeply engrained coding for the future.” This explains the extensive system of antiblack discrimination and “Jim Crow” segregation in northern states before the Civil War. Later, freed slaves and their descendants who migrated there from the South came into a socioeconomic system already coded to subordinate African Americans.

THE DEVELOPMENT OF AN ANTIBLACK IDEOLOGY

Truly racist ideologies—with “race” conceptualized in biologically inferiority terms—appear only in modern times. St. Clair Drake (1987) has shown that in the Greek and Roman periods most Europeans attached greater significance to Africans’ culture and nationality than to their physical and biological characteristics. Beginning with Portuguese and Spanish imperialism in the fifteenth century, a racist ideology was gradually developed to rationalize the brutal conquest of the lands and labor undertaken in the period of European imperialism (Snowden 1983).

The system of antiblack racism that developed in the Americas is rooted deeply in European and Euro-American consciousness, religion, and culture. Europeans have long viewed themselves, their world, and the exploited “others” within a parochial perspective, one that assumes European culture is superior to all other cultures, which are ripe for exploitation (Ani 1994). For the colonizing Europeans it was not enough to bleed Africa of its labor. A well-developed anti-African, antiblack ideology rationalized this oppression and thus reduced its moral cost for whites. As it developed, this ideology accented not only the alleged physical ugliness and mental inferiority of Africans and African Americans, but also their supposed immorality, family pathologies, and criminality. Notions that African Americans were, as the colonial settlers put it, “dangerous savages” and “degenerate beasts,” were apparently an attempt by those who saw themselves as civilized Christians to avoid blame for the carnage they had created. As historian George Frederickson put it, “otherwise many whites would have had to accept an intolerable burden of guilt for perpetrating or tolerating the most horrendous cruelties and injustices” (Frederickson 1971, p. 282).

CREATING WHITE WEALTH WITH BLACK LABOR

In his masterpiece *The Souls of Black* (1903), the pioneering sociologist W. E. B. Du Bois anticipated current research on the significance of African Americans for U.S. prosperity and development:

“Your country. How came it yours? Before the Pilgrims landed we were here. Here we have brought our three gifts and mingled them with yours: a gift of story and song—soft, stirring melody in an ill-harmonized and unmelodious land; the gift of sweat and brawn to beat back the wilderness, conquer the soil, and lay the foundations of this vast economic empire two hundred years earlier than your weak hands could have done it; the third, a gift of the spirit” (Du Bois 1989 [1903], pp. 186–187). The past and present prosperity of the nation is substantially the result of the enforced labor of millions of African Americans under slavery and segregation.

Under common law, an innocent individual who benefits unknowingly from wealth gained illegally or by unjust actions in the past generally cannot, if the ill-gotten gains are discovered, claim a right to keep them (Cross 1984, p. 510; Williams 1991, p. 101). A coerced taking of one’s possessions by an individual criminal is similar to the coerced taking of one’s labor by a white slaveholder or discriminator. Over centuries great wealth was unjustly created for white families from the labor of those enslaved, as well as from the legal segregation and contemporary racist system that came after slavery.

Some researchers (see America 1990) have examined the wealth that whites have unjustly gained from four hundred years of the exploitation of black labor. Drawing on James Marketti (1990, p. 118), one can estimate the dollar value of the labor taken from enslaved African Americans from 1620 to 1861—together with lost interest from then to the present—as between two and five *trillion* dollars (in current dollars). Adding to this figure the losses to blacks of the labor market discrimination in place from 1929 to 1969 (plus lost interest) would bring the total figure to the four to nine trillion dollar range (see Swinton 1990, p. 156). Moreover, since the end of legal segregation African Americans have suffered more economic losses from continuing discrimination. For more than two decades now the median family income of African-American families has been about 55 to 61 percent of the median family income of white families. Compensating African Americans for the value of the labor stolen would clearly require a very large portion of the nation’s

current and future wealth. And such calculations do not take into account the many other personal and community costs of slavery, segregation, and modern racism.

Research has shown that for centuries whites have benefited from large-scale government assistance denied to African Americans. These programs included large-scale land grants from the 1600s to the late 1800s, a period when most blacks were ineligible. In the first decades of the twentieth century many government-controlled resources were given away, or made available on reasonable terms, to white Americans. These included airline routes, leases on federal lands, and access to radio and television frequencies. During the 1930s most federal New Deal programs heavily favored white Americans. Perhaps the most important subsidy program benefiting whites was the Federal Housing Administration (FHA) loan insurance that enabled millions of white families to secure homes and accumulate equity later used for education of their children (Sitkoff 1978). During the long segregation period from the 1890s to the late 1960s, black families received much less assistance from government programs and were unable to build up wealth comparable to that of white families.

WHITENESS DEVELOPS IN RELATION TO BLACKNESS

From the beginning of the nation, the ideas of “whiteness” and “blackness” were created by whites as an integral part of the increasingly dominant racist ideology. The first serious research on whiteness was perhaps that of Du Bois (1992 [1935]), who showed how white workers have historically accepted lower monetary wages in return for the *public and psychological wage* of white privilege. In return for not unionizing or organizing with black workers, and thus accepting lower monetary wages, white workers were allowed by employers to participate in a racist hierarchy where whites enforced deference from black Americans. Several social scientists (Roediger 1991; Allen 1994; Brodtkin 1998) have shown how nineteenth-century and twentieth-century immigrants from Europe—who did not initially define themselves as “white” but rather as Jewish, Irish, Italian, or other European

identity—were pressured by established elites to view themselves and their own groups as white. Racial privileges were provided for new European immigrants as they aligned themselves with the native-born dominant Anglo-American whites and actively participated in antiblack discrimination.

Today, whites still use numerous myths and stereotypes to defend white privilege (Frankenberg 1993; Feagin and Vera 1995). Such fictions often describe whites as “not racist” or as “good people” even as the same whites take part in discriminatory actions (for example, in housing or employment) or express racist ideas. In most cases, the positive white identity is constructed against a negative view of black Americans.

RACIAL DISCRIMINATION TODAY

Racial discrimination involves the practices of dominant group members that target those in subordinate groups for harm. Discrimination maintains white wealth and privilege. A National Research Council report noted that by the mid-1970s many white Americans believed “the Civil Rights Act of 1964 had led to broad-scale elimination of discrimination against African Americans in public accommodations” (Jaynes and Williams 1989, p. 84). However, social science research still finds much racial discrimination in housing, employment, education, and public accommodations.

Many scholars accent current black economic progress. In the 1980s and 1990s the number of black professional, technical, managerial, and administrative workers has increased significantly. Yet African Americans in these categories have been disproportionately concentrated in those jobs with lower status. Within the professional-technical category, African Americans today are most commonly found in such fields as social and recreational work, public school teaching, vocational counseling, personnel, dietetics, and health-care work; they are least often found among lawyers and judges, dentists, writers and artists, engineers, and university teachers. Within the managerial-administrative category African Americans are most commonly found among restaurant and bar managers, health administrators, and government officials; they are least commonly found among top corporate executives, bank and financial managers, and wholesale sales managers. Such patterns

of job channeling indicate the effects of intentional and indirect racial discrimination over several centuries.

Studies have shown that housing segregation remains very high in U.S. metropolitan areas, North and South. This is true for both low-income and middle-income African Americans. Change in residential balkanization has come very slowly. Census data indicate that from 1980 to 1990 there were only small decreases in the level of residential segregation in thirty major U.S. metropolitan areas; fewer changes than for the previous decade. Two-thirds of the black residents of the southern metropolitan areas and more than three-quarters in northern metropolitan areas would have to move from their present residential areas if one wished to create proportional desegregation in housing arrangements in these cities (Massey and Denton 1993, pp. 221–223). U.S. cities remain highly segregated along racial lines.

At all class levels, African Americans still face much discrimination. After conducting pioneering interviews with forty black women in the Netherlands and the United States, social psychologist Philomena Essed (1990) concluded that racial discrimination remains an omnipresent problem in both nations. She showed that black accounts of racism are much more than discrete individual accounts, for they also represent systems of knowledge that people collectively accumulate to make sense of the racist society. Research by U.S. social scientists has confirmed and extended these findings. Lois Benjamin (1991), Kesho Y. Scott (1991), and Joe Feagin and Melvin Sikes (1994) conducted in-depth interviews to move beyond the common litany of black underclass pathologies to document the racial discrimination that still provides major barriers to black mobility in U.S. society. These field studies have revealed the everyday character of the racial barriers and the consequent pain faced by blacks at the hands of whites in employment, housing, education, and public accommodations.

Researchers Nancy Krieger and Stephen Sidney (1996) gave about 2,000 black respondents a list of seven settings where there might be discrimination. Seventy percent of the female respondents and 84 percent of the male respondents reported facing discrimination in at least one area.

The majority reported discrimination from whites in at least three settings. Several national surveys as well have found substantial racial discrimination. For example, a 1997 Gallup survey (1997, pp. 29–30, 108–110) inquired of black respondents if they had faced discrimination in five areas (work, dining out, shopping, with police, in public transportation) during the last month. Forty-five percent reported discrimination in one or more of these areas in that short period.

Discrimination for most black Americans entails much more than an occasional discriminatory act, but rather a lifetime of thousands of blatant, covert, and subtle acts of differential treatment by whites—actions that cumulate to have significant monetary, psychological, family, and community effects. African Americans contend against this discrimination in a variety of ways, ranging from repressed rage to open resistance and retaliation (Cobbs 1988). This cumulative and persisting discrimination is a major reason for the periodic resurgence of civil rights organizations and protest movements among African Americans (see Morris 1984).

ANTIBLACK RACISM AND OTHER AMERICANS OF COLOR

During the 1990s numerous researchers from Latino, Asian, and Native-American groups accentuated their own group's perspective on racial and ethnic relations and their experience with discrimination in the United States. They have often criticized a binary black-white paradigm they feel is dominant in contemporary research and writing about U.S. racial-ethnic relations (see Perea 1997). From this perspective, the binary black-white paradigm should be abandoned because each non-European group has its distinctive experiences of oppression.

However, a few scholars (Feagin 2000; Ani 1994) have shown the need to adopt a broader view of the long history and current realities of U.S. racism. The racist foundation of the nation was laid in the 1600s by European entrepreneurs and settlers as they enslaved Africans and killed or drove off Native Americans. By the middle of the seventeenth century African Americans were treated by whites, and by the legal system, as chattel

property—a position held by *no other group* in the four centuries of American history. This bloody article-of-property system created great wealth for whites and was soon rationalized in the aforementioned racist ideology. Ever since, whites have remained in firm control of all major U.S. institutions; they have perpetuated a racist system that is still imbedded in all these institutions.

White-on-black oppression is a comprehensive system originally designed for the exploitation of African Americans, one that for centuries has shaped the lives of every American, regardless of background, national origin, or time of entry. This long-standing white-racist framework has been extended and tailored for each new non-European group brought into the nation. Immigrants from places other than Europe, such as Chinese and Japanese immigrants from the mid-1800s to the 1950s and Mexican immigrants after 1900, were often oppressed for white gain and constructed as racialized inferiors without citizenship rights (Takaki 1990). Other types of white racism have been important in U.S. history, but white-on-black racism is the most central case. While it has changed in some ways as time has passed, this systemic racism has stayed roughly constant in its fundamentals. U.S. society is not a multiplicity of disconnected racisms, but has a central white-racist core that was initially developed by whites as they drove Native Americans off their lands and intensely exploited enslaved African Americans. Scholarship (Takaki 1990; Feagin 2000) has shown how this framework was gradually extended and adapted for the oppression of all other non-European groups.

POSSIBILITIES FOR CHANGE

Some African-American scholars have expressed great pessimism about the possibility of significant racial change in the United States. The constitutional scholar Derrick Bell (1992) argues that racism is so fundamental that white Americans will never entertain giving up privileges and thus that black Americans will never gain equality.

There is a long history of African Americans and other people of color resisting racism. The development of resistance movements in the 1950s and 1960s was rooted in activism in local organizations, including churches, going back for centuries

(Morris 1984). Given these deep and persisting roots, many other analysts, black and nonblack, remain optimistic about the possibility of civil rights action for social change. Thus, legal scholar Lani Guinier (1994) has spelled out new ideas for significantly increasing the electoral and political power of black Americans. While the Voting Rights Act (1965) increased the number of black voters and elected officials, it did not give most of these officials an adequate or substantial influence on political decisions in their communities. Guinier suggests new strategies to increase black influence, including requiring supermajorities (a required number of votes from black officials who are in the minority) on key political bodies when there are attempts to pass major legislation.

Some scholars and activists are now pressing for a two-pronged strategy that accents both a continuing civil rights struggle outside black communities and an internal effort to build up self-help projects within those communities. A leading scholar of civil rights, Roy Brooks (1996), has documented the failures and successes of the traditional desegregation strategy. Though still supportive of integration efforts, Brooks has argued that blacks must consider separatist, internally generated, community development strategies for their long-term economic, physical, and psychological success. Working in the tradition of W. E. B. Du Bois and Malcolm X, numerous African-American scholars and community leaders have reiterated the import of traditional African and African-American values for the liberation of their communities from continuing discrimination and oppression by white Americans.

JOE R. FEAGIN

AFRICAN STUDIES

African studies simply defined is the systematic, scientific study of African peoples, and their institutions, culture, and history. But such a simple definition fails to encompass adequately the complexity of this important but often neglected arena for sociological theory and research.

THE GEOGRAPHY OF AFRICA

In sociology, the definition of one's unit of study is prerequisite to undertaking any research project. However, facts of history make the task of defining what encompasses African studies elusive. Geographic or spatial definitions are generally clear-cut, so if one asks, "Where is Africa?" a concise answer is expected. The continent of Africa is easily identifiable on any atlas or globe. By association African studies could be defined as all research falling within the identified physical boundaries of this continental landmass. This is a simple and neat solution—or so it would seem. In reality, however, even the task of defining the physical boundaries of Africa can be daunting. As a vast continent of rich cultural, linguistic, political, and historical diversity, Africa is subject to considerable geographical disaggregation. Thus, what is one continent is approached and conceived of as several subcontinents or subregions. For example, many people—both lay and professional alike—are not accustomed to thinking of Egypt and the northern Islamic states (e.g., Algeria, Libya, Algeria, Morocco) as part of the African continent. These African states are routinely separated in scholarly discourse from Africa and African studies, and are generally treated as parts of the Middle East or Mediterranean.

The tendency toward geographic disaggregation in the conceptualization and study of Africa is also apparent at levels beyond the "North African" versus "sub-Saharan African" distinction. African studies in the so-called "sub-Saharan" context is usually divided into presumably distinct regions of this vast continent: East Africa (e.g., Kenya, Somalia, Tanzania, Uganda); West Africa (e.g., Nigeria, Ghana, Senegal); Central Africa (e.g., Zaire, Congo, Central African Republic); and Southern Africa (e.g., South Africa, Zimbabwe, Lesotho).

An additional complication in approaching the geography of Africa is represented by the partitioning of the continent into arbitrarily designated and imposed nation-states. Climaxing during the critical decades between 1870 and 1914, Western European imperialists divided Africa among themselves in order to share in the exploitation of the continent's rich natural and human resources. The Berlin Conference, a meeting among various European powers, was held from November 15, 1884 to February 26, 1885 in response to envy and mistrust spurred by competing attempts to claim and colonize Africa. The gathering produced negotiated guidelines for the division and governance of Africa by Europeans. As one striking example, the Congo River basin, envied and hotly contested by several European powers (e.g., Portugal, Britain, France, Germany, Belgium), was by consensus ceded to King Leopold II and Belgium. As another example, while some contested claims were settled, West Africa continued to be divided unequally among the colonizing countries that were fighting amongst themselves for the land and the people: Portugal claimed 14,000 square miles; Germany took possession of 33,000 square miles; Britain declared ownership of 450,000 square miles; and France laid claim to 1.8 million square miles of African soil. In claiming the land, these European powers also declared dominion over the people who occupied these lands.

By 1898 Europeans had colonized most of Africa. Since the lines of demarcation were drawn with European rather than African interests in mind, these artificially imposed geographic boundaries often dissected cultural and national groups or tribes that had been unified entities for centuries before the arrival of Europeans. The political or national boundaries arbitrarily established by European conquest had profound, far-reaching consequences. These boundaries are largely responsible for contemporary borders and nation-states in Africa. Moreover, these artificial divisions or mergers, or both, damaged historic patterns and relationships and, by so doing, contributed in some degree to ongoing ethnic conflicts in Africa. As with icebergs formed over centuries where we only can see the tip, these historic machinations provided the impetus for many "modern" conflicts in Africa. In these cases, colonial influence persists long after independence was proclaimed.

As a strategy, colonizers chose and groomed new African leadership to reinforce the ideals of newly formed, imposed nation-states, thereby creating a native elite and fostering division and mistrust among the colonized. The strategic approach to implementation varied for different colonial powers. France and Britain were the most successful Western European colonizing powers. Interestingly, their approaches to subduing and exploiting the African colonies differed vastly. The French saw traditional African heads-of-state as occupying the least important position within their new administrative system. Existing African governments were viewed as obstacles to the ultimate integration of Africans with French culture and society. Thus, achieving the French goal necessitated the utter destruction of established governmental systems as well as the absolute eradication of traditional cultures. Similar to American laws during the era of slavery, practicing ancestral religions, speaking traditional languages, and participating in customs such as dancing were deemed unlawful and were punishable by whipping, torture, and even death. The British, on the other hand, were more indirect. They sought to mold traditional governmental structures to accomplish their goals at the district level, while closely regulating the colonial administration nationally. The intention was for their African colonies to follow the examples of Canada and Australia, eventually emerging as self-governing extensions of the British Empire.

The institutionalized practice of misrepresenting the scale of Africa in relation to other continents is another point of contention. A European-inspired and -dominated cartography has successfully institutionalized blatantly misrepresentative views of African topography. The traditional world map portrays Europe's landmass as much larger than its true physical reality. Since the 1700s, the Mercator map scale, the most widely used cartographic scale in the world, has distorted the sizes of continents to favor the Northern Hemisphere. While traditional mapmaking and representations have instilled a picture of North America as equal in size to Africa, the Sahara Desert alone is in fact roughly the same size as the United States. The African continent has nearly four times the landmass of North America and comprises approximately twenty percent of the world's landmass.

More subtly, the world's geographic view of Africa has evolved to attribute a unidimensional image of Africa as consisting wholly of lush, impenetrable, tropical forests. This view of African geography fails to do justice to the rich, variegated landscape of this vast continent. Tropical rainforests represent only the smallest fraction of Africa's myriad landscape, which ranges from snow-capped mountains to deserts to high plains to hardwood forests, from rippling fields of grain to placid lakes. In fact the world's largest desert, the world's longest river, and natural wonders from the spectacular Victoria Falls to snow-capped Mount Kilimanjaro, all characterize the diversified topography of this continent.

THE PEOPLE OF AFRICA

"Where is Africa?" We see that the answer to this, the most essential or rudimentary of originating questions for sociological research, can be quite elusive. Facts of history and perception combine to make what should be a simple interrogatory quite complicated. Equally elusive, if not more so, is the task of defining "Who is African?" The answer to this seemingly straightforward question seems obvious. More often than not, answers to this question conform to the widespread view of Africans as a race of black people characterized by dark skin, curly hair, broad noses and numerous other physical features. In fact, the biological diversity of Africans matches and, at points, surpasses Africa's vast geographic diversity. Few other continents in the world approach or match the breadth of human biology and physiology historically found in Africa. Africans run the gamut of the human color spectrum, encompassing the range of human prototypes—the Negroid, the Mongoloid, the Caucasoid. For centuries the continent of Africa has been home not only to people of traditional biophysical description, but also to people descended from Europeans, Asians, Arabs, and Hispanics. Moreover, centuries of biological intermingling have produced a continent of hybrid people. Africa is truly a continent where the human reality defies attempts to neatly categorize race and racial identity.

Traditional images of race fail to embrace or represent the African reality adequately. Modern

conceptions of race are derived from a hierarchical European worldview that assigns the lowest status to Africans, who are equated with blackness—the opposite of whiteness or European ancestry. When carefully examined in either an African or European context, racial identity loses much of its force as a concept. “White” and “black” are more political designations than physical ones. Thus, although there are indigenous Africans who have lighter complexions than some indigenous Europeans, widespread views of Europe as white and Africa as black persist. By the same token, race is often reified and incorrectly attributed characteristics that are in point of fact intellectual, social, cultural, or economic rather than biological. Generally speaking, race is incorrectly presumed to incorporate characteristics that extend far beyond human physical traits.

Apartheid in South Africa provides an excellent example of the politically motivated, exclusionary nature of racial classification systems (as does the historical case of “Jim Crow” segregation in the U.S. South). The assignment of people to categories of White, Coloured, and African (Black) in South Africa, coupled with the subdivision of each racial category into smaller racial groups (e.g., Whites = Afrikaner and English-speaking; Asians = East Indian and Malaysian; Coloureds = European/African and Asian/African; and Blacks = Zulu, Xhosa, Sotho), was largely determined by white efforts, as a demographic minority of the population, to maintain their historic political, economic, and social dominance. Apartheid relied on an elaborate system of “racial markers,” such as hair texture, skin color, and parentage, to classify people into distinct racial groups. Associated with each racial group were certain privileges and restrictions. Restrictions were heaviest and privileges least for black Africans, the group at the bottom of the South African color hierarchy. Thus race, as a socially constructed, politically manipulated reality in South Africa, exerted overwhelming force in limiting black and coloured Africans’ access and opportunities. The myth of the color hierarchy became—to some degree—a self-fulfilling, self-perpetuating prophecy in that many people, irrespective of race, internalized this value system. The result was often self-imposed ranking, with people of color creating additional levels within the established hierarchy, thereby constructing

intricate designations for race that extended far beyond traditional definition.

Discussions of African racial identity are additionally complicated by the vast global population of people of African ancestry. People of African descent are present in sizeable numbers in the Americas, Western Europe, and in parts of Asia and the South Pacific. In most instances, the dispersion of African people around the world—notably in Brazil, the United States, the Caribbean, and Britain—is directly traceable to the European conquest, domination, and distribution of African people. Europe created, installed, and operated a system of racial slave trade that fueled the economic, agricultural, and industrial development of the Americas and of Europe. The slave trade displaced millions of Africans and struck a crippling blow to social, economic, political, and cultural life on the African continent. The traffic in slaves was a demographic disaster for the African continent, taking away people in the prime of their reproductive and productive lives. The African slave trade left in its wake destroyed villages, ruined crops, disrupted cultures, and crumbling social institutions. So traumatic was the devastation of this trade in human lives, and the subsequent colonial exploitation of Africa for natural resources, that four centuries later Africa has not yet fully recovered.

Dramatic and extensive dispersion of Africans confounded questions of race and racial identity because of the extensive intermingling of Africans with other so-called racial groups. This was particularly true in the Americas, where systematic and legalized rape was characteristic of the era of enslavement. The manipulation of race and racial identity was a central feature in this drama. White men used sexual subjugation as another means of reinforcing their domination, resulting in the established pattern of African hybrid identity. Yet under the legal guidelines of American enslavement, the children who resulted from this institutionalized rape were considered black, and thereby referred to by Chief Justice Taney (*Dred Scott v. Sandford*, U.S. Supreme Court, 1857) as a people with “no rights which the white man was bound to respect.” African ancestry combined with Native American, Asian, and European bloodlines to further diversify the already rich biological heritage of Africans. The extension of the African diaspora

to the Americas produced a people represented by black Chinese in Mississippi, Jamaica, and Trinidad; black Amerindians in Florida (Seminoles), Oklahoma (Cherokee), and Surinam (Arawaks); black Irish in Virginia, black English in Barbados, black Portuguese in Brazil; and black East Indians in Guyana, black French Canadians in Montreal; and black Mexicans in Vera Cruz. A veritable human rainbow resulted from the transplantation of Africans to the “New World” and points beyond. Yet throughout the diaspora, Social Darwinism assigned Africans the lowest position on the evolutionary hierarchy and laid the foundation for elaborate ideology and pseudoscience that offered justifications for the continued subjugation of Africans. Ideologies founded upon the rationalization that lent credence to this travesty persist today, further plaguing Africans throughout the diaspora.

THE CULTURAL AND SOCIAL INSTITUTIONS OF AFRICA

We have seen the complexity that underlies the seemingly simple questions of “Where is Africa” and “Who is African.” The task of defining for sociological study a people who are both geographically and genetically dispersed is extremely challenging. Additional complication results when we ask the next question, “What is African?” Here we simply raise the logical question of which institutions, customs, values, institutions, cultural features, and social forms can be characterized or labeled as distinctively African.

The survival (albeit in evolved form) of indigenous African customs, values, and institutions is remarkable, especially considering the abundance of historical barriers and complications. First among these is the reality of African conquest and domination by other cultures, most notably European, but also including cultures from the Islamic world. The experience of conquest and domination by external powers, often designed to annihilate African civilization, makes the myriad existing retentions all the more amazing. One of the best examples of these retentions is what Africa and people of African ancestry have done with the abundance of nonindigenous languages that were imposed upon them during colonization.

Language plays a vital role in the process of cultural and personal affirmation. Therefore, it is not surprising to note that the conquest experience of Africa and Africans in the diaspora was commonly associated with systematic attempts to suppress or eliminate indigenous languages. The African continent can be divided into European language communities that parallel the geographic regions associated with European domination and partition of Africa (e.g., Anglophone, Francophone). In a similar fashion, members of the African diaspora have adopted the dominant languages of the cultures and regions where they found themselves, speaking Arabic, Portuguese, Spanish, English, French, or Dutch. However, before European languages were introduced, there were well over 800 languages spoken by various African ethnic groups, most of which can be classified between three of the principal language families—Niger-Kordofian, Nilo-Saharan, and Khoisian. Numerically, these African-selected language groups incorporate approximately 300 million people.

Many if not most Africans are minimally bilingual, routinely speaking several languages in addition to their own. However, colonial tongues are generally recognized as the country’s “official” language. Part of the devastation of colonization is the demise of original languages as the primary means of communication. These languages are forgotten, ignored, and sometimes even mocked by those who would assimilate into Westernized ideals. Strikingly, many independent African nations have embarked on programs aimed at the regeneration of indigenous languages, often creating written forms for languages that were previously solely oral. Other African nations have substituted indigenous languages for European languages (derived from the country’s colonial experience) as the country’s “official” language. South Africa is an example of a country where multiple national languages were officially established in a process that validated the myriad of mother tongues as well as the colonizers’ language.

Attempting to strip Africans of their language was an essential feature of the move to supplement military, economic, and political domination with cultural domination. However, understanding the essential connection between language, worldview, personal identity, and cultural survival,

many Africans fought to retain their indigenous languages. They believed their survival as a unique people hinged on successful retention of their original languages, and the culture, values, self-affirmation, and history embodied within those native tongues. Interesting variations in the retention of African language forms are observable throughout Africa and the African diaspora. The patois (patwa) spoken in Jamaica contains many words that need no translation from Twi, the language spoken by the Ghanaian Ashanti who constituted the majority of the slaves brought in to work on Jamaican plantations. French has been transformed in both Louisiana and Haiti with varieties of Kreyol. In North America we can observe the Gullah people, primarily found in South Carolina and Georgia, who infuse their English-based Creole with the language of their enslaved African ancestors. Standard black American English (sometimes referred to as Ebonics) also retains evidence of similar African-derived language structures. A related case is provided by places like Bahia in Brazil where Yoruba, an indigenous African language, was successfully transplanted and maintained outside the continent. There are nations on the African continent where indigenous languages were practiced throughout the colonial experience and reinstated after independence. However, as we have observed, the most common case across the diaspora is the synthesis of African syntax with the dominant European language syntax to create a new language.

The pattern of adaptive acculturation or synthesis that occurs with language also characterizes other sociocultural institutions in Africa and across the diaspora. Art and music provide distinctive examples. African people traditionally use visual art as a means of communication. Cloth making, for example, is not simply an aesthetic undertaking. Often, messages are inscribed or embedded within the very combinations of patterns and colors chosen to create the fabric. Among the Ashanti in Ghana, funeral cloth is often adorned with what are known as Adinkra symbols. The symbols impressed upon the cloth convey different meanings, thereby transmitting messages to those who are knowledgeable. The Touaregs, a people concentrated in Niger, are also known to transcribe messages on cloth in the distinctive alphabet that characterizes their language. Within Rastafarian

culture in Jamaica, sculpture is used as another method of communicating and reinforcing the beliefs of the practitioners. Moreover, African-American artists often draw from the diaspora in their creation of visual art. Lois Mailou Jones traversed the French-speaking African world, and her work was influenced by the various cultures she studied.

Artistic products of African people, especially those living outside of the continent, reflect the mixture of cultural influences—part indigenous, part nonindigenous—that characterize the African experience. The synthesis contains elements that are obviously African-derived alongside elements that are obviously European or Islamic. Yet the final tune or drawing is often truly syncretic, possessing emergent qualities greater than the sum of the influences. It is in the realm of cultural production, music and art, where the African influence on world society has been most readily apparent. During the period of colonization, ruling cultures often defined the oppressed as “others” in an effort to justify their subhuman treatment. Historic views of African-American culture provide powerful examples of objectification and stereotypes such as “Sambo,” the happy darkie, or “Jezebel,” the promiscuous black female. These false perceptions permeated the fabric of American society, allowing whites to embrace the racial stereotypes and notions that blacks were content in their status as second-class citizens. In order to perpetuate these false images, blacks were allowed to prosper in media and occupations that coincided with and reinforced views of their subservient status. To do otherwise was to risk retribution from whites. Thus, the entertainment industry (and its related variant, professional sports) has historically provided socially acceptable, non-threatening roles for blacks.

Many blacks recognized the power inherent in these media and used them for empowerment and to accomplish larger goals. For example, we can note the themes of resistance embodied in traditional spirituals sung during slavery. It is also interesting to observe the tremendous impact of music during the civil rights movement. In many instances, a syncretic merger has been achieved that fuses indigenous African “authenticity” with nonindigenous traits to create new forms of music

(e.g., rap). People of African descent have facilitated the growth of myriad musical genres, such as reggae, zouk, jazz, blues, soca, zaico, calypso, go-go, Hip Hop, and gospel. In yet other instances, Africans have chosen to embrace, master, and operate within the unmodified European form (e.g., opera, classical music).

Religion is another excellent example of a sociocultural institution that challenges us to define what is distinctively African. Forms of indigenous African religion are as diverse as the continent and people themselves. Christianity, Islam, and Judaism all have long histories on the continent. The same is true for traditional, animistic African religions that imbue all features of the environment with spiritual qualities. It is perhaps the long tradition of polytheism—or, more correctly, the belief in, and acceptance of a Supreme God who is in turn represented in the world by several intermediary spirits—that made Africa and African people such fertile ground for the spread of diverse religions.

In addition, colonial powers felt a need to control all forms of thought and expression in order to ensure their continued dominion over the indigenous people. Religion was recognized as an especially powerful medium with immense capacity to control the daily behavior of people. Thus, religion was a central component in the colonial arsenal and pattern of domination. In spite of this, many traditional African religions have survived the test of time. Both the original forms and syncretic amalgamations of Western and traditional religion are found throughout the diaspora. On the island of Jamaica, one can observe how the Ashanti religion Kumina has flourished and grown over time into the distinctly Jamaican Pukumina (Pocomania). Linkages such as the one between the Gabonese sect known as Bwiti and Haitian vodun continue, in which the words for traditional healer are almost the same. Continuities are also seen in Shango/Santeria (Brazil) and Rastafarianism (Jamaica and internationally). Religious forms throughout the African diaspora range from the classical European through the traditional African into the Islamic, with a large variety of syncretic forms interspersed throughout.

The organization of social and community life in Africa and across the African diaspora also runs

the spectrum from indigenous to nonindigenous. In a now familiar pattern, there exist places in Africa or in the African diaspora where traditional African forms of family life, dating back centuries, persist. Similarly, there are places where family forms are closer to the European or the Islamic model. The same observations can be offered about education and the organization of schools among Africans in a given society.

Predictably, given Africa's history of subjugation, it is in realms of international power and influence, economics, government, and the military, that African development has been most restricted. Historical deprivation has resulted in the ranking of Africa and people of African ancestry at the bottom of all indicators of economic development. While other formerly colonized countries have managed to advance economically (e.g., Brazil, Singapore, and Korea), much of Africa and the African diaspora continue to be economically dependent. Coupled with this economic dependence are persistently high rates of unemployment, disease, educational disadvantage, and population growth. Africans continue to be without significant representation at the centers of international power, judged by economic clout, political influence, and military might. In each of these aspects, Africa remains the suppressed giant, unable to exert world influence commensurate to her nearly billion people, strategic geopolitical location, and rich mineral and human resources. The emergence of Africa onto the world stage, like Japan's in 1960 and China's in 1980, will have to wait.

UNIFYING THEMES IN AFRICAN STUDIES

Due to historical context, we have seen there are no simple answers to the basic questions for orienting any scientific, sociological study of Africa and her people. The African diaspora has been uniquely shaped by experiences of conquest and domination, resistance and survival. The experiences of slavery, colonization, and external domination have left in their wake considerable devastation. Yet one also sees the amazing strength of a people able to adapt and diversify, and to love and live, and ultimately continue to be.

Studies of African people and institutions commonly reveal the creative retention of authentic or

indigenous traits. Such creative responses have been, in their own way, acts of resistance enabling cultural perpetuation. These adaptive responses have assured the ultimate survival of many aspects of African culture and institutions. It must also be noted that with time comes transition. Many things traditionally African have been altered, progressing from their original, indigenous form to completely new and different forms. It is perhaps in this tension, the reconciliation of the old with the new, the indigenous with the nonindigenous, that African studies will find its most exciting terrain for future inquiry. The challenge will be to discover the cultures and the people who have been historically distorted by the twin activities of concealment from within, and degradation and misperception from without.

AMERICAN SCHOLARSHIP AND AFRICAN STUDIES

The dismissal of the importance of African studies preceded its acceptance as a scholarly discipline. While clearly diminished today, the white male Eurocentric focus has historically dominated university curricula. Both grassroots and academic movements pointed to the need for recognition of the African contribution to world and American culture. The early to mid-1900s saw the emergence of black intellectuals in Africa (e.g., Léopold Sédar Senghor, Patrice Lumumba, Cheikh Anta Diop), the Caribbean (Frantz Fanon, Aimé Césaire, Claude McKay), and America (W.E.B. Du Bois, Langston Hughes, Anna Julia Cooper), who spoke of parallel movements based on the assumption that black people in all parts of the world were a community with shared interests and identity (e.g., Negritude, Pan-Africanism). The goals of these scholars emphasized the uplift of people of African ancestry worldwide through education, research, politics, and cultural activities. These international movements among black intellectuals were in direct response to theories of black inferiority and the systematic oppression of Africans (both on the continent and abroad). Herbert Spencer, among others, launched the ideology of Social Darwinism, which developed into a popular, pseudoscientific justification for racial hierarchies. Social Darwinism assigned Africans, and thereby African Americans, to the lowest rung in the evolutionary ladder.

A nineteenth-century phenomenon, Social Darwinism and its associated beliefs persisted well into the twentieth century. Its philosophy is still heard in the remnants of eugenics, in the present-day interest in sociobiology, and in recurring assertions of black innate intellectual inferiority.

Before the incorporation of African studies into predominantly white colleges, black educators and leaders had stressed the value of black America's ties to Africa for decades. Notable activists from William Monroe Trotter to Booker T. Washington and Marcus Garvey called for "Back to Africa" movements. Zora Neale Hurston was an anthropologist whose studies of African Americans emphasized retentions and links with original African cultures. The distinguished sociologist W.E.B. Du Bois founded the Pan-African Congress in 1921, supported by notables such as the author Jessie Redmon Fauset, in order to explicitly link the problems and fortunes of African Americans to those of blacks in Africa and elsewhere. Moreover, much of his work over a long and illustrious career focused on Africa. Ultimately Du Bois renounced his American citizenship and accepted Kwame Nkrumah's invitation to settle in Ghana.

Within white-dominated institutions, the value of African studies had strange origins. Egyptologists and anthropologists gathered information from Africa during colonial rule. In such instances, sociology was both friend and foe. Early sociologists promoted cross-cultural studies as well as research into the social conditions under which blacks lived. However, many of these sociologists embraced Social Darwinism and its belief in the inherent inferiority of blacks. Rarely did these early academics speak out or take active stances against the oppression of Africa and African people by Europeans.

Some American colleges remained racially segregated until the 1960s. The inclusion of African-American students, and later African-American studies classes, came in response to student activism, which occurred against the backdrop of the push for civil rights and amidst significant racial unrest. The black power movement of this time strongly influenced many African Americans to reclaim their heritage in everyday life and to demand that black history and culture be included in school and university curricula. There was—and

continues to be—significant struggle around these questions, since what is at risk here was (is) the control and validation of knowledge in the society. The black studies movement paved the way for further interest in African studies. The publication of Alex Haley's *Roots*, a volume which traced his family lineage back to Gambia, West Africa, followed by a popular television miniseries, was a signal moment in the development of black Americans' interest in Africa. In addition, many African Americans celebrate Kwanzaa, a holiday founded upon principles of the African harvest, as another conscious link with their cultural roots. Ironically, the growing interest of black Americans in their cultural roots in Africa helped to fuel a resurgence of ethnic pride and the search for roots among other racial groups in this country. Interestingly, in contemporary universities, the field of African-American studies tends to be dominated by African Americans, while African-studies programs tend to be dominated by European Americans.

CONCLUSION

African studies is a woefully underdeveloped area of institutionalized research in the field of sociology. Researchers need to mount aggressive programs determined to "ask new questions and to question old answers." For this research to be successful, it must be located in broader context, recognizing the unique historical, economic, social, cultural, political, and academic relationships that determine reality for Africans on the continent and throughout the diaspora. In each of these areas, relationships are generally structured hierarchically, with African worldviews, values, institutional forms, methodologies, and concerns being considered subordinate to those of Europeans or whites. Such distorted structural relations lead inevitably to distortions in research and conclusions. The irony is that clear understanding of African people and institutions will help pave the way to better understanding Whites and European heritage, institutions, and experiences.

AGGRESSION

In its most extreme forms, aggression is human tragedy unsurpassed. Hopes that the horrors of World War II and the Holocaust would produce a worldwide revulsion against the taking of another human's life, resulting in the end of genocidal practices and a reduction in homicide rates, have been dashed by the realities of increasing homicide and genocide in the last half of the twentieth century. The litany of genocidal events is both long and depressing, including major massacres in Uganda, Cambodia, Rwanda, Burundi, Zaire, Bosnia, Serbia, Croatia, and Herzegovina, among others. Homicide rates have risen in a number of industrialized countries since World War II, most notably in the United States.

We have seen slight declines in the homicide rate in the United States during the 1990s. But despite six consecutive years of decreases, the 1997 homicide rate was still 133 percent of the 1965 rate, and 166 percent of the 1955 rate. For these and related reasons, interest in understanding the causes of aggression remains high, and there have been major advances in the social psychology of aggression.

WHAT IS AGGRESSION?

Definitions have varied widely over time and across research domains. However, a consensus has emerged among most social psychologists studying human aggression about what constitutes "aggression" in general and what constitutes the major forms or "ideal types" of aggression. (See the following books for current definitions and perspectives on aggression: Baron and Richardson

1994; Berkowitz 1993; Geen 1990; Geen and Donnerstein 1998; Tedeschi and Felson 1994).

Basic Definitions. *Aggression vs. Assertiveness vs. Violence.* Human aggression is behavior performed by one person (the aggressor) with the intent of harming another person (the victim) who is believed by the aggressor to be motivated to avoid that harm. "Harm" includes physical harm (e.g., a punch to the face), psychological harm (e.g., verbal insults), and indirect harm (e.g., destroying the victim's property).

Accidental harm is not "aggressive" because it is not intended. Harm that is an incidental by-product of actions taken to achieve some superordinate goal is also excluded from "aggression" because the harm-doer's primary intent in such cases is to help the person achieve the superordinate goal and because the harm-recipient doesn't actively attempt to avoid the harm-doer's action. For example, pain delivered during a dental procedure is not "aggression" by the dentist against the patient.

In their scientific usages "aggressiveness" is very different from "assertiveness" even though the general public frequently uses these words interchangeably. When people say that someone is an "aggressive" salesperson they typically mean that he or she is assertive—pushy or confident or emphatic or persistent—but they do not truly mean "aggressive" unless, of course, they believe that the salesperson intentionally tries to harm customers. Similarly, coaches exhorting players to "be more aggressive" seldom mean that players should try to harm their opponents; rather, coaches want players to be more assertive—active and confident.

Violence, on the other hand, is a subtype of aggression. The term "violence" is generally used to denote extreme forms of aggression such as murder, rape, and assault. All violence is aggression, but many instances of aggression are not violent. For example, one child pushing another off a tricycle is considered aggressive but not violent. For example, one child pushing another off a tricycle is considered aggressive but not violent.

Affective vs. Instrumental Types of Aggression. "Affective" aggression has the primary motive of harming the target, and is thought to be based on

anger. It is sometimes labeled hostile, impulsive, or reactive aggression, though these labels often carry additional meaning. When aggression is merely a tool to achieve another goal of the aggressor, it is labeled “instrumental” aggression. Most robberies are primarily instrumental, whereas most murders and assaults are affective. Similarly, Jack may hit Jim merely to obtain a desirable toy, a case of instrumental aggression. Jim may get angry and respond by hitting Jack in order to hurt him, a case of affective aggression.

Proactive vs. Reactive Types of Aggression. “Proactive” aggression occurs in the absence of provocation. It is usually instrumental, as when Jack hit Jim to get the toy. “Reactive” aggression is a response to a prior provocation, such when Jim retaliated. There is an asymmetrical relation between proactive and reactive aggression. Children who are high on proactive aggression usually are high on reactive aggression as well, but many children who are high on reactive aggression engage in little proactive aggression.

Thoughtful vs. Thoughtless Aggression. A more recent distinction among types of aggression concerns whether the aggressive act resulted from thoughtful or thoughtless (impulsive) psychological processes. In past work, instrumental aggression has usually been seen as thoughtful, involving the careful weighing of potential costs and benefits. But more recent work reveals that frequent use of aggression to obtain valued goals can become so automatized that it also becomes thoughtless. Affective aggression has usually been seen as thoughtless, but people sometimes consider various possible courses of action and decide that an angry outburst is the best way to achieve those goals. This distinction between thoughtful and thoughtless aggression has important implications for the development of and intervention in aggression.

Distinguishing among types of aggression is difficult because underlying motives and psychological processes must be inferred. Is Jim’s angry attack on Jack purely anger-based, solely intended to harm Jack, or is there also some instrumental component? There is a growing realization that these ideal types of aggression rarely exist in pure form in the real world of human interaction. Indeed, a few scholars have argued that all aggression is instrumental, serving goals such as social control, public-image management, private-image

management (i.e., self-esteem), and social justice. Nonetheless, most aggression scholars still find these distinctions helpful for theoretical, rhetorical, and application-oriented reasons.

WHAT CAUSES AGGRESSION?

The causes of aggression can be analyzed at two different levels: the proximal causes (in the immediate situation) and the more distal causes that set the stage for the emergence and operation of proximate causes.

Distal Causes: Biological Factors. Distal causes of aggression are those that make people ready and capable of aggression. Some are structural, built into the human species. Others are developmental, based on the particular environmental history of the individual, and result in individual differences in preparedness to aggress.

Genetics. In the broadest sense aggression is a species characteristic. That is, the human species has physical, cognitive, and emotional systems capable of intentionally inflicting harm on other humans. The genetic basis of aggression is easier to identify in nonhuman species, in which fighting behaviors can be produced by stimulating certain regions of the limbic system. Similar physiological systems exist in humans, but human behavior is much more complexly determined.

In the more usual sense genetic influences refer to individual differences in aggressiveness that are linked to genetic differences within the species. Human twin studies have yielded mixed results in estimates of the genetic contribution to human aggression. Miles and Carey (1997) did a meta-analysis (i.e., statistical review) on twenty-four “genetically informative” studies. Two important conclusions were: (1) up to 50 percent of variation in self- or parent-reported aggression was attributable to genetic effects; and (2) when aggressiveness was measured by careful observation of laboratory behaviors, the genetic effect disappeared and a strong family-environment effect emerged. These contradictory findings highlight the complexity of human aggression as well as the need for additional studies.

Mechanisms. Several biological mechanisms appear plausible as potential causes of individual differences in aggressiveness. Hormones (e.g.,

testosterone), neurochemicals (e.g., serotonin), attention deficit hyperactivity disorder, and general levels of arousal have all been linked to aggression. For example, Eysenck and Gudjonsson (1989) proposed that individuals whose nervous system is relatively insensitive to low levels of environmental stimulation seek out high-risk activities, including criminal ones, to increase their arousal.

But many biological effects on aggression are neither as strong nor as consistent as the general public believes. For example, testosterone is frequently cited as the explanation for male/female differences in violence rates, but the human literature on testosterone effects is far from clear. Testosterone levels in humans seems more closely linked to social dominance, which in turn may well influence aggression under some limited circumstances (Campbell, Muncer, and Odber 1997; Geary 1998).

Other psychological variables with links to aggression also appear to have some genetic basis. Empathy, behavioral inhibition, negative affectivity, extraversion, neuroticism, and psychoticism all have yielded evidence of some genetic heritability, and have obvious links to aggression. General intelligence may also link biological variation to aggressiveness; low intelligence increases the occurrence of frustrating failures and aversive conditions, which might increase the likelihood of a person developing an aggressive personality.

Distal Causes: Environmental and Psychological Factors. Numerous social, environmental, and psychological factors contribute to the development of habitual aggressiveness. Learning stands out as the most important factor of all.

Learning. Bandura's social-learning theory of aggression (1973) has been most influential. One key idea in this and all modern learning approaches is that much of human development is based on learning by observing how other people behave. Patterson, DeBaryshe, and Ramsey (1989) presented a detailed look at the maladaptive social-learning processes found in families of aggressive children. Among the key problems are parental use of poor disciplinary measures and inadequate monitoring of their children's activities. Similarly, Olweus (1995) has identified a number of child-rearing factors that are conducive to creating bullies: caretakers with indifferent attitudes toward the child; permissiveness for aggressive behavior

by the child; and the use of physical punishment and other power-assertive disciplinary techniques.

Cognitive psychology has also been crucial in the present understanding of the aggressive personality, as can be seen in books by Berkowitz (1993) and Geen (1990), and in Huesmann's (1998) information-processing theory of aggressive personality development. In brief, humans begin learning from infancy how to perceive, interpret, judge, and respond to events in the physical and social environment. We learn perceptual schemata that help us decide what to look for and what we "see." We learn rules for how the social world works. We learn behavioral scripts and use them to interpret events and actions of others and to guide our own behavioral responses to those events. These various *knowledge structures* develop over time. They are based on the day-to-day observations of and interactions with other people: real (as in the family) and imagined (as in the mass media). For example, the long-term exposure to media violence can increase later aggressive behavior by influencing a variety of aggression-related knowledge structures. Such long-term media violence effects have been shown to be substantial in size and long lasting in duration (Huesmann and Miller 1994).

As knowledge structures develop, they become more complex, interconnected, and difficult to change. Developing knowledge structures are like slowly hardening clay. Environmental experiences shape the clay. Changes are relatively easy to make at first, when the clay is soft, but later on changes become increasingly difficult. Longitudinal studies suggest that aggression-related knowledge structures begin to harden around age eight or nine, and become more perseverant with increasing age.

People learn specific aggressive behaviors, the likely outcome of such behaviors, and how and when to apply these behaviors. They learn hostile perception, attribution, and expectation biases, callous attitudes, and how to disengage or ignore normal empathic reactions that might serve as aggression inhibitors.

The pervasiveness, interconnectedness, and accessibility of any learned knowledge structure is largely determined by the frequency with which it is encountered, imagined, and used. With great

frequency even complex perception-judgment-behavior knowledge structures can become *automatized*—so overlearned that they are applied automatically with little effort or awareness. Frequent exposure to aggressive models is particularly effective in creating habitually aggressive people, whether those models are in the home, neighborhood, or mass media. Once the use of any particular knowledge structure has become automatized, it becomes very difficult for the person to avoid using it because the perceptions and behavioral impulses it produces seem to be based on “how the world really is.”

Social Processes. Several common social processes contribute to disproportionate exposure to and learning of aggression-related knowledge structures. Low intellect (social or academic) creates excessive failures and frustration in a variety of developmental contexts. Low social intelligence, for example, leads to problems in interpersonal interactions, whereas low academic intelligence creates problems in school settings. Problems in either context typically lead to higher-than-normal levels of aggression, which lead to further frustrating encounters with parents, teachers, and peers. The resulting social ostracism often forces children to spend more time with other social misfits who also have highly aggressive behavior patterns. This “gang” can impede further intellectual development and reward additional antisocial tendencies.

Environments. Many social environments foster the development of an aggressive personality. Such factors include poverty; living in violent neighborhoods; deviant peers; lack of safe, supervised child recreational areas; exposure to media violence; bad parenting; and lack of social support. Growing up in a culture of fear and hate, as in many ethnic-minority communities around the world, may well be the most extreme version of an aggressive-personality-fostering environment, and may well account for the generation after generation of ethnic and religious hatreds and genocidal tendencies that occasionally erupt into genocidal wars (Keltner and Robinson 1996; Staub 1989, 1998). The perceptual knowledge structures modeled and explicitly taught in these contexts guarantee continued mistrust, misunderstanding, and hatred of key outgroups.

Even in its simplest form, poverty is associated with more frustrations, bad role models, and lack

of good role models. Bad parenting includes several particularly common and damaging factors such as lack of parental attention, inconsistent discipline, harsh and abusive discipline, and inattention to nonaggressive efforts at problem solving by the child. Privation, victimization, and violence in a social milieu of long-standing ethnic/religious conflicts provide a powerful learning environment that is mightily resistant to change.

Short-term impoverishment, such as that brought on by a general decline in economic activity (e.g., a recession or depression), has been proposed as a causal factor in aggression directed against ethnic minorities. The dominant model is that the frustration engendered by such economic downturns leads to increased aggression against relatively powerless target groups. However, research casts considerable doubt on this hypothesis. For example, Green, Glaser, and Rich (1998) reanalyzed data on lynchings and data on “gay-bashing,” and showed no evidence of short-term fluctuations in economic conditions and violence directed at minorities.

Child abuse and neglect. Child abuse and neglect itself are self-perpetuating problems. Abused or neglected children are particularly likely to become abusing and neglecting parents and violent criminal offenders. Children learn maladaptive beliefs, attitudes, and values from their abusive or neglectful parents (Azar and Rohrbeck 1986; Peterson, Gable, Doyle, and Ewugman 1997).

Proximate Causes: Individual Differences. The distal causes described in earlier sections set the stage for human aggression of various types. Proximate causes are those that are present in the current situation. One type of proximate cause consists of individual differences between people that have been created by their biological and social pasts. People differ widely in readiness for aggressing. These differences show considerable consistency across time and situations (Huesmann and Moise 1998).

Hostility Biases. Hostility biases have been identified in aggressive adults and children, some as young as six years. The *hostile perception bias* is the tendency of aggression-prone people to perceive social behaviors as more aggressive than do normal people, whereas the *hostile expectation bias* is the tendency of aggression-prone people to expect

and predict others to behave relatively more aggressively (Dill, Anderson, Anderson, and Deuser 1997). The more widely studied *hostile attribution bias* is the tendency of aggression-prone people to attribute hostile intent to others' accidentally harmful behaviors. For example, Dodge (1980) had aggressive and nonaggressive children listen to a story about a boy who hurt another boy by hitting him with a ball. When asked, aggressive children attributed more hostile intent to the boy who threw the ball than did nonaggressive children.

Attitudes and Beliefs. Aggression-prone people hold favorable attitudes toward aggression, believing that aggressive solutions to problems are effective and appropriate. Aggressive thoughts and aggressive solutions come to mind quickly and easily. However, creating nonaggressive alternatives is particularly difficult for the aggressive person.

For example, Malamuth, Linz, Heavey, Barnes, and Acker (1995) found that sexually aggressive males hold relatively positive attitudes toward the use of aggression against women, believe in numerous rape myths, engage in more impersonal sex, and are likely to aggress against women in nonsexual contexts as well. Research (Anderson and Anderson 1999) reveals that sexually aggressive men are specifically aggressive only against women, in both sexual and nonsexual contexts, but are not unusually aggressive against other men.

Narcissism and Self-Esteem. The predominant view of the link between self-esteem and violence has been that low self-esteem contributes to high violence. However, research from several perspectives has demonstrated a very different pattern. Certain individuals with high self-esteem are most prone to anger and are most aggressive when their high self-image is threatened. Specifically, it is high self-esteem people who react most violently to threats to their self-esteem—if their high self-esteem is inflated (undeserved), unstable, or tentative. In other words, narcissists are the dangerous people, not those with low self-esteem or those who are confident in their high self-image (Baumeister, Smart, and Boden 1996; Bushman and Baumeister 1998; Kernis, Grannemann, and Barclay 1989).

Sex. Males and females differ in aggressive tendencies, especially in the most violent behaviors of homicide and aggravated assault. The ratio of male to female murderers in the United States is

almost 10:1. Laboratory studies show the same type of sex effect, but provocation has a greater effect on aggression than does sex. Bettencourt and Miller (1996) used meta-analytic procedures and found that sex differences in aggression practically disappear under high provocation.

Men and women also appear to differ in what provokes them. Bettencourt and Miller showed that males are particularly sensitive to negative intelligence provocations whereas females are particularly sensitive to insults by a peer and to physical attacks. Geary, Rumsey, Bow-Thomas, and Hoard (1995) showed that males are more upset by sexual infidelity of their mates than by emotional infidelity, whereas the opposite pattern occurs for females. Buss and Shackelford (1997) showed similar sex differences in the effects of infidelity on mate-retention tactics, including use of violence.

Biology. Other biological differences that people bring with them to the current situation may also contribute to aggression, but as noted earlier many biological effects on aggression are neither as strong nor as consistent as the general public believes. For example, testosterone is frequently cited as the explanation for male/female differences in violence rates, but the human literature on testosterone effects is mixed.

Proximate Causes: Situational Factors. The second type of proximate causes of aggression consists of the situational factors currently present. Some of these factors are so powerful that even normally nonaggressive individuals can be made to behave aggressively.

Provocation. Most aggressive incidents can be directly linked to some type of perceived provocation. Some are direct and obvious, such as verbal insults and physical assaults. Some are less direct, as when an expected pay raise fails to materialize. Most murders and assaults in normal (i.e., nonwar) contexts are the result of provocations of one kind or another, usually in a series of escalatory provocations, threats, and counterthreats. Federal Bureau of Investigation data reveal that most murders in the United States occur during arguments among family, friends, or acquaintances. The tendency for stranger-based homicides to be relatively rare is even more pronounced in other industrialized cultures than in the United States. Frequently, the provocations involve sexual or emotional infidelity, or perceived insults to one's honor.

Frustration. Frustration is both an event and an emotional reaction. It occurs when something blocks the attainment or threatens the continued possession of a valued goal objective. For example, a supervisor's bad report may prevent a promotion, a spouse's infidelity may threaten the continued existence of a marriage, or a flood may destroy one's home. If the frustrating agent is another person, then the frustrating event is also a provocation.

The original form of the frustration-aggression hypothesis by Dollard, Doob, Miller, Mowrer, and Sears (1939) stated that: (1) all acts of aggression are the result of previous frustration; (2) all frustration leads to aggression. But some frustrations do not yield aggression, and some aggression is not the result of a prior frustration. Indeed, many contemporary scholars believe that if a frustrating event is fully justified, the frustrated person would show no residual inclination to aggress. However, Berkowitz (1989) claimed that even fully justified frustration can produce aggressive tendencies. This prediction was recently confirmed by Dill and Anderson (1995).

In a similar vein, Miller and Marcus-Newhall (1997) have shown that provocations can lead to increased aggressive tendencies against individuals who were not part of the frustrating event at all, a phenomenon typically labeled *displaced aggression*. Miller and Marcus-Newhall also suggest that such displaced aggression is increased if the displacement target provides a minor "triggering" provocation, and if the displacement target is a member of a disliked outgroup.

Incentives. Incentives are the rewards or benefits a person expects for having performed a particular action. Many situations in politics, the business world, and sports encourage aggression by their incentives. People often expect their chances of winning an election, getting a contract, or defeating an opponent to be enhanced by harming their competitor. Research on television violence has shown that seeing a character rewarded (or not punished) for aggressing increases subsequent aggression by the viewer more so than does unrewarded (or punished) television violence, presumably by increasing the perceived incentive value of aggressive behavior.

The prototypical incentive-based example of individual aggression is the contract killer, who

murders purely for money. The Iraqi assault and takeover of Kuwait, as well as NATO's subsequent attack on Iraq are clear examples of incentive-based institutional aggression (though other factors also clearly played a role). Contract murders account for only a small percentage of homicide totals, but they nicely illustrate the concept of relatively anger-free instrumental aggression.

Aversive Stimulation and Stress. Almost any form of aversive stimulation can increase the likelihood of aggression—noise, pain, crowding, cigarette smoke, heat, daily hassles, and interpersonal problems illustrate a few such aversive factors. When the cause of an aversive stimulus is an identifiable person, such as a smoker, these factors are also provocations. As such, they can increase aggression directed at the person identified as the provocateur, as well as against other "displaced" targets.

In cases where there is no identifiable human agent causing the aversive stimulation the effects on aggression are often less noticeable, but much research demonstrates their reality. The most studied of these effects, with relevant data gathered for over one hundred years, is the heat effect. Anderson and Anderson (1998) showed that a wide array of studies across time, culture, and method converge on the conclusion that hot temperatures increase aggressive tendencies. People who live in hotter cities have higher violent crime rates than those in cooler cities. This effect persists even when controlling for poverty, education, and culture. Violent crime rates are higher during hotter years, seasons, months, and days. When people are hot, they think more aggressive thoughts, feel more hostile, and behave more aggressively.

Alcohol and Drugs. Bushman (1993) reviewed studies on alcohol and drug effects on aggression, and found that central nervous system depressants increase aggression. Neither actual alcohol consumption nor the mere belief that one has consumed alcohol were individually sufficient to produce reliable increases in aggression, but when research participants believed they had consumed alcohol and had actually consumed alcohol, aggression increased. The exact mechanisms underlying these drug effects are not yet fully understood. Steele and Josephs (1990) proposed an "alcohol myopia" explanation, in which alcohol

impairs key perceptual processes necessary to normal inhibitions against extreme and risky behavior. Bushman's review (1997) confirmed this view.

Aggression Cues. Objects or events associated with aggression in semantic memory can cue or "prime" aggression-related thoughts, affects, and behavior programs also stored in memory. For instance, seeing a gun can prime aggressive thoughts (Anderson, Benjamin, and Bartholow 1998) and increase aggressive behavior. This phenomenon, labeled the "weapons effect" by Berkowitz and LePage (1967), has been found in field and laboratory studies, in several different countries, with pictures of weapons and with real weapons.

As mentioned earlier, one prevalent source of aggressive cues in modern society is the mass media. Television shows, movies, and video games are filled with violence. Over 1,000 empirical comparisons, compiled by Paik and Comstock (1994) have conclusively demonstrated that even short-term exposure to media violence increases aggression. The immediate impact of viewing violent media is more pronounced for people with strong aggressive tendencies (Bushman 1995). Unfortunately, aggressive people also are the most likely to seek out violent media.

Many people in modern society believe that viewing aggression (e.g., on television) or behaving in a mildly aggressive way within protected environments (e.g., playing football) will reduce later aggressive behavior. This catharsis hypothesis, though, has been thoroughly debunked (Bushman, Baumeister, and Stack in press; Geen and Quanty 1977).

Opportunity. Some situations restrict opportunities to aggress; others provide "good" opportunities. Church service situations have many impediments to aggression—there are witnesses, strong social norms against aggression, and specific nonaggressive behavioral roles for everyone in attendance. Country and Western bars on Saturday nights present better opportunities for aggression, because many aggression facilitators are present: alcohol, aggression cues, aggression-prone individuals, males competing for the attention of females, and relative anonymity.

Removal of Self-Regulatory Inhibitions. One often-neglected facet of human aggression has

garnered increased attention; the aggression inhibitions that normally operate in most people. Several different research groups have independently identified and discussed how these inhibitions are sometimes overridden (Bandura, Barbaranelli, Caprara, and Pastorelli 1996; Keltner and Robinson 1996; Staub 1989, 1998). Most people do not commit extreme acts of violence even if they could do so with little chance of discovery or punishment. Such self-regulation is due, in large part, to the fact that people cannot easily escape the consequences that they apply to themselves. Self-image, self-standards, and sense of self-worth—in other words moral standards—are used in normal self-regulation of behavior.

However, people with apparently normal moral standards sometimes behave reprehensibly toward others, including committing such actions as murder, torture, even genocide. Two particularly important mechanisms that allow people to disengage their normal moral standards involve moral justification and dehumanizing the victim. Common justifications for extreme and mass violence include "it is for the person's own good," or the good of the society, or that personal honor demands the violent action. These justifications can be applied at multiple levels, from a parent's abuse of a child to genocidal war. Dehumanizing the victim operates by making sure that one's moral standards are simply not applicable. War propaganda obviously fits this mechanism, but people also use this mechanism at an individual level. Potential victims are placed in the ultimate outgroup—one that has no human qualities.

The Escalation Cycle. Many proximate causal factors seem too trivial or weak to contribute to serious aggression. How can seeing a weapon, being uncomfortably hot, or watching a violent movie increase murder rates? The answer lies in the escalation cycle. As noted earlier, assaults and homicides do not typically result from one brief encounter or provocation. The parties involved usually know each other and have had a series of unpleasant exchanges. The final encounter may well begin as a relatively minor dispute, but one person escalates the level of aggression. The other person responds in kind and subsequently increases the aggressiveness of the next response. A shouting match can quickly become a shoving match, which can lead to fists, guns, and death. Seemingly trivial factors increase the likelihood of violence by

increasing the accessibility of aggressive thoughts, affect, and behavioral acts at each turn of the escalation cycle.

INTERVENTION: PREVENTION AND TREATMENT

The knowledge structure approach explains the difficulty of rehabilitating adults who repeatedly commit violent crimes, or of changing the genocidal climate of groups that have long histories of hate and violence. At the individual level, a lifetime of developing aggressive behavior scripts and automatized hostile perception, expectation, and attribution biases cannot be unlearned easily. However, this approach also reveals that preventing the development of an aggressive or genocidal personality is a more reasonable goal if appropriate steps are taken prior to full maturation.

Preventing and Treating Aggressive Personality. There are three main loci for preventing a child from developing into an aggressive adult. First, one can reduce exposure to events that teach aggressive behaviors or scripts. This would include direct modeling (e.g., by abusive or violent parents) as well as indirect modeling (e.g., exposure to media violence). Second, one can reduce exposure to events that teach that aggression is rewarding. For example, most media violence is highly rewarding for the perpetrator, especially when it is the protagonist who is committing the violence. Similarly, adult violence against children (e.g., by parents or school officials) appears highly rewarding to the child because the adult “wins” the encounter and there are no obvious costs to the adult for harming the child. Third, one can reduce exposure to events that teach hostile perception, expectation, and attribution biases. Once again, the entertainment media is one source of violence exposure that increases the perception that the world is a dangerous place. A heavy dose of media violence (e.g., television, movies, video games, music) can increase all three hostility biases. Witnessing high levels of violence in one’s neighborhood also increases these biases.

At all three loci, reducing exposure to aggression-enhancing factors would seem much easier to do in the context of a normal and relatively non-violent culture than in the context of a genocidal culture. Though the following statements focus on

dealing with the aggressive personality, the general principles apply to dealing with the genocidal personality.

Furthermore, treating people who have already developed a strong and stable aggressive personality is much more difficult than preventing the development of such a personality. People with aggressive personalities must learn new nonhostile knowledge structures ranging from perceptual schemata through attributional ones to behavioral scripts. The knowledge structure approach outlined earlier explains why it is easiest to intervene successfully in younger children whose personalities are still malleable, harder to succeed with violent juvenile offenders and young abusive parents, and hardest of all to succeed with habitually violent adult criminals.

Child Abuse: Treatment and Prevention. Early intervention attempts relied primarily on intensive dynamic psychotherapy with the abuser, but this approach has repeatedly failed. Cognitive behavioral interventions have had much greater success, largely because they deal directly with the knowledge structure issues that are so important in this domain (Wolf 1994). This approach succeeds by teaching abusive caregivers to use nonaggressive child compliance techniques, personal anger control, and developmentally appropriate beliefs about childhood abilities.

Reducing Exposure to Aggressive Social Models. Reducing children’s exposure to aggressive social models would reduce the percentage who grow up believing in and using aggressive tactics. One way of doing this is to reduce exposure to violent media, especially television and video games. The research literature on television violence has conclusively demonstrated that early and repeated exposure to violent television causes children to develop into aggressive adults. For example, kids who watch a lot of violent television at age eight are more likely to have criminal records at age thirty, even after statistically controlling for a variety of other relevant social variables. Research has suggested that exposure to violent video games has a similar effect.

Reducing other types of exposure to violent social models would also help. Reducing parental violence towards children, reducing the frequency

and visibility of violence in children's neighborhoods, reducing violence in schools—including violence by school authorities in attempts to control children—would all have a positive impact on the overall level of aggressiveness in society.

Treating Violent Juvenile Offenders. Many treatments have been tried with violent juvenile offenders, including such things as "boot camps," individual therapy, "scared straight" programs, and group therapy; there is little evidence of sustained success for any of these approaches. One problem is that these standard approaches do not address the wide range of factors that contribute to the development and maintenance of violent behavior. However, there is evidence that treatment can have a significant beneficial impact on violent juvenile offenders (e.g., Simon 1998). Tate, Reppucci, and Mulvey (1995) drew attention to one approach with impressive results—the Multisystemic Therapy developed by Henggeler and Borduin (e.g., Henggeler, Schoenwald, Borduin, Rowland, and Cunningham 1998). Multisystemic Therapy is a family-based approach that first identifies the major factors contributing to the delinquent and violent behaviors of the particular individual undergoing treatment. Biological, school, work, peers, family, and neighborhood factors are examined. Intervention is then tailored to fit the individual constellation of contributing factors. Opportunities to observe and commit further violent and criminal offenses are severely restricted, whereas prosocial behavior opportunities (including studying school subjects, developing hobbies) are greatly enhanced, and are rewarded. Both the long-term success rate and the cost/benefit ratio of this approach have greatly exceeded other attempts at treating this population.

Adults. Attempts at treatment or "rehabilitation" of violent adults, usually done in the context of prison programs, have led to a general consensus of failure. However, several studies have yielded some evidence of a positive effect of treatment on the behavior of violent adults (e.g., Simon 1998). Rice (1997) reported that an intensive program for violent offenders cut recidivism rates in half for nonpsychopathic offenders. Unfortunately, the recidivism rate for psychopathic offenders was significantly increased by this particular treatment program.

MAKING MODERN SOCIETIES LESS VIOLENT

Several controversial suggestions for social change emerge from the past forty years of research on human aggression. These suggestions, designed to decrease aggression and violence levels generally rather than to treat already-violent individuals, are controversial for political rather than scientific reasons. Research results clearly support each of them.

1. Reduce exposure to media violence and other aggressive role models, especially for children and adolescents.
2. Replace the use of corporal punishment with more positive child-control techniques.
3. Reduce social rewards for aggressive activities, including those previously thought to be cathartic.
4. Increase social rewards and social support for nonaggressive prosocial activities (e.g., learning in school) while making success at such activities possible (e.g., reducing class sizes).
5. Increase the quality of prenatal and postnatal care, to decrease the proportion of the population suffering from developmental difficulties that interfere with normal learning and socialization processes (Anderson in press).
6. Increase the quality of parenting, by providing instruction, social support, and economic support.

AGING AND THE LIFE COURSE

Social gerontology, or the sociology of aging, has two primary foci: (a) social factors during late life, and (b) social antecedents and consequences of aging. Thus, social gerontology includes examination of both the status of being old and the process

of becoming old. Increasingly, theories and methods of the life course are replacing the earlier emphasis on late life as a separate topic of inquiry. This is a vast arena, and the sociology of aging is appropriately informed by the theories and methods of many sociological subspecialties ranging from macrohistorical and demographic perspectives to the microorientations of social psychology and interpretive sociology.

HISTORY OF THE FIELD

Historically, social gerontology emerged from a social-problems orientation and focused on the deprivations and losses that were expected to characterize late life (e.g., Burgess 1960; Cain 1959). Early research in the field focused on issues such as poverty during late life; old age as a marginal status, reflecting problems of social integration; the negative effects of institutionalization and poor quality of long-term care; and ageism and age discrimination. Early on, however, some investigators saw the dangers of allowing a crisis orientation to dominate the study of aging and focused attention on patterns of “normal” and “successful” aging (Havighurst 1963; Palmore 1970). A significant proportion of research also focuses on the problems of late life. Investigators remain concerned about social integration and adaptation to loss. The majority of funding for aging research is provided by the National Institute on Aging, which is mandated to support health-related research. Consequently, much aging research focuses on illness and the health care delivery system. The dramatic aging of the population (U.S. Bureau of the Census 1987)—a trend that will peak with the aging of the Baby Boom cohorts—leads to questions about the capacities of social institutions and public policies to meet the needs of an unprecedented number and proportion of older adults. Scholars using political economy theories focus on the ways in which societies respond to the dependency needs of older adults and the social implications of those responses.

Although much research remains focused on the problems of late life, sociologists now recognize the broader importance and implications of old age and aging. Two primary factors appear to have been the driving forces that account for this broader and more complex view. First, despite the social-problems orientation of most early research,

empirical data failed to confirm a uniformly bleak picture of old age. For example, in spite of higher rates of illness and disability, the vast majority of older adults are competent and able to live independent lives (Kunkel and Applebaum 1992). Similarly, rather than representing involuntary loss of a treasured role, retirement is actively sought by the majority of older workers and seldom poses adaptive problems (e.g., Hardy and Quadagno 1995). In addition, some of the problems observed in early studies of older adults have been remedied by the increased resources that recent cohorts have brought to late life, as well as to effective public policies. Thus, although health care costs remain a burden for many older adults, Medicare and Medicaid substantially reduced barriers to health care among older people. Similarly, as a result of improvements in Social Security benefits and increased participation in private pensions, older Americans now are no more likely to live in poverty than younger adults and, indeed, are less likely to live in poverty than children (U.S. Bureau of the Census 1997). Such findings pushed social gerontology toward more complex and empirically defensible perspectives on old age and aging.

Second, sociologists came to recognize that age plays a fundamental role in social structure and social organization. As a parameter of social organization, age affects the allocation of social resources and social roles. Along with sex and race, age is an ascribed status. But age is unique among ascribed statuses in that it changes over time, and movement across age categories results in changing expectations for behavior, changing access to social resources, and changing personal and social responsibilities. The structural quality of age is best articulated in *age stratification theory* (Riley 1987). Age stratification refers to the division of society into meaningful age groups that differ in social value and the allocation of social resources. The concept of age stratification has proven to be useful in a variety of ways. At the broadest level, it reminds us that age is a fundamental parameter of social organization. Age stratification has been particularly useful in highlighting age-related roles and norms. It has a social-psychological facet as well: age consciousness or awareness and identification with members of one's age group (Day 1990). Moreover, the structural and individual facets of age stratification operate in both directions. On the one hand, the structural

component of age stratification allocates roles and resources and assigns differential social value to age strata. Thus, ageism is largely an effect of age stratification. On the other hand, by promoting age consciousness, age stratification sets the stage for age-based public policies and collective efforts by older adults to protect or increase their share of societal resources (e.g., voting and lobbying efforts based on the self-interests of the elderly).

In the 1990s, the sociology of aging focused on change and stability across the life course. Life-course perspectives have enriched aging research in several ways (e.g., Elder 1995; George 1993). First, a life-course approach is attractive because it recognizes that the past is prologue to the future. That is, status and personal well-being in late life depend in large part on events and achievements experienced earlier in the life course. Second, life-course perspectives emphasize relationships across life domains, recognizing that, for example, family events affect and are affected by work and health. Traditionally, sociological research has focused on specific life domains (e.g., the sociology of work, the sociology of the family); life-course perspectives, in contrast, are person-centered rather than domain-centered. Third, life-course perspectives focus on the intersection of history and personal biography. Although the macro-micro schism remains difficult to bridge, life-course research has documented some of the complex ways that historical conditions affect personal lives both contemporaneously and over subsequent decades.

THE AGE-PERIOD-COHORT PROBLEM

Isolating the effects of age and characterizing the aging process are difficult tasks. Because many factors affect social structure and individual behavior, it is always difficult to isolate the effects of a specific factor. But this task is especially difficult with regard to age, because it is inherently confounded with the effects of two other factors: cohort and period. *Age*, of course, refers to time since birth, and *age effects* refers to patterns resulting from the passage of time or sheer length of life. *Cohort* refers to the group of persons born at approximately the same time (e.g., the 1920 cohort, the 1940–1944 cohort). There are two primary kinds of *cohort effects*. One type results from historical factors. For example, cohorts who lived through the Great Depression or World War II

had different life experiences than cohorts who were not exposed to those historical events. And, as a further complication, the effects of historical events vary depending on the ages of those who experience them. The second type of cohort effect reflects compositional characteristics. For example, large cohorts (such as the Baby Boomers) may face greater competition for social resources than smaller cohorts (e.g., those born during the Great Depression, when fertility rates were low). Both types of cohort effects can have persistent effects on the life course, and, hence, late life. *Period effects* (also called *time of measurement effects*) result from events or situations that happen at a specific time, and tend to affect individuals regardless of age or cohort. For example, faith in government decreased in all Americans (regardless of age or cohort) at the time of the Watergate scandal.

Age, cohort, and period effects are intertwined. If one knows when an individual was born and also knows the time of measurement, simple subtraction provides accurate information about the individual's age. Similarly, if one knows an individual's age and time of measurement, one can easily calculate date of birth or birth cohort. Statistically, there are no easy methods for disentangling age, period, and cohort. In general, however, the most compelling research results are those that are based on examination of multiple cohorts at multiple times of measurement. If the same age patterns are observed across different cohorts measured at different times, those patterns are likely to reflect age effects. If patterns are not similar across cohorts and times of measurement, however, they are likely to reflect cohort or period effects.

The issue of age-period-cohort effects has lost some of its appeal; critics point out that simply knowing, for example, that there is a cohort effect leaves unanswered what it is about those cohorts that generated the observed differences. This is an appropriate criticism; nonetheless, it is immensely helpful in searching for causal explanations to know whether the underlying mechanism is consistent across time and place (an aging effect), had strong contemporaneous effects on persons of all ages (a period effect), or affected only specific cohorts (a cohort effect). Age, cohort, and period effects are all important in aging research. Age effects provide information about human development as it unfolds in social context. Cohort effects permit us to observe the social implications

of shared history and cohort composition. Period effects provide information about the effects of contemporaneous events and situations on social structure and individual behavior. Distinguishing among age, period, and cohort effects also has important implications for the generalization of research results. Age effects are the same or highly similar across time and place; thus, they are generalizable. In contrast, cohort and period effects are, by definition, variable across time. Consequently, generalization is limited.

Examination of age-period-cohort effects requires large data bases in which multiple cohorts are observed on multiple occasions over long periods of time. Because of these stringent requirements, few aging studies focus specifically on disentangling these confounded factors. But recognition of these sources of confounding appropriately temper investigators' generalizations. In addition, this issue has sensitized researchers to the need to examine change over time, with the result that longitudinal studies have become the dominant research design in efforts to characterize the aging process.

No single theme nor easily summarized list of topics does justice to the scope and diversity of research on aging and the life course. However, three major research domains can provide a general sense of the current major avenues of aging and life-course research: aged heterogeneity, life-course dynamics, and life-course trajectories.

AGED HETEROGENEITY

The majority of research on older adults focuses on heterogeneity in that population. In many ways, this is the legacy of the problem orientation upon which initial aging research in the social sciences rested. Even now, most aging research focuses on differences among older adults and the complex configurations of social factors that can account for individual differences during late life. And, although there are many exceptions, a majority of research in this domain focuses on the social factors that explain individual behavior and personal well-being.

The specific topics that are examined in research on aged heterogeneity are extensive. Health and disability are major concerns in this research tradition, including physical illness; mental illness,

especially depression; cognitive status and dementing illness; functional status and disability; and health behaviors. Health service utilization is a corollary emphasis; there are numerous studies on both utilization in general (e.g., doctors visits, hospitalizations) and specialized health care settings and providers (e.g., long-term care facilities, emergency room visits, screening programs and other preventative services, mental health professionals, dentists). There also has been extensive research on the use of social and community services and living arrangements—both of which are strongly driven by health during late life.

Along with health, socioeconomic status has been a high-volume, long-standing focus in research on aged heterogeneity. Economic status, in the form of income and, to a lesser extent, assets has been the primary emphasis of this research, with studies of the antecedents and consequences of retirement ranking as a close second. Pensions have been shown to have strong effects upon the adequacy of postretirement income, which has spurred substantial investigation of the determinants of pension acquisition and value.

From a more social-psychological perspective, there are strong research traditions examining multiple psychosocial states that can be subsumed under the umbrella of "quality of life." Life satisfaction and morale have received paramount attention in this regard. But several dimensions of the self (e.g., self-esteem, locus of control, sense of mastery) also have rich research traditions.

Two common elements of the wide range of research conducted on the topic of aged heterogeneity merit note. First, a common thread in this research is the desire to understand the processes that render some older adults advantaged and others disadvantaged. This is often described as the "applied" character of aging research. However, it also is a focus on stratification in the broadest sense, which is one of the most persistent and cherished issues in mainstream sociology. Research on aging and the life course has contributed much to our understanding of how broadly life chances and life quality are linked to social factors, as well as to the multiple powerful social bases of stratification.

Second, examination of heterogeneity among the elderly has proven to be a strategic site for

testing and refining multiple middle-range theories and concepts that are central to sociological research. A few examples will illustrate this point. Research on health and disability during late life has been enriched by attention to issues of social stress and social support; conversely, the older population has proven to be ideal for testing theoretical propositions about the effects of stress and social support. Similarly, the issue of social integration, which has an honored tradition in sociology, has been reactivated in studies of older adults, who vary widely in number and quality of links to social structure. And issues such as the “feminization of poverty” and the “double/triple jeopardy hypothesis” (i.e., the potential interacting deprivations associated with being female, nonwhite, and old) have highlighted the extent to which socioeconomic stratification rests on ascribed rather than achieved statuses.

LIFE-COURSE DYNAMICS

While the issue of heterogeneity focuses attention on differences across individuals, life-course dynamics focus on the persisting effects of social factors over time and stages of life; that is, on intraindividual change. At least three types of life-course studies have received substantial attention in aging research.

The Intersection of History and Personal Biography. There now is substantial evidence that historical events can permanently alter personal lives. Most research to date has focused on two historical events: the Great Depression and World War II; both historical events have been linked to life circumstances during late life. Elder (1974, 1999) has compellingly documented, for example, that entering the labor market during the Depression had a permanent negative effect on occupation and income, which in turn affected socioeconomic status during late life. In contrast, younger men, who entered the labor force immediately after World War II experienced historically unparalleled occupational opportunities (and, if they were veterans, government-subsidized college educations).

Other studies by Elder and colleagues focused on the life-course consequences of combat experience during World War II (Elder, Shanahan, and Clipp 1994, 1997). Exposure to combat was strongly related to subsequent health problems, not only

immediately after the war, but also during late life. Social factors loom large in these dynamics. First, social factors were strongly predictive of which soldiers were exposed to combat. Second, social resources and deprivations were strong predictors of the onset or avoidance of health problems.

The effects of historical events on the life course appear on two levels. When an historical event is pervasive, one method of observing its effects is via cohort differences. That is, an event with wide-ranging effects will render those who experience it discernibly different from cohorts that come before and after it. At the same time, historical events do not have the same immediate or long-term consequences for all members of a cohort. For example, families were differentially affected by the economic dislocations of the Depression, with some suffering extensive economic deprivation and others experiencing little or no change in their economic fortunes. Thus, not everyone who “lives through” a major historical event will experience serious life-course consequences. One of the tasks of the life-course scholar is to identify the social factors that determine whether or not an historical event alters personal biography.

The Persisting Effects of Early Traumas and Deprivations. A second research focus that illustrates the power of life-course perspectives is investigation of the consequences of early traumas and deprivations on well-being in middle and late life. A growing body of research documents the far-reaching effects of severe childhood experiences—including parental divorce and, to a lesser extent, parental death; childhood poverty; and childhood physical and sexual abuse—on the course of adulthood. Most research to date has focused on the implications of these traumas and deprivations on physical and mental health (e.g., Krause 1998; Landerman, George, and Blazer 1991). The robust relationships between events experienced during childhood and health fifty to sixty years later, controlling on contemporaneous risk factors for morbidity, is strong evidence of the power of fateful events to alter the life course.

Again, social factors are strongly implicated in the processes that account for the relationships between childhood traumas and health and well-being during late life. First, the availability of social resources *at the time* of the trauma can dampen its negative effects in both the short and the long

term. For example, financial security and adequate supervision ameliorate most of the negative effects of parental divorce on subsequent socioeconomic achievements and physical and mental health (e.g., Kessler and Magee 1994). Second, two of the primary mechanisms by which childhood traumas generate poor health in later life are socioeconomic achievement and high-quality social relationships (e.g., McLeod 1991). That is, childhood traumas are often associated with lower socioeconomic status and poor-quality relationships during adulthood—both of which are risk factors for physical and mental illness. If, however, individuals who experienced childhood traumas manage to achieve adequate financial resources and supportive social ties during adulthood, their excess risk of illness in middle and late life is reduced substantially.

The Persisting Effects of Early Life Decisions. There now is substantial evidence that the decisions that individuals make during early adulthood have important consequences for their life circumstances in late life. Studies of retirement income provide perhaps the best illustration of this research domain. The strongest predictor of retirement income is occupational history. Throughout adulthood, individuals “sort themselves” into jobs that differ not only in income, but also in benefits (i.e., total compensation packages). Of these, the availability and quality of pensions is most important for retirement income. There is strong evidence that the provision of pensions differs not only by occupation, but also by industrial sector (Quadagno 1988). Thus, when individuals make occupational choices—including job changes throughout adulthood—they are inevitably determining, in part, their retirement incomes.

Research on women’s retirement income has broadened our understanding of the life-course consequences of early decisions. Women and men tend to be concentrated in different occupations and different industrial sectors—and those in which women dominate have, on average, lower earnings and lower likelihood of pension coverage (O’Rand 1988). Moreover, family formation decisions strongly affect women’s job histories. Compared to men, women are less likely to work full-time and work fewer total years, largely as a result of parental responsibilities. All of these factors combine to produce substantially lower retirement incomes for women than for men (O’Rand and Landerman 1984).

LIFE-COURSE TRAJECTORIES AND PERSON-CENTERED RESEARCH

The two research domains described above focus on *interindividual differences* in late life and *intraindividual change* over the life course. A third domain, less developed than the others but exciting in its scope, attempts to examine interindividual differences and intraindividual change simultaneously. At this point, two emerging research traditions illustrate the nature and potential of this approach.

Life-Course Trajectories. Trajectories refer to long-term patterns of stability and change. They can be examined at both the aggregate (e.g., the “typical” career, the modal pathway to nursing home placement) and individual levels. Thus, trajectories capture patterns of intraindividual change. Examination of heterogeneity can be pursued in two ways. In the first, the trajectory that best describes the sample or population is constructed. Subsequently, using techniques such as hierarchical linear modeling or growth-curve analysis, investigators can examine the extent to which factors of interest alter the shape of the trajectory. For example, a trajectory of earnings across adulthood can be constructed for a given sample. Investigators can then examine the degree to which factors such as sex, education, and race affect the shape of the earnings trajectory. In the second approach, multiple common trajectories are identified and investigators then determine the characteristics associated with those trajectories. Using this approach, for example, several common trajectories of earnings during adulthood could be identified (e.g., consistently increasing earnings, earnings peaking during mid-life and then decreasing, consistently decreasing earnings, a relatively flat earnings history). Factors such as sex, education, and race could then be examined to determine their association with these distinctive earnings trajectories.

Trajectory-based research, with its focus on both interindividual differences and intraindividual change, is very attractive. The major limitation to the use of this approach is the availability of data, because longitudinal data covering long periods of time are required if one wishes to understand life-course patterns. It should be noted, however, that trajectory-based research can also be useful for studying shorter processes (e.g., patterns of illness

outcome, with relatively short-term trajectories of death, chronicity, recovery, and relapse).

Trajectory-based research relevant to our understanding of middle and late life is gradually accumulating. This is especially true for long-term patterns of health and functioning, providing evidence about both the dynamics of disability during late life (e.g., Maddox and Clark 1992; Verbrugge, Reoma, and Gruber-Baldini 1994) and long-term patterns of stability, improvement, and decline in health over the course of adulthood (e.g., Clipp, Pavalko, and Elder 1992). Important trajectory-based research on pathways to retirement (Elder and Pavalko 1993) and place of death (Merrill and Mor 1993) is also available.

The concept of trajectories has been valuable in theoretical development, as well as empirical inquiry. The theory of *cumulative advantage/disadvantage* has intersected well with studies of life-course trajectories. This theory posits that heterogeneity is greater in late life than earlier in the life course as a result of the accumulation of assets (advantage) or liabilities (disadvantage) over time. The theory of cumulative advantage/disadvantage has been especially useful in understanding socioeconomic heterogeneity in late life, especially differences in total net worth (e.g., Crystal and Shea 1990; O’Rand 1996). However, it can be applied to other sources of heterogeneity in late life as well (e.g., health). Investigators who prefer examination of the multiple distinctive trajectories within a sample would offer a caution to cumulative advantage/disadvantage theory, however. They would note that although trajectories of increasing and decreasing advantage are undoubtedly common, there are likely to be other important trajectories as well—e.g., a trajectory of cumulating advantage that is reversed as a result of a personal (e.g., serious illness) or societal (e.g., severe economic downturn) catastrophic event.

Person-centered research. A more recent contribution to the sociological armamentarium for understanding aging and the life course is *person-centered research*. As the label implies, the focus of this emerging research strategy is to analyze “people” rather than “variables.” In practice, this means that members of a sample are first grouped into subsets on the dependent variable of interest. Subsequently, those categories are further disaggregated into groups based on distinctive

pathways or life histories associated with the outcome of interest.

Work by Singer, Ryff, and Magee (1998) provides the richest example of person-centered aging research to date. The dependent variable of interest was mental health. In the first stage of their research, groups of middle-aged women were divided into groups that differed on levels of mental health. Subsequently, the large archive on longitudinal data obtained from these women over the previous three decades was examined to identify distinctive pathways associated with mid-life mental health. For example, the group of women who exhibited high levels of mental health and well-being were further subdivided into two groups that Singer et al. (1999) labeled the healthy and the resilient. Healthy women were those who had life histories that were relatively free of major stressors or traumas, enjoyed adequate or higher levels of social and economic resources, and exhibited stable patterns of robust mental health. Resilient women were those who had achieved robust mental health at mid-life despite earlier evidence of poor mental health and/or histories of stress and/or inadequate social and economic resources. Clearly the life histories of women who were mentally healthy at mid-life varied in important ways. Moreover, the healthy women illustrate the benefits of leading relatively “charmed” lives, while the resilient women help us to understand the circumstances under which “risky” life histories can be turned around to produce health and personal growth.

There are clear similarities between person-centered research and trajectory-based research. Both are based on long-term patterns of change and stability and both are designed to understand both life-course dynamics and heterogeneity in those dynamics. But there also are important differences between the two approaches. In trajectory-based research, the trajectory or pathway itself is the “dependent variable” of interest and the “independent variables” are factors that have the potential to alter the shape(s) of those pathways. In person-centered research, the “dependent variable” is an outcome of interest (e.g., mental health), and trajectories of the “independent variables” are constructed to explain that outcome. Both are currently at the cutting edge of research that attempts to simultaneously examine life-course dynamics and life-course heterogeneity.

Aging and the life course is an important sociological specialty. It provides us with information about aging and being "old," and about the antecedents and consequences of stability and change during late life. The increasing life-course focus of aging research is especially important in that it concentrates sociologists' attention on the dynamics of intraindividual change and on the intersections of social structure, social change, and personal biography. At its best, aging and life-course research effectively link processes and dynamics at the macrohistorical and societal levels with individual attitudes and behaviors. In addition, the life course in general, and late life in particular, provide excellent contexts for testing and, indeed, challenging some commonly held assumptions and hypotheses about the dynamics of social influence. In this way, it offers valuable contributions to the larger sociological enterprise.

LINDA K. GEORGE

AGRICULTURAL INNOVATION

Getting a new idea adopted can be very difficult. This is all the more frustrating when it seems to the proponents of the new idea that it has very obvious advantages. It can be a challenge to try to introduce new ideas in rural areas, particularly in less-developed societies, where people are somewhat set in their ways—ways that have evolved slowly, through trial and error. It's all the more difficult when those introducing new ideas don't understand why people follow traditional practices. Rural sociologists and agricultural extension researchers who have studied the diffusion of agricultural innovations have traditionally been oriented toward speeding up the diffusion process (Rogers 1983). Pro-innovation bias has sometimes led sociologists to forget that "changing people's customs is an even more delicate responsibility than surgery" (Spicer 1952).

Although innovation relies on invention, and although considerable creativity often accompanies the discovery of how to use an invention,

innovation and invention are not the same thing. Innovation does, however, involve more than a change from one well-established way of doing things to another well-established practice. As with all innovations, those in agriculture involve a change that requires significant imagination, break with established ways of doing things, and create new production capacity. Of course, these criteria are not exact, and it is often difficult to tell where one innovation stops and another starts. The easiest way out of this is to rely on potential adopters of an innovation to define ideas that they perceive to be new.

Innovations are not all alike. New ways of doing things may be more or less compatible with prevalent norms and values. Some innovations may be perceived as relatively difficult to use and understand (i.e., complex), while others are a good deal simpler. Some can be experimented with in limited trials that reduce the risks of adoption (i.e., divisible). Innovations also vary in the costs and advantages they offer in both economic and social terms (e.g., prestige, convenience, satisfaction). In the economists' terms, innovation introduces a new production function that changes the set of possibilities which define what can be produced (Schumpeter 1950). Rural sociologists have studied the adoption of such agricultural innovations as specially bred crops (e.g., hybrid corn and high-yield wheat and rice); many kinds of machines (e.g., tractors, harvesters, pumps); chemical and biological fertilizers, pesticides, and insecticides; cropping practices (e.g., soil and water conservation); and techniques related to animal husbandry (e.g., new feeds, disease control, breeding). Often they have relied upon government agencies such as the U.S. Department of Agriculture to tell them what the recommended new practices are.

The diffusion of agricultural innovations is a process whereby new ways of doing things are spread within and between agrarian communities. Newness implies a degree of uncertainty both because there are a variable number of alternatives and because there is usually some range of relative probability of outcomes associated with the actions involved. Rogers (1983) stresses that the diffusion of innovations includes the communication of information, by various means, about these sets of alternative actions and their possible outcomes. Information about innovations may come via impersonal channels, such as the mass

media, or it may pass through social networks. From an individual's point of view, the process of innovation is usually conceived to start with initial awareness of the innovation and how it functions. It ends with adoption or nonadoption. In between these end points is an interactive, iterative process of attitude formation, decision making, and action. The cumulative frequency of adopters over time describes an S-shaped (logistic) curve. The frequency distribution over time is often bellshaped and approximately normal.

Individual innovativeness has been characterized in five ideal-type adopter categories (Rogers 1983). The first 2 to 3 percent to adopt an innovation, the "innovators," are characterized as venturesome. The next 10 to 15 percent, the "early adopters," are characterized as responsible, solid, local opinion leaders. The next 30 to 35 percent are the "early majority," who are seen as being deliberate. They are followed by the "late majority" (30 to 35 percent), who are cautious and skeptical, and innovate under social and economic pressures. Finally, there are the "laggards," who comprise the bottom 15 percent. They are characterized as "traditional," although they are often simply in a precarious economic position. Earlier adopters are likely to have higher social status and better education, and to be upwardly mobile. They tend to have larger farms, more favorable attitudes toward modern business practices (e.g., credit), and more specialized operations. Earlier adopters are also argued to have greater empathy, rationality, and ability to deal with abstractions. They are less fatalistic and dogmatic, and have both positive attitudes toward change and science, and higher achievement motivation and aspirations. Early adopters report more social participation and network connections, particularly to change agents, and greater exposure to both mass media and interpersonal communication networks.

Although Rogers (1983) provides dozens of such generalizations about the characteristics of early and late adopters, he admits that the evidence on many of these propositions is somewhat mixed (Downs and Mohr 1976). Even the frequently researched proposition that those with higher social status and greater resources are likely to innovate earlier and more often has garnered far less than unanimous support (Cancian 1967, 1979; Gartrell 1977). Cancian argues that this is a result of "upper middle-class conservatism," but

subsequent meta-analysis has clearly demonstrated that the relationship between status and innovation is indeed linear (Gartrell and Gartrell 1985; Lewis et al. 1989). If anything, those with very high status or resources show a marked tendency to turn their awareness of innovations into trial at a very high rate (Gartrell and Gartrell 1979).

Ryan and Gross (1942) provide a classic example of diffusion research. Hybrid corn seed, developed by Iowa State and other land-grant university researchers, increased yields 20 percent over those of open-pollinated varieties. Hybrid corn also was more drought-resistant and was better suited to mechanical harvesting. Agricultural extension agents and seed company salesmen promoted it heavily. Its drawback was that it lost its hybrid vigor after only one generation, so farmers could not save the seed from the best-looking plants. (Of course, this was not at all a drawback to the seed companies!)

Based on a retrospective survey of 259 farmers in two small communities, Ryan and Gross found that 10 percent had adopted hybrid corn after five years (by 1933). Between 1933 and 1936 an additional 30 percent adopted, and by the time of the study (1941) only two farmers did not use the hybrid. Early adopters were more cosmopolitan, and had higher social and economic status. The average respondent took nine years to go from first knowledge to adoption, and interpersonal networks and modeling were judged to be critical to adoption. In other cases diffusion time has been much shorter. Beginning in 1944, the average diffusion time for a weed spray (also in Iowa) was between 1.7 years for innovators and 3.1 years for laggards (Rogers 1983, p. 204). Having adopted many innovations, farmers are likely to adopt others more quickly.

Adoption-diffusion research in rural sociology has dominated all research traditions studying innovation. Rural sociology produced 791 (26 percent) of 3,085 studies up to 1981 (Rogers 1983, p. 52). Most of this research relied upon correlational analysis of survey data based on farmers' recall of past behaviors. This kind of study reached its peak in the mid 1960s. By the mid 1970s the farm crisis in the United States and the global depression spurred rural sociologists to begin to reevaluate this tradition. By the 1980s global export markets had shrunk, farm commodity prices had fallen, net

farm incomes had declined, and high interest rates had resulted in poor debt-to-asset ratios. What followed was a massive (50 percent) decapitalization of agriculture, particularly in the Midwest and Great Plains.

Criticisms of adoption-diffusion research include (1) pro-innovation bias; (2) a lack of consideration of all the consequences of innovation; (3) an individual bias; (4) methods problems; (5) American ethnocentric biases; (6) the passing of the dominant modernization-development paradigm. The pro-innovation bias of researchers has led them to ignore the negative consequences of innovation (van Es 1983). Indeed, innovativeness itself is positively valued (Downs and Mohr 1976). The agencies that fund research and the commercial organizations (e.g., seed companies) that support it have strong vested interests in promoting diffusion. Furthermore, successful innovations leave visible traces and can be more easily studied using retrospective social surveys, so researchers are more likely to focus on successful innovations.

Since most researchers are well aware of this problem, it can be addressed by deliberately focusing on unsuccessful innovations, and by studying discontinuance and reinvention. It can also be avoided by the use of prospective research designs, including qualitative comparative case studies, that track potential innovation and innovators' perceptions and experiences. This should facilitate the investigation of noncommercial innovations and should result in a better understanding of the reasons why people and organizations decide to use new ideas. Moreover, these methods will likely lead to a better understanding of the system context in which innovations diffuse.

One of the most strident critiques of the pro-innovation bias of the "land-grant college complex" was voiced by Hightower (1972). Agricultural scientists at Davis, California, worked on the development and diffusion of hard tomatoes and mechanized pickers (Friedland and Barton 1975). They ignored the effects of these innovations on small farms and farm labor, except in the sense that they designed both innovations to solve labor problems expected when the U.S. Congress ended the bracero program through which Mexican workers were brought in to harvest the crops. In the six years after that program ended (1964 to 1970) the mechanical harvester took over the industry. About

thirty-two thousand former hand pickers were out of work. They were replaced by eighteen thousand workers who rode machines and sorted tomatoes. Of the four thousand farmers who produced tomatoes in California in 1962, only six hundred were still in business in 1971. The tomato industry honored the inventor for saving the tomato for California, and consumers got cheaper, harder tomatoes—even if they preferred softer ones.

Several other classic examples of agricultural innovation illustrate problems that result from not fully considering the consequences of innovation (Fliegel and van Es 1983). Until the late 1970s rural sociologists, among others, studiously ignored Walter Goldschmidt's 1940s study (republished in 1978) of the effects of irrigation on two communities in California's San Joaquin Valley. Dinuba had large family farms, and it also had more local business, greater retail sales, and a greater diversity of social, educational, recreational, and cultural organizations. Arrin was surrounded by large industrial corporate farms supported by irrigation. These farms had absentee owners and Mexican labor. This produced a much lower quality of life that was confirmed three decades later (Buttel et al. 1990, p. 147).

The enforced ban on earlier chemical innovations in agriculture by the U.S. Food and Drug Administration provides another interesting example. Chemical innovations such as DDT insecticide, 2,4-D weed spray, and DES cattle feed revolutionized farm production in the 1950s and 1960s. In 1972, DDT was banned because it constituted a health threat (Dunlap 1981), and 2,4-D, DES, and similar products were banned soon afterward. Finally, in 1980 the U.S. Department of Agriculture reversed its policy and began to advise farmers and gardeners to consider alternative, organic methods that used fewer chemicals.

The impact of technical changes in U.S. agriculture, particularly the rapid mechanization begun in the Great Depression, put farmers on the "treadmill of technology" (Cochran 1979; LeVein 1978). Larger farmers who are less risk-averse adopt early, reap an "innovation rent," reduce their per-unit costs, and increase profits. After the innovation spreads to the early majority, aggregate output increases dramatically. Prices then fall disproportionately, since agricultural products have low elasticity of demand. Lower, declining prices

force the late majority to adopt, but they gain little. They have to adopt to stay in business, and some late adopters may be forced out because they cannot compete. This treadmill increases concentration of agricultural production and benefits large farmers, the suppliers of innovations, and consumers. Indeed, it helps to create and to subsidize cheap urban labor. When it comes to environmental practices, however, large farms are not early innovators (Pampel and van Es 1977; Buttel et al. 1990).

The individual bias of adoption-diffusion research is evident in its almost exclusive focus upon individual farmers rather than upon industrial farms or other agribusiness. There is also a tendency to blame the victim if anything goes wrong (Rogers 1983). Change agents are too rarely criticized for providing incomplete or inaccurate information, and governments and corporations are too infrequently criticized for promoting inappropriate or harmful innovations. Empirical surveys of individual farmers also lead to a number of methodological problems. As noted above, if surveys are retrospective, recall relies on fallible memory and renders unsuccessful innovations difficult to study. These surveys are commonly combined with correlational analysis that makes it difficult to address issues of causality. After all, the farmer's attitudes and personality are measured at the time of the interview, and the innovation probably occurred some time before. As we have pointed out, these issues can be addressed by prospective designs that incorporate other methods, such as qualitative case studies and available records data, and focus on the social context of innovation.

Taking into account the social context of innovation involves shifting levels of analysis from individual farmers to the social, economic, and political structures in which they are embedded. Contextual analysis of social structures has evolved in two directions, both of which have been inspired by the adoption-diffusion paradigm. The first considers social structure as a set of social relations among farmers, that is, a social network. Typically, social network structure has been studied from the point of view of individual farmers. For instance, farmers are more likely to innovate if they are connected to others with whom they can discuss new farming ideas (Rogers and Kincaid 1981; Rogers 1983; Warriner and Moul 1992). In

this type of analysis, "connectedness" becomes a variable property of individual farmers that is correlated with their innovativeness. It is much less common to find studies that consider how agricultural innovation is influenced by structural properties of entire networks, such as the presence of subgroups or cliques, although other types of innovation have been studied within complete networks (see, e.g., Rogers and Kincaid 1981 on the diffusion of family planning in Korean villages). Field studies of subcultural differences in orientations to innovation report what amount to network effects, though networks are rarely measured directly. For instance, studies of Amish farmers have revealed that members of this sect restrict certain kinds of social contacts with outsiders in order to preserve their beliefs, which include environmental orientations based on religious beliefs (for a review, see Sommers and Napier 1993). Given the growing importance of social network analysis in contemporary sociology (Wasserman and Faust 1995), and the demonstrated importance of networks of communication and influence in innovation research (Rogers and Kincaid 1981), future studies of agricultural innovation could profitably incorporate network models and data in their research designs.

A second type of social structural analysis has considered how agricultural innovation is influenced by distributions of resources within farming communities. Much of this research has focused on the so-called "Green Revolution." This term refers to the increases in cereal-grain production in the Third World, particularly India, Pakistan, and the Philippines, in the late 1960s, through the use of hybrid seeds and chemical fertilizer. In Indian villages where knowledge of new farming technology and agricultural capital were highly concentrated, the rate at which individual farmers translated their knowledge into trial was higher (Gartrell and Gartrell 1979). Yet overall levels of innovation tended to be lower in such high-inequality villages. Had the primary goal of India's development programs been to maximize the rate at which knowledge of new farming practices is turned into innovation, then these results could have been seen as a vindication of a development strategy that concentrated on well-to-do cultivators and high-inequality villages. Yet, this and other assessments of the Green Revolution in the

1970s suggested that development would likely exacerbate rural inequality; that most of the benefits of innovation would accrue to farmers who were wealthy enough to afford the new inputs (Frankel 1971; Poleman and Freebairn 1973); and that the rural poor would be further marginalized and forced to seek employment in the increasingly capital-intensive industries developing in cities. The Green Revolution, so the thinking went, contained the seeds of civil unrest in the cities—an urban Red Revolution (Sharma and Poleman 1993).

Recent research in agricultural economics paints a more optimistic portrait of the long-run distributional effects of the Green Revolution. Once small farmers were given the necessary infrastructural support, their productivity and incomes increased. Growing rural incomes and the resulting growth in consumption demand stimulates the development of a wide variety of off-farm and noncrop employment opportunities. Through participation in these “second generation” effects of the Green Revolution, the incomes of landless and near-landless households have increased dramatically (Sharma and Poleman 1993). These indirect consequences of agricultural innovation are not limited to the Green Revolution. Innovation in agriculture and the expansion of rural, nonagricultural manufacturing were strongly associated in the development of Western Europe and East Asia as far back as the eighteenth century (Grabowski 1995). We tend to think of the Industrial Revolution as an urban phenomenon in which agricultural surplus labor was transferred from occupations of low productivity in agriculture to those of high productivity in urban manufacturing. Yet in this early phase of industrialization, the flow of people and economic activity went the other way—from town to country. Then, as now, agricultural innovation influenced and was influenced by the growth of rural manufacturing. Expanding commercialization of rural areas fosters innovation by providing many of the inputs needed by agriculture, as well as sources of credit for farm operations and alternative sources of income to buffer the risks associated with innovations. These reciprocal effects have been observed in the experience of China in the 1990s (Islam and Hehui 1994).

Economists have argued that agricultural innovation is induced by changes in the availability

and cost of major factors of production, particularly land and labor (Binswanger and Ruttan 1978). Historical, cross-national studies show that countries differently endowed with land and labor have followed distinct paths of technological change in agriculture. Population pressures on land resources have impelled technological change and development (Boserup 1965, 1981; Binswanger 1986). Rather than focusing on individual farmers’ adoption decisions, research in this tradition has examined variation in innovation by region according to demographic and other conditions.

The social context of innovation also has an important political dimension. Political structures powerfully influence the path of innovation. When family farms were turned over to collective management by the Democratic Republic of Vietnam, local farmers in both the lowland and upland areas were unable to use their own knowledge of farm management (Jamieson et al. 1998). Traditional knowledge passed down over many generations became lost to new generations of farmers. Yet local knowledge systems are often crucial to the successful implementation of modern farming technologies brought in from the outside. Such problems are compounded when the power to make decisions about the course of development is centralized in national agencies, as is the case in Vietnam.

Innovation can also call forth new political structures. India’s Green Revolution became politicized as the terms and prices at which agricultural inputs could be obtained and the price at which agricultural products could be sold were determined by government and its local agencies. Peasant movements arose as a response to concern about access to the new farming technology. The incidence of improved agricultural practices has been associated with the rise of political parties such as the Lok Dal of Uttar Pradesh, which most clearly articulated rural interests (Duncan 1997). By asserting new identities and interests created in the changed circumstances brought about by the Green Revolution, the Lok Dal was able to mobilize across traditional lines of caste and locality.

The social, economic, and political structures of the social context of innovation do not exist in isolation from one another. In any development setting, a contextually informed understanding of

agricultural innovation must consider the relationships among these different types of structures (Jamieson et al. 1998). While it may no longer be as fashionable as it once was, the adoption-diffusion model still has much to offer in such efforts. The model refers implicitly to structural effects of socioeconomic status and communication behavior, though these are conceptualized at an individual level (Black and Reeve 1992). Structural analysis has recently moved more firmly into this interdisciplinary realm, particularly in economics (see "Economic Sociology"). With the appropriate structural tools, rural sociologists could make notable contributions to our understanding of how the social structures of markets influence innovation.

Technological change in agriculture is still vitally important throughout the world and, correctly applied, diffusion research can assist in its investigation. It is important to consider the consequences of technological change as well as the determinants of adoption of innovation. It is critical to apply the model to environmental practices and other "noncommercial" innovations in agriculture. In-depth case studies over time are needed to further our understanding of how and why individuals and agricultural social collectives adopt technological change. Above all, the social, economic, and political contexts of innovation must be studied with the models and methods of modern structural analysis. All this provides a basis for continuing to build on a wealth of research materials.

ALCOHOL

INTRODUCTION

The sociological study of alcohol in society is concerned with two broad areas. (1) The first area is the study of alcohol behavior, which includes: (a) social and other factors in alcohol behavior, (b) the prevalence of drinking in society, and (c) the group and individual variations in drinking and alcoholism. (2) The second major area of study has to do with social control of alcohol, which includes: (a) the social and legal acceptance or disapproval of alcohol (social norms), (b) the social and legal regulations and control of alcohol in society, and (c) efforts to change or limit deviant drinking behavior (informal sanctions, law enforcement, treatment, and prevention). Only issues related to the first area of study, sociology of alcohol behavior, will be reviewed here.

PHYSICAL EFFECTS OF ALCOHOL

There are three major forms of beverages containing alcohol (ethanol) that are regularly consumed. Wine is made from fermentation of fruits and usually contains up to 14 percent of ethanol by volume. Beer is brewed from grains and hops and contains 3 to 6 percent ethanol. Liquor (whisky, gin, vodka, and other distilled spirits) is usually 40 percent (80 proof) to 50 percent (100 proof) ethanol. A bottle of beer (12 ounces), a glass of wine (4 ounces), and a cocktail or mixed drink with a shot of whiskey in it, therefore, each have about the same absolute alcohol content, one-half to three-fourths of an ounce of ethanol.

Alcohol is a central nervous system depressant, and its physiological effects are a direct function of the percentage of alcohol concentrated in

the body's total blood volume (which is determined mainly by the person's body weight). This concentration is usually referred to as the BAC (blood alcohol content) or BAL (blood alcohol level). A 150-pound man can consume one alcoholic drink (about three-fourths of an ounce) every hour essentially without physiological effect. The BAC increases with each additional drink during that same time, and the intoxicating effects of alcohol will become noticeable. If he has four drinks in an hour, he will have an alcohol blood content of .10 percent, enough for recognizable motor-skills impairment. In almost all states, operating a motor vehicle with a BAC between .08 percent and .10 percent (determined by breathalyzer or blood test) is a crime and is subject to arrest on a charge of DWI (driving while intoxicated). At .25 percent BAC (about ten drinks in an hour) the person is extremely drunk, and at .40 percent BAC the person loses consciousness. Excessive drinking of alcohol over time is associated with numerous health problems. Cirrhosis of the liver, hepatitis, heart disease, high blood pressure, brain dysfunction, neurological disorders, sexual and reproductive dysfunction, low blood sugar, and cancer, are among the illnesses attributed to alcohol abuse (National Institute on Alcohol Abuse and Alcoholism 1981, 1987; Royce 1990; Ray and Ksir 1999).

SOCIAL FACTORS IN ALCOHOL BEHAVIOR

Alcohol has direct effects on the brain, affecting motor skills, perception, and eventually consciousness. The way people actually behave while drinking, however, is only partly a function of the direct physical effects of ethanol. Overt behavior while under the influence of alcohol depends also on how they have learned to behave while drinking in the setting and with whom they are drinking with at the time. Variations in individual experience, group drinking customs, and the social setting produce variations in observable behavior while drinking. Actions reflecting impairment of coordination and perception are direct physical effects of alcohol on the body. These physical factors, however, do not account for "drunken comportment"—the behavior of those who are "drunk" with alcohol before reaching the stage of impaired muscular coordination (MacAndrew and Edgerton 1969). Social, cultural, and psychological factors are more

important in overt drinking behavior. Cross-cultural studies (MacAndrew and Edgerton 1969), surveys in the United States (Kantor and Straus 1987), and social psychological experiments (Marlatt and Rohsenow 1981), have shown that both conforming and deviant behavior while "under the influence" are more a function of sociocultural and individual expectations and attitudes than the physiological and behavioral effects of alcohol. (For an overview of sociocultural perspectives on alcohol use, see Pittman and White 1991)

Sociological explanations of alcohol behavior emphasize these social, cultural, and social psychological variables not only in understanding the way people act when they are under, or think they are under, the influence of alcohol but also in understanding differences in drinking patterns at both the group and individual level. Sociologists see all drinking behavior as socially patterned, from abstinence, to moderate drinking, to alcoholism. Within a society persons are subject to different group and cultural influences, depending on the communities in which they reside, their group memberships, and their location in the social structure as defined by their age, sex, class, religion, ethnic, and other statuses in society. Whatever other biological or personality factors and mechanisms may be involved, both conforming and deviant alcohol behavior are explained sociologically as products of the general culture and the more immediate groups and social situations with which individuals are confronted. Differences in rates of drinking and alcoholism across groups in the same society and cross-nationally reflect the varied cultural traditions regarding the functions alcohol serves and the extent to which it is integrated into eating, ceremonial, leisure, and other social contexts. The more immediate groups within this sociocultural milieu provide social learning environments and social control systems in which the positive and negative sanctions applied to behavior sustain or discourage certain drinking according to group norms. The most significant groups through which the general cultural, religious, and community orientations toward drinking have an impact on the individual are family, peer, and friendship groups, but secondary groups and the media also have an impact. (For a social learning theory of drinking and alcoholism that specifically incorporates these factors in the social and cultural context see Akers 1985, 1998; Akers and La

Greca 1991. For a review of sociological, psychological, and biological theories of alcohol and drug behavior see Goode 1993.)

SOCIAL CHARACTERISTICS AND TRENDS IN DRINKING BEHAVIOR

Age. Table 1 shows that by time of high school graduation, the percentages of current teen-age drinkers (still under the legal age) is quite high, rivaling that of adults. The peak years for drinking are the young adult years (eighteen to thirty-four), but these are nearly equaled by students who are in the last year of high school (seventeen to eighteen years of age). For both men and women, the probability that one will drink at all stays relatively high from that time up to age thirty-five; about eight out of ten are drinkers, two-thirds are current drinkers, and one in twenty are daily drinkers. The many young men and women who are in college are even more likely to drink (Berkowitz and Perkins 1986; Wechsler et al. 1994). Heavy and frequent drinking peaks out in later years, somewhat sooner for men than women. After that the probability for both drinking and heavy drinking declines noticeably, particularly among the elderly. After the age of sixty, both the proportion of drinkers and of frequent or heavy drinkers decrease. Studies in the general population have consistently found that the elderly are less likely than younger persons to be drinkers, heavy drinkers, and problem drinkers (Cahalan and Cisin 1968; Fitzgerald and Mulford 1981; Meyers et al. 1981-1982; Borgatta et al. 1982; Holzer et al. 1984; Akers 1992).

Sex. The difference is not as great as it once was, but more men than women drink and have higher rates of problem drinking in all age, religious, racial, social class, and ethnic groups and in all regions and communities. Teenage boys are more likely to drink and to drink more frequently than girls, but the difference between male and female percentages of current drinkers at this age is less than it is in any older age group. Among adults, men are three to four times more likely than women (among the elderly as much as ten times more likely) to be heavy drinkers and two to three times more likely to report negative personal and social consequences of drinking (National Institute on Alcohol Abuse and Alcoholism 1987).

Percentages Reporting Drinking by Age Group (1997)

Age Group	Lifetime	Past Year	Past Month
12-17	39.7	34	20.5
High School Seniors	81.7	74.8	52.7
18-25	83.5	75.1	58.4
26-34	88.9	74.6	60.2
35+	87	64.1	52.8

Table 1

SOURCE: Substance Abuse and Mental Health Services Administration 1998; University of Michigan (for high school seniors) 1998.

Social Class. The proportion of men and women who drink is higher in the middle class and upper class than in the lower class. The more highly educated and the fully employed are more likely to be current drinkers than the less educated and unemployed. Drinking by elderly adults increases as education increases, but there are either mixed or inconsistent findings regarding the variations in drinking by occupational status, employment status, and income (Holzer 1984; Borgatta 1982; Akers and La Greca 1991).

Community and Location. Rates of drinking are higher in urban and suburban areas than in small towns and rural areas. As the whole country has become more urbanized the regional differences have leveled out so that, while the South continues to have the lowest proportion of drinkers, there is no difference among the other regions for both teenagers and adults. Although there are fewer of them in the South, those who do drink tend to drink more per person than drinkers in other regions (National Institute on Alcohol Abuse and Alcoholism 1998a).

Race, Ethnicity, and Religion. The percent of drinking is higher among both white males and females than among African-American men and women. Drinking among non-Hispanic whites is also higher than among Hispanic whites. The proportion of problem or heavy drinkers is about the same for African Americans and white Americans (Fishburne et al. 1980; National Institute on Drug Abuse, 1988; National Institute on Alcohol Abuse and Alcoholism 1998a). There may be a tendency for blacks to fall into the two extreme categories, heavy drinkers or abstainers (Brown and Tooley

1989), and black males suffer the highest rate of mortality from cirrhosis of the liver (National Institute on Alcohol Abuse and Alcoholism 1998b). American Indians and Alaskan Natives have rates of alcohol abuse and problems several times the rates in the general population (National Institute on Alcohol Abuse and Alcoholism 1987).

Catholics, Lutherans, and Episcopalians have relatively high rates of drinking. Relatively few fundamentalist Protestants, Baptists, and Mormons drink. Jews have low rates of problem drinking, and Catholics have relatively high rates of alcoholism. Irish Americans have high rates of both drinking and alcoholism. Italian Americans drink frequently and heavily but apparently do not have high rates of alcoholism (see Cahalan et al. 1967; Mulford 1964). Strong religious beliefs and commitment, regardless of denominational affiliation, inhibit both drinking and heavy drinking among teenagers and college students (Cochran and Akers 1989; Berkowitz and Perkins 1986).

Trends in Prevalence of Drinking. There has been a century-long decline in the amount of absolute alcohol consumed by the average drinker in the United States. There was a period in the 1970s when the per capita consumption increased, and the proportion of drinkers in the population was generally higher by the end of the 1970s than at the beginning of the decade, although there were yearly fluctuations up and down. The level of drinking among men was already high, and the increases came mainly among youth and women. But in the 1980s the general downward trend resumed (Keller 1958; National Institute on Alcohol Abuse and Alcoholism 1981, 1987, 1998). Until the 1980s, this per capita trend was caused mainly by the increased use of lower-content beer and wine and the declining popularity of distilled spirits rather than a decreasing proportion of the population who are drinkers.

Alcohol-use rates were quite high in the United States throughout the 1970s and into the 1980s (see table 2). Since then, there have been substantial declines in use rates in all demographic categories and age groups. In 1979 more than two-thirds of American adolescents (twelve to seventeen years of age) had some experience with alcohol and nearly four out of ten were current drinkers (drank within the past month). In 1988, these proportions

had dropped to one-half and one-fourth respectively. In 1997, adolescent rates had dropped even lower to four out of ten having ever used alcohol and only two out of ten reporting use in the past month. Current use in the general U.S. population (aged twelve and older) declined from 60 percent in 1985 to 51 percent in 1997. Among the adult population eighteen years of age and older, current use declined from 71 percent in 1985 to 55 percent in 1997. Lifetime use rates have also declined from 88.5 percent in 1979 to 81.9 percent in 1997 (aged twelve and older). Generally, there have been declines in both annual (past year) prevalence of drinking (decreases of 3 to 5 percent) and current (past month) prevalence of drinking (decreases of 7 to 10 percent) among high school seniors, young adults, and older adults. Although lifetime prevalence is not a sensitive measure of short-term change in the adult population (since the lifetime prevalence is already fixed for the cohort of adults already sampled in previous surveys), it does reflect an overall decline in alcohol use. It should be remembered, however, that most of this is light to moderate consumption; the modal pattern of drinking for all age groups in the United States has long been and continues to be nondeviant, light to moderate social drinking.

The relative size of the reductions in drinking prevalence over the last two decades have been rather substantial; however, the proportions of drinkers remains high. By the time of high school graduation, one-half of adolescents are current drinkers and the proportion of drinkers in the population remains at this level throughout the young adult years. Three-fourths of high school seniors and young adults and two-thirds of adults over the age of thirty-five have consumed alcohol in the past year (see table 1).

Although lifetime use and current use rates appear to be continuing a slight decline in all categories, there have been some slight increases in rates of frequent (daily) drinking among high school seniors and young adults. While these increases do not approach the rates observed in the 1980s they may indicate that the overall rates are stabilizing and hint of possible increases in alcohol use rates in the future.

Estimates of Prevalence of Alcoholism. In spite of these trends in lower levels of drinking,

**Percentages Reporting Lifetime, Past Year, and Past Month Use of Alcohol
in the U.S. Population Aged 12 and Older (1979-1997)**

	1979	1985	1991	1993	1997

alcoholism remains one of the most serious problems in American society. Alcohol abuse and all of the problems related to it cause enormous personal, social, health, and financial costs in American society. Cahalan et al. (1969) in a 1965 national survey characterized 6 percent of the general adult population and 9 percent of the drinkers as “heavy-escape” drinkers, the same figures reported for a 1967 survey (Cahalan 1970). These do not seem to have changed very much in the years since. They are similar to findings in national surveys from 1979 to 1988 (National Institute on Alcohol Abuse and Alcoholism 1981, 1987, 1988, 1989; Clark and Midanik 1982), which support an estimate that 6 percent of the general population are problem drinkers and that about 9 percent of those who are drinkers will abuse or fail to control their intake of alcohol. Royce (1989) and Vaillant (1983) both estimate that 4 percent of the general population in the United States are “true” alcoholics. This estimate would mean that there are perhaps 10.5 million alcoholics in American society (see also Liska 1997). How many alcoholics or how much alcohol abuse there is in our society is not easily determined because the very concept of alcoholism (and therefore what gets counted in the surveys and estimates) has long been and remains controversial.

THE CONCEPT OF ALCOHOLISM

The idea of alcoholism as a sickness traces back at least 200 years (Conrad and Schneider 1980). There is no single, unified, disease concept, but the prevailing concepts of alcoholism today revolve around the one developed by E. M. Jellinek (1960) from 1940 to 1960. Jellinek defined alcoholism as a disease entity that is diagnosed by the “loss of control” over one’s drinking and that progresses through a series of clear-cut “phases.”

The final phase of alcoholism means that the person is rendered powerless by the disease to drink in a controlled, moderate, nonproblematic way.

The disease of alcoholism is viewed as a disorder or illness for which the individual is not personally responsible for having contracted. It is viewed as incurable in the sense that alcoholics can never truly control their drinking. That is, sobriety can be achieved by total abstention, but if even one drink is taken, the alcoholic cannot control how much more he or she will consume. It is a “primary” self-contained disease that produces the problems, abuse, and “loss of control” over drinking by those suffering from this disease. It can be controlled through proper treatment to the point where the alcoholic can be helped to stop drinking so that he or she is in “remission” or “recovering.” “Once an alcoholic, always an alcoholic” is a central tenet of the disease concept. Thus, one can be a sober alcoholic, still suffering from the disease even though one is consuming no alcohol at all. Although the person is not responsible for becoming sick, he or she is viewed as responsible for aiding in the cure by cooperating with the treatment regimen or participation in groups such as Alcoholics Anonymous.

The disease concept is the predominant one in public opinion and discourse on alcohol (according to a 1987 Gallup Poll, 87 percent of the public believe that alcoholism is a disease). It is the principal concept used by the vast majority of the treatment professionals and personnel offering programs for alcohol problems. It receives widespread support among alcohol experts and continues to be vigorously defended by many alcohol researchers (Keller 1976; Vaillant 1983; Royce 1989). Alcoholics Anonymous, the largest single program for alcoholics in the world, defines alcoholism as a disease (Rudy 1986). The concept of

alcoholism as a disease is the officially stated position of the federal agency most responsible for alcohol research and treatment, the National Institute of Alcoholism and Alcohol Abuse (National Institute on Alcohol Abuse and Alcoholism 1987).

Nonetheless, many sociologists and behavioral scientists remain highly skeptical and critical of the disease concept of alcoholism (Trice 1966; Cahalan and Room 1974; Conrad and Schneider 1980; Rudy 1986; Fingarette 1988, 1991; Peele 1989). The concept may do more harm than good by discouraging many heavy drinkers who are having problems with alcohol, but who do not identify themselves as alcoholics or do not want others to view them as sick alcoholics, from seeking help. The disease concept is a tautological (and therefore untestable) explanation for the behavior of people diagnosed as alcoholic. That is, the diagnosis of the disease is made on the basis of excessive, problematic alcohol behavior that seems to be out of control, and then this diagnosed disease entity is, in turn, used to explain the excessive, problematic, out-of-control behavior.

In so far as claims about alcoholism as a disease can be tested, "Almost everything that the American public believes to be the scientific truth about alcoholism is false" (Fingarette 1988, p.1; see also Peele 1989; Conrad and Schneider 1980; Fingarette 1991; Akers 1992). The concept preferred by these authors and by other sociologists is one that refers only to observable behavior and drinking problems. The term *alcoholism* then is nothing more than a label attached to a pattern of drinking that is characterized by personal and social dysfunctions (Mulford and Miller 1960; Conrad and Schneider 1980; Rudy 1986; Goode 1993). That is, the drinking is so frequent, heavy, and abusive that it produces or exacerbates problems for the drinker and those around him or her including financial, family, occupational, physical, and interpersonal problems. The heavy drinking behavior and its attendant problems are themselves the focus of explanation and treatment. They are not seen as merely symptoms of some underlying disease pathology. When drinking stops or moderate drinking is resumed and drinking does not cause social and personal problems, one is no longer alcoholic. Behavior we label as alcoholic is problem drinking that lies at one extreme end of a continuum of drinking behavior with

abstinence at the other end and various other drinking patterns in between (Cahalan et al. 1969). From this point of view, alcoholism is a disease only because it has been socially defined as a disease (Conrad and Schneider 1980; Goode 1993).

Genetic Factors in Alcoholism. Contrary to what is regularly asserted, evidence that there may be genetic, biological factors in alcohol abuse is evidence neither in favor of nor against the disease concept, any more than evidence that there may be genetic variables in criminal behavior demonstrates that crime is a disease. Few serious researchers claim to have found evidence that a specific disease entity is inherited or that there is a genetically programmed and unalterable craving or desire for alcohol. It is genetic susceptibility to alcoholism that interacts with the social environment and the person's drinking experiences, rather than genetic determinism, that is the predominant perspective.

The major evidence for the existence of hereditary factors in alcoholism comes from studies that have found greater "concordance" between the alcoholism of identical twins than between siblings and from studies of adoptees in which offspring of alcoholic fathers were found to have an increased risk of alcoholism even though raised by nonalcoholic adoptive parents (Goodwin 1976; National Institute on Alcohol Abuse and Alcoholism 1982; U.S. Department of Health and Human Services 1987; for a review and critique of physiological and genetic theories of alcoholism see Rivers 1994). Some have pointed to serious methodological problems in these studies that limit their support for inherited alcoholism (Lester 1987). Even the studies finding evidence for an inherited alcoholism report that only a small minority of those judged to have the inherited traits become alcoholic and an even smaller portion of all alcoholics have indications of hereditary tendencies. Whatever genetic variables there are in alcoholism apparently come into play in a small portion of cases. Depending upon the definition of alcoholism used, the research shows that biological inheritance either makes no difference at all or makes a difference for only about one out of ten alcoholics. Social and social psychological factors are the principal variables in alcohol behavior, including that which is socially labeled and diagnosed as alcoholism (Fingarette 1988; Peele 1989).

RONALD L. AKERS
THOMAS R. HEFFINGTON

ALIENATION

Since 1964, many commentators have been speaking of a crisis of confidence in the United States, a malaise marked by widespread public belief that major institutions—businesses, labor unions, and especially the government, political parties, and political leaders—are unresponsive, remote, ineffective, and not to be trusted (Lipset and Schneider 1983). *Alienation* became the catchword for these sentiments, detected among discontented workers, angry youth, and militant minority groups. American leaders concerned about the increase in alienation found new relevance in ongoing discussions among sociologists and other social scientists, who have defined alienation, used survey research to measure the level of alienation in society, and have debated the causes, significance, and consequences of alienation and particularly, political alienation.

DIMENSIONS OF ALIENATION AND POLITICAL ALIENATION

Theorists and sociological researchers have developed different definitions of alienation (Seeman 1975). Scholars influenced by the philosophical writings of Karl Marx have used the word *alienation* to mean self-estrangement and the lack of self-realization at work (Blauner 1964; Hodson 1996). Marx argued that although humans by their very nature are capable of creative and intrinsically rewarding work, the Industrial Revolution alienated workers from their creative selves and reduced workers to the unskilled tenders of machines (Braverman 1974). The worker produced machinery and other commodities that formed the capitalist system of workplace hierarchies and global markets, which the worker could not control. Rather, the system dominated workers as an alienated, “reified” force, apart from the will and interests of workers (Meszaros 1970). Whereas this oldest definition links alienation to the development of capitalism in modern society, some scholars see alienation as a characteristic reaction to the postmodern condition of fragmented multiple images and loss of individual identities and any shared meanings (Geyer 1996).

Alienation can also refer to the isolation of individuals from a community—a detachment from the activities, identifications, and ties that a community can provide. In addition, the concept of alienation has included the notion of cultural radicalism or estrangement from the established values of a society. Inglehart (1981) has argued that the highly educated generation that came of age in the counterculture of the 1960s rejected their elders’ traditional values of materialism, order, and discipline. Easterlin (1980, pp. 108–111) suggests that it is the relatively large cohort size of the Baby Boom generation that led them to suffer competition for jobs, psychological stress, discontent, and hence, generalized political alienation. On the contrary, Inglehart (1997) argues that baby boomers and succeeding generations will only express alienation against specific authoritative institutions, such as the police, the military, and churches. With succeeding generations increasingly espousing “postmaterialist” values such as the quality of life, self-realization, and participatory democracy, Inglehart finds a worldwide increase in some activities that reduce alienation such as petition-signing and political conversation.

Much of the literature on alienation in the 1990s focused on alienation from political institutions, and some writers have examined how alienation has changed in former authoritarian nations such as Argentina and South Africa and in Eastern Europe (Geyer 1996; Geyer and Heinz 1992). Sociologists interested in the political well-being of the United States have measured the extent to which individuals feel powerless over government (i.e., unable to influence government) and perceive politics as meaningless (i.e., incomprehensible; Seeman 1975). Such attitudes may be connected to a situation of normlessness, or *anomie*, which occurs when individuals are no longer guided by the political rules of the game (Lipset and Raab 1978). Social scientists have been concerned that alienation might reduce political participation through institutional channels such as voting, and might lead to nonconventional activity like protest movements and collective violence.

MEASUREMENT AND CONSEQUENCES OF POLITICAL ALIENATION

Political alienation consists of attitudes whereby citizens develop (or fail to develop) meanings and evaluations about government and about their own power (or powerlessness) in politics. Specifically, political alienation is composed of the attitudes of distrust and inefficacy. Distrust (also called cynicism) is a generalized negative attitude about governmental outputs: the policies, operations, and conditions produced by government. Compared to the simple dislike of a particular policy or official, distrust is broader in scope. Whereas distrust is an evaluation of governmental outputs, inefficacy is an expectation about inputs, that is, the processes of influence over government. People have a sense of inefficacy when they judge themselves as powerless to influence government policies or deliberations (Gamson 1971).

Researchers have sought to find opinion poll questions that yield responses consistently correlated to only one underlying attitude, of distrust for example. Mason, House, and Martin (1985) argue that the most “internally valid” measures of distrust are two questions: “How much of the time do you think you can trust the government in Washington to do what is right—just about all of the time, most of the time, or only some of the time?” and “Would you say that the government is

pretty much run by a few big interests looking out for themselves or that it is run for the benefit of all people?" Similarly, a person's sense of inefficacy can be measured by asking the person to agree or disagree with the following statements, which contain the words "like me": "People like me don't have any say about what the government does" and "I don't think public officials care much what people like me think."

During election years since the 1950s, the Center for Political Studies at the University of Michigan at Ann Arbor has posed these and other questions to national samples of citizens. Those replying that you can trust the government only some of the time or none of the time comprised 22 percent in 1964 but 73 percent in 1980. This percentage fell during President Ronald Reagan's first term but then increased through 1994 (reaching 78 percent) before falling to 67 percent in 1996. Those disagreeing with the statement that public officials care rose from 25 percent in 1960, to 52 percent in 1980 and 66 percent in 1994 (Orren 1997; Poole and Mueller 1998).

In addition, polls indicate that in the same time period, increasing numbers of citizens felt that government was less responsive to the people (Lipset and Schneider 1983, pp. 13–29). This attitude, which can be termed *system unresponsiveness*, was measured by asking questions that did not use the words "like me." Responses to the questions thus focused not on the respondents' evaluations of their own personal power, but rather on their judgments of the external political system. (Craig 1979 conceptualizes system unresponsiveness as "output inefficacy").

What are the consequences of the increase in political alienation among Americans? Social scientists have investigated whether individuals with highly alienated attitudes are more likely to withdraw from politics, engage in violence, or favor protest movements or extremist leaders. Research findings have been complicated by the fact that the same specific alienated attitudes have been linked to different kinds of behaviors (Schwartz 1973, pp. 162–177).

The alienated showed little tendency to support extremist candidates for office. (The only exception was that high-status alienated citizens supported Goldwater's presidential campaign in 1964. See Wright 1976, pp. 227, 251; Herring

1989, p. 98.) Social scientists have generally agreed that politically alienated individuals are less likely to participate in conventional political processes. During four presidential elections from 1956 to 1968, citizens with a low sense of efficacy and a low level of trust were less likely to vote, attend political meetings, work for candidates, contribute money, or even pay attention to the mass media coverage of politics. Although some studies fail to confirm that those with low *trust* are likely to be apathetic (Citrin 1974, p. 982), those with a low sense of political *efficacy* are indeed likely to be nonvoters, mainly because they are also less educated (Lipset and Schneider 1983, p. 341). In the United States, the percentage of eligible voters who actually cast ballots declined between 1960 and 1980, while the percentage who expressed political inefficacy rose in the same period; Abramson and Aldrich (1982) estimate that about 27 percent of the former trend is caused by the latter. (See Shaffer 1981 for confirmation but Cassel and Hill 1981 and Miller 1980 for contrary evidence).

Piven and Cloward (1988) vigorously dispute the notion that the alienated attitudes of individuals are the main cause for the large numbers of nonvoters in the United States. Piven and Cloward construct a historical explanation—that in the early twentieth century, political reformers weakened local party organizations in cities, increased the qualifications for suffrage, and made voting registration procedures more difficult. Legal and institutional changes caused a sharp decrease in voting, which only then led to widespread political alienation. Voting participation, especially among the minority poor in large cities, continues to be low because of legal requirements to register in advance of election day and after a change in residence, and because of limited locations to register.

Some researchers have found that the politically alienated are more likely to utilize nonconventional tactics such as political demonstrations or violence. College students who participated in a march on Washington against the Vietnam War, compared to a matched sample of students from the same classes at the same schools, expressed more alienated attitudes, stemming from an underlying sense of inefficacy and system unresponsiveness (Schwartz 1973 pp. 138–142). Paige's (1971) widely influential study drew on Gamson's distinctions between trust and efficacy and showed

that Blacks who participated in the 1967 riot in Newark, New Jersey, had low levels of political trust but high levels of political efficacy (i.e., high capabilities and skills to affect politics, measured indirectly in this instance by the respondents' level of political knowledge). However, Sigelman and Feldman's (1983) attempt to replicate Paige's findings in a seven-nation study discovered that the participants and supporters of unconventional political activity were only slightly more likely to feel both efficacious and distrusting. Rather than being generally distrusting, participants and supporters in some nations were more likely to be dissatisfied about specific policies. (See also Citrin 1974, p. 982 and Craig and Maggiotto 1981 for the importance of specific dissatisfactions).

Even though politically alienated individuals may sometimes be found in social movements, the alienation of individuals is not necessarily the cause of social movements. McCarthy and Zald (1977) have argued that alienation and indeed policy dissatisfactions and other grievances are quite common in societies. Whether or not a social movement arises depends on the availability of resources and the opportunities for success. The civil rights movement, according to McAdam (1982), succeeded not when blacks believed that the political system was unresponsive, but rather when blacks felt that some national leaders showed signs of favoring their cause.

DISTRIBUTION AND SIGNIFICANCE OF POLITICAL ALIENATION

Social scientists have argued that political alienation is concentrated in different types of groups—among those who dislike politicians of the opposing political party, in certain economic and racial groups, and among those dissatisfied with government policy. Each of these findings supports a different assessment of the causes and the importance of political alienation.

Partisan Bickering? First of all, high levels of political distrust can be found among those who have a negative view of the performance of the presidential administration then in office. Citrin (1974) concludes that widespread expressions of political distrust (cynicism) merely indicate Democratic versus Republican Party rivalries as usual.

Cynicism, rather than being an expression of deep discontent, is nothing more than rhetoric and ritual and is not a threat to the system. Even partisans who intensely distrust a president from an opposing party are proud of the governmental system in the United States and want to keep it. However, King (1997) argues that distrust stems from a more serious problem, that congressional leaders and activists in political parties have become more ideological and polarized (see Lo and Schwartz 1998 on conservative leaders). The public has remained in the center but is becoming alienated from politicians whose ideologies are seen as far removed from popular concerns.

The alienation of social classes and minorities. Second, other researchers interested in finding concentrations of the politically alienated have searched not among people with varying partisan identifications, but rather in demographic groups defined by such variables as age, gender, education, and socioeconomic class. Many public opinion surveys using national samples have found alienation only weakly concentrated among such groups (Orren 1997). In the 1960s, the sense of inefficacy increased uniformly throughout the entire U.S. population, rather than increasing in specific demographic groups such as blacks or youth (House and Mason 1975). Using a 1970 survey, Wright (1976) noted that feelings of inefficacy and distrust were somewhat concentrated among the elderly, the poorly educated, and the working class. Still, Wright's conclusion was that the alienated were a diverse group that consisted of both rich and poor, black and white, and old and young, making it very unlikely that the alienated could ever become a unified political force.

Research on the gender gap, that is, the differing political attitudes between women and men (Mueller 1988), indicates that women are not more politically alienated than men (Poole and Muller 1998). In fact, a higher percentage of women compared to men support more government spending on social programs and a more powerful government with expanded responsibilities (Clark and Clark 1996) and thus are less distrustful of the broad scope of government. Some studies have shown that the politically alienated are indeed concentrated among persons with less education and lower income and occupational status (Wright

1976, p. 136; Lipset and Schneider 1983, pp. 311–315; Finifter 1970; Form and Huber 1971). Research that directly focuses on obtaining the opinions of minority and poor respondents has uncovered high degrees of political alienation among these groups. A survey of roughly equal numbers of blacks and whites in metropolitan Detroit in 1992 showed that blacks, compared to whites, evaluated schools and the police more negatively, distrusted local government more, and thought that participation in local politics was less efficacious (Bledsoe et al. 1996). Bobo and Hutchings (1966) oversampled minority residents of Los Angeles County and found that higher percentages of blacks compared to whites expressed “racial alienation,” that is, the opinion that blacks faced inferior life chances, fewer opportunities, and unfair treatment. Blacks living in Detroit neighborhoods where over 20 percent of the residents are poor, were more likely than other blacks to say that they had little influence in community decisions and that community problems were complex and unsolvable (Cohen and Dawson 1993).

Wright argues that even though sizable numbers of persons express alienated attitudes, these people pose little threat to the stability of regimes, because they rarely take political action and even lack the resources and skills to be able to do so. Lipset (1963) has argued that apathy is a virtue because it allows elites in democratic societies to better exert leadership. (For a critique see Wolfe 1977, p. 301.) For many social scientists in the 1950s, widespread apathy was a welcome alternative to the alleged mass activism that had produced the fascist regimes in Germany and Italy. However, Wright (1976, pp. 257–301) counters that since the alienated masses actually pose no threat to the contemporary political system, an increase in mass democratic participation, perhaps the mobilization of workers on the issues of class division, could very well be beneficial.

But the class mobilization that Wright envisions might turn out to be a middle-class affair (Teixeira 1996) rather than a working-class revolt. Whereas Lipset and Wright have been concerned about the concentration of political alienation in the lower socioeconomic strata, Warren (1976) emphasizes the alienation among “Middle American Radicals,” who believe that they are disfavored by a government that gives benefits to the poor and to the wealthy. Feelings of inefficacy and

distrust have increased the most among the middle strata—private-sector managers, middle-income workers, and a “new layer” of public-sector professionals (Herring 1989).

Unlike the poor, the middle strata have the resources to protest and to organize social movements and electoral campaigns, exemplified by protests against the property tax that culminated with the passage of Proposition 13 in California and Proposition 2 1/2 in Massachusetts. Property tax protesters were middle-class homeowners who expressed their political alienation when they condemned “taxation without representation.” Citizens who felt cut off from political decision making were the most likely to support the tax revolt (Lowery and Sigelman 1981). Protests centered around unresponsive government officials who continued to increase assessments and tax rates, without heeding the periodic angry protests of homeowners. Movement activists interpreted their own powerlessness and power in community and metropolitan politics, thereby shaping the emerging tactics and goals of a grass-roots citizens’ movement (Lo 1995).

A Crisis for Democracy? Finally, other social scientists have found intense alienation among those with irreconcilable dissatisfactions about government policy, thus threatening to make effective government impossible. Miller (1974) argued that between 1964 and 1970, political distrust (cynicism) increased simultaneously among those favoring withdrawal and those favoring military escalation in the Vietnam War. Similarly, distrust increased both among blacks who thought that the civil rights movement was making too little progress, and among white segregationists who held the opposite view. The 1960s produced two groups—cynics of the left and cynics of the right, each favoring polarized policy alternatives (see also Lipset and Schneider 1983, p. 332). Cynics of the right, for example, rejected both the Democratic and Republican parties as too liberal. (Herring 1989 has developed a similar “welfare split” thesis, that more social spending has different effects on the distrust level of various groups but, overall, raises political distrust.) Miller concludes that increased cynicism, along with a public bifurcated into extreme stances on issues, makes it difficult for political leaders to compromise and build support for centrist policies. While agreeing with Wright that the alienated are divided amongst themselves,

Miller argues that this fragmentation does indeed constitute a crisis of legitimacy for American politics.

For some social theorists, widespread political alienation is a sign of even deeper political contradictions. Throughout American history, as citizens have fought to extend their democratic freedoms and personal rights, businesses have used the notion of property rights to protect their own interests and stifle reform (Bowles and Gintis 1987). Wolfe (1977) sees political alienation as a symptom of how the democratic aspirations of the citizenry have been frustrated by the state, which has attempted to foster the growth of capitalism while at the same time maintaining popular support.

OVERCOMING ALIENATION

One diagnosis for overcoming alienation has been proposed by Sandel, Etzioni (1996), and others from the communitarian perspective, which promotes the values of civic commitment. Sandel (1996) argues that citizens today feel powerless over their fate and disconnected from politics because of an excessively individualist culture in the United States. America's leaders must encourage devotion to the common good, attachments to communities, volunteerism, and moral judgments and dialogues. Political alienation can be overcome through the associations and networks of civil society.

Others also trace political alienation back to its roots in society, but focus on work and economic hardships, which Marx long ago characterized as alienating and that now prevent the emergence of the caring and democratic public life envisioned by the communitarians (Bennett 1998). According to Lerner (1991), people experience a deep and debilitating sense of inefficacy (what he terms "surplus powerlessness") in their personal and family lives. Surplus powerlessness can be overcome through such measures as communities of compassion, occupational stress groups, and family support groups, which will build the attachments and religious values sought by the communitarians, while at the same time compassionate unions will seek to change power relations at work and in the society at large.

Alienation, originally a Marxist concept depicting the economic deprivations of industrial workers, is now a political concept portraying the

plight of citizens increasingly subjected to the authority and the bureaucracy of the state in advanced capitalist societies. Perhaps returning to the original theorizing about alienation in the economic sphere can deepen our analysis of contemporary political alienation.

CLARENCE Y.H. LO

ALTERNATIVE LIFESTYLES

Lifestyles that were considered "alternative" in the past are becoming less unusual and increasingly normative. Many people, for example, experience cohabitation, divorce, and remarriage. Other lifestyles, such as singlehood, gay and lesbian relationships, or remaining childfree may not be rising drastically in frequency, but they are less stigmatized and more visible than they were in recent decades.

It was during the 1960s and 1970s that the utility and the structure of many social institutions were seriously questioned. This included the institution of the family. What was the purpose of

family? Was it a useful social institution? Why or why not? How can it be improved? The given cultural milieu of the period, such as resurgence of the women's movement, concerns about human rights more generally, and improvements in our reproductive and contraceptive technology, exacerbated these questions. In increasing numbers individuals began to experiment with new and alternative ways in which to develop meaningful relationships, sometimes outside the confines of marriage. Literature soon abounded among both the academic community and the popular press describing and deliberating on these new lifestyles. In 1972, a special issue of *The Family Coordinator* was devoted to the subject of alternative lifestyles, with a follow-up issue published in 1975. The subject was firmly entrenched within the field of family sociology by 1980 when the *Journal of Marriage and Family* devoted a chapter to alternative family lifestyles in their decade review of research and theory.

Despite the increased visibility and tolerance for a variety of lifestyles during the 1990s, concern is voiced from some people over the "demise" of the family. The high divorce rate, increased rates of premarital sexuality, cohabitation, and extramarital sex are pointed to as both the culprits and the consequences of the deterioration of family values. Popenoe and Whitehead write about cohabitation, for example: "Despite its widespread acceptance by the young, the remarkable growth of unmarried cohabitation in recent years does not appear to be in children's or the society's best interest. The evidence suggests that it has weakened marriage and the intact, two-parent family and thereby damaged our social well-being, especially that of women and children" (1999, p. 16). What do the authors mean by "society's best interest"? And what type of family relationship would be in our "best interest"? What invariably comes to mind is the married, middle-class, traditional two-parent family in which the father works outside the home and the mother stays at home to take care of the children, at least while they are young. This monolithic model, however, excludes the majority of the population; indeed, a growing number of persons do not desire such a model even if it were attainable. It is based on the false notion of a single and uniform intimate experience that many argue has racist, sexist, and classist connotations.

This distress about the demise of the family is not particularly new. For at least a century American observers and social critics have warned against the negative consequences of changes in the family. Yes, the family has indeed changed, but the vast majority of the population, both then and now, still prefers to marry, have children, and live in a committed, monogamous relationship. The most profound changes to date have not occurred in alternatives *to* marriage but rather in alternatives *prior* to marriage, and alternative ways in *structuring* marriage itself, while keeping the basic institution and its purposes intact. For example, nonmarital sex, delayed marriage and childbearing, and cohabitation are practiced with increasing frequency and are tolerated by a larger percentage of the population than ever before. And within marriage itself, new behaviors and ideologies are becoming increasingly popular, such as greater equality between men and women (although gender equality is more an ideal than a reality in most marriages).

NEVER-MARRIED SINGLES

A small but growing percentage of adult men and women remain single throughout their lives. In the United States, approximately 5 percent never marry (U.S. Bureau of the Census 1998). These individuals experience life without the support and obligations of a spouse and usually children. While often stereotyped as either “swingers” or “lonely losers,” Stein reports that both categorizations are largely incorrect (1981). Instead, singles cannot be easily categorized and do not constitute a single social type. Some have chosen singlehood as a preferred option, perhaps due to career decisions, sexual preference, or other family responsibilities. Others have lived in locations in which demographic imbalances have affected the pool of eligibles for mate selection. And others have been lifelong isolates, have poor social skills, or have significant health impairments that have limited social contacts.

Attitudes toward singlehood have been quite negative historically, especially in the United States, although change has been noted. Studies report that during the 1950s, remaining single was viewed as pathology, but by the mid-1970s singlehood was not only tolerated but also viewed by many as an

avenue for enhancing one’s happiness. In the early 1990s, when asked about the importance of being married, approximately 15 percent of unmarried white males and 17 percent of unmarried white females between the ages of 19 and 35 did not agree with the statement that they “would like to marry someday.” The percentage of blacks that did not necessarily desire marriage was even higher, at 24 percent and 22 percent of black males and females, respectively. Interestingly, the gap in attitudes between males and females was the largest among Latinos, with only 9 percent of Latino males, but 25 percent of Latina females claiming that they did not necessarily want to marry (South 1993).

Despite this gender gap, single males are viewed more favorably than are single females. Males are stereotyped as carefree “bachelors,” while single women may still be characterized as unattractive and unfortunate “spinsters.” In the popular card game “Old Maid,” the game’s loser is the one who is stuck with the card featuring an old and unattractive unmarried woman. Oudijk (1983) found that the Dutch population generally affords greater lifestyle options to women, and only one-quarter of his sample of married and unmarried persons reported that married persons are necessarily happier than are singles.

Shostak (1987) has developed a typology in which to illustrate the divergence among the never-married single population. It is based on two major criteria: the voluntary versus involuntary nature of their singlehood, and whether their singlehood is viewed as temporary or stable. *Ambivalents* are those who may not at this point be seeking mates but who are open to the idea of marriage at some time in the future. They may be deferring marriage for reasons related to schooling or career, or they may simply enjoy experimenting with a variety of relationships. *Wishfuls* are actively seeking a mate but have been unsuccessful in finding one. They are, generally, dissatisfied with their single state and would prefer to be married. The *resolved* consciously prefer singlehood. They are committed to this lifestyle for a variety of reasons; career, sexual orientation, or other personal considerations. A study of 482 single Canadians reported that nearly half considered themselves to fall within this category (Austrom and

Hanel 1985). They have made a conscious decision to forgo marriage for the sake of a single lifestyle. Small but important components of this group are priests; nuns; and others who, for religious reasons, choose not to marry. Finally, *regretfuls* are those who would rather marry but who have given up their search for a mate and are resigned to singlehood. They are involuntarily stable singles.

While the diversity and heterogeneity among the never-married population is becoming increasingly apparent, one variable is suspected to be of extreme importance in explaining at least some variation: gender. Based on data gathered in numerous treatises, the emerging profiles of male and female singles are in contrast. As Bernard (1973) bluntly puts it, the never-married men represent the “bottom of the barrel,” while the never-married women are the “cream of the crop.” Single women are generally thought to be more intelligent, are better educated, and are more successful in their occupations than are single men. Additionally, research finds that single women report to be happier, less lonely, and have a greater sense of psychological well-being than do their single male counterparts.

One reason why single women are more likely to be the “cream of the crop” as compared to men is that many well-educated and successful women have difficulty finding suitable mates who are their peers, and therefore have remained unmarried. Mate-selection norms in the United States encourage women to “marry up” and men to “marry down” in terms of income, education, and occupational prestige. Thus, successful women have fewer available possible partners, because their male counterparts may be choosing from a pool of women with less education and income. A second reason for the gender difference is that some highly educated and successful women do not *want* what they interpret as the “burdens” of a husband and children. Career-oriented women are not rewarded, as are career-oriented men, for having a family. Someone who is described as a “family man” is thought to be a stable and reliable employee; there is no semantic equivalent for women. Thus, well-educated, career-oriented women may see singlehood as an avenue for their success, whereas well-educated, career-oriented men may see marriage as providing greater benefits than singlehood.

Demographers predict that the proportion of singles in our population is likely to increase slightly in the future. As singlehood continues to become a viable and respectable alternative to marriage, more adults may choose to remain single throughout their lives. Others may remain single not out of choice but due to demographic and social trends. More people are postponing marriage, and it is likely that some of these will find themselves never marrying. For example, the number of women between the ages of forty and forty-four today who have never married is double the number in 1980, at approximately 9 percent (U.S. Bureau of the Census 1998). Some of these women may marry eventually, but many will likely remain unmarried. Moreover, the increasing educational level and occupational aspirations of women, coupled with our continued norms of marital homogamy, help to ensure that the number of never-married single persons—women in particular—is likely to increase somewhat into the twenty-first century.

COHABITATION

Cohabitation, or the sharing of a household by unmarried intimate partners, is quickly becoming commonplace in the United States. Some people suggest that it is now a normative extension of dating. According to the U.S. Bureau of the Census, the number of cohabiting couples topped 4 million in 1997, up from less than one-half million in 1960. Approximately one-half of unmarried women between the ages of twenty-five and thirty-nine have lived with a partner or are currently doing so, and over half of all first marriages are now preceded by cohabitation. Approximately one-third of these unions contain children (U.S. Bureau of the Census 1998). Cohabitation is now seen as an institutionalized component to the larger progression involving dating, courtship, engagement, and marriage.

Given the attitudes of even younger persons, we expect trends in cohabitation to continue to increase in the United States. Nearly 60 percent of a representative sample of high school seniors “agreed,” or “mostly agreed” with the statement “it is usually a good idea for a couple to live together before getting married in order to find out whether they really get along” (Survey Research Center, University of Michigan 1995).

Cohabitation is not a recent phenomenon, nor one unique to the United States. In Sweden and other Scandinavian countries, for example, cohabitation has become so common that it is considered a social institution in and of itself. It is a variant of marriage rather than of courtship; approximately 30 percent of all couples in Sweden who live together are unmarried (Tomasson 1998). People who cohabit have the same rights and obligations as do married couples with respect to taxation, inheritance, childcare, and social welfare benefits. Many of these unions have children born within them, and there is little stigma attached to being born "out of wedlock." Another study of eighty-seven Canadian couples, located through newspaper wedding announcements, reported that 64 percent of the couples had cohabited for some period, 43 percent of these for over three months. In contrast, cohabitation is relatively rare in more traditional and Roman Catholic nations such as Italy.

Cohabitors tend to differ from noncohabitators in a variety of sociodemographic characteristics. For example, cohabitators tend to see themselves as being more androgynous and more politically liberal, are less apt to be religious, are more experienced sexually, and are younger than married persons. Although cohabitators may argue that living together prior to marriage will enhance the latter relationship by increasing their knowledge of their compatibility with day-to-day living prior to legalizing the union, such optimism is generally not supported. While some studies indicate no differences in the quality of marriages among those who first cohabited and those that did not, others find that those people who cohabit have higher rates of divorce. This may, however, have nothing to do with cohabitation per se but rather may be due to other differences in the personalities and expectations of marriage between the two groups.

A wide variety of personal relationships exist among cohabiting couples. Several typologies have been created to try to capture the diversity found within these relationships. One particularly useful one, articulated by Macklin (1983), is designed to exemplify the diversity in the stability of such relationships. She discusses four types of cohabiting relationships. These include: (1) *temporary or casual* relationships, in which the couple cohabits for

convenience or for pragmatic reasons; (2) *going together*, in which the couple is affectionately involved but has no plans for marriage in the future; (3) *transitional*, which serves as a preparation for marriage; and (4) *alternative to marriage*, wherein the couple opposes marriage on ideological or other grounds.

Although attitudes toward cohabitation have become increasingly positive, especially among younger persons, Popenoe and Whitehead (1999) remind us that cohabitation was illegal throughout the United States before 1970 and remains illegal in a number of states based on a legal code outlawing "crimes against chastity" (Buunk and Van Driel 1989). These laws, however, are rarely if ever enforced. In the Netherlands, or in other countries where cohabitation is institutionalized, the majority of the population sees few distinctions between cohabitation and marriage. Both are viewed as appropriate avenues for intimacy, and the two lifestyles resemble one another much more so than in the United States in terms of commitment and stability.

The future of cohabitation, and the subsequent changes in the attitudes toward it, is of considerable interest to sociologists. Many predict that cohabitation will become institutionalized in the United States to a greater degree in the near future, shifting from a pattern of courtship to an alternative to marriage. Whether it will ever achieve the status found in other countries, particularly in Scandinavia, remains to be seen.

CHILDFREE ADULTS

There is reason to believe that fundamental changes are occurring in the values associated with having children. As economic opportunities for women increase; as birth control, including abortion, becomes more available and reliable; and as tolerance increases for an array of lifestyles, having children is likely to become increasingly viewed as an option rather than a mandate. Evidence is accumulating to suggest that both men and women are reevaluating the costs and benefits of parenthood. Approximately 9 percent of white and African-American women and 6 percent of Latina women indicate that they would like to have no children (U.S Bureau of the Census 1998).

This trend is occurring not only in the United States but in many industrialized countries in Europe as well. The decline in childbearing there has been referred to as the “second demographic transition” (Van de Kaa 1987). Davis (1987) posits that features of industrial societies weaken the individual’s desire for children. He lists several interrelated traits of industrialization, including the postponement of marriage, cohabitation, and high rates of divorce, claiming that these trends decrease the need for both marriage and childbearing.

Remaining childfree is not a new phenomenon, however. In 1940, for example, 17 percent of married white women between the ages of thirty-five and thirty-nine were childfree. Some of these women were simply delaying parenthood until their forties; however, many remained childfree. This percentage began to drop considerably after World War II, and by the late 1970s only 7 percent of women in the thirty-five to thirty-nine age group did not have children. Today the figure has risen to over 13 percent among this age group (U.S. Bureau of the Census 1998). This increase is due to a multitude of factors: delayed childbearing, infertility, and voluntary childlessness.

An important distinction to make in the discussion of childlessness is whether the decision was voluntary or involuntary. *Involuntary* childlessness involves those who are infecund or subfecund. For them, being childfree is not a choice. Unless they adopt or create some other social arrangement, they are inevitably committed to this lifestyle. *Voluntary* childlessness, the focus of this discussion, involves those who choose to remain childfree. Large differences exist within members of this group; *early articulators* have made their decision early in their lives and are committed to their choice. *Postponers*, on the other hand, begin first by delaying their childbearing, but wind up being childfree due to their continual postponement. Early articulators generally exhibit less stereotypical gender roles, are more likely to cohabit, and enjoy the company of children less than do postponers. Seccombe (1991) found that among married persons under age forty who have no children, wives are more likely than their husbands to report a preference for remaining childfree (19 percent and 13 percent, respectively).

Despite increasing rates of voluntary childlessness, most research conducted within the United States

documents the pervasiveness of pronatalist sentiment. Those who voluntarily opt to remain childfree are viewed as selfish, immature, lonely, unfulfilled, insensitive, and more likely to have mental problems than are those who choose parenthood. In the past, females, persons with less education, those with large families of their own, Catholics, and residents of rural areas were most apt to judge the childfree harshly. However, more recently, data from a nationally representative sample suggest that women are more likely to want to remain childfree than are men (Seccombe 1991).

Most studies report that those persons who opt to remain childfree are well aware of the sanctions surrounding their decision yet are rarely upset by them (see Houseknecht 1987 for a review). In her review of twelve studies, Houseknecht found only three that reported that childfree individuals had trouble dealing with the reaction from others. Sanctions apparently are not strong enough to detract certain persons from what they perceive as the attractiveness of a childfree lifestyle. Houseknecht (1987), in a content analysis of twenty-nine studies reporting the rationales for remaining childfree, identified nine primary motivations. These are, in order of the frequency in which they were found: (1) freedom from child-care responsibilities: greater opportunity for self-fulfillment and spontaneous mobility; (2) more satisfactory marital relationship; (3) female career considerations; (4) monetary advantages; (5) concern about population growth; (6) general dislike of children; (7) negative early socialization experience and doubts about the ability to parent; (8) concern about physical aspects of childbirth and recovery; and (9) concern for children given world conditions. Gender differences were evidenced in a number of areas. Overall, females were more likely to offer altruistic rationales (e.g., concern about population growth, doubts about the ability to parent, concern for children given world conditions). The male samples, conversely, were more apt to offer personal motives (e.g., general dislike of children, monetary advantages).

The consequences of large numbers of persons in industrialized societies forgoing parenthood are profound. For example, the demographic structure in many countries is in the process of radical change; populations are becoming increasingly aged. More persons are reaching old age than ever before, those persons are living longer,

and birth rates are low. The cohort age eighty-five or older, in fact, is the fastest-growing cohort in the United States. The question remains: Who will care for the elderly? Some Western European countries provide a variety of services to assist elderly persons in maintaining their independence within the community as long as possible. But social policies in other countries, including the United States, rely heavily on adult children to provide needed care to elderly parents. Formal support services, when available, tend to be uncoordinated and expensive. The question of who will provide that needed care to the large numbers of adults who are predicted to have no children has yet to be answered.

GAY AND LESBIAN RELATIONSHIPS

Not long ago homosexuality was viewed by many professionals as an illness or a perversion. It was only as recently as 1973, for example, that the American Psychiatric Association removed homosexuality from its list of psychiatric disorders. Today, due in large part to the efforts of researchers such as Kinsey and associates (1948, 1953), Masters and Johnson (1979), and to organizations such as the Gay Liberation Front during the late 1960s, homosexuality is slowly but increasingly being viewed as a lifestyle rather than an illness. The work of Kinsey and associates illustrated that a sizable minority of the population, particularly males, had experimented with same-sex sexual relationships, although few considered themselves exclusively homosexual. Thirty-seven percent of males, they reported, had experienced at least one homosexual contact to the point of orgasm, although only 4 percent were exclusively homosexual. Among females, 13 percent had a same-sex sexual contact to the point of orgasm, while only 2 percent were exclusively homosexual in their orientation.

Obviously not all people who have had a homosexual experience consider themselves to be gay or lesbian. Most do not. One national probability sample of adult males interviewed by telephone found that 3.7 percent reported to have either a homosexual or bisexual identity (Harry 1990). Others suggest that the percentages are higher, that perhaps 3 to 5 percent of adult women and 5 to 10 percent of adult men are exclusively lesbian or gay (Diamond 1993).

Cross-cultural evidence suggests that the majority of cultures recognize the existence of homosexual behavior, particularly in certain age categories such as adolescence, and most are tolerant of homosexual behavior. Culturally speaking, it is rare to find an actual *preference* for same-sex relations; a preference tends to occur primarily in societies that define homosexuality and heterosexuality as mutually exclusive, as in many industrial countries.

There still remains a tremendous degree of hostility to homosexual relationships by large segments of society. Many regions in the United States, particularly in the South and in the West, still have laws barring homosexual activity among consenting adults. The results of national polls indicate that the majority of adults believe that homosexuals should still be restricted from certain occupations, such as elementary-school teacher, and should not be allowed to marry. Gays and lesbians report that their sexual orientation has caused a variety of problems in securing housing and in the job market. They often report that negative comments or acts of violence have been levied on them in public.

This contrasts sharply with the view toward homosexuality in the Scandinavian countries. In 1989 Denmark lifted the ban on homosexual marriages, the first country to do so. Norway and Sweden followed suit in the 1990s. These changes extend to gays and lesbians the advantages that heterosexual married couples experience with respect to inheritance, taxation, health insurance, and joint property ownership.

There is a growing amount of research illuminating various aspects of homosexual relationships, such as gender roles; degree of commitment; quality of relationships; and the couples' interface with other relationships, such as children, ex-spouses, or parents. However, because of unique historical reactions to gays and lesbians, and the different socialization of men and women in our society, it is important to explore the nature of lesbian and gay male relationships separately. Gender differences emerge in homosexual relations within a variety of contexts; for example, lesbians are more apt to have monogamous, stable relationships than are gay men, although the popular stereotype of gays as sexually "promiscuous"

has been exaggerated. The majority of gay men, just like lesbians, are interested in monogamous, long-term relationships. The lack of institutional support for gay and lesbian relationships and the wide variety of obstacles not encountered among heterosexuals, such as prejudice and discriminatory behavior, take their toll on these relationships, however.

The AIDS epidemic has had an enormous impact on the gay subculture. While the impact on lesbians is significantly less, they have not been untouched by the social impact of the devastating medical issue, despite the slow response of the world's governments.

DIVORCE AND REMARRIAGE

Throughout most of history in America, the primary reason that marriages ended was because of death. In 1970, the trends were reversed, and for the first time in our nation's history, more marriages ended by divorce than by death (Cherlin 1992). The United States now has the highest rate of divorce in the world, at approximately 20 divorces per 1,000 married women aged fifteen and over in the population (U.S. Bureau of the Census 1998). This is twice as high as the divorce rate found in Canada, four times that of Japan, and ten times as high as Italy. But, it's important to note that the divorce rate has actually leveled off, or even declined somewhat in the United States after peaking in the early 1980s.

Who divorces? Research has shown that those at greatest risk for divorcing are people who marry young, especially after only a brief dating period; those who have lower incomes, although very high-earning women are also more likely to divorce; African Americans, who are about 25 percent more likely to divorce than whites; people who have been divorced before or whose parents divorced; and those who are not religious or claim no religious affiliation. The likelihood of divorce is particularly high among couples who marry in their teens because of an unplanned pregnancy. Women are almost twice as likely as men to petition for divorces, reflecting the fact that women are more often dissatisfied with their marriages than are men.

There are a variety of reasons why the rate of divorce has increased so dramatically in many

Western nations during the twentieth century: (1) there is increasing emphasis on individualism and individual happiness over the happiness of the group—or a spouse and children; (2) divorce is more socially acceptable and less stigmatized than in the past; (3) divorce is easier to obtain, as “fault” is generally no longer required; (4) women are less financially dependent on men, on average, and therefore can end an unhappy marriage more easily; (5) there is an increase in the number of adult children who grew up in divorced households, who are more likely to see divorce as a mechanism to end an unhappy marriage; and (6) today's marriages experience increased stress, with outside work consuming the time and energy people used to devote to their marriages and families.

One of the consequences of divorce is that many children will live at least a portion of their lives in single-parent households. Single-parent households are becoming increasingly normative, with approximately half of all children under age eighteen spending some portion of their lives living with only one parent, usually their mother. Single-parent households are more likely to be poor and often lack the social capital available in two-parent households, and consequently place the child at greater risk for a variety of negative social and health outcomes. Commonly the absentee parent does not pay the child support that is due, and fails to see the children with regularity.

Although divorce has become common in many industrialized nations, it would be incorrect to assume that this represents a rejection of marriage. Four out of five people who divorce remarry, most often within five years. Men are more likely to remarry than are women. This difference is due to the greater likelihood that children will be living with their mothers full-time, rather than their fathers; the cultural pattern of men marrying younger women; and the fact that there are fewer men than women in the population in general.

Remarriage often creates “blended families” composed of stepparents and possibly stepsiblings. It is estimated that approximately one-third of all children will live with a stepparent for at least one year prior to reaching age eighteen. Despite the increasing commonality of this type of family, it has been referred to as an “incomplete institution” because the social expectations are less clear

than in other family structures. There are no well-established rules for how stepparents and children are supposed to relate, or the type of feelings they should have for one another. Without a clear-cut set of norms, blended families may be seen as "alternative lifestyles," but yet they are becoming increasingly common in modern industrialized societies where divorce is common.

CONCLUDING COMMENTS

There is considerable accumulating evidence to suggest that family lifestyles are becoming more varied and that the public is becoming increasingly tolerant of this diversity. The data indicate that traditional marriage itself *per se* may be less important in sanctioning intimacy. The review by Buunk and Hupka (1986) of seven countries reveals that individualism, as expressed by following one's own personal interests in intimate relationships, was more prevalent in affluent democratic countries such as the United States and in most of Western Europe than in poorer and nondemocratic nations.

This does not mean, however, that people are discarding the institution of marriage. In the United States, as elsewhere, the vast majority of the population continues to endorse marriage and parenthood in general, and for themselves personally. Most still plan to marry and have children, and optimism remains high that theirs will be a lasting union despite high national frequencies of divorce.

Alternative lifestyles are not replacing marriage. Instead, they are gaining acceptance because they involve, for some, modifications of the family structure as an adaptation to changing conditions in society. The lifestyles discussed here, as well as others, reflect the broader social changes in values, relationships, and even technology that are found within society as a whole. As Macklin notes, the family is not disappearing, but "continuing its age-old process of gradual evolution, maintaining many of its traditional functions and structures while adapting to changing economic circumstances and cultural ideologies" (1987, p. 317). This process has merely accelerated during the past several decades, and these changes have caught the attention of the general public. College classes and their corresponding textbooks within this discipline of sociology are still often titled *Marriage and the*

Family, as if there were only one model of intimacy. Yet perhaps a more appropriate title would be *Marriages, Families, and Intimate Relationships*. This would reflect not only the diversity illustrated here but would also acknowledge the tremendous ethnic and class variations that make for rich and meaningful personal relationships.

ALTRUISM

Three terms are commonly used in the broad research area that investigates positive interpersonal action: prosocial behavior, helping behavior, and altruism. "Prosocial behavior" is the broadest of the three; it refers to any behavior that can be construed as consistent with the norms of a given society. Thus, murder, when enacted on behalf of one's country on a battlefield, is as prosocial a behavior as intervening to prevent a crime. "Helping behavior" refers simply to any behavior that

provides some benefit to its recipient. "Altruism" is the narrowest of the three concepts. Altruism is behavior that not only provides benefits to its recipient but also provides no benefits to the actor and even incurs some costs. If one conceives of psychological rewards as benefits to the actor, this definition of altruism is so narrow that it excludes virtually all human behavior. Hence, many social psychologists maintain simply that altruistic behavior need exclude only the receipt of material benefits by the actor. Some theorists require as part of the definition that the act be motivated "with an ultimate goal of benefiting someone else" (Batson 1991, p. 2), but do not rule out the incidental receipt of benefits by the actor.

Related terms include philanthropy, charity, volunteering, sharing, and cooperating. Philanthropy and charity have largely come to mean donation of money or material goods. Volunteering, similarly, generally refers to giving time for the ultimate purpose of benefiting others, under the aegis of some nonprofit organization. Sharing and cooperating refer to coordinated actions among members of a group or collectivity in the service of better outcomes for the group as a whole. All of these terms may be subsumed under the generic term "prosocial behavior," and often under "helping behavior," although they would seldom meet the stringent criteria for altruism.

HISTORY

The origins of the contemporary study of altruism have been traced back to August Comte, who explored the development of altruism and "sympathetic instincts." The existence of an altruistic instinct was emphasized in McDougall's *Introduction to Social Psychology* (1908) but argued against by the naturalistic observational research of Lois Murphy (1937). Early symbolic interactionists attributed altruistic behavior to the capacity to "take the role of the other"—to imagine oneself in another person's situation (Mead 1934). The developmental study of altruism has built on the theoretical work of Piaget (1932), who explored stages in the development of sharing behavior, as well as on the work of Kohiberg (1969) on the development of moral judgment. Hartshorne and May conducted one of the earliest series of empirical studies (1928-30), focusing on honesty and

altruism in children. Sorokin (1950, 1970[1950]) wrote extensively on love and altruism, and carried out the first empirical work on informal helping and volunteering by studying individuals nominated by others as “good neighbors.” It is only since the mid-1960s, however, that altruism has been extensively examined through systematic research.

Most social psychology textbooks attribute this upsurge of interest in altruism and helping behavior to the murder of Kitty Genovese in 1964 and the failure of the thirty-nine witnesses to intervene. The subject of widespread media coverage, this incident motivated Latané and Darley’s experimental investigations of bystander inaction, published in *The Unresponsive Bystander: Why Doesn’t He Help?* (1970). During the 1970s, helping behavior became one of the most popular topics in social psychological research, although this emphasis declined considerably through the 1980s and 1990s (see Batson 1998 for figures on the number of published studies by decade). Because of this beginning, the vast majority of the studies deal with intervention in the momentary problems of strangers. Only since the 1990s has there been much attention to informal and formal volunteering, charitable donation, and blood donation. Virtually all textbooks now have a chapter on altruism and helping behavior, and a number of books on the topic have been published in the past three decades.

THEORIES OF ALTRUISM AND HELPING BEHAVIOR

Helping behavior has been explained within a variety of theoretical frameworks, among them evolutionary psychology, social learning, and cognitive development. One sociobiological approach maintains that helping behavior and altruism have developed through the selective accumulation of behavioral tendencies transmitted genetically. Three mechanisms have been suggested: kin selection, reciprocal altruism, and group selection (see Sober and Wilson 1998). These mechanisms explain the evolution of altruistic behavior as a function of, in turn: the greater likelihood that altruists would save kin, through perpetuating an altruistic gene shared among them; a tendency to help others who have engaged in helpful acts, presumably based on a reciprocity gene; and the greater

likelihood of survival of entire groups that include a higher proportion of altruists. A second sociobiological theory maintains that helping behavior has developed through sociocultural evolution, the selective accumulation of behavior retained through purely social modes of transmission. (See Krebs and Miller [1985] for an excellent review of this literature.) The cognitive-developmental approach to the development of helping behavior in children emphasizes the transformation of cognitive structures and experiential role-taking opportunities as determinants. Social learning theory explains altruism and helping behavior as learned through interaction with the social environment, mainly through imitation and modeling, but also through reinforcement. Reflecting the same behaviorist principles, exchange theory suggests that individuals perform helping acts while guided by the principles of maximizing rewards and minimizing costs. Helping behavior is instrumental in acquiring rewards that may be material, social, or even self-administered. A more explicitly sociological framework suggests that individuals help out of conformity to social norms that prescribe helping. Three norms have received special attention: the norm of giving, which prescribes giving for its own sake; the norm of social responsibility, which prescribes helping others who are dependent; and the norm of reciprocity, which prescribes that individuals should help those who have helped them.

Reflecting the contemporary social psychological emphasis on cognition, several decision-making models of helping behavior have guided much of the research into adult helping behavior (Latané and Darley 1970; Piliavin et al. 1981; Schwartz and Howard 1981). These models specify sequential decisions that begin with noticing a potential helping situation and end with a decision to help (or not). Research has focused on identifying those personality and situational variables that influence this decision-making process and specifying how they do so. There also has begun to be more attention to the social and sociological aspects of helping—to the context in which helping occurs, to the relationship between helper and helped, and to structural factors that may affect these interactions (Gergen and Gergen 1983; Callero 1986). A very active focus of work, mainly identified with Batson (see, e.g., Batson 1991) and Cialdini and colleagues, has been the attempt to

demonstrate (or refute) the existence of “true” altruistic motivations for helping.

RESEARCH ON ALTRUISM AND HELPING BEHAVIOR

Person Variables. There has been an extensive and confused debate, due both to definitional and measurement problems, about the existence of an altruistic personality (see Schroeder et al. 1995). There is now good evidence of a pattern of prosocial personality traits that characterize individuals whose behavior involves long-term, sustained forms of helping behavior (e.g., community mental health workers, see Krebs and Miller 1985; volunteers who work with AIDS patients, see Penner et al. 1995; Penner and Finkelstein 1998). The traits that make up the prosocial personality include empathy, a sense of responsibility, concern for the welfare of others, and a sense of self-efficacy. With regard to helping in emergencies, the evidence is stronger for person by situation effects; that is, interactions of characteristics of both individuals and situations that influence helping in emergencies. For example, self-confidence and independence can predict differentially how individuals will behave in emergency situations when there are others present or when the person is alone (Wilson 1976). And Batson and his colleagues have found that prosocial personality characteristics correlate with helping, but only when helping is egoistically motivated, not when true altruism is involved. The general proposal that individual difference factors are most effective when situational pressures are weak seems generally applicable in the helping area.

Internalized values as expressed in personal norms have also been shown to influence helping. Personal norms generate the motivation to help through their implications for self-based costs and benefits; behavior consistent with personal norms creates rewards such as increased self-esteem, whereas behavior that contradicts personal norms generates self-based costs such as shame. This influence has been demonstrated in high-cost helping such as bone marrow donation (Schwartz 1977). Other personality correlates of helping are less directly related to the costs and benefits of the helping act itself. For example, information-processing styles such as cognitive complexity influence helping.

Clary and Snyder (1991) have pursued a functional approach to understanding motivations for helping. They have developed a questionnaire measure that distinguishes six potential motives for long-term volunteering (e.g. value expression, social motivation, career orientation) and have demonstrated both predictive and discriminant validity for the instrument (Clary, Snyder et al. 1998). In one study, they showed that it was not the more purely altruistic motivations that predicted long-term commitment. Temporary emotional states or moods may also affect helping. A series of studies by Isen (1970) and her colleagues demonstrate that the “glow of good will” induces people to perform at least low-cost helping acts such as helping someone pick up a pile of dropped papers, and research by Cialdini and colleagues has shown that helping can be motivated by the need to dispel a bad mood.

Situation Variables. Characteristics of the situation also influence the decision to help. The salience and clarity of a victim’s need influence both the initial tendency to notice need and the definition of the perceived need as serious. Salience and clarity of need increase as the physical distance between an observer and a victim decreases; thus, victims of an emergency are more likely to be helped by those physically near by. Situational cues regarding the seriousness of another’s need influence whether need is defined as serious enough to warrant action. Bystanders are more likely to offer aid when a victim appears to collapse from a heart attack than from a hurt knee, for example, presumably because of perceived seriousness. The presence of blood, on the other hand, can deter helping, perhaps because it suggests a problem serious enough to require medical attention.

One of the most strongly supported findings in the area of helping is that the number of others present in a potential helping situation influences an individual’s decision to help. Darley and Latané (1968) demonstrated experimentally that the higher the number of others present, the lower the chance of any one individual helping. One process underlying this effect involves the diffusion of responsibility: the higher the number of potential helpers, the less any given individual perceives a personal responsibility to intervene. The presence of an individual who may be perceived as having special competence to help also reduces the felt

responsibility of others to help. Thus, when someone in medical clothing is present at a medical emergency, others are less likely to help. A second process underlying the effect, when bystanders can see each other, involves definition of the situation. If no one moves to intervene, the group may collectively provide a social definition for each other that the event is not one that requires intervention.

Social Variables. Research has also demonstrated the influence of other social variables on helping. Darley and Latané (1968) showed experimentally that people were more likely to provide help in an emergency in the presence of a friend rather than in the presence of strangers. They reasoned that in emergency situations in which a friend does not respond, one is not likely to attribute this to lack of concern, but rather will seek other explanations. In addition, bystanders who are acquainted are more likely to talk about the situation. Thus, preexisting social relationships among bystanders affect helping. Individuals are also more likely to help others who are similar to them, whether in dress style or in political ideology. The perceived legitimacy of need, a variable defined by social norms, also affects rates of helping. In one field study of emergency intervention, bystanders were more likely to help a stranger who collapsed in a subway car if the distress was attributed to illness rather than to drunkenness (Piliavin, Rodin, and Piliavin 1969).

Other demographic variables, such as sex, age, socioeconomic status, and race have also been investigated. Race appears to affect helping mainly when the costs for helping are relatively high, or when failure to help can be attributed to factors other than prejudice (Dovidio 1984). In the study cited above (Piliavin et al. 1969) the rate of helping by white and black bystanders was unrelated to the race of the victim who appeared to be ill, but help offered to the drunk was almost always by people of his own race. Females are usually helped more than males, but who helps more depends heavily on the nature of the help required. Males tend to help females more than they help males, whereas females are equally helpful to females and males (see Piliavin and Unger 1985). This pattern may reflect stereotypic gender roles: Females are stereotyped as dependent and weaker than males. Other studies of the effect of social statuses on helping

indicate, consistent with social categorization theory, that members of one's own group tend to be helped more than outgroup members. Studies of reactions following natural disasters show that people tend to give aid first to family members, then to friends and neighbors, and last to strangers.

THE SOCIOLOGICAL CONTEXT OF HELPING

Gergen and Gergen (1983) call for increased attention to the social structural context of helping and to the interactive history and process of the helping relationship (see also Piliavin and Charng 1990). Social structure is clearly important as a context for helping. Social structure specifies the pool of social roles and meaning systems associated with any interaction (Callero, Howard, and Piliavin 1987). Social structure also influences the distribution of resources that may be necessary for certain helping relationships. One needs money to be able to donate to a charity and medical expertise to be able to help earthquake victims. Wilson and Musick (1997) have presented data in support of a model using both social and cultural capital as predictors of involvement in both formal and informal volunteering. Social structure also determines the probability of both social and physical interaction among individuals and thus influences the possibility of helping.

Interaction history is also crucial to understanding helping behavior. If a relationship has been positive and mutually supportive, this context suggests that beneficial actions should be defined as helping. If a relationship has been characterized by competition and conflict, this context does not support defining beneficial action as helping. In this case, alternative, more self-serving motivations may underlie helping. Thus the provision of U.S. foreign aid to countries with which the United States has had conflict is often viewed as a strategic tool, whereas when such aid has been provided to countries with which the United States has had positive relationships, it is viewed generally as genuine helping. Such patterns illustrate this influence of interaction history on the interpretation of helping behavior.

Another sociological approach emphasizes helping as role behavior and is guided by Mead's

(1934) conception of roles as patterns of social acts framed by a community and recognized as distinct objects of the social environment. Roles define individual selves and thus also guide individual perception and action. Helping behavior has been shown to express social roles. A series of studies of blood donors (Callero, Howard, and Piliavin 1987; Piliavin and Callero 1991) demonstrate that role-person merger (when a social role becomes an essential aspect of self) predicts blood donation, independent of the effects of both personal and social norms, and is more strongly associated with a history of blood donation than are social or personal norms. This study demonstrates the importance of helping for self-validation and reproduction of the social structure as expressed in roles. More recent research has shown similar effects for identities tied to volunteering time and giving money (Grube and Piliavin in press; Lee, Piliavin, and Call in press). This attention to concepts such as roles, interaction history, and social structure is evidence of the sociological significance of altruism and helping behavior.

CROSS-CULTURAL RESEARCH IN ALTRUISM

Until the last few decades, little work had been done systematically comparing altruism and helping behavior across cultures. Beginning in the 1970s, researchers have compared helping in rural and urban areas, rather consistently finding that helping of strangers, although not of kin, is more likely in less densely populated areas all around the world. In a real sense, urban and rural areas have different "cultures"; small towns are more communal or collective, while cities are more individualistic. A review of other cross-cultural comparisons (Ting and Piliavin forthcoming) examines similarities and differences not only in the helping of strangers but also in the development of moral reasoning, socialization of prosocial behavior, and participation in "civil society." The collectivism-individualism distinction across societies provides a good organizing principle for understanding many of the differences that are found. Not only do societies differ in the level of helping, but in the pattern. For example, in communal societies, the difference between the amount of help offered to ingroup and outgroup members is exaggerated in comparison with the more individualistic societies.

ALTRUISM RESEARCH IN OTHER FIELDS

Scholars from many fields other than social psychology have also addressed the question of altruism. The long debate in evolutionary biology regarding the possibility that altruism could have survival value appears to have been answered in the affirmative (Sober and Wilson 1998). Some authors (e.g. Johnson 1986; Rushton 1998) in fact view patriotism or ethnic conflict, or both, as rooted in altruism fostered by kin selection. Game theorists have discovered that in repeated prisoner's dilemma games and public goods problems, some individuals consistently behave in more cooperative or altruistic ways than do others (Liebrand 1986). Even economists and political scientists, who have long held to the belief that all motivation is essentially selfish, have begun to come to grips with evidence (such as voting behavior and the public goods issue) that indicates that this is not true (see Mansbridge 1990; Clark 1998).

Recommended reading. The interested reader is referred Schroeder et al., *The Psychology of Helping and Altruism* (1995) for a relatively nontechnical overview of the field, or Batson, "Altruism and Prosocial Behavior" (1998) for a briefer, more technical approach emphasizing work demonstrating that "true altruism" can be a motivation for helping. For an excellent examination of approaches to the topic of altruism by economists and political scientists, read Mansbridge, *Beyond Self-Interest* (1990). For an engaging read on the topic of both evolutionary and psychological altruism, try Sober and Wilson's *Unto Others* (1998). Finally, for a view toward the practical application of ideas from altruism research, read Oliner et al., *Embracing the Other* (1992). AMERICAN FAMILIES

Many long-standing assumptions about American families have been challenged by family scholars.

Among these assumptions is the belief that in colonial times the American family was extended in its structure, with three generations living together under one roof. It has been commonly believed that the nuclear family came about as a result of industrialization, with smaller families better able to meet the demands of an industrialized economy. However, historical data show that the extended family was not typical in the colonial era and that the earliest families arriving from Great Britain and other western European countries were already nuclear in structure (Demos 1970; Laslett and Wall 1972).

Some commonly held views about contemporary families also have been debunked in the research literature. For example, it has been commonly thought that American families neglect their elder members and are quick to place them in nursing homes. However, research shows that most older Americans have frequent contact with one or more members of their family, and that families typically provide extensive, long-term care to older persons when such care is needed. In most cases, families turn to placement in a nursing home as a last resort rather than a first option when elder members grow ill or frail.

More generally, family scholars have successfully challenged the notion of "the American family." As Howe (1972, p. 11) puts it, "the first thing to remember about the American family is that it doesn't exist. Families exist. All kinds of families in all kinds of economic and marital situations." This review will show the great diversity of family patterns that characterize the United States of the past, the present, and the foreseeable future.

HISTORICAL OVERVIEW

It is unfortunate that textbooks intended for courses on the family rarely include a discussion of Native Americans, for a historical examination of these groups shows a striking range of variation in family patterns. In fact, virtually all the variations in marriage customs, residence patterns, and family structures found the world over could be found in North America alone (Driver 1969). Though some of these traditional family patterns have survived to the present day, others have been disrupted over the course of U.S. history. It is important to

note however, that research has not confirmed the commonly held assumption that Native-American societies were placid and unchanging prior to European contact and subsequent subjugation. Important changes were taking place in Native-American societies long before the arrival of Europeans (Lurie 1985).

As has been noted, European immigrants to the American colonies came in nuclear rather than extended families (and also came as single persons—for example, as indentured servants). It was long believed that colonial families were very large, with some early writers claiming an average of ten to twelve children per family, and that most people lived in extended rather than nuclear families. Family scholars, however, have cited evidence showing somewhat lower numbers of children, with an average of eight children born to colonial women (Zinn and Eitzen 1987). Scholars also have distinguished between number of children born per woman and family size at a given point in time. Average family size was somewhat smaller than the average number of children born, due to high infant mortality and because the oldest children often left home prior to the birth of the last child. Evidence suggests an average family size of five to six members during colonial times (Nock 1987). Thus, although the average size of colonial families was somewhat larger than today's families, they were not as large as has been commonly assumed. Furthermore, most people in colonial America lived in nuclear rather than extended family settings.

To understand the size and composition of colonial households, consideration must be given to nonrelated persons living in the home. Servants often lived with prosperous colonial families, and other families took in boarders and lodgers when economic conditions required such an arrangement (Zinn and Eitzen 1987). Households might also include apprentices and other employees. The presence of nonfamily members has important implications for family life. Laslett (1973) has argued that the presence of nonkin meant that households offered less privacy to families and hence provided the opportunity for greater scrutiny by "outsiders." Colonial homes also had fewer rooms than most American homes today, which also contributed to the relatively public nature of these households.

Colonial communities placed great importance on marriage, particularly in New England, where sanctions were imposed on those who did not marry (for example, taxes were imposed on single men in some New England colonies). However, historical records indicate that colonists did not marry at especially young ages. The average age at marriage was twenty-four to twenty-five for men and twenty-two to twenty-three for women (Leslie and Korman 1989). Older ages at marriage during this era reflect parental control of sons' labor on the farm (with many sons delaying marriage until their fathers ceded land to them) and also reflect the lower relative numbers of women (Nock 1987). Parents also typically exerted strong influence over the process of mate selection but did not control the decision. Divorce was rare during this period. The low divorce rate cannot be equated with intact marriages, however. Spousal desertion and early widowhood were far more common experiences than they are today.

The population for the American colonies came primarily from Great Britain, other western European countries, and from western Africa. Initially brought to the colonies in 1619 as indentured servants, hundreds of thousands of Africans were enslaved and transported to America during the colonial period (by 1790, the date of the first U.S. census, African Americans composed almost 20 percent of the population; Zinn and Eitzen 1987). It has been commonly assumed that slavery destroyed the cultural traditions and family life of African Americans. The reasoning behind this assumption was that slave families often were separated for sale to other masters, males were unable to provide for or protect their families, and slave marriages were not legal. The stereotype of "matriarchal" black families, in which women are the family heads and authorities, usually assumes that slavery produced this family form. Empirical research challenges these assumptions. Though slave families lived in constant fear of separation (Genovese 1986), many slave marriages were strong and long-lasting (Gutman 1976). Marriages were legitimized within the slave community (symbolized, for example, by the ritual of "jumping over a broomstick"; Boris and Bardaglio 1987), and two-parent families were common among slaves as well as among free blacks in the North and the South (Gutman 1976). A variety of family structures,

including female-headed households, were found in the slave community and attested to the importance placed on kin ties. Rather than the “absent family” assumed to characterize slave life, slaves were connected to one another through extensive kinship networks (Genovese 1986). Extended kin ties continue to be an important aspect of African-American families today.

For decades, the heritage of slavery and its presumed effects on family life have been invoked to explain social problems in poor black communities (e.g., Moynihan 1965). The historical evidence described above does not lend support to this explanation. Most writers today argue that social problems experienced in poor black communities can more accurately be attributed to the effects of discrimination and the disorganizing effects of mass migration to the urbanized North rather than to the heritage of slavery (e.g., Staples 1986).

Societal changes associated with the Industrial Revolution profoundly affected all types of American families, though the specific nature and extent of these effects varied by social class, race, ethnic origins, and geographic region. Prior to the Industrial Revolution, family members worked together as an economic unit. Their workplace was the home or family farm, with families producing much of what they consumed. Family life and economic life were one and the same, and the boundaries between “private life” in the family and “public life” in the community were blurred. With the development of a commercial economy, the workplace was located away from the family unit. Separation of work and family life created a sharp distinction between the “public” realm of work and the “private” realm of family. Particularly for women’s roles, changes initiated by the Industrial Revolution have been long-lasting and far-reaching. Increasingly, women’s roles were defined by activities assumed to be noneconomic, in the form of nurturing and caring for family members. This was especially true for middle-class women, and married women were excluded from many jobs. Poor and working-class women often participated in wage labor, but this work was generally seen as secondary to their family roles. Men were viewed as having primary responsibility for the economic welfare of their families. No longer an economically interdependent unit, families were

transformed such that women and children became economically dependent on the primary wage earner.

Thus, children’s roles and family relationships also changed with industrialization. In contrast to earlier times, in which children were viewed as miniature adults and engaged in many of the same tasks they would also perform as adults, childhood came to be seen as a special stage of life characterized by dependence in the home. And although children in working-class homes were more likely to work for pay, the evidence suggests that these families also viewed childhood as a stage of life distinct from adulthood (Zinn and Eitzen 1987). Overall, the family became increasingly defined as a private place specializing in the nurturance of children and the satisfaction of emotional needs, a “haven in a heartless world” (Lasch 1977).

Family structures also changed during the 1800s. Family size declined to an average of four to five members. (Of course, average numbers obscure variation in family sizes across social classes and other important dimensions such as race and ethnicity.) Though the average size of nineteenth-century American families was close to that of today’s families, women bore more children during their lifetimes than do American women today. Infant and child mortality was higher and births were spaced further apart, thus decreasing the average size of families at a given point in time. Household size also declined, with fewer households including nonrelated persons such as boarders or apprentices. The average ages at which women and men married were similar to those of colonial times, with an average of twenty-two for women and twenty-six for men. However, greater life expectancy meant that marriages typically lasted longer than they did during the colonial period (Nock 1987).

From 1830 to 1930 the United States experienced two large waves of immigration. The first wave, from 1830 to 1882, witnessed the arrival of more than ten million immigrants from England, Ireland, Germany, and the Scandinavian countries. During the second wave, from 1882 to 1930, over twenty-two million people immigrated to the United States. Peoples from northern and western Europe continued to come to the United States during this second wave, but a large proportion of

immigrants came from southern and eastern Europe as well (Zinn and Eitzen 1987). Immigrants' family lives were shaped by their ethnic origins as well as by the diverse social and economic structures of the cities and communities in which they settled.

Ethnic traditions also helped Mexican-American families adapt to changing circumstances. Annexation of territory from Mexico in 1848 and subsequent immigration from Mexico produced sizable Mexican-American communities in the Southwest. Immigrants from Mexico often reconstructed their original family units within the United States, typically including extended as well as nuclear family members. Extended family households are more common today among Mexican Americans than among non-Hispanic whites, reflecting Mexican Americans' strong family orientation (or "familism") as well as their less advantaged economic circumstances (Zinn and Eitzen 1987).

Imbalanced sex ratios among Chinese and Japanese immigrants greatly influenced the family experiences of these groups. First coming to the United States in the early 1900s, Chinese immigrants were predominantly male. The Chinese Exclusion Act of 1882 barred further immigration, and only wealthy Chinese men were able to bring brides to the United States (Boris and Bardaglio 1987). As of 1910, there were 1,413 Chinese men in the United States to every 100 Chinese women. This sex ratio was still skewed in 1940, when there were 258 men to every 100 women. In contrast to the extended family networks typical of traditional Chinese culture, many Chinese-American households consisted of single men living alone (Marden and Meyer 1973).

Substantial immigration from Japan took place between 1885 and 1924. Like traditional Chinese families, Japanese families were based on strong extended kin networks. As was true for Chinese immigration, most Japanese immigrants were male. In addition to immigration restrictions, Japanese-American families (especially those on the West Coast) were disrupted by property confiscation and the mass relocations that took place during World War II (Marden and Meyer 1973).

In addition to the "old" immigration of the mid-nineteenth century and the "new" immigration of the late nineteenth and early twentieth

centuries, a third wave of large-scale immigration to the United States began in the mid-1960s. In contrast to the earlier waves, when most immigrants came from European countries, most immigration in this third wave has been from Latin America and Asia. However, as has been true of earlier periods of immigration, public controversies surround the economic and social absorption of these new groups (Marger 1991). In addition to occupational and economic challenges facing immigrant families, social challenges include the continuing debate over whether schools should provide bilingual education to non-English-speaking children.

MARRIAGE AND FAMILY TRENDS IN THE UNITED STATES

The separation of paid work and family life, associated with the transition to an industrialized society, gave rise to profound changes in family life. Over the course of the twentieth century, women's roles were defined primarily by family responsibilities within the "private sphere" of the home, but except for a brief period following World War II, women's labor-force participation rose steadily. As of 1997, nearly half (46 percent) of all employed workers were women. Increases in labor-force participation were especially great among married women. In 1900, less than 4 percent of married women were in the labor force. By 1997, that figure had risen to 62 percent (U.S. Bureau of the Census 1998). In contrast to earlier eras of American history, when African-American women were more likely to work for pay than white women, rates of labor force participation are now nearly the same for women in these racial groups, for both married and unmarried women. Married Hispanic women are slightly less likely to be employed than married African-American and non-Hispanic white women (U.S. Bureau of Labor Statistics 1991). As discussed below, women's labor-force participation has important implications for many dimensions of family life.

Though American families have changed in important ways over the past 100 years, examination of historical trends also reveals continuation of some family patterns begun long ago. Notably, the period of the 1950s is commonly thought to

mark the end of a golden age of family life. However, historical data show that for a number of family patterns, the 1950s was an unusual period. Lower rates of divorce, lower ages at marriage, and higher rates of childbearing observed during the 1950s have been attributed mainly to greater economic prosperity following the Great Depression and World War II (Cherlin 1992).

Age at First Marriage. According to U.S. census data, the average (median) age at first marriage in the United States was twenty-five years for women and 26.7 years for men in 1998 (U.S. Bureau of the Census 1998). These average ages are higher than for most U.S. population censuses of the past century, but the current median age for men is comparable to that documented for (white) men near the turn of the twentieth century. In 1890, the median age at first marriage was twenty-two for women and 26.1 for men. The average age at marriage declined until 1956, when the median age at first marriage was 20.1 for women and 22.5 for men. The average age at marriage subsequently began to rise (Saluter 1996). Comparison of non-Hispanic whites, blacks, and Hispanic whites shows that age at first marriage climbed more rapidly for blacks than for non-Hispanic whites, with blacks marrying later than non-Hispanic whites. In contrast, Hispanics marry at younger ages than do other groups. It is difficult to assess whether Hispanics' lower age at marriage reflects long-term trends within the United States due to the large numbers of Mexican Americans who immigrated in the 1980s and 1990s (Sweet and Bumpass 1987).

Factors promoting later age at marriage include greater societal acceptance of singlehood and cohabitation as well as greater emphasis on educational attainment. The relationship between age at marriage and level of education is nearly linear for non-Hispanic white men and women, with more education associated with later age at marriage. This relationship is more complex for minority groups, and especially for black and Hispanic men. For these men, later age at marriage is associated both with lower and higher educational levels, producing a U-shaped relationship between education and age at marriage. Minority men with low education are likely to have especially poor job prospects, which in turn affect prospects for marriage. Overall, less racial and ethnic diversity in age

at marriage is shown for those with higher educational attainment (Sweet and Bumpass 1987).

Interracial Marriage. Most American marriages are homogamous with regard to race. In 1997, there were 1.3 million interracial marriages, representing only 2.3 percent of all marriages. Many Americans equate interracial marriage with black-white marriage, but only one-quarter of American interracial marriages are between blacks and whites. Currently, 4 percent of black men and 2 percent of black women are married to a white partner. Marriage between African Americans and Asian Americans is even less common than black-white marriages (U.S. Bureau of the Census 1998). Asian Americans are more likely than African Americans to marry a partner of another race. A 1990 study found that 23 percent of Asian Americans intermarry, and that over 40 percent of Japanese-American women are married to a man of a different race (Lee and Yamanaka 1990).

Although the total number of interracial marriages is quite small, the rate of growth in these marriages has been increasing. The number of interracial marriages in the United States increased fourfold between 1970 and 1998. During this period, the total number of marriages grew by only 24 percent (U.S. Bureau of the Census 1998).

Singles. Throughout U.S. history a proportion of individuals have remained unmarried. High levels of singlehood were recorded in the late 1800s, when 15 percent of women and 27 percent of men had not married by the age of thirty-four. In 1940, 15 percent of women and 21 percent of men had not married by this age, but by 1970, these proportions had dropped dramatically. By 1970, just 6 percent of women and 9 percent of women had not married by the age of thirty-four (Kain 1990). The size of the unmarried population has been increasing since the 1970s. In 1994, 20 percent of women and 30 percent of men had not married by age thirty-four (Saluter 1996). Women's changing roles have been linked with the rise in singleness: Women with higher education and higher personal income are less likely to marry or have children. Also, in contrast to earlier eras, there is greater societal tolerance of singlehood, providing greater freedom for both women and men to choose a single lifestyle.

Since few individuals marry for the first time at the age of sixty-five or older, a more accurate

picture of the never-married population is provided when attention is restricted to the older population. At present, 3.8 percent of men and 4.7 percent of women age sixty-five and older have never married (Lugaila 1998). Due to the continuing stigmatization of homosexuality, it is difficult to ascertain the numbers of single persons who are gay or lesbian. Researchers have estimated that 4 percent of men and 2 percent of women are exclusively homosexual (Collins 1988). Though homosexual marriages are not legally recognized, many gay and lesbian couples form lasting unions.

Childbearing. Childbearing patterns have varied somewhat over the past century. Women born in 1891 had an average of three children. Women born in 1908, who bore children during the Great Depression, had an average of two children. This figure increased to three children per mother during the 1950s and has since declined to two children per mother on average today (Sweet and Bumpass 1987; U.S. Bureau of the Census 1998). In addition to fewer numbers of children born, current trends in childbearing include higher age at first childbirth and longer intervals of time between births. These trends are interrelated. Waiting longer to have a first child and spacing births further apart decrease the average number of children born per mother. The timing of childbearing also has important effects on other life experiences, including educational and occupational attainment. Lower rates of childbearing are associated with higher educational levels and higher incomes.

Fewer married couples are having their first child in the period immediately following marriage, but there are some important differences by race. In 1960, 54 percent of non-Hispanic white couples had children within twelve to seventeen months of marriage. In 1980 this figure dropped to 36 percent. Little change was shown over this period for black couples, who had children within twelve to seventeen months of marriage. Compared to the total population, black couples are likely to have more children on average and to have a child present at the time of marriage. For whites (Hispanics and non-Hispanics) as well as blacks, nine-tenths of all couples have children within seven to eight years of marriage (Sweet and Bumpass 1987).

Childbearing among single women has increased greatly over the past several decades. While just 5 percent of all births were to single women in 1960, approximately one-third (32.2 percent) of all births were to single women in 1995 (Saluter 1996; U.S. Bureau of the Census 1998). As is true for many family patterns, there are substantial variations across racial-ethnic groups. Asian Americans and Pacific Islanders show a relatively low rate of nonmarital births, at 16.3 percent of all births in this group. In contrast, 25.3 percent of all births among whites are to unmarried women, and the rate for Hispanics (who may be of any race) is 40.8 percent. Nearly 70 percent of African-American children are born to single women (U.S. Bureau of the Census 1998). Although socioeconomic factors do not account completely for births to single women, nonmarital childbearing in the United States tends to be higher among those who are poor. Socioeconomic factors can help to explain why African Americans, who are disproportionately likely to be poor, have had higher rates of nonmarital childbearing.

Divorce. A rising divorce rate has been a feature of U.S. society since the Civil War. At that time, the divorce rate per 1,000 existing marriages was just 1.2 (Jacobson 1959). By the early 1990s, the rate had increased to more than 20 divorces per 1,000 existing marriages (Cherlin 1996). This long-term trend does not show a smooth and progressive rise, however. Divorce rates have risen more sharply after every major war during this century. Divorce also increased following the Great Depression, apparently reflecting stresses associated with unemployment and economic deprivation. Economic prosperity as well as a greater emphasis on family life have been linked to the lower divorce rate observed from 1950 to 1962. Following 1962, dramatic increases in the divorce rate occurred, with a 100 percent increase between 1963 and 1975 (Cherlin 1992). By the early 1970s, the chance of eventual divorce reached almost 50 percent. The divorce rate has more or less stabilized since that time, such that approximately 50 percent of all first marriages are projected to terminate eventually in divorce. The chances of divorce are higher for second marriages, of which 60 percent are projected to end in divorce (Olson and DeFrain 1994).

Population trends have been linked with the increased rate of divorce. Among these trends is

greater longevity, with an average life expectancy at birth of approximately eighty years for women and seventy-three years for men who were born in 1991. When they reach the age of sixty-five, women who were born in 1991 can expect to live an additional nineteen years, while men of that birth cohort can expect to live fifteen more years (U.S. Bureau of the Census 1996). (These figures are for the total population. Life expectancies are lower for members of racial and ethnic minorities.) In contrast, the life expectancy at birth for those born in 1900 was forty-eight years for women and forty-six years for men (Grambs 1989). Unsatisfactory marriages that formerly may have been terminated by the death of one partner are now more likely to be dissolved by divorce (Uhlenberg 1986). Scholars have also noted the apparent connection between women's increasing levels of labor-force participation and the increased rate of divorce in the United States. Divorce is more likely to occur in couples where the wife is able to support herself financially.

The risk of divorce also varies with age at marriage, duration of the marriage, education, race, and ethnicity. Age at marriage is one of the most important factors, with the likelihood of divorce twice as great among couples where the wife was seventeen or younger than among couples where the wife was in her early twenties. Further, most divorces take place within the first few years of marriage. The longer a couple has been together, the less likely they will be to get divorced. This pattern also holds among couples in which one or both partners have remarried. Education also seems to be an important factor, with a higher divorce rate observed among high school dropouts than among college graduates. However, the effect of education is due in large part to the fact that college graduates tend to marry at later ages. Looking across racial and ethnic groups, the risk of divorce is greater among African Americans than among whites, and especially high divorce rates are observed for Hispanics (Puerto Ricans in particular), Native Americans, and Hawaiians. Divorce is less common among Asian Americans (Sweet and Bumpass 1987).

Widowhood. Rising life expectancies have increased the average age of widowhood. Among women, the median age at widowhood was fifty-one in 1900, compared to sixty-eight in 1979. The median age at widowhood for men was forty-five

in 1900 and seventy-one in 1979 (Grambs 1989). Lower average ages of bereavement for men compared to women in 1900 are linked with women's risks for death in childbirth in that era. Women today can expect to live longer in a widowed status compared to widowed men. This gender gap is explained primarily by higher female life expectancy and lower rates of remarriage among women, and also because women tend to marry men several years older than themselves. Nearly one-half (45 percent) of all American women who are age sixty-five or older are widowed, while 15 percent of men in this age group are widowed. Among the oldest-old—those who are eighty-five years of age and older—these figures rise to 77 percent for women and 42 percent for men (Lugaila 1998).

Remarriage. Due in large part to the fact that widowhood tends to occur later in life, fewer men and women remarry following the death of a spouse, compared to those who remarry following a divorce. Most people who divorce eventually remarry, but the likelihood of remarriage varies greatly according to gender, age, and race. Approximately five out of six men eventually remarry following a divorce, compared to two out of three women who do so (Cherlin 1992). As noted above, men are also more likely than women to remarry following the death of a spouse. The probability of remarriage declines with age, especially among women. Only one in four women who divorce at age forty or older eventually remarry (Levitan, Sar, and Gallo 1988). Race differences also are observed for remarriage. The proportion of women who remarry following divorce is approximately 50 percent for African Americans and 75 percent for whites (Bumpass, Sweet, and Castro Martin 1990).

Increased rates of divorce and remarriage are transforming American families. "Blended" families or stepfamilies are becoming increasingly common, whereby one or both spouses bring children into a remarriage. One in four children will spend some time in a blended family (Furstenberg and Cherlin 1991). Nearly all of these children live with their biological mothers.

Household Structure. As defined by the U.S. Bureau of the Census, "family households" contain persons who are related to the household head (the person in whose name the home is

owned or rented) by blood ties, marriage, or adoption. “Nonfamily households” consist of individuals who live alone or with one or more unrelated persons. Historically, most American households have been family households, and most of these have included married couples. In 1910, 80 percent of all households included married couples. By 1998 this percentage had declined to 53 percent (Casper and Bryson 1998). In contrast, the proportion of single-person households has risen dramatically over the century. In 1890, only 4 percent of all households were of this type (Sweet and Bumpass 1987). As of 1998, single-person households accounted for one-quarter of all U.S. households. Nearly 12 percent of all households consist of men living alone, 15 percent consist of women living alone (Lugaila 1998).

Breakdowns of family structure by race and ethnicity have shown that Americans of Korean, Filipino, Vietnamese, and Mexican heritage are most likely to live in family households (for each group, about 84 percent reported living in family households). African Americans and non-Hispanic whites are somewhat less likely to live in family households. Also, compared to other racial and ethnic groups, Puerto Ricans are most likely to live in a household consisting of a mother and one or more children (with 23 percent living in this type of household), followed by African Americans, Native Americans, and Hawaiians (Sweet and Bumpass 1987).

Type of household is tied closely with economic status. While the “typical” dual-earner couple with children earned an average annual income of \$46,629 in 1991, the average income for mother-only households was only \$13,012 (McLanahan and Casper 1998). Of all household types, those headed by a woman with no husband present have the highest poverty rate. In 1997, nearly 32 percent of these households had incomes that fell below the poverty line (Dalaker and Naifeh 1998).

Due largely to women’s risks for poverty and the rise in female-headed households, children are more likely to be poor today than they were several decades ago. The proportion of American children living in poor families declined during the 1960s—from 26.5 percent in 1960 to 15 percent in 1970—but has since increased. Nearly one-quarter of all American children live in poor families. For children who live in a female-headed household,

the chances of living in poverty rise to 46 percent for white-Hispanic and non-Hispanic children, and to 82 percent for African-American children (Ollenburger and Moore 1998).

IMPACT OF FAMILY TRENDS ON CHILDREN AND OLDER PERSONS

The majority of the family patterns described here represent long-term trends in the United States and are unlikely to represent the demise of American families, as has been decried by some social observers. Indeed, marriage remains as “popular” as ever. Although Americans are marrying somewhat later on average than they did in the 1950s and 1960s, the majority of women and men continue to marry and have children. Those who divorce tend to remarry. Although these trends did not originate in the late twentieth century, it is nonetheless true that divorce, single-parent households, employed mothers, and nonmaternal childcare are more typical features of American life today than they were in the past. The impact of these family patterns on children’s development and well-being has been a matter of great concern to researchers and policymakers. The impact of women’s employment and changes in family composition also have given rise to concerns regarding the provision of informal care to elderly parents.

Divorce. Parents’ divorce has been linked with a range of negative outcomes for children in the areas of psychological adjustment, life satisfaction, academic achievement, and social relationships. These effects are strongest in the first year or two following the divorce, but some long-term consequences also have been found. The experience of parents’ divorce can continue to have negative effects on a child’s well-being as she or he grows into young adulthood (Cherlin, Chase-Lansdale, and McRae 1998).

Although divorce typically is a stressful experience, studies have found a great deal of variation in how children adapt to parents’ divorce. Among the factors identified as important to consider are the family’s socioeconomic status, race-ethnicity, the child’s gender and his or her age at the time of the parents’ divorce or separation. For example, the effects of divorce apparently are more acute for children of school age than for preschool children. Marital disruption also brings greater

risks to children when the parent-child relationship suffers as a result of the divorce and when one or both parents experience multiple divorces (Amato and Booth 1991).

The level and type of conflict present in the family prior to a divorce also is important in understanding the effects of divorce on children. Children whose families were highly conflictual may show increased well-being following a divorce. Conversely, problems of adjustment have been found among children whose parents did not divorce, but whose family lives were characterized by high levels of conflict (Furstenberg and Cherlin 1991).

Individuals who experienced "low-stress" parental divorces do not appear to differ significantly from those who grew up in happy, intact families (Amato and Booth 1991). In general, negative consequences of divorce are not found for children when parents maintain a positive relationship with the child and with one another, and when the child is provided with adequate social and economic resources. As discussed below, economic difficulties pose a central challenge for single-parent (usually single-mother) households.

Single-parent households. Just as the impact of divorce on children depends upon multiple factors, no one pattern characterizes how children's well-being is influenced by living in a single-parent household. The circumstances of single parenthood are diverse—single parents can be divorced, widowed, or never-married—and they have access to varying levels and types of social and economic resources. Households may include only the single parent and one or more children, or may include extended family or other household members. Noncustodial parents may or may not be part of the child's life.

It has been noted that single-parent households are more likely than dual-parent households to be poor, and that mother-headed households are especially likely to be poor. Following a divorce, women's subsequent income declines 27 percent on average, while men's average income increases by 10 percent (Peterson 1996). Some of this income gap is due to the fact that children are more likely to live with their mothers than their fathers following a divorce. Currently one child in four lives in a single-parent family, and women head 83 percent of these families (U.S. Bureau of the Census 1998).

Many of the problems associated with single-parent households are associated with problems of poverty. The economic difficulties faced by single parents are compounded when child support payments from the noncustodial parent are not provided regularly. About one-half of custodial mothers were awarded child support payments in 1992. Of the women who had been awarded child support, 76 percent received full or partial payment. A significant amount of awarded child support is not received by the custodial parent: one-third of all awarded child support was not paid in 1991. Among custodial parents, mothers have higher child support award rates and payment rates than fathers, but they are also much more likely to be poor. Single custodial mothers are two and one-half times more likely to be poor than single custodial fathers (U.S. Bureau of the Census 1995).

In addition to economic strains, single parents report problems arising from role and task overload, in coordinating a social life and parenting responsibilities, and difficulties with former spouses. Strains experienced by the parent can in turn impact the well-being of children (Richards and Schmiede 1993). Some evidence also suggests that single parents provide less supervision of children compared to two-parent families (married or cohabiting) (e.g., Astone and McLanahan 1991).

Although research has focused primarily on problems of single-parent households, some potential benefits of these households have been identified for children's development and well-being. For example, children in single-parent households have been found to take greater responsibility for household tasks than children in two-parent households. Along with increased responsibilities within the home, children in one-parent households also apparently develop higher levels of personal autonomy and independence (see Richards and Schmiede 1993).

Nonmaternal Childcare. With more American women working for pay than ever before, more preschool-age children are receiving care from their fathers, other family members, or from nonrelatives during their mothers' hours of employment. As of 1991, 9.9 million children age five or younger required care during the hours their mothers were employed. Of these children, the majority were cared for in a home environment:

36 percent were cared for in their own homes (usually by the father or another relative); 31 percent were cared for in another home (usually by a nonrelative in the care provider's home). A further 9 percent were cared for by their mothers while they worked—this was generally in a home environment as well, as most of these mothers had home-based paid work. Approximately one-quarter of the children who required care while their mothers worked were enrolled in an organized day care facility (U.S. Bureau of the Census 1995).

With the increasing use of childcare provided by individuals other than the mother, concerns have been raised regarding the impact of nonmaternal care on children's physical, cognitive, and psychological development. The majority of studies on this topic have concluded that nonmaternal childcare, and nonparental childcare more generally, is not in itself harmful to children. In fact, day care settings apparently aid the development of children's social skills. However, the quality of the care—whether in a family or nonfamily setting—is extremely important for children's development and well-being. A comprehensive report published by the National Research Council found that children whose families were undergoing psychological stress or economic deprivation were more likely to receive care in lower quality settings. Hence, these children are vulnerable not only to poverty and psychological stress within the home, but they are also likely to suffer from the effects of poor-quality care outside the home (Hayes, Palmer, and Zaslow 1990).

Eldercare. Most older Americans live independently in the community and are in relatively good health. Most also provide economic and other support to their adult children, such as providing babysitting or other services. It is only when the elder's health or economic status is severely compromised that the balance of exchange tips in the direction of receiving a greater amount of support than elders provide to their children.

The bulk of care provided to older Americans who are frail or ill is provided by family members, usually women, who are typically spouses or children of the elder (Stone, Cafferata, and Sangl 1987; Wolf, Freedman, and Soldo 1997). If a spouse or child is not available, other relatives or a friend may provide care (though assistance from these latter sources is typically less intensive and for

brief periods of time). Much research attests to the extensive and prolonged care provided by family members to elders within a home environment (see Dwyer and Coward 1992). In many if not most cases, it is only after families have exhausted their physical, economic, and emotional resources that a decision is made to place an elder in a long-term care facility. Indeed, only 5 percent of all Americans age sixty-five and older reside in a nursing home or other long-term care facility at a given point in time. The chances of nursing home placement rise with age: Nearly 25 percent of those age eighty-five or older live in a nursing home. However, even among this "oldest-old" age group, the majority of individuals reside in the community rather than a nursing home (Morgan and Kunkel 1998).

Recognizing that women typically are the primary care providers to older family members, researchers and policymakers have raised concerns that such care will be curtailed in the future due to trends in women's employment and an increasing older population. The prevalence of elder care among the employed population is difficult to estimate due to variations in sampling across studies and how caregiving is defined. However, an averaged estimate from studies on this topic is that about one in five employees has some elder care responsibilities (Gorey, Rice, and Brice 1992).

Research has shown that caregiving can be emotionally gratifying for individuals who are providing care to a loved one (Lechner 1992). However, intensive, long-term caregiving can produce serious physical, economic, and emotional strains, especially when caregiving interferes with the provider's work or household responsibilities (Gerstel and Gallagher 1993). A number of studies have found that employment status does not alter the type or amount of care provided to the elderly by their families, but some family members reduce or terminate their employment in order to provide elder care. A national survey found that 9 percent of employees in the study had quit their jobs and a further 20 percent had altered their work schedules to accommodate their caregiving responsibilities. Women were more likely than men to rearrange their work schedules or to reduce or terminate their employment in order to provide family care (Stone, Cafferata, and Sangl 1987).

The strains of intensive caregiving can compromise the provider's ability to continue in the caregiving role. A number of researchers have concluded that greater assistance from the government as well as from the workplace is needed to assist family members and others who provide care to older adults in the community (e.g. Lechner 1992). Such assistance not only benefits the health and well-being of care providers and recipients, but also allows elders to continue living in the community setting for a longer period of time, as is preferred by most elders and their families.

CROSS-NATIONAL COMPARISONS

The family trends described here are not unique to the United States. Other western societies also have witnessed a rise in the age at first marriage, an increased divorce rate, increased numbers of children born to unmarried women, and an increase in the numbers of women who participate in paid labor. Although the trajectories of these trends are similar for most western societies, differing proportions of individuals and families are represented in these trends across societies. For example, although the average age at marriage has been rising in the United States and most other western societies, the average age at first marriage is lower in the United States than in most of the European countries. And although a rising divorce rate has been a feature of the majority of western societies, the rate of divorce is highest in the United States. Out-of-wedlock births also have increased in western societies over the course of the century. However, in contrast to Scandinavian countries including Sweden and Denmark, more children in the United States live in a single-parent household than with cohabiting parents.

A striking gap between the United States and a number of other countries is found in its relatively high rate of infant mortality. Infant mortality is linked with poverty and the lack of adequate nutrition and health care. The wealth enjoyed by the United States as a nation belies the economic deprivation experienced by subgroups within the society. In 1988, the U.S. infant mortality rate was 10 babies per 1,000 live births. This rate was higher not only as compared with other western societies, but also compared with many nonwestern countries. In a ranking of infant mortality rates worldwide, which were ordered from the lowest to the

highest rates, the United States ranked eighteenth from the bottom. This rate was higher than that found in countries including Singapore, Spain, and Ireland, which are poorer relative to the United States, but which have lower levels of economic inequality within the society (Aulette 1994). A statement from the Children's Defense Fund illustrates the high risks for infant mortality faced by racial-ethnic minority groups within the United States: "A black child born in the inner-city of Boston has less chance of surviving the first year of life than a child born in Panama, North or South Korea or Uruguay" (Children's Defense Fund 1990, p. 6, cited in Aulette 1994, p. 405). (The famine experienced within North Korea during the 1990s likely would remove that country from this listing.)

The United States is unique among western societies in its lack of a national health care program, which helps to explain its higher infant mortality rate. In 1997, 43.4 million Americans, or slightly over 16 percent of the U.S. population, had no health insurance coverage for the entirety of that calendar year. The lack of health insurance is especially acute among the poor. Although the Medicaid program is intended to provide health coverage to the poor, 11.2 million poor Americans, or one-third of all poor people in the United States, had no health coverage in 1997 (Bennefield 1998).

In the absence of concerted social policy measures, infant mortality and other risks faced by poor Americans are unlikely to diminish in the near future. Using the Gini index (a measure of income concentration), the U.S. Bureau of the Census reported that income inequalities within the country increased by 16 percent between 1968 and 1992. Even greater inequalities have developed since 1992: Between 1968 and 1994 the rate of increase in U.S. income inequality was over 22 percent (Weinberg 1996). At the same time, the percentage of Americans with incomes below the poverty line also increased—from 11.7 percent in 1979 to 13.3 percent in 1997 (Dalaker and Naifeh 1997).

AMERICAN FAMILIES AND THE FUTURE

Traditional distinctions between "family" and nonfamily" are increasingly challenged. Though

still a relatively small proportion of all households (about 4 percent; U.S. Bureau of the Census 1998), the number of cohabiting heterosexual couples has increased greatly in the past several decades. Marriage between homosexuals is not legally recognized, but some have elected to adopt each other legally, and a growing number are raising children. In addition to the “traditional” nuclear family form of two parents with children, other family types can be expected to continue in the future. These include single parents, blended families resulting from remarriage, and households in which other relatives such as grandparents reside.

Increased longevity has brought about some of the most important changes in American family life over the past century. Children are more likely than ever before to interact with their grandparents. Further, many persons are becoming grandparents while their own parents are still alive (Uhlenberg 1986). Research has documented the prevalence and importance of social interaction, emotional support, financial help, and other assistance between the generations. For all types of American families, indications are that high levels of interaction and assistance between the generations will continue in the future. It remains to be seen how U.S. social policy will respond to the needs of family care-providers, and to the needs of poor Americans and their families, in the years to come.

AMERICAN INDIAN STUDIES

American Indian Studies blends many fields in the social sciences and humanities; history and anthropology have been especially prominent, along with education, sociology, psychology, economics, and political science. For convenience, this literature can be grouped into several subject areas: demographic behavior, socioeconomic conditions, political and legal institutions, and culture and religion. Of course, there is a great deal of overlap. To date, this literature deals mostly with aboriginal North Americans and their descendants. As the field has evolved, little attention has been devoted to the natives of South America or the Pacific Islanders. However, there is a growing interest in common experiences of indigenous peoples around the world (e.g. Fleras and Elliot 1992).

DEMOGRAPHY

Historical Demography. Historical demography is important for understanding the complexity of indigenous North American societies and for assessing the results of their contacts with Europeans. For example, complex societies require large populations to generate economic surpluses for trade, and large populations often entail highly developed systems of religion, culture, and governance. Because American Indians almost disappeared in the late nineteenth century, large numbers of pre-Columbian Indians would indicate that devastating mortality rates and profound changes in native social organization followed the arrival of Europeans.

No one knows with certainty when populations of *Homo sapiens* first appeared in the Western

Hemisphere. The first immigrants to North America probably followed game from what is now Siberia across the Beringia land bridge, now submerged in the Bering Sea. This land bridge has surfaced during several ice ages, leading to speculation that the first populations arrived as early as 40,000 years ago or as recently as 15,000 years ago—25,000 years ago is a credible estimate (Thornton 1987, p. 9).

In 1918 a Smithsonian anthropologist, James Mooney, published the first systematic estimates of the American Indian population. He reckoned that 1.15 million American Indians were living around 1600. Alfred Kroeber (1934) subsequently reviewed Mooney's early estimates and deemed them correct, though he adjusted the estimate downward to 900,000 (Deneven 1976). The Mooney-Kroeber estimates of approximately one million American Indians in 1600 have been the benchmark for scholars throughout most of this century. These estimates were flawed, however, because they failed to take epidemic disease into account; European pathogens devastated native populations.

Noting the shortcomings of the Mooney-Kroeber figures, Henry Dobyns (1966) revised the estimate for the 1492 precontact population, suggesting that it was as large as twelve million. His article ignited an intense debate that is still not fully resolved. Conservative estimates now number the indigenous 1492 population at approximately three to five million (Snipp 1989). Dobyns (1983) later raised his estimate to eighteen million.

Population estimates substantially larger than the Mooney-Kroeber figures are consistent with the archaeological record, which indicates that relatively complex societies occupied the Southwest, the Pacific Northwest, and the Mississippi River valley before the Europeans arrived (Thornton 1987). The effects of European contact were certainly greater than once believed. European diseases, slavery, genocidal practices, and the intensification of conflicts nearly exterminated the native people. Huge population losses undoubtedly caused large-scale amalgamation and reorganization of groups struggling to survive and wrought profound changes in their cultures and social structures.

Despite long and heated debates about the likely number of pre-Columbian North Americans, there is relatively little consensus about this figure. It seems likely that it will never be known

with certainty. As scholars realize the elusiveness of this number, there is less interest in trying to establish the definitive estimate and more in attempting to understand the complex demographic behavior related to depopulation (Thornton et al. 1991; Verano and Ubelaker 1992).

Contemporary Demography. During the twentieth century, the American Indian population grew very quickly, from about 228,000 in 1890 to about 1.96 million in 1990 (Shoemaker 1999). American Indian fertility is exceedingly high (Snipp 1996). Indians often have better access to health care (from the Indian Health Service) than other equally impoverished groups, and they are experiencing diminishing infant mortality and increasing longevity (Young 1994; Snipp 1996).

A peculiar characteristic of American Indian population growth, at least since 1970, is that a large share of the increase has resulted from persons switching the racial identification they report to the census from another category (such as black or white) to American Indian (Passell and Berman 1986; Harris 1994). The U.S. census, virtually the only comprehensive source of data for American Indians, depends on voluntary racial self-identification. Declining racial discrimination, growing ethnic pride, and resurgence in tribal organization have been cited as reasons that persons of mixed heritage may choose to report themselves as American Indian (Passell and Berman 1986). Evidence indicates that persons who change their identity so they may claim their Native-American heritage tend to be relatively well-educated (Eschbach et al. 1998).

The fluidity of the American Indian population underscores a particularly problematic concern for demographers: namely, defining population boundaries. Definitions abound, and there is no single agreed-upon standard. Some federal agencies and a number of tribes use an arbitrary measure of descent, such as one-fourth blood quantum; standards for tribal membership vary greatly from one-half to one-sixty-fourth Indian blood.

For many other applications, genealogical verification of blood quantum standards is too complex. Agencies such as the U.S. Bureau of the Census thus simply rely on self-identification. By default, most studies of American Indians also rely

on self-identification, especially if they use secondary data from federal government sources. To complicate the matter, the Canadian government uses a somewhat different set of standards to define the boundaries of its native Indian population (Boldt 1993).

Beyond the complexities of counting, studies show that American Indians, more than other minorities, are concentrated in rural areas; slightly less than one-half reside in cities. Most live west of the Mississippi River, primarily because nineteenth-century removal programs were directed at eastern American Indians. A large number of studies document that American Indians are one of the least educated, most often unemployed, poorest, and least healthy groups in American society (see Sandefur et al. 1996). Nonetheless, American Indians are more likely than other groups, especially blacks, to live in a large husband-wife household, and about one-third of them speak an Indian language—provisional evidence of the continuing influence of traditional culture in family organization and language use (Sandefur and Liebler 1996).

STUDIES OF SOCIAL AND ECONOMIC STATUS

Studies of the early social and economic status of American Indians focus on the historical development of so-called dependency relations between them and Euro-Americans (White 1983, 1991; Chase-Dunn and Mann 1998). Dependency theory, a variant of neo-Marxist World Systems Theory, has been widely criticized for its shortcomings, but it has gained some acceptance among scholars of white-Indian relations (Wolf 1982; White 1983; Hall 1989). In this view, economic dependency arose from trade relations in which Euro-Americans enjoyed disproportionate economic advantage stemming from a near monopoly over items such as manufactured goods and rum (Wolf 1982; White 1983). European business practices, such as the use of credit, also fostered dependency.

Dependency relations promoted highly exploitative conditions that were a frequent source of conflict and periodically erupted into serious violence. Unscrupulous traders and a growing commerce in Indian captives, for example, spawned the Yamasee War, which ended Indian slavery in

the Southeast (Merrell 1989). Early colonial officials frequently complained about the conflicts created by the unethical practices of frontier traders and sought to curb their abuses, though with little success (White 1991).

Nevertheless, European traders introduced innovations that altered cultures and lifestyles forever. In the Southwest, for example, guns and horses revolutionized relations between nomadic and sedentary groups and allowed the Spanish to exploit traditional antagonisms (Hall 1989).

The emergence of industrial capitalism, large-scale manufacturing, growing urbanization, and an influx of immigrants from Europe and slaves from Africa changed dramatically the relations between Euro-Americans and indigenous peoples. Trading with Indians subsided in favor of policies and measures designed to remove them from lands desired for development (Jacobsen 1984). Throughout the nineteenth century, American Indians were more or less forcibly induced to cede their lands for the development of agriculture, timber, and water. In the late nineteenth century, U.S. corporations began to develop petroleum, coal, and other minerals on tribal lands (Miner 1976).

Exploitation of Indian lands has continued, prompting some scholars to argue that American Indian tribes have a quasi-colonial status within the U.S. economy (Snipp 1986). Natural resources such as timber, water, and minerals are extracted from reservations and exported to distant urban centers where they are processed. In exchange, manufactured goods are imported for consumption. The value of the imported goods typically exceeds the value of the exported resources. The deficit between imports and exports contributes to the persistent poverty and low levels of economic development on many reservations.

The Meriam Report, published in 1928, furnished the first systematic empirical assessment of the economic status of American Indians. Since its publication, numerous studies have documented the disadvantaged status of American Indians (Levitan and Miller 1993). Although many reports have described economic conditions in detail, fewer have attempted to isolate the causes of poverty and unemployment. Clearly, a number of factors can be blamed. American Indians have very little formal education, limiting their access to jobs.

Whether racial discrimination limits opportunities is unclear. Some research suggests that discrimination is not a significant disadvantage for American Indians (Sandefur and Scott 1983), but other studies disagree with this conclusion (Gwartney and Long 1978).

Conditions on reservations, where about one-third of American Indians live, are particularly harsh. Unemployment rates above 50 percent are not unusual. Studies of reservation economies usually blame the isolated locales for many of their woes. The collision of traditional native values and the ethics of capitalism (Cornell and Kalt 1992) frequently complicates economic development in Indian country. In the 1990s, some reservations have enjoyed limited (and in a few instances, spectacular) success in spurring economic development, especially in tourism, gambling, and light manufacturing (Snipp 1995).

Urban American Indians enjoy a higher standard of living than their counterparts in reservation areas (Snipp 1989). Even so, there is disagreement about the benefits of rural-urban migration for American Indians; earlier studies have identified tangible benefits for urban immigrants (Clinton, Chadwick, and Bahr 1975; Sorkin 1978), but later research found contrary evidence (Gundlach and Roberts 1978; Snipp and Sandefur 1988). Federal programs that encouraged urban immigration for American Indians in the 1950s and 1960s were abandoned amid controversies over their effectiveness and overall results (Fixico 1986).

The economic hardships facing rural and urban American Indians alike have been a major source of other serious distress. Alcoholism, suicide, and homicide are leading causes of death for American Indians (Snipp 1996).

POLITICAL ORGANIZATION AND LEGAL INSTITUTIONS

The political and legal status of American Indians is an extremely complicated subject, tangled in conflicting treaties, formal laws, bureaucratic regulations, and court decisions. Unlike any other racial or ethnic group in U.S. society, American Indians have a distinctive niche in the legal system. As a result of this legal history, a separate agency within the federal government (the Bureau of Indian Affairs [BIA]), a volume of the Code of Federal

Regulations, and a multiplicity of other rules exist for dealing with American Indians.

The political status of American Indian tribes is difficult to characterize. In 1831, Chief Justice John Marshall described tribes as “domestic, dependent nations,” setting forth the principle that tribes are autonomous political entities that enjoy a quasi-sovereignty yet are subject to the authority of the federal government (Pommersheim 1995; Boldt 1993). The limits on tribal political autonomy have fluctuated as a result of court decisions and federal legislation curtailing or extending tribal powers. Since the early 1900s, tribal governments have greatly increased their autonomy (Pommersheim 1995).

One of the most significant political developments in this century for American Indians was the passage of the Wheeler-Howard Indian Reorganization Act (IRA) of 1934. This legislation made it possible for tribes legally to reconstitute themselves for the purpose of limited self-government (Prucha 1984, ch. 37). Subject to the democratic precepts imposed by the federal government, tribes were allowed to have representative governments with judicial, executive, and legislative branches. Other forms of tribal governance—based on the inheritance of authority, for example—were not permitted by the IRA legislation. Today, virtually every reservation has a form of representative government (O’Brien 1989).

Tribal sovereignty is a complex legal doctrine affecting the political autonomy of tribal governments. It is distinct from a closely aligned political principle known as self-determination. The principle of self-determination, unlike tribal sovereignty, is relatively recent in origin and was first posed as a claim for administrative control of reservation affairs. As a political ideology, self-determination developed in response to the unilateral actions of the federal government in implementing policies such as the Termination legislation of the 1950s. In the 1960s, it was a rallying theme for promoting greater tribal involvement in federal policies affecting American Indians. The principle was formally enacted into public law with the passage of the Indian Self-Determination and Educational Assistance Act of 1975, P.L. 97-638. Since its passage, federal agencies have gradually divested control over programs and services such as those once administered by the BIA. For example, many tribal

governments have contracts to provide social services similar to the arrangements made with state and local governments.

In recent years, ideas about self-determination have developed to the point where self-determination is nearly indistinguishable from tribal sovereignty (O’Brien 1989). The most influential statement merging the two is a report presented to the U.S. Senate by the American Indian Policy Review Commission (AIPRC) in 1976. The AIPRC report was a comprehensive, though highly controversial evaluation of federal Indian policy. Every presidential administration since Richard Nixon’s has endorsed the principle of tribal sovereignty. Shortly after taking office, the Clinton Administration endorsed this principle and there is no indication of a reversal in the foreseeable future.

The political revitalization of American Indians accelerated with the civil rights movement. Some observers have suggested that Indian political activism in the 1960s was a response to postwar termination policies (Cornell 1988), which tried to dissolve the federal reservation system and liquidate the special status of the tribes. Relocation programs in the 1950s accelerated the urbanization of American Indians and, at the very least, may have contributed to the political mobilization of urban Indians, as well as their reservation counterparts (Fixico 1986). Though often complementary, the political agendas of urban and reservation Indians are not always in strict accord.

The diverse tribal composition of urban Indian populations has meant that it is virtually impossible to organize them around issues affecting only one or a few tribes. In the face of this constraint, the ideology of “pan-Indianism” is particularly appealing to urban Indian groups (Hertzberg 1971; Nagel 1996). Pan-Indianism is a supratribal ideology committed to broad issues such as economic opportunity and social justice and to cultural events such as intertribal pow-wows.

The roots of modern pan-Indian organizations can be traced first to the Ottawa leader Pontiac and later to the Shawnee leader Tecumseh and Joseph Brant, a Mohawk. These men led pan-Indian movements opposing Euro-American frontier settlement in the late eighteenth and early nineteenth centuries (e.g., Pontiac’s Revolt 1763). In the late nineteenth century, pan-Indian messianic

movements known as Ghost Dances swept across the West (Thornton 1986).

Pan-Indian organizations have been active throughout the twentieth century, but urbanization hastened their development in the 1950s and 1960s (Cornell 1988; Nagel 1996). Some, such as the National Congress of American Indians (founded in 1944), have moderate political agendas focused on lobbying; others, such as the American Indian Movement, are highly militant. The latter was involved in the sacking of the Washington, D.C., BIA office in 1972 and in the armed occupation of Wounded Knee, South Dakota, in 1973 (Smith and Warrior 1996). Today, most cities with large Indian populations have pan-Indian organizations involved in political organization, cultural events, and social service delivery (Johnson et al. 1997).

CULTURE AND RELIGION

The cultures of American Indians are extremely diverse, and the same can be said, in particular, about their religious beliefs. Not much is known about the spiritual life of American Indians before the fifteenth century. Only from archaeological evidence is such knowledge available, and this seldom captures the rich complexity of religious symbol systems. Most of what is known about American Indian religions is based on the later reports of explorers, missionaries, traders, and anthropologists (Brown 1982).

Contemporary spiritual practices reflect several different types of religious observances: Christian, neotraditional, and traditional. Participation in one type does not necessarily preclude participation in another. Furthermore, there is a great deal of tribal variation.

American Indians who are practicing Christians represent the legacy of European missionaries. The Christian affiliation of many, perhaps most, American Indians reflects their tribal membership and the denomination of the missionaries responsible for their tribe's conversion. Numerical estimates are not available, but there are many Catholic Indians in the Southwest, and American Indians in the Midwest are often Lutheran, to mention only two examples.

American Indians who participate in neotraditional religions often belong to a branch of the

Native American Church (NAC). NAC is a pan-Indian religion practiced throughout the United States and Canada. It combines elements of Christianity with traditional religious beliefs and practices.

Traditional religions are often practiced in informally organized groups such as sweatlodge or feasting societies. Some of these groups are remnants of older religious movements such as the Ghost Dance. Not much is written about them because they are ordinarily not open to outsiders; the Sun Dance is an exception. It is perhaps best known for the ritual scarification and trances of its participants (Jorgenson 1972).

The secrecy in which many traditional religions are practiced may be due to the intense repression once directed at their observances by the federal government. In 1883, the BIA established Courts of Indian Offenses that prosecuted people for practicing native religions. Among other things, the courts forbade traditional medicines, shaman healers, and all traditional ceremonial observances. Despite their dubious legal foundation, the Courts of Indian Offenses were active until their mandate was rewritten in 1935 (Prucha 1984).

In 1935, the federal government ended its official repression of tribal culture and religion. But the conflicts between government authorities and American Indians trying to practice non-Christian religions did not end. Many Indians regard freedom of religion as an elusive promise. Most controversies involve NAC ceremonies, the preservation of sacred areas, and the repatriation of religious artifacts and skeletal remains in museum collections (Loftin 1989; Echohawk 1993). NAC ceremonies are controversial because they sometimes involve the use of peyote (a hallucinogen) as a sacrament. Although peyote was once outlawed, the NAC won the right to use it within narrowly defined limits prescribed by the courts. The U.S. Supreme Court upheld a case in which Oregon banned the use of peyote, however, raising concerns about how the conservative court will interpret freedom of religion cases in the future (Echohawk 1993).

Preservation of sacred areas places Indian groups at odds with land developers, property owners, local governments, and others who would use sites deemed sacred by spiritual leaders. In one

case, the Navajo and Hopi in 1983 went to court to petition against the development of a ski resort that intruded on sacred grounds. In this case and several similar ones, the courts ruled against the Indians (Loftin 1989). Similar conflicts have arisen over the repatriation of religious artifacts and skeletal remains in museums. These issues pit academics such as scientists and museum curators against Indian groups. In some instances, remains and artifacts have been returned to tribes; Stanford University returned burial remains to the Ohlone tribe in California, for example. Other institutions have opposed repatriation or are studying the matter. The Smithsonian has developed a complex policy for repatriation, and the University of California appointed a committee to develop a policy. For the foreseeable future, the controversy is likely to linger in the courts, Congress, and academic institutions.

Compared to repatriation, cultural studies are a less controversial though no less important domain of American Indian Studies. Indian religion represents one of the central forms of native culture, but cultural studies also emphasize other elements of Indian lifestyles, values, and symbol systems. Some of these studies focus on the content of tribal culture; other research deals with the consequences of tribal culture.

For decades, ethnologists recording for posterity details about Indian culture, especially material culture, or documenting the ways that European contact influenced the content of tribal culture dominated studies of American Indians. The popularity of this type of research has declined significantly, partly because there are few "pristine" cultures left anywhere in the world, much less in North America. Another reason, perhaps more damaging, is the growing realization that studies purporting to document precontact Indian culture were based on secondhand accounts of groups that were not truly pristine. The influence of European diseases and trade goods often arrived far in advance of Europeans (Ramenofsky 1987).

Many studies of American Indian culture now resemble literary or artistic criticism. Others focus on how European innovations have been incorporated into tribal culture in unique ways; silversmithing and rug weaving are two well-known examples. A related set of studies deals with the

resurgence of traditional culture, such as the increase in the use of American Indian languages (Leap 1988).

The behavioral consequences of culture are perhaps most prominent in a large literature on American Indian mental health, education, and rehabilitation (Bennett and Ames 1985; Foster 1988). Many studies show that education and rehabilitation efforts can be made more effective if they are sensitive to cultural nuances (LaFromboise 1995). In fact, many specialists take this idea as a point of departure and focus their research instead on the ways in which Euro-American educational and therapeutic practices can be adapted to the cultural predisposition of American Indian clients (Lafromboise 1995).

Like the American Indian population, American Indian Studies is a highly diverse and growing field of inquiry. It is interdisciplinary and eclectic in the perspectives it uses. Once primarily the domain of historians and anthropologists, American Indian Studies has rapidly expanded beyond the bounds of these disciplines with contributions from scholars in a wide variety of fields.

AMERICAN SOCIETY

The term *American society* is used here to refer to the society of the United States of America. This conventional usage is brief and convenient and implies no lack of recognition for other societies of North, Central, and South America.

Boundaries of modern national societies are permeable and often socially and culturally fuzzy and changeable. Lines on maps do not take into account the cross-boundary flows and linkages of trade, tourists, information, workers, diseases, military arms and personnel, ethnic or linguistic affiliations, and the like. As a large, heterogeneous country, the United States well illustrates such interdependence and cultural diversity.

During the second half of the twentieth century it became increasingly plain that an understanding of American society required analysis of its place in a global system. National societies have become highly interdependent through extensive flows of capital, technology, goods and services, ideas and beliefs, cultural artifacts, and symbols. A world system of politico-military relationships (blocs and hierarchies) interacts with a global system of trade, finance, and population transfers, and both systems are influenced by cultural interpenetration (including organizational forms and procedures).

While these developments were under way, the American people became healthier, life expectancy increased, educational levels rose, income and wealth increased, major new technologies developed (e.g., the so-called Information Revolution), and ethnic and racial minorities gained in income, occupational status, and political participation (Farley 1996). On the other hand, economic inequality increased sharply, the prison population grew rapidly (and became disproportionately made up of African Americans), divorce rates remained at high levels, single-parent households increased, and infant mortality remained high, as did violent crime (Farley 1996).

Containing less than 5 percent of the world's population, the United States is a polyglot nation of nations that now accepts a greater and more diverse inflow of legal immigrants than any other country—an average of about one million a year from 1990 to 1995. It is often called a young nation, but elements of its culture are continuous with the ancient cultures of Europe, Asia, and Africa, and its political system is one of the most long-enduring constitutional democracies. Many writers have alleged that its culture is standardized, but it continues to show great diversity of regions, ethnic groupings, religious orientations, rural-urban contrasts, age groupings, political views, and general lifestyles. It is a society in which many people seem convinced that it is undergoing rapid social change, while they hold firmly to many values and social structures inherited from the past. Like all other large-scale societies, in short, it is filled with ambiguities, paradoxes, and contradictions.

This society emerged as a product of the great period of European expansion. From 1790 to 1990, the U.S. land area expanded from fewer than 900,000 square miles to well over three million; its populations from fewer than four million to about 265 million. The United States has never been a static social system in fixed equilibrium with its environment. Peopled primarily by history's greatest voluntary intercontinental migration, it has always been a country on the move. The vast growth of metropolitan areas is the most obvious sign of the transformation of a rural-agricultural society into an urban-industrial society. In 1880, the nation had four million farms; in 1992 it had 1.9 million. From 1949 to 1979 the index of output per hour of labor went from about twenty to about 200. The most massive change in the occupational structure, correspondingly, has been the sharply decreasing proportion of workers in agriculture—now less than 1 percent of the labor force.

The technological transformations that have accompanied these trends are familiar. The total horsepower of all prime movers in 1940 was 2.8 billion; in 1963 it was 13.4 billion; by 1978 it was over 25 billion. Productive capacities and transportation and communication facilities show similar long-term increases. For example, from 1947 to 1995, the annual per capita energy consumption in the United States went from 230 to 345 million

BTUs—an increase of about 50 percent. The American people are dependent to an unprecedented degree on the automobile and the airplane. (As of the late 1980s, the average number of persons per passenger car was 1.8; by 1995, there were 201 million motor vehicles in a population of some 263 million—1.6 persons per vehicle.) Mass transit is only weakly developed. During the single decade of the 1960s there was a 50 percent increase in the number of motor vehicles, and in many cities such vehicles account for 75 percent of the outdoor noise and 80 percent of the air pollution. With about 200 million motor vehicles in 1998, it is even possible to imagine an ultimate traffic jam—total immobilization from coast to coast.

All indicators of what we may call “heat and light” variables have increased greatly: energy consumption, pieces of mail handled by the U.S. Postal Service (from 106 billion in 1980 to 183 billion in 1996), televisions (2.3 sets per household in 1995), telephones (93.9 percent of households had one in 1995), radios, electronic mail (29 million persons using the Internet), cellular phones, and fax. A vast flood of messages, images, and information criss-crosses the continent.

In American households, the average number of hours that the television was on increased from 5.6 in 1963 to 6.8 in 1976, and continues to slowly increase. The effects of television viewing are complex, although there is general agreement among researchers that mass exposure is selective, does focus attention on some matters rather than others (raising public awareness), influence attitudes on specific issues—especially those on which information is scanty—and probably has cumulative effects on a variety of beliefs and preferences (cf. Lang and Lang 1992).

In short, this is a society of high technology and extremely intensive energy use. It is also a country that has developed a tightly organized and elaborately interdependent economy and social system, accompanied by vast increases in total economic productivity. Thus the real gross national product doubled in just two decades (1959–1979), increasing at an average rate of 4.1 percent per year (Brimmer 1980, p. 98). But beginning with the sharp increases in oil prices after 1973, the society entered a period of economic stagnation and low productivity that was marked in the 1980s by large trade deficits, greatly increased

federal budget deficits, and increased problems of international competitiveness. Coming after a long period of sustained growth, the changes of the 1980s resulted in an economy of low savings, high consumption, and low investment—a situation of “living beyond one’s means.” In the 1990s, a sustained period of low inflation and rising stock markets marked a somewhat uneasy sense of prosperity, seen as insecure as the decade ended.

MAJOR INSTITUTIONS

“Institution” here means a definite set of interrelated norms, beliefs, and values centered on important and recurrent social needs and activities (cf. Williams 1970, chap. 3). Examples are family and kinship, social stratification, economic system, the polity, education, and religion.

Kinship and Family. American kinship patterns are essentially adaptations of earlier European forms of monogamous marriage, bilateral descent, neolocal residence, and diffuse extended kinship ties. All these characteristics encourage emphasis on the marriage bond and the nuclear family. In an urbanized society of great geographical and social mobility and of extensive commercialization and occupational instability, kinship units tend to become small and themselves unstable. Since the 1950s, the American family system has continued its long-term changes in the direction of greater instability, smaller family units, lessened kinship ties, greater sexual (gender) equality, lower birth rates, and higher rates of female-headed households. The percentage of married women in the labor force rose from 32 in 1960 to 61 in the 1990s. The so-called “traditional” family of husband, wife, and children under eighteen that comprised 40 percent of families in 1970 had declined to 25 percent in 1995. Over one-fifth of households are persons living alone. Marriage rates have decreased, age at marriage has increased, and rates of divorce and separation continue to be high. The percentage of children under eighteen years of age living in mother-only families increased in the years between 1960 and 1985, from 6 to 16 among white, and from 20 to 51 among black Americans (Jaynes and Williams 1989, p. 522). As individuals, Americans typically retain commitment to family life, but external social and cultural forces are producing severe family stresses.

Social Stratification. Stratification refers to structural inequalities in the distribution of such scarce values as income, wealth, power, authority, and prestige. To the extent that such inequalities result in the clustering of similarly situated individuals and families, “strata” emerge, marked by social boundaries and shared styles of life. When succeeding generations inherit positions similar to previous generations, social classes can result.

The American system is basically one of open classes, with relatively high mobility, both within individual lifetimes and across generations. A conspicuous exception has been a caste-like system of racial distinctions, although this has eroded substantially since the civil rights movement of the 1960s (Jaynes and Williams 1989). The 1980s and 1990s were marked by growing income inequality, as the rich became richer and the poor did not. Large increases in earnings inequality accrued during the 1980s; meanwhile labor unions had large membership losses and labor markets were deregulated (unions lost over 3 million members between 1980 and 1989—see Western 1998, pp. 230–232). Union membership declined from 20.1 percent of workers in 1983 to 14.5 percent in 1996 (*Statistical Abstract of the United States, 1997*, p. 441).

In the early 1990s, the United States had the highest income inequality of any of twenty-one industrialized countries (the income of individuals of the highest decile was over six times the income of the lowest decile). The United States differs from other industrialized countries in the especially great disadvantage of its poorest people. This result arises from very low wages at the bottom of the distribution and low levels of income support from public programs (Smeeding and Gottschalk 1998, pp. 15–19).

The end-of-the-century levels of inequality are less than in the early decades of the 1900s, but represent large increases since the lower levels at the end of the 1960s (Plotnick, Smolensky, Evenhouse, and Reilly 1998, p. 8). By 1996, the richest 20 percent of Americans received about 47 percent of total income, while the poorest got 4.2 percent.

The dominant ideology remains individualistic, with an emphasis on equality of opportunity and on individual achievement and success. Although extremes of income, power, and privilege

produce strong social tensions, the system has shown remarkable stability.

The history of stratification has included conquest of Native Americans, slavery of African peoples, and extensive discrimination against Asians, Hispanics, and various immigrants of European origin. Assimilation and other processes of societal inclusion have moved the whole society increasingly toward a pluralistic system, but deep cleavages and inequalities continue. A fundamental tension persists between principles of equality of opportunity and individual merit, on the one hand, and practices of ascribed status and group discrimination, on the other (cf. Myrdal, Sterner, and Rose 1944).

As a consequence of increased openness since the Immigration Act of 1965, the population contains increased proportions of persons whose backgrounds are in Asia and Latin America; this development complicates ethnic/racial boundaries and alignments, including political formations (Edmonston and Pasell 1994). The increased receptivity to immigrants was enhanced by the Refugee Act of 1980, the Immigration and Control Act of 1986, and the Immigration Act of 1990. The result is that the number of immigrants admitted per year has soared to an average of about a million during the period 1990–1995 (*Statistical Abstract of the United States, 1997*, p. 10). Although vigorous political controversy surrounds immigration, the country remains committed to a general policy of acceptance and to citizenship by residence rather than by ethnic origin.

Although much reduced in its most obvious forms, discrimination against African Americans continues to be widespread, in housing (Yinger 1995), credit, and employment (Wilson 1996; Jaynes and Williams 1989). Residential segregation continues at high levels, although the 1980s brought a small movement toward more residential mixing, primarily in smaller Southern and Western cities (Farley and Frey 1994).

The Economy. The American economic system is a complex form of “high capitalism” characterized by large corporations, worldwide interdependence, high levels of private consumption, and close linkages with the state.

Increased specialization leads both to increased complexity and to increased interdependence, two

sides of the same coin. In the United States, as in all industrialized countries, the movement from the primary extractive and agricultural industries to manufacturing was followed by growth of the tertiary exchange-facilitating activities, and then to expansion of occupations having to do with control and coordination and those ministering directly to the health, education, recreation, and comfort of the population. As early as 1970, nearly two-thirds of the labor force was in pursuits other than those in “direct production” (primary and secondary industries).

Since the late 1970s, there has been rapid growth in involuntary part-time jobs and in other insecure and low-paying employment as the economy has shifted toward trade and services and corporations have sought to lower labor costs (Tilly 1996).

As the economy has thus shifted its focus, the dominance of large corporations has become more and more salient. In manufacturing, the total value added that is accounted for by the 200 largest companies went from 37 percent in 1954 to 43 percent in 1970. Of all employees in manufacturing, the percent working in multi-unit firms increased from 56 percent in 1947 to 75 percent by 1972 (Meyer 1979, pp. 27–28). The top 500 industrial companies account for three-fourths of industrial employment (Wardwell 1978, p. 97).

Meanwhile, organized labor has not grown correspondingly; for decades, overall unionization has remained static, increasing only in the service, technical, and quasi-professional occupations. The importance of the great corporations as the primary focus of production and finance continues to increase. Widespread dispersion of income rights in the form of stocks and bonds has made the giant corporation possible, and this same dispersion contributes directly to the concentration of control rights in the hands of salaried management and minority blocs of stockholders. With widened markets for mass production of standardized products, strong incentives were created for effective systems of central control. Although such tendencies often overreached themselves and led to a measure of later decentralization, the modern corporation, not surprisingly, shows many of the characteristics of the most highly developed forms of bureaucracy.

The interpenetration of what were previously regarded as separate political and economic affairs is a central fact. The interplay takes many different forms. For a long time government has set rules for maintaining or lessening business competition; it has regulated the plane or mode of competition, the conditions of employment, and the place and functioning of labor unions. Pressure groups, based on economic interests, ceaselessly attempt to influence law-making bodies and executive agencies. Governmental fiscal and monetary policies constitute a major factor influencing economic activity. As the economic role of the state has expanded, economic forces increasingly affect government itself and so-called private corporations increasingly have come to be “public bodies” in many ways, rivaling some sovereign states in size and influence. The post-1980s political movements for a smaller role for the central government resulted in a partial dismantling of the “welfare state” but did not remove the important linkages of state and economy.

Political Institutions. In ideology and law the American polity is a parliamentary republic, federal in form, marked by a strong central executive but with a tripartite separation of powers. From the highly limited state of the eighteenth century, the actual government has grown in size and scope and has become more complex, centralized, and bureaucratized. Partly because of pervasive involvement in international affairs, since World War II a large permanent military establishment has grown greatly in size and importance. In 1996, the Department of Defense included 3.2 million persons, and total defense and veterans outlays amounted to \$303 billion. The executive agencies, especially the presidency, became for decades increasingly important relative to the Congress, although the 1990s brought a resurgence of congressional power. Among other changes, the following appear to be especially consequential:

1. Continuing struggles over the character of the “welfare state,” dedicated to maintaining certain minimal safeguards for health and economic welfare;
2. High development of organized interest groups, which propose and “veto” nearly all important legislation. The unorganized general public retains only an episodic and delayed power to ratify or reject whole

programs of government action. A rapid increase in the number of Political Action Committees—from 2551 in 1980 to 4016 in 1995—is only one indication of the importance of organized interests;

3. Decreased cohesion and effectiveness of political parties in aggregating interests, compromising parties in conflict, and reaching clear public decisions;
4. Increasingly volatile voting and diminished party regularity and party commitment (split-ticket voting, low rates of voting, large proportion of the electorate with no firm party reference).

American political parties are coalitions of diverse actors and interests, with accompanying weak internal discipline, but they remain relatively stable under a system of single-member districts and plurality voting—“first past the post.” Although the polity is subject to the hazards of instability associated with a presidential rather than parliamentary system, the national federal system, the separation of powers, and the centrality of the Constitution and the judiciary combine to support the traditional two-party electoral arrangement, although support for a third party appears to be growing (Lipset 1995, p. 6).

Historically, political parties in the United States have been accommodationist: They have served to articulate and aggregate interests through processes of negotiation and compromise. The resulting “packages” of bargains have converted diverse and diffuse claims into particular electoral decisions. To work well, such parties must be able to plan nominations, arrange for representativeness, and sustain effective competition. In the late twentieth century, competitiveness was weakened by volatile elections—for example, landslides and deadlocks with rapidly shifting votes—and by party incoherence. In the nominating process the mass media and direct primaries partly replaced party leaders and patronage. Representativeness was reduced by polarization of activists, single-issue voting, and low turnouts in primaries. And the inability of parties to protect legislators seemed to increase the influence of single-issue organizations and to enlarge the scope of “symbolic” actions. Hard choices, therefore, tended to be deferred (cf. Fiorina 1980, p. 39).

The existence of an “interest-group” polity was clearly indicated. The political system readily expressed particular interests but found difficulties in articulating and integrating partly incompatible demands into long-term national programs.

As the century drew to a close, many commentators expressed concerns about the increasing expense of political campaigns, the increasing importance of very large contributions through Political Action Committees, the potential influence upon voters of “vivid soundbites” on television, and the increasing centralization of control of the mass media. At the same time, the conspicuous behavior of so-called independent counsels (special prosecutors) raised the fears that a “Fourth Branch” of government had arisen that would be relatively free of the checks and balances, traditional in the tripartite system of governance. Public opinion polls showed increased disaffection with political institutions and processes, and lower voting turnouts indicated much apathy in the electorate. As investigations, prosecutions, and litigation have escalated and have been rendered omnipresent by the media, erosion of trust in government has likewise increased greatly (Lipset 1995).

Yet detailed analysis of data from national public opinion surveys in the last decade of the century failed to find the alleged extreme polarization that had been suggested by acrimonious partisanship between the political parties and in the Congress. Thus, a major study (DiMaggio, Evans, and Bryson 1996) found little evidence of extreme cleavages in social opinions between 1974 and 1994, with two exceptions: attitudes toward abortion diverged sharply, and the attitudes of those who identify with the Democratic and Republican parties have become more polarized. Instead of moderating dissension, the party system between 1970 and the 1990s appears to have sharpened cleavages. There is a possibility that some political leaders have been pulled away from centrist positions by militant factions within their own party. The total picture seemed to be that of extreme contentiousness within the central government while the wider society showed much greater tolerance, consensus, and stability.

Education. In addition to diffuse processes of socialization found in family and community, specialized educational institutions now directly involve one-fifth of the American people as teachers,

students, and other participants. In the twentieth century, an unparalleled expansion of mass education occurred. Nearly 80 percent of the appropriate age group graduate from secondary school and 62 percent of these attend college; in 1993, 21.3 percent had completed four years of college or more.

Historically, the educational system was radically decentralized, with thousands of school districts and separate educational authorities for each state (Williams 1970, chap. 8). In contrast to countries with strong central control of education and elitist systems of secondary and higher education, the United States for most of its history has had a weak central state and a mass education system. Education was driven by demands for it rather than by state control of standards, facilities, tests, curricula, and so on (cf. Garnier, Hage, and Fuller 1989).

These characteristics partly derive from widespread faith in education as a means of social advancement as well as from commitments to equality of opportunity and to civic unity. Inequalities of access were long enforced by involuntary racial segregation, now somewhat reduced since 1954, when the Supreme Court declared such segregation unconstitutional. Inequalities of access due to social class and related factors, of course, continue (Jencks et al. 1979). Formal educational attainments have come to be so strongly emphasized as a requirement for employment and advancement that some observers speak of the development of a “credential society” (Collins 1979). Meanwhile the slow but steady decline in students’ test scores has aroused much concern but little agreement as to remedial measures.

Religious Institutions. Major characteristics of institutionalized religion include: formal separation of church and state, freedom of religious expression and practice, diversity of faiths and organizations, voluntary support, evangelism, high rates of membership and participation, widespread approval of religion and acceptance of religious beliefs, complex patterns of partial secularization, frequent emergence of new religious groupings, and important linkages between religious affiliations and social class and ethnicity (cf. Williams 1970, chap. 9; Wilson 1978).

Many of these characteristics are causally interrelated. For example, earlier sectarian diversity

encouraged separation of church and state and religious toleration, which, in turn, favored further diversity, voluntarism, evangelism, and religious innovations. Self-reported religious affiliations in social surveys shows these percentages: Protestant, 60; Catholic, 25; Jewish, 2; other, 4; none, 9. These broad categories cover hundreds of diverse groupings (General Social Surveys 1994).

Changes include growth in membership of evangelical Protestant denominations (now one-fifth of the population, Hunter 1997), closer ties between religious groupings and political activities, and the rise of many cults and sects. Separation of church and state was increasingly challenged in the 1990s, and religious militancy in politics increased. Nevertheless, national surveys (1991) showed that the religiously orthodox and theological progressives were not polarized into opposing ideological camps across a broad range of issues—although there were sharp divisions on some particular issues (Davis and Robinson 1996).

Among industrialized Western countries, the United States manifests extraordinary high levels of membership and participation. Thus, although there has been extensive secularization, both of public life and of the practices of religious groups themselves, religious influence remains pervasive and important (Stark and Bainbridge 1985).

SOCIAL ORGANIZATION

The long-term increase in the importance of large-scale complex formal organizations, salient in the economy and polity, is evident also in religion, education, and voluntary special-interest associations. Other trends include the reduced autonomy and cohesion of small locality groupings and the increased importance of special-interest formal organizations and of mass publics and mass communication. The long-term effects of the saturation of the entire society with advertising, propaganda, assorted information, and diverse and highly selective world views remain to be ascertained. Local communities and kinship groupings have been penetrated more and more by formal, centralized agencies of control and communication. (Decreasing localism shows itself in many forms. A well-known and striking example is the continuous decrease in the number of public school districts.)

These changes have moved the society as a whole in the direction of greater interdependence, centralization, formality, and impersonality.

VALUES AND BELIEFS

Beliefs are conceptions of realities, of how things are. Values are conceptions of desirability, of how things should be (Williams 1970, chap. 11). Through shared experience and social interaction, communities, classes, ethnic groupings, or whole societies can come to be characterized by similarities of values and beliefs.

The weight of the evidence for the United States is that the most enduring and widespread value orientations include an emphasis on personal achievement (especially in occupational activity), success, activity and work, stress on moral principles, humanitarianism, efficiency and practicality, science, technology and rationality, progress, material comfort, equality, freedom, democracy, worth of individual personality, conformity, nationalism and patriotism; and, in tension with most other values, values of group superiority and racism. Mixed evidence since the 1970s seems to indicate complex shifts in emphasis among these orientations—primarily in the direction of success and comfort, with lessened commitment to more austere values. Some erosion in the emphasis placed on work and some lessening in civic trust and commitment may have occurred.

In contrast to many images projected by the mass media, national surveys show that most Americans still endorse long-standing beliefs and values: self-reliance, independence, freedom, personal responsibility, pride in the country and its political system, voluntary civic action, anti-authoritarianism, and equality within limits (Inkeles 1979; Williams 1970, chap. 11). And for all their real disaffections and apprehensions, most Americans see no other society they prefer: As late as 1971, surveys in eight countries found that Americans were less likely than persons in any other country to wish to live elsewhere (Campbell, Converse, and Rodgers 1976, pp. 281–285). Americans in national public opinion surveys (1998) ranked second among twenty-three countries in pride in the country and in its specific achievements. Thus, popular attitudes continue to reflect a perennial satisfaction and positive nationalism (Smith and Jarkko 1998).

AMERICAN SOCIOLOGICAL ASSOCIATION AND OTHER SOCIOLOGICAL ASSOCIATIONS

The American Sociological Association (ASA) will celebrate its centennial year in 2005; since its inception, it has grown in size, diversity, programs, and purpose. Current ASA goals are as follows:

- Serving sociologists in their work,
- Advancing sociology as a science and as a profession,
- Promoting the contributions and use of sociology to society.

While the first goal remains the *raison d'être* for the membership organization, over the ASA's 100 years, there have been ebbs and flows, support and controversy, about the latter two goals and how the association embodies them.

ASA MEMBERSHIP TRENDS

An interesting perspective on the ASA's history is revealed through an examination of membership trends. Table 1 shows fairly slow but stable growth up until 1931. During the years of the Great Depression, there were substantial declines. Despite these declines, however, sociologists were becoming very visible in government agencies such as the U.S. Department of Agriculture and the U.S. Bureau of the Census. Between 1935 and 1953, for example, there were an estimated 140 professional social scientists, the great majority of them sociologists, employed in the Division of Farm Population and Rural Life. This activity reached its peak between 1939 and 1942, when there were approximately sixty professionals working in Washington, D.C. and in regional offices. Sociologists are well placed in many federal agencies and non-profit organizations in Washington; however, they are "undercover," working under a variety of job titles.

The years following World War II saw a rapid increase in ASA membership—the number nearly quadrupled between 1944 (1,242) and 1956 (4,682). Between 1957 and 1967, membership more than doubled, from 5,223 to 11,445, and continued upward to 15,000 during the heights of the social protest and anti-Vietnam War movements. However, during the latter half of the 1970s, membership gradually drifted downward and reached a seventeen-year low of 11,223 in 1984. In the next fifteen years, the membership increased by 2,000 and has remained stable at over 13,000 in the 1990s.

The growth and decline in the ASA can be accounted for in part by a combination of ideological and demographic factors as well as the gradually changing nature of work in American society, particularly since the end of World War II. For example, the GI bill made it possible for an ordinary veteran to get a college education. The college population jumped from one-half million in 1945 to several million within three years. Gradually, while urban and metropolitan populations grew, the number and percentage of people in the manufacturing sector of the labor force declined, and the farm population declined even more dramatically, while the service sector grew. Within the service sector, information storage, retrieval, and exchange grew in importance with the coming of the computer age. These societal changes helped to stimulate a growth in urban problems involving areas such as family, work, and drugs, and these changes led to a growth of these specialty areas in sociology.

Membership in the ASA rapidly increased in the 1960s and early 1970s, an era of many social protest movements. Sociology was seen as offering a way of understanding the dynamic events that were taking place in this country. Substantive areas within the ASA and sociology were also affected by these social changes. As Randall Collins (1989) points out, the social protest movements of the 1960s and 1970s coincided with the growth within the ASA of such sections as the Marxist, environmental, population, world systems, collective behavior and social movements, and racial and ethnic minorities sections. In addition, the growing public concerns in the late 1970s and early 1980s about aging and equality for women were reflected within the ASA by new sections on sex and gender and aging. Similarly, the "me" generation, in the aftermath of the protest movements and the

Table 1

disillusionment that set in after the Vietnam War, may have contributed both to a decline in student enrollments in sociology courses and in ASA membership. The growth of the college student population and some disillusionment with purely vocational majors, as well as sociology's intrinsic interest to students, led to a gradual rise in membership in the 1990s.

ASA membership trends can also be examined in the context of the availability of research money. Postwar federal support for sociology grew with the development of sponsored research and the growth of research labs and centers on university campuses. Coincident with an increase in ASA membership, research funding from federal agencies during the 1960s and 1970s grew steadily. In the early 1980s, however (particularly in 1981 and 1982), cutbacks in research funding for the social sciences were especially noticeable. In the 1990s, major efforts to educate Congress on the importance of social science research won support for sociology and the other social sciences. The result has been a reversal of the negative trend and a slow but steady improvement in funding, not only for basic research but also in greater amounts for research with an applied or policy orientation.

ASA SECTIONS, PUBLICATIONS, AND PROGRAMS

The increase in the number of sections in the ASA and of membership in them is another sign of growth within the association in the 1990s. Despite a decline in overall ASA membership in the early 1980s, the number of sections increased from nineteen in 1980 to twenty-six in 1989 and to thirty-nine a decade later. The new sections represent some new fields of study (or at least a formal nomenclature for these specialties) such as sociology of emotions, sociology of culture, rational choice, and sociology of sexualities. Furthermore, this overall increase in sections was not achieved by simply redistributing members already in sections but resulted from an actual growth in section members from 8,000 to 11,000 to 19,000 in the three time periods. More than half the ASA members belong to at least one section; the modal membership is in two sections. The ASA has learned from other associations, such as psychology and anthropology, about the possible pitfalls of subgroups within "the whole." The ASA continues to require members to belong to ASA as a condition for joining a section, so that everyone has a connection to the discipline at large as well as to their

specialty groups. This approach has prevented the ASA from becoming a federation of sections and probably has minimized “split off” groups. The annual meeting grew by a thousand participants in the decade of the 1990s, now topping 5,000 people who find professional development in the broad program as well as in section involvement.

The growth of the ASA is also reflected in the growth of the number of journal publications. Since 1936, when the first issue of the *American Sociological Review* was published, ASA publications have expanded to include seven additional journals: *Contemporary Sociology*; *Journal of Health and Social Behavior*; *Social Psychology Quarterly*; *Sociological Methodology*; *Sociological Theory*; *Sociology of Education*; and *Teaching Sociology*. In addition, a *Rose Series* (funded from the estate of Arnold and Caroline Rose) publishes monographs that are important “small market” books in sociology. That series shifted from very specialized academic monographs to integrative pieces of broad appeal. The ASA’s newest journal is a general perspectives journal, aimed at the social science community (including students), and the educated lay public.

The Sydney S. Spivack Program in Applied Social Research and Social Policy (funded from a donation from Spivack’s estate) sponsors Congressional seminars and media briefings on timely topics for which there is a body of sociological knowledge. From these events, the ASA has published a series of issue briefs on topics ranging from youth violence to welfare-to-work to immigration to affirmative action. These publications are useful to ASA members but also to a wider public audience.

The teaching of sociology in kindergarten through high school and in undergraduate and graduate schools has received varying degrees of emphasis over the course of the ASA’s history. In particular, in the late 1970s and early 1980s, when sociology enrollments and membership in the ASA were at a low point, the ASA Teaching Services Program was developed. Now part of the Academic and Professional Affairs Program (APAP), the Teaching Services Program includes providing opportunities through seminars and workshops to improve classroom teaching and to examine a wide range of new curricula for almost all sociology courses. The Teaching Resources Center in the

ASA’s executive office produces over a hundred resources, including syllabi sets and publications on topics such as classroom techniques, curriculum, departmental management, and career information. APAP works concertedly with departments and chairs to build strong departments of sociology and excellent curricula. The ASA sponsors an annual conference for chairs, a meeting of directors of graduate study, and an electronic broadcast, CHAIRLINK, for chairs.

Odd as it may seem, the ASA often did not collect or have access to data on the profession. In 1993, the Research Program on the Discipline and Profession remedied the situation by conducting surveys of members and departments, and a tracking survey of a cohort of Ph.D.s. The program routinely publishes “research briefs” that share these data and aid departments and individuals with planning and trend analysis.

TRANSITION FROM SECRETARIAT TO A PROFESSIONAL ASSOCIATION

The ASA has undergone an organizational transformation over its century of serving the professional interests of sociologists. The shape and mission of the executive office reflects the shifts. In the early years, the office was essentially a secretariat—a place where records were kept, and dues and payments were processed. The first executive officer, Matilda White Riley, appointed in 1963, jokes that the office was a file card box on her kitchen table.

As the American Sociological Society (as it was named until 1959) grew and flourished, it adopted the model of a “learned society,” primarily concerned with the production of new disciplinary knowledge. The society/association centered its resources on the annual meeting and the journals. The executive office personnel, primarily clerical, staffed those functions.

The expansion period of the 1960s and 1970s, and the societal context of those times, led the ASA to add many programs and activities (for a detailed description, see Simpson and Simpson 1994). The ASA transformed into a professional association, with a wider range of services and benefits to its members as well as to a broader

public. As Simpson and Simpson (1994) describe the change: “ASA reacted to the pressures of the 1960s and 1970s mainly by absorbing the pressure groups into its structure. A result has been to expand the goals and functions of the association beyond its initial disciplinary objective. Functions are more differentiated now, encompassing more professional and activist interests” (p. 265). The executive office grew slightly, with the growth in Ph.D.-level sociology staff who led these new ventures. In addition to the executive officer, these sociologists had titles (e.g., Staff Sociologist for Minorities, Women, and Careers) that reflected their work.

In the last ten years, some significant organizational changes have occurred. The executive office has been professionalized, with new hires often having at least a B.A. in sociology. The senior sociology staff direct the core programs (see below) and no longer have fixed terms of employment. As such, the office is more programmatic and proactive.

Key changes in the ASA’s governance include:

- Passage of an ASA mission and goals statement, with six core programs in the executive office (the six programs are:

Minority Affairs; Academic and Professional Affairs; Public Affairs; Public Information; Research on the Discipline and Profession; and the Spivack Program),

- The launch of the ASA's Spivack Program in applied social research and social policy and a continuous, intentional effort to bring research to bear on public policy issues,
- The beginning, and end, of the ASA's certification program,
- The beginning, and end, of the journal *Sociological Practice Review*,
- The beginning of the MOST program (Minority Opportunities for Summer Training for the first five years and Minority Opportunities through School Transformation, for the next five years, funded by the Ford Foundation),
- Greater autonomy for sections and an increase in the number of sections,
- New policies on ASA resolutions and policymaking,
- Revision of the Code of Ethics, as an educative document, which serves as a model for aligned sociological groups,
- Restructuring of ASA committees to a more targeted "task force" model,
- Addition of a new "perspectives" journal,
- Increased attention to science policy and funding, including collaborations with many other groups,
- Increased attention to sociology departments as units, and to chairs as their leaders, as shown in the Department Affiliates program,
- Active collaboration between the ASA and higher education organizations such as the American Association for Higher Education and the American Association of Colleges and Universities.

Members (and nonmember sociologists) have differing views about the current form of the ASA, which is discussed at the end of this article.

The ASA is but one organization in a network of sociological organizations or associations in

which sociologists comprise a significant part of the membership. These groups operate in a complementary way to the ASA; some were formed in juxtaposition to the ASA to fulfill a need the ASA was not serving or to pressure the ASA to change. The genres of these organizations are briefly discussed below.

REGIONAL AND STATE ASSOCIATIONS

In many disciplines, a national association includes state and regional chapters. In sociology, those regional and state groups have always been independent entities, with their own dues, meetings, and journals. Nonetheless, the ASA has worked collaboratively with these associations. The ASA sends staff representatives to their annual meetings, offers to serve on panels and meet with their councils, sends materials and publications, and convenes a meeting of regional and state presidents at the ASA's annual meeting. In the 1960s regional representatives sat on the ASA council. Everett Hughes (1962) provided a sociological critique of this approach to governance, suggesting that the ASA was a disciplinary not a professional association. He argued that the ASA should not be organized as a federation of such representatives, and this regional delegate format ended in 1967. Later, candidates for the Committee on Committees and the Committee on Nominations were nominated by district (not identical to regional associations) to ensure regional representation. That approach ended in 1999.

Twenty-four states (or collaborations among states) have sociological associations. Some are extremely active (e.g., Wisconsin, Minnesota, North Carolina, Illinois, Georgia) and have some special foci that link to their state-based networks. The Georgia Sociological Association, for example, sponsors a workshop for high school teachers; the association also honors a member of the media for the best presentation of sociological work. Wisconsin sociologists used the Wisconsin Sociological Association to organize to defeat a licensure bill that would have prevented sociologists from employment in certain social service jobs. The Minnesota sociologists have made special outreach efforts to practitioners and include these colleagues on their board.

Table 3

ALIGNED ASSOCIATIONS

Many of the aligned associations offer a small, vital intellectual home for sociologists interested in a particular specialty. Over time, a few of these organizations have consciously decided to form a section within the ASA. The various sociology of religion groups did so recently, to have a “place” within the ASA as well as their own meeting and publications. Many of the aligned groups have members from many disciplines including sociology.

INTERDISCIPLINARY TIES

The most significant interdisciplinary organization is the Consortium of Social Science Associations (COSSA), formed in 1980. The budget cutting of the Reagan administration served as a catalyst for the major social science associations to establish this umbrella organization to lobby for funding for social science research. In the 1980s and 1990s, COSSA, with its own professional staff, has become a well-respected voice on social science policy, federal funding, and the professional concerns of social scientists (e.g., data archiving, confidentiality protection, and support for research on controversial topics). COSSA is, of course, an organization of organizations.

In 1997, the ASA offered membership discounts with other societies, so that individuals could join several of these groups. The interdisciplinary discounts now apply to: the American Political Science Association, the American Educational Research Association, the Society for Research in Child Development, and the Academy of Management.

**POLITICAL PRESSURES ON AND IN ASA:
FEMINISM AND ACTIVISM**

Of the many aligned associations, two organizations provide association missions that the ASA does not (or does not sufficiently) satisfy, and have an agenda to change the ASA.

Sociologists for Women in Society (SWS), founded in 1970, has had a two-pronged mission: to use the tools and talents in sociology to improve the lives of women in society; and secondly, to enhance the participation, status, and professional contributions of feminist sociologists. Most SWS members are also ASA members. Originally named the Women’s Caucus, the group’s 1970 statement of demands summarized the gender issues in the ASA quite clearly: “What we seek is effective and dramatic action; an unbiased policy in the selection of stipend support of students; a concerted commitment to the hiring and promotion of women sociologists to right the imbalance that is represented by the current situation in which 67 percent of the women graduate students in this country do not have a single woman sociology professor of senior rank during the course of their graduate training, and when we participate in an association of sociologists in which NO woman will sit on the 1970 council, NO woman is included among the associate editors of the *American Sociological Review*, and NO woman sits on the thirteen member committee on publications and nominations” (Roby, p. 24). Over time, as the founding mothers of SWS moved through their career trajectories, more and more SWS members became part of the leadership of the ASA. In 2000, nine of twenty ASA council members are women. Since its founding, SWS has sought to pressure the ASA in more feminist directions, and to supplement what the

ASA seemed not to offer. SWS runs its annual meeting program parallel to the ASA's annual meeting. In the earlier years, many sessions concentrated on work in sex and gender, as well as on informal networking, and mentoring workshops. Over time, as the ASA's section on sex and gender has become the largest in the association, the SWS program has downplayed scholarly papers on sex and gender, and has emphasized instead informal networking, socializing, and political organizing.

SWS proposed that the ASA publish a journal on *Sex & Gender*, but the ASA declined, due to a rather full publication portfolio. SWS entered an agreement with Sage Publishers to start such a journal, which has been a successful intellectual and business venture. At various points in its history, SWS has been explicit in its watchdog role over the ASA. Members came to observe the ASA council meetings; the membership endorsed candidates for ASA offices; and candidates were asked

to complete a survey that was sent to all SWS members.

The Society for the Study of Social Problems (SSSP), founded in 1951, pursued the insider-outsider strategy as well. The SSSP meets prior to (often with a day of overlap) the ASA annual meeting. As the name implies, the topics for sessions and for the divisions deal with social problems, what sociologists know about them, and their solutions. The SSSP journal, *Social Problems*, is well regarded and well subscribed.

In the 1950s, the ASA centered on positivism and “objective” scientific pursuits. Twenty years earlier, a group of ASA members had warned that the achievement of scientific status and academic acceptance were hindered by the application of sociology to social problems. The motion read, in part: “The undersigned members, animated by an ideal of scientific quality rather than of heterogeneous quantity, wish to prune the Society of its excrescences and to intensify its scientific activities. This may result in a reduction of the members and revenues of the society, but this is preferable to having many members whose interest is primarily or exclusively other than scientific” (Rhoades 1981, pp. 24–25). The SSSP has been a vital counterpoint to those views, keeping sociology’s leftist leanings alive.

THE APPLIED SIDE

In 1978, two new sociological associations formed to meet the needs of sociological practitioners. The Clinical Sociology Association (CSA), now called the Sociological Practice Association (SPA), centered on sociologists engaged in intervention work with small groups (e.g., family counseling) or at a macro-level (e.g., community development). This group emphasized professional training and credentials. Most of the members were employed primarily outside of the academe; many felt they needed additional credentials to meet state licensure requirements or to receive third-party payments, or both. The SPA established a rigorous certification program, where candidates with a Ph.D. in sociology and substantial supervised experience in clinical work, would present their credentials and make a presentation as part of the application for certification. Those who passed this review could use the title Certified Clinical Sociologist.

The Society for Applied Sociology (SAS) was formed by a group of colleagues in Ohio, most of whom are primarily academics, but who engage in extensive consulting and applied work. The core of the SAS centers on applied social research, evaluation research, program development, and other applications of sociological ideas to a variety of organizational settings. The SAS has worked extensively with curriculum and program development to prepare the next generation of applied sociologists. The SAS has also focused on the master’s-level sociologist much more than other organizations.

Both of these practice organizations hold an annual meeting and sponsor a journal. At various times in the twenty years of each group, members have advocated a merger to reduce redundancy, strengthen the membership base, and use resources together. One place where the two groups have worked in tandem is through their joint Commission on Applied and Clinical Programs, which accredits sociology programs that meet the extensive criteria set forth by the commission. In this sense, these applied sociology programs (usually a part or a track within a regular sociology department) are modeling professional programs such as social work, which have an accrediting mechanism. Both societies held a joint meeting prior to the ASA meeting in 2000, which may portend future collaboration.

The history of the ASA shows the ebb and flow in interest in applied sociology, certainly going back to President Lester Frank Ward, and evident again with the election of contemporary Presidents William Foote Whyte, Peter Rossi, and Amitai Etzioni. Within the ASA, there is an active, though not large, section on sociological practice, drawing overlapping membership with the SPA and the SAS. The ASA published a journal, *Sociological Practice Review*, as a five-year experiment (1990–1995) but dropped the publication when there were insufficient subscribers and few manuscripts. In the early 1980s, in response to member interest, the ASA began a certification program, through which Ph.D.-level sociologists could be certified in six areas (demography, law and social control, medical sociology, organizational analysis, social policy and evaluation research, and social psychology). At the master’s level, sociologists could take an exam; passing the test would result in

certification in applied social research. The certification program received few applicants and was terminated by the ASA council in 1998.

Since the 1980s, there have been forces pushing for more involvement of practitioners in the ASA, and thus more membership benefits to serve non-academic members, as the paring down of those benefits (as in the case of the *Sociological Practice Review* and certification) when interest wanes. In part, there is greater “within group” variance among practitioners than “between group” variance between practitioners and academics. Thus while there is clearly a *political constituency* for applied work, it is less clear there is a core intellectual constituency.

In 1981, the ASA held a conference on applied sociology, from which a book of proceedings was published by Jossey-Bass. That event was a springboard for the introduction of applied issues within the ASA. A committee on sociological practice, a section on sociological practice, and an ASA award for a distinguished career in sociological practice were created. In 1999, about 25 percent of ASA members had primary employment in nonacademic positions; the estimate of the number of Ph.D.s (some of whom were nonmembers) in sociological practice was higher. The diversity of the nonacademic membership and their professional needs has been a challenge to the ASA. In a 1984 article in the *American Sociological Review*, Howard Freeman and Peter Rossi wrote of the significant changes that might be needed in departments of sociology and in the reward structure of the profession to reduce the false dichotomy between applied and basic research.

COMMITMENT TO DIVERSITY

The ASA has made concerted efforts to be inclusive of women and minorities in its activities and governance. Since 1976, the ASA has undertaken a biennial report on the representation of women and minorities in the program (invited events and open submissions), on editorial boards, in elections, and in the governance (committees) of the ASA.

In 1987, the ASA appointed a task force on participation designed to identify ways to more fully enfranchise colleagues in two- and four-year colleges. That task force held a number of open hearings and met for five years before issuing a

report of recommendations to the council. As a spin-off from the committee on teaching, a task force on community colleges made recommendations to the council in 1997 and 1998 about how to more actively involve these colleagues in ASA affairs.

The ASA council adopted the following policy in 1997:

Much of the vitality of ASA flows from its diverse membership. With this in mind, it is the policy of the ASA to include people of color, women, sociologists from smaller institutions or who work in government, business, or other applied settings, and international scholars in all of its programmatic activities and in the business of the Association.

At the same time, the demographics of the profession have been shifting (Roos and Jones 1993). Over 55 percent of new Ph.D.s are women, and about 45 percent of ASA members are female. The Minority Fellowship Program, begun in 1974, has provided predoctoral funding and mentoring support for minority sociologists. The program boasts an astounding graduation record of 214 Ph.D.s; many of these colleagues from the early cohorts are now senior leaders in departments, organizations, and in the ASA.

DEMOCRATIZATION OR CONSOLIDATION?

The ASA membership has diverse views about the extent to which the current organizational structure and goals are optimal. Simpson and Simpson argue that core disciplinary concerns have taken a back seat at the ASA; they speak of the “disciplinary elite and their dilution” (1994, p. 271). Their analysis of ASA budgets, as a indicator of priorities, shows shifts from disciplinary concerns (e.g., journals and meetings) to professional priorities (e.g., jobs, teaching, applied work, and policy issues). Other segments of the profession allege that the ASA leadership is too elite (Reynolds 1998) and has a falsely rosy view of the field (p. 20). Demographically and programmatically, the ASA has changed in its century of service to sociology. With a solid membership core and generally positive trends in the profession, the ASA will continue to sit at the hub of a network of sections and aligned organizations.

ANALYSIS OF VARIANCE AND COVARIANCE

Analysis of variance (ANOVA) and analysis of covariance (ANACOVA) are statistical techniques most suited for the analysis of data collected using experimental methods. As a result, they have been used more frequently in the fields of psychology and medicine and less frequently in sociological studies where survey methods predominate. These techniques can be, and have been, used on survey data, but usually they are performed within the analysis framework of linear regression or the "general linear model." Given their applicability to experimental data, the easiest way to convey the logic and value of these techniques is to first review the basics of experimental design and the analysis of experimental data. Basic concepts and procedures will then be described, summary measures and assumptions reviewed, and the applicability of these techniques for sociological analysis discussed.

EXPERIMENTAL DESIGN AND ANALYSIS

In a classical experimental design, research subjects are randomly assigned in equal numbers to two or more discrete groups. Each of these groups is then given a different treatment or stimulus and observed to determine whether or not the different treatments or stimuli had predicted effects on some outcome variable. In most cases this outcome variable has continuous values rather than discrete categories. In some experiments there are only two groups—one that receives the stimulus (the experimental group) and one that does not (the control group). In other studies, different levels of a stimulus are administered (e.g., studies testing the effectiveness of different levels of drug dosages) or multiple conditions are created by administering multiple stimuli separately and in combination (e.g., exposure to a violent model and reading pacifist literature).

In all experiments, care is taken to eliminate any other confounding influences on subjects' behaviors by randomly assigning subjects to groups. As a result of random assignment, preexisting differences between subjects (such as age, gender, temperament, experience, etc.) are randomly distributed across groups making the groups equal in terms of the potential effects of these preexisting differences. Since each group contains approximately equal numbers of subjects of any given age, gender, temperament, experience, etc., there should be no differences between the groups on the outcome variable that are due to these confounding influences. In addition, experiments are conducted in standardized or "physically controlled" situations (e.g., a laboratory), thus eliminating any extraneous external sources of difference between the groups. Through random assignment and standardization of experimental conditions, the researcher is able to make the qualifying statement "Other things being equal. . ." and assert that any differences found between groups on the outcome measure(s) of interest are due solely to the fact that one or more groups received the experimental stimulus (stimuli) and the other group did not.

Logic of analysis procedures. Analysis of variance detects effects of an experimental stimulus by first computing means on the outcome variable for the experimental and control groups and then comparing those means. If the means are the

same, then the stimulus didn't "make a difference" in the outcome variable. If the means are different, then, because of random assignment to groups and standardization of conditions, it is assumed that the stimulus caused the difference. Of course, it is necessary to establish some guidelines for interpreting the size of the difference in order to draw conclusions regarding the strength of the effect of the experimental stimulus. The criterion used by analysis of variance is the amount of random variation that exists in the scores within each group. For example, in a three-group comparison, the group mean scores on some outcome measure may be 3, 6, and 9 on a ten-point scale. The meaningfulness of these differences can only be assessed if we know something about the variation of scores in the three groups. If everyone in group one had scores between 2 and 4, everyone in group two had scores between 5 and 7, and everyone in group three had scores between 8 and 10, then in every instance the variation within each group is low and there is no overlap across the within group distributions. As a result, whenever the outcome score of an individual in one group is compared to the score of an individual in a different group, the result of the comparison will be very similar to the respective group mean score comparison and the conclusions about who scores higher or lower will be the same as that reached when the means were compared. As a result, a great deal of confidence would be placed in the conclusion that group membership makes a difference in one's outcome score. If, on the other hand, there were several individuals in each group who scored as low or as high as individuals in other groups—a condition of high variability in scores—then comparisons of these subjects' scores would lead to a conclusion opposite to that represented by the mean comparisons. For example, if group one scores varied between 1 and 5 and group two scores varied between 3 and 10, then in some cases individuals in group one scored higher than individuals in group two (e.g., 5 vs. 3) even though the mean comparisons show the opposite trend (e.g., 3 vs. 6). As a result, less confidence would be placed in the differences between means.

Although analysis of variance results reflect a comparison of group means, conceptually and computationally this procedure is best understood through a framework of explained variance. Rather than asking "How much difference is there

between group means?" the question becomes "How much of the variation in subjects' scores on the outcome measure can be explained or accounted for by the fact that subjects were exposed to different treatments or stimuli?" To the extent that the experimental stimulus has an effect (i.e., group mean differences exist), individual scores should differ from one another because some have been exposed to the stimulus and others have not. Of course, individuals will differ from one another for other reasons as well, so the procedure involves a comparison of how much of the total variation in scores is due to the stimulus effect (i.e., group differences) and how much is due to extraneous factors. Thus, the total variation in outcome scores is "decomposed" into two elements: variation due to the fact that individuals in the different groups were exposed to different conditions, experiences, or stimuli (explained variance); and variation due to random or chance processes (error variance). Random or chance sources of variation in outcome scores can be such things as measurement error or other causal factors that are randomly distributed across groups through the randomization process. The extent to which variation is due to group differences rather than these extraneous factors is an indication of the effect of the stimulus on the outcome measure. It is this type of comparison of components of variance that provides the foundation for analysis of variance.

BASIC CONCEPTS AND PROCEDURES

The central concept in analysis of variance is that of *variance*. Simply put, variance is the amount of difference in scores on some variable across subjects. For example, one might be interested in the effect of different school environments on the self-esteem of seventh graders. To examine this effect, random samples of students from different school environments could be selected and given questionnaires about their self-esteem. The extent to which the students' self-esteem scores differ from each other both within and across groups is an example of the variance.

Variance can be measured in a number of ways. For example, simply stating the range of scores conveys the degree of variation. Statistically, the most useful measures of variation are based on the notion of the *sums of squares*. The sums of squares is obtained by first characterizing a sample

or group of scores by calculating an average or mean. The mean score can be thought of as the score for a “typical” person in the study and can be used as a reference point for calculating the amount of differences in scores across all individuals. The difference between each score and the mean is analogous to the difference of each score from every other score. The variation of scores is calculated, then, by subtracting each score from the mean, squaring it, and summing the squared deviations (squaring the deviations before adding them is necessary because the sum of nonsquared deviations from the mean will always be 0). A large sum of squares indicates that the total amount of deviation of scores from a central point in the distribution of scores is large. In other words, there is a great deal of variation in the scores either because of a few scores that are very different from the rest or because of many scores that are slightly different from each other.

Decomposing the sums of squares. The total amount of variation in a sample on some outcome measure is referred to as the *total sums of squares* (SS_{total}). This is a measure of how much the subjects’ scores on the outcome variable differ from one another and it represents the phenomenon that the researcher is trying to explain (e.g., Why do some seventh graders have high self-esteem, while others have low or moderate self-esteem?). The procedure for calculating the total sums of squares is represented by the following equation:

$$SS_{\text{TOTAL}} = \sum_i \sum_j (Y_{ij} - \bar{Y}_{..})^2 \quad (1)$$

where, $\sum_i \sum_j$ indicates to sum across all individuals (i) in all groups (j), and $(Y_{ij} - \bar{Y}_{..})^2$ is the squared difference of the score of each individual (Y_{ij}) from the grand mean of all scores ($\bar{Y}_{..} = \sum_{ij} Y_{ij} / N$). In terms of explaining variance, this is what the researcher is trying to account for or explain.

The total sums of squares can then be “decomposed” or mathematically divided into two components: the *between-groups sums of squares* (SS_{BETWEEN}) and the *within-groups sums of squares* (SS_{WITHIN}).

The between-groups sums of squares is a measure of how much variation in outcome scores exists between groups. It uses the group mean as the best single representation of how each individual in the group scored on the outcome measure. It essentially assigns the group mean score to

every subject in the group and then calculates how much total variation there would be from the grand mean (the average of all scores regardless of group membership) if there was no variation within the groups and the only variation comes from cross-group comparisons. For example, in trying to explain variation in adolescent self-esteem, a researcher might argue that junior high schools place children at risk because of schools’ size and impersonal nature. If the school environment is the single most powerful factor in shaping adolescent self-esteem, then when adolescents are compared to each other in terms of their self-esteem, the only comparisons that will create differences will be those occurring between students in different school types, and all comparisons involving children in the same school type will yield no difference. The procedure for calculating the between-groups sums of squares is represented by the following equation:

$$SS_{\text{BETWEEN}} = \sum_j N_j (\bar{Y}_{.j} - \bar{Y}_{..})^2 \quad (2)$$

where, \sum_j indicates to sum across all groups (j), and $N_j (\bar{Y}_{.j} - \bar{Y}_{..})^2$ is the number of subjects in each group (N_j) times the difference between the mean of each group ($\bar{Y}_{.j}$) and the grand mean ($\bar{Y}_{..}$).

In terms of the comparison of means, the between-groups sums of squares directly reflects the difference between the group means. If there is no difference between the group means, then the group means will be equal to the grand mean and the between-groups sums of squares will be 0. If the group means are different from one another, then they will also differ from the grand mean and the magnitude of this difference will be reflected in the between-groups sums of squares. In terms of explaining variance, the between-groups sums of squares represents only those differences in scores that come about because the individuals in one group are compared to individuals in a different group (e.g., What if all students in a given type of school had the same level of self-esteem, but students in a different school type had different levels?). By multiplying the group mean difference score by the number of subjects in the group, this component of the total variance assumes that there is no other source of influence on the scores (i.e., that the variance within groups is 0). If this assumption is true, then the SS_{BETWEEN} will be equal to the SS_{TOTAL} and the group effect could be

said to be extremely strong (i.e., able to overshadow any other source of influence). If, on the other hand, this assumption is not true, then the SS_{BETWEEN} will be small relative to the SS_{TOTAL} because other influences randomly dispersed across groups are generating differences in scores not reflected in mean score differences. This situation indicates that group differences in experimental conditions add little to our ability to predict or explain differences in outcome scores. In the extreme case, when there is no difference in the group means, the SS_{BETWEEN} will equal 0, indicating no effect.

The within-groups sums of squares is a measure of how much variation exists in the outcome scores within the groups. Using the same example as above, adolescents in a given type of school might differ in their self-esteem in spite of the esteem-inflating or -depressing influence of their school environment. For example, elementary school students might feel good about themselves because of the supportive and secure nature of their school environment, but some of these students will feel worse than others because of other factors such as their home environments (e.g., the effects of parental conflict and divorce) or their neighborhood conditions (e.g., wealth vs. poverty). The procedure for calculating the within-groups sums of squares is represented by the following equation:

$$\sum_i \sum_j (Y_{ij} - \bar{Y}_j)^2 \quad (3)$$

where \sum_i , \sum_j indicates to sum across all individuals (i) in all groups (j), and $(Y_{ij} - \bar{Y}_j)^2$ is the squared difference between the individual scores (Y_{ij}) and their respective group mean scores (\bar{Y}_j).

Both in terms of comparing means and explaining variance, the within-groups sums of squares represents the variance due to other factors or “error”; it is the degree of variation in scores despite the fact that individuals in a given group were exposed to the same influences or stimuli. This component of variance can also serve as an estimate of how much variability in outcome scores occurs in the population from which each group of respondents was drawn. If the within-groups sums of squares is high relative to the between-groups sums of squares (or the difference between the means), then less confidence can be placed in the conclusion that any group differences are meaningful.

SUMMARY MEASURES

Analysis of variance procedures produce two summary statistics. The first of these— ETA^2 —is a measure of how much effect the predictor variable or factor has on the outcome variable. The second statistic— F —tests the *null hypothesis* that there is no difference between group means in the larger population from which the sample data was randomly selected.

ETA². As noted above, a large between-groups sums of squares is indicative of a large difference in the mean scores between groups. The meaningfulness of this difference, however, can only be judged against the overall variation in the scores. If there is a large amount of variation in scores relative to the variation due exclusively to between-groups differences, then group effects can only explain a small proportion of the total variation in scores (i.e., a weak effect). ETA^2 takes into account the difference between means and the total variation in scores. The general equation for computing ETA^2 is as follows:

$$ETA^2 = \frac{SS_{\text{BETWEEN}}}{SS_{\text{TOTAL}}} \quad (4)$$

As can be seen from this equation, ETA^2 is the proportion of the total sums of squares explained by group differences. When all the variance is explained, there will be no within-group variance, leaving $SS_{\text{TOTAL}} = SS_{\text{BETWEEN}}$ ($SS_{\text{TOTAL}} = SS_{\text{BETWEEN}} + 0$). Thus, ETA^2 will be equal to 1, indicating a perfect relationship. When there is no effect, there will be no difference in the group means ($SS_{\text{BETWEEN}} = 0$) and ETA^2 will be equal to 0.

F Tests. Even if ETA^2 indicates that a sizable proportion of the total variance in the sample scores is explained by group differences, the possibility exists that the sample results do not reflect true differences in the larger population from which the samples were selected. For example, in a study of the effects of cohabitation on marital stability, a researcher might select a sample of the population and find that, among those in his or her sample, previous cohabitators have lower marital satisfaction than those without a history of cohabitation. Before concluding that cohabitation has a negative effect on marriage in the broader population, however, the researcher must assess the probability that, by chance, the sample used in

this study included a disproportionate number of unhappy cohabitators or overly satisfied noncohabitators, or both. There is always some probability that the sample will not be representative, and the F statistic utilizes probability theory (under the assumption that the sample was obtained through random selection) to assess that likelihood.

The logic behind the F statistic is that chance fluctuations in sampling are less likely to account for differences in sample means if the differences are large, if the variation in outcome scores in the population from which the sample was drawn is small, if the sample size is large, or if all these situations have occurred. Obviously, large mean differences are unlikely due to chance because they would require many more extremely unrepresentative cases to be selected into the sample. Selecting extreme cases, however, is more likely if there are many extremes in the population (i.e., the variation of scores is great). Large samples, however, reduce the likelihood of unrepresentative samples because any extreme cases are more likely to be counteracted by extremes in the opposite direction or by cases that are more typical.

The general equation for computing F is as follows:

$$F = \frac{MS_{\text{BETWEEN}}}{MS_{\text{WITHIN}}} \quad (5)$$

The MS_{BETWEEN} is the mean square for between-group differences. It is an adjusted version of the SS_{BETWEEN} and reflects the degree of difference between group means expressed as individual differences in scores. An adjustment is made to the SS_{BETWEEN} because this value can become artificially high by chance as a function of the number of group comparisons being made. This adjustment factor is called the *degrees of freedom* (DF_{BETWEEN}) and is equal to the number of group comparisons ($k-1$, where k is the number of groups). The formula for the MS_{BETWEEN} is:

$$MS_{\text{BETWEEN}} = SS_{\text{BETWEEN}} / (k-1) \quad (6)$$

The larger the MS_{BETWEEN} the greater the value of F and the lower the probability that the sample results were due to chance.

The MS_{WITHIN} is the mean square for within-group differences. This is equivalent to the SS_{WITHIN} ,

with an adjustment made for the size of the sample minus the number of groups (DF_{WITHIN}). Since the SS_{WITHIN} represents the amount of variation in scores within each group, it is used in the F statistic as an estimate of the amount of variation in scores that exists in the populations from which the sample groups were drawn. This is essentially a measure of the potential for error in the sample means. This potential for error is reduced, however, as a function of the sample size. The formula for the MS_{WITHIN} is:

$$MS_{\text{WITHIN}} = SS_{\text{WITHIN}} / (N-k) \quad (7)$$

As can be seen in equations six and seven, when the number of groups is high, the estimate of variation between groups is adjusted downward to account for the greater chance of variation. When the number of cases is high, the estimation of variation within groups is adjusted downward. As a result, the larger the number of cases being analyzed, the higher the F statistic. A high F value reflects greater confidence that any differences in sample means reflect differences in the populations. Using certain assumptions, the possibility that any given F value can be obtained by chance given the number of groups ($DF1$) and the number of cases ($DF2$) can be calculated and compared to the actual F value. If the chance probability is only 5 percent or less, then the null hypothesis is rejected and the sample mean differences are said to be “significant” (i.e., not likely due to chance, but to actual effects in the population).

ADJUSTING FOR COVARIATES

Analysis of variance can be used whenever the predictor variable(s) has a limited number of discrete categories and the outcome variable is continuous. In some cases, however, an additional continuous predictor variable needs to be included in the analysis or some continuous source of extraneous effect needs to be “controlled for” before the group effects can be assessed. In these cases, analysis of covariance can be used as a simple extension of the analysis of variance model.

In the classical experimental design, the variable(s) being controlled for—the covariate(s)—is frequently some background characteristics or pre-test scores on the outcome variable that were not

adequately randomized across groups. As a result, group differences in outcome scores may be found and erroneously attributed to the effect of the experimental stimulus or group condition, when in fact the differences between groups existed prior to, or independent of, the presence of the stimulus or group condition.

One example of this situation is provided by Roberta Simmons and Dale Blyth (1987). In a study of the effects of different school systems on the changing self-esteem of boys and girls as they make the transition from sixth to seventh grade, these researchers had to account for the fact that boys and girls in these different school systems had different levels of self-esteem in sixth grade. Since those who score high on a measure at one point in time (T1) will have a statistical tendency to score lower at a later time (T2) and vice versa (a negative relationship), these initial differences could lead to erroneous conclusions. In their study, if boys had higher self-esteem than girls in sixth grade, the statistical tendency would be for boys to experience negative change in self-esteem and girls to experience positive change even though seventh-grade girls in certain school systems experience more negative influences on their self-esteem.

The procedure used in adjusting for covariates involves a combination of analysis of variance and linear regression techniques. Prior to comparing group means or sources of variation, the outcome scores are adjusted based upon the effect of the covariate(s). This is done by computing predicted outcome scores based on the equation:

$$\hat{Y} = a + b_1 X_1 \quad (8)$$

where \hat{Y} is the new adjusted outcome score, a is a constant, and b_1 is the linear effect of the covariate (X_1) on the outcome score (Y). The difference between the actual score and the predicted score ($Y_{ij} - \hat{Y}_{ij}$) is the residual. These residuals represent that part of the individuals' scores that is not explained by the covariate. It is these residuals that are then analyzed using the analysis of variance techniques described above. If the effect of the covariate is negative, then those who scored high on the covariate will have their scores adjusted upward. Those who scored lower on the covariate would have their scores adjusted downward. This would counteract the reverse effect that the covariate

has had. Group differences could then be assessed after the scores have been corrected.

This model can be expanded to include any number of covariates and is particularly useful when analyzing the effects of a discrete independent variable (e.g., gender, race, etc.) on a continuous outcome variable using survey data, where other factors cannot be randomly assigned and where conditions cannot be standardized. In such situations, other preexisting difference between groups (often, variables measured on continuous scales) need to be statistically controlled for. In these cases, researchers often perform analysis of variance and analysis of covariance within the context of what has been termed the "general linear model."

GENERAL LINEAR MODEL

The *general linear model* refers to the application of the linear regression equation to solve analysis problems that initially do not meet the assumptions of linear regression analysis. Specifically, there are three situations where the assumptions of linear regression are violated but regression techniques can still be used: (1) the use of nominal level measures (e.g., race, religion, marital status) as independent variables—a violation of the assumption that all variables be measured at the interval or ratio level; (2) the existence of interaction effects between independent variables—a violation of the assumption of additivity of effects; and (3) the existence of a curvilinear effect of the independent variable on the dependent variable—a violation of the assumption of linearity. The linear regression equation can be applied in all of these situations provided that certain procedures and operations on the variables are carried out. The use of the general linear model for performing analysis of variance and analysis of covariance is described in greater detail below.

Regression with dummy variables. In situations where the dependent variable is measured at the interval level of measurement (ordered values at fixed intervals) but one or more independent variables are measured at the nominal level (no order implied between values), analysis of variance and covariance procedures are usually more appropriate than linear regression. Linear regression analysis can be used in these circumstances, however, as long as the nominal level variables are

first “dummy coded.” The results will be consistent with those obtained from an analysis of variance and covariance, but can also be interpreted within a regression framework.

Dummy coding is a procedure where a separate dichotomous variable is created for each category of the nominal level variable. For example, in a study of the effects of racial experience, the variable for race can have several values that imply no order or degree. Some of the categories might be white, black, Latino, Indian, Asian, and other. Since these categories imply no order or degree, the variable for race cannot be used in a linear regression analysis.

The alternative is to create five dummy variables—one for each race category except one. Each of these variables measures whether or not the respondent is the particular race or not. For example, the first variable might be for the category “white,” where a value of 0 is assigned if the person is any other race but white, and a value of 1 is assigned if the person is white. Similarly, separate variables would be created to identify membership in the black, Latino, Indian, and Asian groups. A dummy variable is not created for the “other” category because its values are completely determined by values on the other dummy variables (e.g., all persons with the racial category “other” will have a score of 0 on all of the dummy variables). This determination is illustrated in the table below.

Since there are only two categories or values for each variable, the variables can be said to have interval-level characteristics and can be entered into a single regression equation such as the following:

$$Y = a + b_1D1 + b_2D2 + b_3D3 + b_4D4 + b_5D5 \quad (9)$$

where Y is the score on the dependent variable, a is the constant or Y -intercept, $b_1, b_2, b_3, b_4,$ and b_5 are the regression coefficients representing the effects of each category of race on the dependent variable, and $D1, D2, D3, D4,$ and $D5$ are dummy variables representing separate categories of race. If a person is black, then his or her predicted Y score would be equal to $a + b_2$, since $D2$ would have a value of 1 ($b_2D2 = b_2 * 1 = b_2$) and $D1, D3, D4,$ and $D5$ would all be 0 (e.g., $b_1D1 = b_1 * 0 = 0$). The effect of race would then be the addition of each of the

Respondent's Race	Values on Dummy Variables				
	D1	D2	D3	D4	D5
White	1	0	0	0	0
Black	0	1	0	0	0
Latino	0	0	1	0	0
Indian	0	0	0	1	0
Asian	0	0	0	0	1
Other	0	0	0	0	0

dummy variable effects. Other dummy or interval-level variables could then be included in the analysis and their effects could be interpreted as “controlling for” the effects of race.

Estimating analysis of variance models. The use of dummy variables in regression makes it possible to estimate analysis of variance models as well. In the example above, the value of a is equal to the mean score on the dependent variable for those who had a score of “other” on the race variable (i.e., the omitted category). The mean scores for the other racial groups can then be calculated by adding the appropriate b value (regression coefficient) to the a value. For example, the mean for the Latino group would be $a + b_3$. In addition, the squared multiple correlation coefficient (R^2) is equivalent to the measure of association used in analysis of variance (ETA^2), and the F test for statistical significance is also equivalent to the one computed using conventional analysis of variance procedures. This general model can be further extended by adding additional terms into the prediction equation for other control variables measured on continuous scales. In effect, such an analysis is equivalent to an analysis of covariance.

APPLICABILITY

In sociological studies, the researcher is rarely able to manipulate the stimulus (or independent variable) and tends to be more interested in behavior in natural settings rather than controlled experimental settings. As a result, randomization of preexisting differences through random assignment of subjects to experimental and control groups is not possible and physical control over more immediate outside influences on behavior cannot be attained. In sociological studies, “other things” are rarely equal and must be ruled out as possible alternative explanations for group differences through “statistical control.” This statistical control is best accomplished through correlational

techniques, although in certain circumstances the analysis of covariance can be used to statistically control for possible extraneous sources of influence.

Where analysis of variance and covariance are more appropriate in sociological studies is: (1) where the independent variable can be manipulated (e.g., field experiments investigating natural reactions to staged incidences, or studies of the effectiveness of different modes of intervention or teaching styles); (2) analyses of typologies or global variables that capture a set of unspecified, interrelated causes or stimuli (e.g., comparisons of industrialized vs. nonindustrialized countries, or differences between white collar vs. blue collar workers); or (3) where independent (or predictor) variables are used that have a limited number of discrete categories (e.g., race, gender, religion, country, etc.).

ANOMIE

The concept *anomie* was used by early sociologists to describe changes in society produced by the Industrial Revolution. The demise of traditional

communities and the disruption of norms, values, and a familiar way of life were major concerns of nineteenth-century philosophers and sociologists. For sociologists, anomie is most frequently associated with Emile Durkheim, although others used it differently even during his lifetime (Wolff 1988).

Durkheim ([1893] 1956) used the French word *anomie*, meaning “without norms,” to describe the disruption that societies experienced in the shift from agrarian, village economies to those based on industry. Anomie is used to describe a state of society, referring to characteristics of the social system, not of individuals, although individuals were affected by this force. Increasingly, this term has taken on a more social psychological meaning. This is not to say that it no longer has uses consistent with the initial definition, but its meaning has been broadened considerably, at times consistent with Durkheim’s usage, at times at substantial variance with it.

There are, no doubt, sociologists who cringe at any expanded usage of this and other concepts, but the fact of the matter is that we have no more control over its usage than Thomas Kuhn (1970) has over abominable uses of the concept “paradigm,” or than computer engineers have over those who say “interface” when they mean “meet with.” Although we cannot completely stop the misappropriation of such terms as anomie we can be careful that sociological extensions of anomie are logically derived from their early uses.

DURKHEIM ON ANOMIE

According to Durkheim, village life based on agriculture had consistent, well-established norms that governed the day-to-day lives of individuals. Norms prescribed patterns of behavior, obligation, and expectations. Durkheim called this pattern of social life mechanical solidarity. Communities characterized by “mechanical solidarity” were self-contained units in which the family and the village provided for all of the needs of their members. With the emergence of industrial capitalism and the beginnings of population shifts from the hinterland to cities, mechanical solidarity could not successfully structure social life. Durkheim believed that a new, “organic solidarity” based on a division of labor would emerge, with a regulating normative structure that would be as functional as mechanical solidarity. The emergence of organic

solidarity would take time, however. The transitional period, characterized by normative disorganization, Durkheim described as anomic. By this he did not mean to imply literal normlessness but, rather, a state of *relative* normative disorder (Coser 1977). Compared with communities characterized by mechanical solidarity, developing larger towns and cities would have a less regulated, less structured, less ordered pattern of social life.

Release from the restraining influence of norms was not a liberating circumstance, according to Durkheim. In this state, without adequate normative direction, people did not know what to expect or how to behave. Many of the social problems that Durkheim witnessed in rapidly changing industrializing Europe, he blamed on inadequate normative regulation. In his classic *Suicide*, Durkheim ([1897] 1951) identifies “anomic suicide” as occurring when the values and norms of the group cease to have meaning or serve as anchors for the individual, leading to feelings of isolation, confusion, and personal disorganization.

CONTEMPORARY USES OF “ANOMIE”

Anomie continues to be used as defined by Durkheim, but it has also been extended during the twentieth century. In addition to extensions similar to past uses of this concept, social psychological conceptions of anomie have become widespread. Robert Merton’s use of “anomie” is very similar to that described by Durkheim. His application (1949) has been the core theoretical statement in one of the twentieth century’s major criminological traditions. “Anomia” is a social psychological derivative used to represent a state of disaffection or disconnectedness.

Merton on Anomie. Merton (1949) used the concept anomie to describe how social structure produced individual deviance. According to Merton, when there existed within a society a disjuncture between the legitimate goals that members of a society were aspiring to and the legitimate means of achieving these goals, then that society was in a state of anomie. For both Durkheim and Merton, frustrated aspirations were an important cause of norm violations, or deviance. They differed in what they saw as the source of aspirations. For Durkheim, it was human nature to have limitless desires, growing from a natural “wellspring” within. Merton argued that desires did not come from

within us, but were advanced by a widely held conception of what constitutes “the good life.”

Durkheim believed that when a society was characterized by anomie, there were inadequate normative constraints on the desires and expectations of people. Peasants could come to believe, even expect, that they could rise to live like the aristocracy, or become captains of newly developing industry. Part of mechanical solidarity was the norms that constrained these expectations, that ordered the intercourse between social classes, that checked the natural wellsprings of desires and encouraged peasants to be happy with their lot in life. Without these checks, desires exceeded reasonable hope of attainment, producing frustration and potentially deviance.

Merton’s conception of anomie placed the society itself in the position of determining both the legitimate goals that people should aspire to and the legitimate means of pursuing these goals. While this goal has often been expressed by researchers as wealth attainment, Merton (1997) believed that wealth attainment was only one example of many societal goals. Unfortunately, society frequently caused people to have grandiose expectations without providing all of its members with reasonable opportunities to pursue them legitimately. This circumstance, where the goals and the means were not both universally available to the members of a society, Merton called anomie.

When individuals were faced with anomie, they had to choose whether to forgo the socially advanced goals, their society’s shared vision of the good life, or to seek these objectives by means not defined as legitimate. Merton described five choices available to these individuals. With “conformity,” the individual uses the socially prescribed means to obtain the goals advanced by that society. “Innovation” is the choice to use illegitimate means to achieve the legitimate goals; much criminal behavior is an example of innovation. When a person goes through the motions of using the legitimate means, fully aware that the socially advanced goals are beyond his reach, this is “ritualism.” “Retreatism” is the choice neither to use the legitimate means nor to strive for the legitimate goals of a society. Finally, “rebellion” is rejecting the society’s means and goals and replacing them with ones defined by the individual as superior.

A common mistake is interpreting Merton as arguing that an individual chooses to live his or her life as a conformist, or innovator, or retreatist. To the contrary, Merton's position is that we all are constantly making choices when faced with behavioral alternatives. At one point during the day one might choose to act as a conformist, but later, when confronted with another choice, one may choose to innovate. For example, a person who engages in robbery, innovation, is not always an innovator; he or she may also have a job, which indicates conformity. While one of these choices may predominate with some people, they should be seen as alternatives that people choose from in deciding how to act in a particular instance, not identities that they assume.

In applying Merton's perspective to Western nations, sociologists have argued that most of these societies are characterized by some degree of anomie, which manifests itself as a lack of equal opportunity. The extent of anomie, the degree of disjuncture between goals and means in a society, can be used to predict the level of crime and deviance that society will experience. The high crime rates of the United States can be linked to great inequalities in income, education, and job opportunities (Loftin and Hill 1974). To explain individual propensity to deviate from norms, one must consider the extent to which individuals have accepted the society's conception of "the good life," and the legitimate means individuals can use to attain it (Cloward and Ohlin 1960). As an explanation of crime, this theory has given way to different approaches, but anomie has been absorbed into larger perspectives to explain the relationship between poverty and crime (Messner 1983).

New Approaches to Anomie. Anomie saw a theoretical resurgence in the late 1980s and 1990s (Agnew and Passas 1997), especially in criminological research. This resurgence first occurred with Agnew's (1985) *general strain theory* and later, with macro-variations such as *institutional anomie* (Messner and Rosenfeld 1994).

Strain Theory. While many have been critical of anomie and strain theories of the past (Hirschi 1969; Kornhauser 1978), Agnew (1985, 1992) argues that research in the areas of medical sociology, social psychology, and psychology can help create new directions for this theory. Agnew (1992)

has proposed a micro-level theory; that "Adolescents are pressured into delinquency by the negative affective states—most notably anger and related emotions—that often result from negative relationships" (p. 48). His extension of traditional strain theories focuses on more than one form of strain or anomie. Agnew (1992) suggests there are three major types of strain that can be experienced by individuals: strain (1) "as the failure to achieve positively valued goals," (2) "as the removal of positively valued stimuli," and (3) "as the presentation of negative stimuli." This extension of anomie or strain theories allows our understanding of the creation of anomie to move even farther away from that first misconception that it *must* be connected to wealth attainment.

Institutional Anomie Theory. Most research on anomie has been at the micro-level (Agnew and Passas 1997). For example, variations such as Agnew's general strain theory have ignored the theoretical implications at the macro-level (Agnew and Passas 1997; see also Bernard 1987; Messner 1988; Messner and Rosenfeld 1994; Rosenfeld 1989). Institutional anomie theory posits that in order to understand any social phenomena we must understand the basics of social organization. These basics are culture and social structure and are best understood by their linking mechanism, social institutions (Messner and Rosenfeld 1994; Rosenfeld and Messner 1997). Rosenfeld and Messner (1994, 1997) suggest that social institutions are both interdependent and in conflict with one another, which leads to a constant, necessary balancing of institutional demands. According to Rosenfeld and Messner (1997) the economy is at the center of this balancing act. Institutional anomie theory helps explain the effect of the domination of the economy over other institutions by suggesting that "economic dominance stimulates the emergence of anomie at the cultural level, and . . . erodes the structural restraints against crime associated with the performance of institutional roles" (Rosenfeld and Messner 1997, p. 213). Institutional anomie theory which, up until this stage, has been used to explain trends in crime, could successfully be extended to other social phenomena.

Social Psychological Conceptions of Anomia. Items designed to measure individual feelings of anomia are now frequently included in surveys such as the General Social Survey, an annual national survey conducted by the National Opinion

Research Center (NORC) at the University of Chicago. Examples of these items illustrate the current uses of the concept, as in the following anomia items from the 1988 NORC survey (respondents were instructed to indicate the extent of their agreement with each statement): “Most public officials (people in public office) are not really interested in the problems of the average man,” and “It’s hardly fair to bring a child into the world with the way things look for the future” (NORC 1988, pp. 215–216). (Nearly 40 percent of the respondents to the second question agreed, and 68 percent agreed with the first.)

IN SUMMARY

Anomie has been and will continue to be a mainstay concept in sociology. Papers discussing the meanings and uses of this concept continue to be written (see, for example, Adler and Laufer 1995; Bjarnason 1998; Deflem 1989; de Man and Labreche-Gauthier 1993; Hackett 1994; Hilbert 1989; Menard 1995; Passas and Agnew 1997; Wolff 1988). The basic meaning of the term anomie, though—both in its initial usage as a description of society and in its modern extensions—is well established and widely understood within the discipline. Students new to sociology should take care to understand that the definitions of the word may not be as broad for sociologists as for the general public. The utility of the concept for the study of society is best maintained by extending it in ways that are consistent with its original definition.

APPLIED SOCIOLOGY

Applied sociology is sociology in use. It is policy-oriented, action-directed, and intends to assist people and groups to think reflectively about what it is they do, or how it is they can create more viable social forms capable of adapting to changing external and internal conditions. The roots of applied sociology in the United States go back to the publication in 1883 of Lester Ward’s *Dynamic Sociology: or Applied Social Science*, a text in which he laid the groundwork for distinguishing between an understanding of causal processes and how to intervene in them to foster social progress. Today applied sociology has blossomed in every arena of sociological endeavor (Olsen and Micklin 1981).

The nature of applied sociology can more easily be grasped by examining those characteristics that distinguish it from basic sociology. Different audiences are involved (Coleman 1972). Basic sociology is oriented toward those who have a concern for the advancement of sociological knowledge. The quality of such work (quantitative or qualitative,) is evaluated in accordance with agreed-upon standards of scientific merit. Applied sociology is oriented more toward those who are making decisions, developing or monitoring programs, or concerned about the accountability of those who are making decisions and developing programs. The quality of applied work is evaluated in accordance with a dual set of criteria: (1) how useful it is in informing decisions, revealing patterns, improving programs, and increasing accountability; and (2) whether its assumptions and methods are appropriately rigorous for the problems under investigation.

If we were to imagine a continuum between pure research and pure practice, applied sociology would occupy a space in the middle of this continuum. This space is enlarged along one boundary when practitioners and applied sociologists collaborate to explain patterns of behavior or develop causal models for predicting the likely impact of different courses of action. It is enlarged on the other boundary when applied and basic sociologists collaborate in the elaboration of abstract theory so as to make it more useful (Lazersfeld and Reitz 1975). There is always tension between the two, however. In part, the tension is attributable to the analytic distance that should characterize sociological analysis more generally (Lofland 1997). In part, it is attributable to the infusion of an ethical position in applied analysis, a posture which, if nothing else, is sensitive to the operation of power.

The boundaries of applied sociology may also be specified by enumerating the activities that play a central role in what it is that applied sociologists do. Freeman and Rossi (1984) have suggested three activities: (1) mapping and social indicator research, (2) modeling social phenomena, and (3) evaluating purposive action. To this could be added at least one more activity: (4) conceptualizing, studying, and facilitating the adaptability of alternative social forms. Examining these activities also permits considering some of the presumed trade-offs that are commonly thought to distinguish basic from applied sociology.

Mapping and social indicator research. Such studies are primarily descriptive, and designed to provide estimates of the incidence and prevalence of phenomena that are social in nature. There may be interest in how these phenomena are distributed in different social categories (e.g., by ethnic group affiliation, lifestyles, or social classes) or are changing over time. For example, corporations may wish to know how consumption patterns for various goods are changing over time for different groups to facilitate the development of marketing strategies. Federal and state agencies may wish to understand how the incidence and prevalence of diseases for different social groups is changing over time to develop more effective prevention and treatment strategies. Neighborhood groups may wish to know how citizen complaints regarding the police, high school graduation, or cervical cancer rates are distributed in relation to income characteristics of neighborhoods.

It is often assumed that applied sociology is less rigorous than basic sociology. Freeman and Rossi (1984) suggest that it is more appropriate to argue that the norms governing the conduct of basic sociological research are universally rigorous, while the norms governing the conduct of applied sociological research, of which mapping and social indicator research are but two examples, have a sliding scale of rigor. For critical decisions, complex phenomena that are either difficult to measure or disentangle, or where precise projections are needed, sophisticated quantitative or qualitative measures, or both, may be required and sophisticated analytic techniques may be needed, or may need to be developed. But as time and budget constraints increase, and the need for precision decreases, “quick and dirty” measures might be more appropriate. The level of rigor in applied sociology, in short, is driven by the needs of the client and the situation as well as the nature of the problem under investigation.

Modeling social phenomena. The modeling of social phenomena is an activity common to both basic and applied sociology. Sociologists of both persuasions might be interested in modeling the paths by which adolescents develop adaptive or maladaptive coping strategies, or the mechanisms by which social order is maintained in illicit drug networks. The applied sociologist would need to go beyond the development of these causal models. For the adolescents, applied sociologists would

need to understand how various interventions might increase the development and maintenance of adaptive strategies. In the case of drug networks, they might need to understand the relative effectiveness of different crime-control strategies in reducing the capacity of drug networks to protect themselves.

Just as with mapping and social indicator research, while there are norms supporting rigor to which basic researchers should adhere in the development of causal models, there is usually a sliding scale of rigor in applied research. There is not a necessary trade-off between doing applied work and levels of rigor. It usually happens, however, that applied problems are relatively more complex and tap into concepts that are less easy to quantify. In trying to capture more of the complexity, precision in the specification of concepts and elegance of form of the overall model may be traded off against an understanding of dynamics that is sufficient to inform decisions.

For both basic and applied work it is imperative that the mechanisms by which controllable and uncontrollable concepts have an impact on the phenomenon of interest are properly specified. Specification decisions must be made with respect to three aspects of the dynamics of situations (Britt 1997). First, the nature of what concepts are (and what they are not) must be specified with regard to the contextually specific indicators that give them meaning. Second, the concepts that are considered sufficiently important to be included in a model (as well as those that are deemed sufficiently unimportant to be left out) must be specified. Finally, the nature of relationships that exist (and do not exist) among the included concepts must be specified. Since these specification decisions interpenetrate one another (i.e., have implications for one another) over time, it may be prudent to think of models as vehicles for summarizing what we think we know about the dynamics of situations (Britt 1997).

The clients of applied researchers, however, are not interested in how elegant models are, but in how well the implications of these models assist them in reducing the uncertainty associated with decisions that must be made. As time and budget constraints increase, or researchers become more confident in their ability to understand which controllable concepts are having the biggest (or

most unanticipated) impact, less formal techniques may be used to develop and evaluate the models under consideration. Elegance must be balanced against usability. Complexity must be balanced against communicability. Theoretical sophistication must be balanced against the capacity of a model to interpret the lives of individuals and groups living through situations.

Evaluating purposive action. Evaluation research is an applied activity in which theories and methods of the social sciences are used to ascertain the extent to which programs are being implemented, services are being delivered, goals are being accomplished, and these efforts are being conducted in a cost-effective manner. These may be relatively small-scale efforts with finite and specific research questions. A manufacturing company may be interested in evaluating the impact of a new marketing program. A drug rehabilitation center may be interested in evaluating the cost-effectiveness of a new treatment modality. A movement organization may be interested in the situational effectiveness of particular strategies for fostering policies that are conducive to the reduction in infant-mortality differentials or the production of higher graduation rates in high-risk areas, or to a more equitable allocation of tax revenues (Maines and McCallion 2000).

These programs may or may not be of national importance, may or may not have large sums of money contingent on the outcomes, and may or may not require an understanding of anything but gross effects. It may be necessary to perform such analyses with limited personnel, time, and money. Under such circumstances, relatively unsophisticated methods are going to be used to conduct the evaluations and reanalysis will not be likely.

On the other hand, programs may involve the lives of many people, and deal with critical and complex social issues. The Coleman report on the equality of educational opportunity was presumably intended to establish once and for all that gross differences in school facilities did exist for black and white children in the United States (Coleman et al. 1966). The report, carried out by a team of sophisticated social scientists in a relatively short time, unleashed a storm of reanalyses and critiques (e.g., Mosteller and Moynihan 1972). These reanalyses attempted to apply the most

sophisticated theoretical and methodological weapons in the sociological arsenal to the task of evaluating the implications of the Coleman report. Similarly, econometric analyses initially conducted to evaluate the impact of capital punishment on the homicide rate spawned very painstaking and sophisticated applied research (e.g., Bowers and Pierce 1975) in an attempt to evaluate the robustness of the conclusions. In these latter two cases, a high level of rigor by any standard was maintained.

Conceptualizing, studying, and facilitating the adaptability of alternative social forms. A legitimate test of applied sociology is whether it can be used as a basis for designing and implementing better social institutions (Street and Weinstein 1975). An element of critical theory is involved here that complicates the distinction between basic and applied sociology, for it challenges applied sociologists and their clients to imagine: (1) alternative social forms that might be more adaptive in the face of changing social, environmental, and technological trends; and (2) alternative environments that must be sought if equitable social forms are to exist. At the level of families, this may mean asking what new role relationships could create more adaptive family structures. Alternatively, it might mean asking in what normative environments egalitarian family roles might exist. Or perhaps, asking what the impact of pressure for reproductive rights might be on the influence of women in families and communities. At the level of work groups faced with changing technologies and dynamic environments, it is appropriate to ask whether flatter organizational structures and more autonomous work groups might better serve both organizational goals and those of its members (e.g., Myers 1985). At the community level, exploring the viability of alternative interorganizational relationships, or how communities respond to the threat of drug dealing are among a host of legitimate questions. Whatever the specific focus of such questions and the role of applied sociologists in working with clients to answer them, questions of power and ethics should never be far away.

In applied sociology, problems drive the development of both theory and method. When problems and their dynamics cannot be explained by existing theories, new assumptions are added (Lazerefeld and Reitz 1975), new ways of thinking about concepts like adaptability are developed

(e.g., Britt 1989), or more fundamental theoretical shifts take place in a manner described by Kuhn (1961). When problems cannot be studied using existing methodological and statistical techniques, new techniques are developed. For example, the computer was developed under a contract from the Census Bureau so that the 1950 census could be conducted, and advances in area sampling theory were stimulated by the Department of Commerce needing to get better unemployment estimates (Rossi 1986). Ragin (1987) developed qualitative comparative analysis to permit the rigorous analysis of relatively rare events such as revolutions. Yet the applied implications of being able to study the alternative combinations of conditions that might give rise to particular outcomes has immense applied value (Britt 1998).

The continuing pressure on applied sociology to adapt to the needs of clients has had two important second-order effects beyond the development of theory and method. The nature of graduate training for applied sociologists is changing by virtue of the wider repertoire of skills needed by applied sociologists, and the dilemmas faced by sociologists vis-à-vis their clients are being confronted, and norms regarding the appropriateness of various courses of action are being developed.

A universal component of graduate applied education is the internship. Learning by doing, and experiencing the array of problems associated with designing and conducting research under time and budget constraints, while still having supportive ties with the academic program, are very important. The range and depth of coursework in qualitative and quantitative methods and statistics is increasing in applied programs to prepare students for the prospect of needing to employ techniques as varied as structural equations, focus groups, archival analysis, and participant observation in order to deal with the complexity of the problems requiring analysis.

There have been corresponding changes in the area of theory, with more emphasis given to moving back and forth from theory to applied problem. And there have been increases in courses designed to train students in the other skills required for successful applied work: networking, problem decomposition, and dealing with client-sociologist dilemmas.

ART AND SOCIETY

There is no consensus as to what art is nor, until the 1970s, had sociologists expended much energy on its study or on the development of a sociology of the arts. While in Europe art had longer been of interest to sociologists than in the United States, even there it had not developed into an identifiable field with clear and internationally accepted parameters. As recently as 1968 the term *sociology of art* was not indexed in the *International Encyclopaedia of the Social Sciences*, which sought to sum and assess the thinking and accomplishments in the rapidly expanding social sciences of the post-World War II period. Yet by the end of the century the study of art had moved into the mainstream of sociological theory and was rapidly becoming a

avored subject for empirical investigation not only in the countries of Central and Western Europe but also in the United States.

Why should art, as a subject for sociological study, have been so neglected as to have virtually disappeared from mention in American textbooks for half a century after World War I? In large part this reflected the inherent tension between sociology and art, which, as noted by Pierre Bourdieu, make an “odd couple.” Artists, believing in the uniqueness of the original creator, resented the social scientist’s attempt to demystify their achievements by dissecting the role of the artist in society, by questioning to what extent artists are “born” rather than “made,” by conceptualizing artistic works as the products of collective rather than individual action, by anthropologically approaching art institutions, by studying the importance of networks in artistic success, and by investigating the economic correlates of artistic productivity. Many scholars in the humanities were also skeptical. For them the appeal of art is something of a mystery and best left that way; they could hardly relate to the attempts of social scientists who, in their quest for objectivity, sought to eliminate any evaluative component from their own research. This practice of disregarding one’s own personal preferences and tastes hardly seemed legitimate to aestheticians. Moreover, in pursuing a rigorous methodology, many sociologists chose to study only those problems that could yield readily to statistical analysis, and art did not seem to be one of those. They also preferred to focus on subjects that were important in the solution of social problems, and, in the United States, the arts were not generally regarded as high on this list.

Nonetheless, there has been—especially since the late 1960s—a slow but steady movement toward the development of a sociology of the arts. This is due, in part, to a narrowing of the intellectual gulf between the humanistic and sociological approaches. On the one hand, art historians have legitimated the study of art within its social context, and, on the other, mainstream sociology has become more hospitable to the use of other than purely “scientific” methodology. In part this progress resulted from the expanded contacts of American sociologists after World War II with their counterparts in other countries where art is regarded as a vital social institution and a public good. And just as art must be understood and

studied within its social context, so too the growing sociological interest in the arts reflects the growing importance of the arts within American society and the recognition of this importance by the government. Despite the concerted opposition of those who believe there is no role for government in funding the arts, at every level of government—federal, state, and local—arrangements for the support of grassroots arts have become institutionalized.

A small but dedicated number of scholars can be credited with sparking this postwar advancement of theory and research in the sociology of culture and, more specifically, in the sociology of the arts. The latter term, though not unknown before then, began to surface with some frequency in the 1950s; thus, in 1954 a session on the sociology of art was listed in the program of the annual meeting of the American Sociological Association. In 1957 a symposium on the arts and human behavior at the Center for Advanced Study in the Behavioral Sciences served as a catalyst for the production of a book, based partially on papers presented there. In its preface, the editor, Robert N. Wilson, concluded that a sociology of art, though in the early stages of its development, was not yet ripe for formalization. Nonetheless, Wilson’s book included a number of articles based on empirical research that attracted attention. In one, Cynthia White, an art historian, and Harrison White, a Harvard sociologist, reported on their investigation into institutional change in the French painting world and how this affected artistic careers. Later expanded and published in book form as *Canvases and Careers* (1965), this research provides a working example of how a changing art form might best be studied and understood within its historical and social context.

Perhaps the most important step toward the development of the field in these postwar years came with the publication of a collection of readings edited by Milton Albrecht, James Barnett, and Mason Griff (1970). Clearly titled as to subject matter—*The Sociology of Art and Literature*—it was intended to serve a classroom purpose but also to advance an institutional approach to its study. In one article, originally published in 1968, Albrecht oriented the reader to art as an institution, using *art* as a collective term for a wide variety of aesthetic products, including literature, the visual arts, and music. In another (“The Sociology of Art”),

Barnett reprinted his state-of-the-field synthesis as it stood in 1959, and, in yet another, Griff published a seminal article on the recruitment and socialization of artists, drawing in some part on his earlier empirical studies of art students in Chicago. Though here, too, the editors spoke of the sociology of art as being still in its infancy, they helped it to take its first steps by including in their reader a large number of empirically grounded articles—by scholars in the humanities as well as the social sciences. Divided into six subjects—forms and styles, artists, distribution and reward systems, tastemakers and publics, methodology, history and theory—it served for many years as an exemplary resource both for those attempting to set up courses on the arts and society and those embarking on research.

Beginning in the 1970s the sociology of art moved toward formalization and started to come into its own. Speeding this development in the new age of television dominance was a growing sociological interest in the mass media, in visual communications, and in the popular arts. The debate about mass versus popular culture was revitalized by new fears about the effects of commercialization, but some scholars began to wonder about the terms in which the debate was being cast. The assumption that art forms could be categorized as “high” or “low” or, put another way, as “mass” or “elite”—an assumption that had fueled the critiques of Theodor Adorno and other members of the Frankfurt School—came into question as reputable researchers looked more closely at the empirical evidence (Gans 1974). Howard S. Becker’s conceptualization of art as collective action (1982) did not so much mute the debate as turn attention away from the circumstances surrounding the production of any particular work—that is, what kind of an artist produced work for what kind of audience under what system of rewards—toward the collective (cooperative) nature of the activity whereby works regarded as art are produced as well as to that collective process itself. As attention turned to the production of culture, the arts came to be widely regarded by sociologists as socially constructed entities whose symbolic meanings reside not in the objects themselves but change as circumstances change.

Recent American studies in the sociology of art have taken varied approaches, both as to subject matter and methodology. Some have focused

on genres that are considered marginal to established categories of fine art, including such “outsider art” as that produced by asylum inmates, “naive artists,” African primitives, and Australian aborigines. Others have researched the process whereby “outsider artists” may make the transition to being “insiders” while still others, extending their interests to the politics of art, have considered what happens to “insiders” (and the art they have produced) when shifts in the political culture recast them as “outsiders.” Sociologists have also extended their inquiries to the economics of art as they have considered the influence of funding and the structure of museums on the creation, production, preservation, and dissemination of art works; case studies of “arts management” abound.

Some inquiries involving genres marginal to established categories of fine art have adopted methodologically unusual approaches. These include Wendy Griswold’s studies of the social factors influencing the revival of Renaissance plays (1986); Robert Crane’s study of the transformation of art styles in post-World War II New York (1987); Liah Greenfeld’s study of taste, choice, and success in the Israeli art worlds (1989); Vera Zolberg’s studies of art patronage and new art forms (1990); and Gladys Lang and Kurt Lang’s study of the building and survival of artistic reputations (1990).

These and other empirical studies that have already appeared in print or are under way are helping to clarify what is meant by a sociology of art. While there still may be no consensus as to what art is—nor need there be—some consensus is shaping up as to the direction in which the field should be moving. Leading theoreticians—Vera Zolberg, Janet Wolff, Paul DiMaggio, Richard Peterson, and Anne Bowler among them—agree on the need to keep the art itself at the center of theoretical concern but continue to disagree on the proper methodological approach to that “centering.” Essentially, this pits the case for focusing on the institutions in which aesthetic objects are produced and received—an analytical approach—against one that emphasizes criticism and textual interpretation of the objects themselves. Zolberg has voiced the need to avoid the narrowness of both social science and aesthetic disciplines, accepting the premise that art should be contextualized in terms of time and place in a general sense as

well as in a specific sense, that is, in terms of institutional norms, professional training, reward, and patronage or other support. To approach art as a part of society's culture, Zolberg argues, is no more potentially reductionist than to treat it, as aestheticians do, as an activity that only restricted groups with special interests and knowledge can hope to comprehend. Literature in the field is growing at a rapid rate as intellectual barriers between humanistic and social science approaches to the study of art begin to crumble.

ASIAN-AMERICAN STUDIES

The term *Asian American* is used in the United States by federal, state, and local governments to designate people of Asian descent, including Pacific Islanders (residents from the Pacific islands that are under U. S. jurisdiction, such as Guam, American Samoa, and the Marshall Islands). Although historically relevant and geographically appropriate, inclusion of the Pacific islands in the generic term *Asian American* stemmed from administrative convenience for the federal government rather than from race or ethnic identifications.

Reflecting deep-seated prejudices against people of color, in 1917 the Congress of the United States created the Asiatic Barred Zone, which stretched from Japan in the east to India in the west. People from within the zone were banned from immigration. The geographic concept was incorporated into the Immigration Act of 1924 (Oriental Exclusion Act), a law that had a profound impact on the demographic structure of Asian-American communities as well as on U.S. foreign policy. Although it is generally assumed that the term *Asian American* has a racial basis,

particularly from the perspective of U.S. immigration history, the racial overtone is muted by the inclusion in the 1980 census of people from India in the "Asian and Pacific Islander" category; they had been classified as "white" prior to 1980.

IMMIGRATION AND RESTRICTIONS OF ASIAN AMERICANS

Asian immigration can be divided into two periods: the old and the new. The old immigration period was marked by nonoverlapping waves of distinct Asian populations who came largely in response to the sociopolitical conditions in their homelands and to the shortage of unskilled labor experienced by special-interest groups in the United States. The new immigration was characterized by the simultaneous arrival of people from the Asia-Pacific Triangle, spurred principally by the 1965 legislative reforms in U.S. immigration policy, shortages of certain skilled and professional labor, the involvement of United States in Asia, and the sociopolitical situations in Asia in the context of the Cold War. In between these two waves, there was another wave of Asian immigrants, who came between the end of World War II and the mid 1960s, though the number was small and involved principally Filipinos and their families because of their services in the US military. This group came outside the fifty-person quota allowed for Filipinos as a result of the *Tydings-McDuffie Act of 1935* when the Republic of the Philippines was granted independence.

The year 1848 marked the beginning of Asian immigration to the United States when the coastal Chinese—mostly from Guangdong—responded to the California gold rush and failures in the rural economy of China. Within fewer than thirty-five years, the Chinese became the first group in U.S. history to be legally barred from becoming citizens because of race. The 1882 Anti-Chinese Exclusion Act was followed by an influx of immigrants from the southern prefectures of Japan during the last decade of the nineteenth century—until that flow ended abruptly with the so-called "Gentlemen's Agreement" of 1907–1908. Unlike the termination of Chinese immigration, and reflecting Japan's position as a world power, cessation of entry by Japanese was accomplished through a diplomatic compromise between the two governments rather than through an act of Congress. Without a

continuous flow of Japanese farm workers to ease the labor shortage on the Hawaiian plantations, contractors turned to the Philippine Islands—which had been a U.S. possession since 1898—for cheap labor. From 1906 to the independence of the Republic of the Philippines in 1946, over 125,000 (predominantly single) Filipino males, the majority of them from the Ilocos region, labored on Hawaiian sugar plantations.

The exclusions of Asians enacted into the National Origins Act of 1924 essentially remained in effect until 1965. By Act of Congress in 1943, however, 105 Chinese were permitted to immigrate annually, and in 1952, under the McCarran-Walter Act, a token one hundred persons from each Asian country were allowed entry. The symbolic opening of immigration doors to Asians was attributed to Walter Judd, a congressman from Minnesota who had spent many years in China as a medical missionary. The provision of a quota of one hundred persons seemed to be an important moral victory for those who wanted the elimination of the exclusion act, but it was in fact a restatement of the 1924 national origin quota basis for immigration.

The new stream of Asian immigrants to the United States reflected the 1965 legislative reform that allowed an equal number of persons (20,000) from each country outside the Western Hemisphere to immigrate. Furthermore, family unification and needed skills became the major admission criteria, replacing national origin. Besides China and the Philippines, Korea and the Indian sub-continent became, and continue to be, the major countries of origin of many newly arrived Asian immigrants. Refugees from Vietnam, Cambodia, and Laos began to enter the United States in 1975, and by 1990, peoples from the former Indochina (Vietnam, Cambodia and Laos) had become the third-largest Asian group, following Chinese and Filipinos. In contrast, Japan's immigration to the United States practically ceased from 1945 to 1965, when it resumed at a much lower rate than those reported for other Asian countries.

SOCIAL CONSEQUENCES OF IMMIGRATION RESTRICTIONS

Several distinct demographic characteristics illustrate most graphically past restrictions and the

1965 revision of the immigration laws. Earlier immigrants from China and the Philippines were predominantly single males. As a result of racial prejudice that culminated in the passage of antimiscegenation laws directed primarily against people of color in many western and southwestern states, the majority of these earlier Asian immigrants remained unmarried. The lack of family life caused unattached immigrants to depend on one another, creating an apparent great solidarity among people of the same ethnic group. Many of the earlier studies of Chinese and Filipino communities depicted themes of social isolation and loneliness, which did not apply to the Japanese community. Paul Siu (1952) portrayed the extreme social isolation of Chinese laundrymen in Chicago in his doctoral dissertation, that was published at the time only as a paper in the *American Journal of Sociology*, with the title "The Sojourner." Although Siu's work was written under the direction of Robert E. Park and Ernest W. Burgess, it was not included in the Chicago School sociological series published by the University of Chicago Press that focused on urban and ethnic social structure of the time allegedly because Siu argued that the Chinese immigrants did not fit the Park-Burgess assimilation model because of the "race factor." Thus a major piece of Asian-American research, *The Chinese Laundryman: A Study in Social Isolation* (Siu 1987) remained unpublished until after the author's death in the mid-1980s.

The existence of single-gender communities of Filipinos and Chinese is clearly demonstrated in the U.S. censuses between 1860 and 1970. In 1860, the sex ratio for Chinese was 1,858 men for every 100 women. By 1890, following the peak of Chinese immigration during the previous decade, the ratio was 2,678 males for every 100 females—the highest recorded. Skewed sex ratios for the Chinese population later declined steadily as the result of legislative revisions in 1930 (46 U.S. Stat. 581) and 1931 (46 U.S. Stat. 1511) that enabled women from China to enter the United States.

A second factor that helped to balance the sex ratio in the Chinese community, particularly among the younger age cohorts, was the presence of an American-born generation. In 1900, U.S.-born persons constituted only 10 percent of the Chinese-American population. By 1970, the figure was 52 percent. Nevertheless, in the 1980 census, the sex ratio remained high for some age groups within

certain Asian-American subpopulations: among Filipinos, for example, the highest sex ratio was found in those sixty-five and older.

The demographic characteristics of Japanese Americans present yet another unusual feature. Under the "Gentlemen's Agreement" between Japan and the United States, Japanese women were allowed to land on the West Coast to join their men though the immigration of male laborers was curtailed. The majority of the women came as picture brides (Glenn 1986, pp. 31–35) within a narrow span of time. Thus, the years following 1910 were the decade of family building for the first (*issei*) generation of Japanese Americans. Since almost all *issei* were young and their brides were chosen from a cohort of marriageable applicants of about the same age, it was not surprising that *issei* began their families at about the same time after marriage. The historical accident of controlled migration of brides resulted in a uniform age cohort of the second-generation Japanese Americans (*nisei*). The relatively homogeneous age group of the *nisei* generation meant that their children, the third generation (known as *sansei*), were also of about the same age. The fourth generation followed the same pattern. The amazingly nonoverlapping age and generational cohorts among Japanese Americans is not known to have had parallels in other population groups.

Fourth, while Asian Americans in general continue to grow in number as a result of new immigration, the size of the Japanese American population increases primarily by the addition of new generations of U.S.-born babies. It is generally believed that the offspring of Japanese women who marry Caucasians have lost their Japanese identity, even though there are no estimates of the impact of intermarriages upon the shrinkage of the Japanese-American community. An educated guess would be that about two-thirds of Japanese Americans marry non-Japanese partners. Given the fact that Japanese immigrants had lower fertility rates than women in Japan during the period prior to and shortly after World War II, and that the number of new immigrants since the war has remained small, Japanese communities have larger percentages of older people than do other ethnic minority populations, including other Asian Americans. In short, Japanese Americans will be a much smaller ethnic minority in the future. The

plurality ranking for all Asian groups placed the Japanese at the top of the list in 1970; they dropped to the third place in 1980, are expected to place fourth in 1990, and to be ranked last by the year 2000.

One more demographic fact is worthy of note. Hawaii and the West Coast states continue to draw large numbers of new immigrants from Asia. Through a process known as "chain migration," relatives are likely to follow the immigrants soon after their arrival. This leads to sudden increases in population within the ethnic enclaves. The post-1965 pattern of population growth in many Chinatowns, for instance, is an example of the renewal and revitalization of ethnic communities—which prior to 1965 were experiencing a decline—as are the formation and expansion of Koreantowns, Filipinotowns, and Little Saigons. Moreover, the settlement of post-1965 immigrants from Asia is more dispersed than that of the earlier groups, owing to the fact that the need for professional and skilled manpower is widely distributed throughout the United States. The emergence of Thai, Malaysian, and Vietnamese communities in major metropolitan areas has added a new dimension to the ethnic composition of Asian Americans.

Two separate chains of immigration resulted from the new immigration legislation of 1965. One chain, largely found in Chinese and Filipino communities, is kin-selective in that the process of settlement follows the family ties of earlier immigrants. The other process is occupation-selective, based on skills and professional qualifications. These two processes created significantly different immigrant populations, with clearly discerned bimodal distributions of status characteristics. It is therefore common to find recent immigrants from Asia among the high-income groups as well as among the families living below the poverty level; some find their homes in the ethnic enclaves of central cities while others live in high-income suburban communities. Any attempt to describe Asian Americans by using average measures of social status characteristics, such as income, education, and occupation, can produce a distorted and misleading profile that fits no particular group, which can be misused by researchers and planners. A more useful description would be the use of standard errors to show the polarities or deviations of the immigrant group from the norm of the majority.

In short, the sociodemographic and socioeconomic characteristics of all Asian American communities since 1850 have been greatly influenced by federal immigration legislation. A clear grasp of the structure and change of Asian-American communities must begin with an understanding of the history of immigration legislation.

ASIAN-AMERICAN RESEARCH

Asian-American research may be divided into six periods: (1) the early period before World War II, which was influenced by, and was a part of, the Chicago School of Sociology that focused on the emergence of a multiethnic urban America. (2) the World War II period, which saw a preponderance of Japanese-American studies that also centered around the University of Chicago; (3) the postwar era, with a strong emphasis on culture and personality studies related to Japanese and Japanese Americans; (4) a shift toward "ethnic" experience as a result of the civil rights movement; and the emergence of a new academic course of Asian-American studies and finally (5) the integration of social science theories and concepts of ethnic inequalities and the changing Asian-American vista in the 1980s and 1990s.

The Early Period. The pioneer sociological studies on the assimilation of immigrants in American urban communities may be attributed to the work of Robert E. Park. Although Park had done little empirical investigation, he had supervised a large number of graduate students and had formulated what was known as the theory of race cycle, which stressed the unidirectional process of competition, accommodation, and assimilation as the basis of race relations in urban America. Park later led a group of researchers to study Chinese and Japanese communities on the Pacific Coast. The results failed to prove the race-cycle theory. In defending his views, according to Lyman (1977, p.4), Park employed the Aristotelian doctrine of "obstacles," which suggests that among Chinese and Japanese the assimilation progress in the hypothesized direction was only delayed.

Early published sociological research on Asian Americans included the works of Bogardus (1928, 1930), who attempted to delineate degrees of prejudice against minorities through an operational concept of "social distance." Other topics were

chosen randomly such as "Oriental crime" in California (Beach 1932); school achievement of Japanese-American children (Bell 1935); and anti-Asian sentiments (Sandmeyer 1939; Ichihashi 1932). A noted pioneer community study of Japanese Americans conducted by Frank Miyamoto (1939) in Seattle in the late 1930s paved the way for the long and significant bibliography on Japanese-American studies that followed.

Perhaps the most significant and ambitious piece of work during the prewar era was the study of social isolation of Chinese immigrants, which took more than a decade to complete. The author, Paul Siu, working under a condition of extreme poverty for a decade, observed the life of Chinese laundrymen. The product of his research endeavors offers a classic text in the study of "unmeltable" immigrants, from which the concept of "sojourner" independently complemented the earlier work of G. Simmel (Siu 1952, 1987).

World War II and Japanese-American Studies. Large-scale systematic studies on Asian Americans began shortly after the Japanese attack on Pearl Harbor, when the United States declared war on Japan. The U.S. government stripped Japanese Americans of their property, relocated them, and housed them in internment camps for several years. Alexander Leighton, a psychiatrist, recruited nisei social science graduates to assist in his work in the camps, monitoring the morale and loyalty of internees; this perhaps was the pioneer work in assessing their group cohesion and structure. A few of Leighton's nisei assistants completed their doctoral studies after the war, maintaining a close and affectionate relationship with him. All had made their own contributions as social scientists and as Asian-American specialists. Leighton's work on the internment of these civilians (both citizens and non citizens) resulted in the publication of a classic text on loyalty (Leighton 1945).

Thomas and Nishimoto (1946), Thomas (1952), and Broom and Kitsuse (1955) also carefully documented the situation and the people of Japanese-American communities. The focus of these studies was the question of loyalty on the part of Japanese-American citizens and their offspring in spite of their brilliant wartime combat duties on behalf of their adopted country in Europe. It was the American home front conditions had sparked an area of

development in social science research that paralleled some of the classic work on the study of the Polish peasant (Thomas and Znaniecki 1946). As a result it increased the general knowledge base on Japanese Americans, including their families and communities, and their sacrifices and contributions to America's wartime efforts.

Culture and Personality Studies in the Post-war Era. During World War II, the U.S. government had reason and the opportunity to question the suitability of Asians as American citizens in regard to loyalty and civic responsibilities. It was also a time to test the myth that Asian immigrants could not assimilate into American society. Social scientists were intrigued by the way culture shapes the personality. Ruth Benedict's classic work on the Japanese personality and society (Benedict 1946) opened a new vista for research. A cohort of young scholars at the University of Chicago, which included Japanese-American graduate students, became known for their pioneer work in studying Japanese behavioral patterns. It had a profound effect on a generation of interested social scientists and resulted in the publication of many classic works on culture and personality (Caudill 1952; Jacobson and Rainwater 1953; Caudill and DeVos 1956; DeVos 1955; Kitano 1961, 1962, 1964; Caudill and Scarr 1961; Babcock and Caudill 1958; Meredith 1966; and Vogel 1961). Similar studies on other Asian-American groups are conspicuously absent.

Ethnic Studies and the Civil Rights Movement. In the 1960s, the civil rights movement, sparked by the death of Martin Luther King, Jr., contributed to the passage of an unprecedented immigration-legislation reform. At the time there existed among Asian Americans on the Pacific Coast, principally in California, a collective search for identity that shared many of the goals and rhetoric of the black movement. Research into the ethnic (Asian) U.S. communities had added two dimensions. The first was the need to raise ethnic consciousness as a part of the social movement. Personal testimonials of experiences as members of an oppressed minority provided insight into the psychology of ethnic minorities. The emphasis on the cathartic, as well as the cathetic quality in much of the writings of the civil-rights era reflected the mood of the period: that there is a need for alternative theories against the early assimilation

model in standard texts on racial and ethnic studies. Second, consistent with the radical theme, was the apparent influence of Marxian views on race and ethnic relations, which posited that African-American and other minorities are victims of oppression in a capitalist society.

Expectedly, the civil rights movement began a renewed interest in research on the experiences of the earliest Asian Americans. With time the titles ranged from well-documented academic publication to insightful popular readings for the lay public (Chen 1980; Daniels 1988; Choy 1979; Ichioka 1988; Miller 1969; Nee and de Bary 1973; Saxton 1971; Sung 1971; Takaki 1989; Wilson and Hosokawa 1980).

Asian-American studies was established in the 1970s as an academic discipline in a number of institutions of higher learning, particularly in California, at a time when there were only a few major publications as sources of information for undergraduates (e.g., Kitano 1961–1976; Lyman 1974; Petersen 1971). The birth of an academic specialty was marked by the conspicuous absence of available materials, particularly on Filipinos, Koreans, Vietnamese, and the peoples of the Indian subcontinent (Min 1989). In response to this void, the Asian-American Studies Center at the University of California at Los Angeles published two collections of papers (*Roots and Counterpoint*) and a quarterly journal, *The Amerasia*. On the Atlantic Coast, a group of U.S.-born professionals published an intellectual nonacademic monthly, *The Bridge*, for nearly a decade. In the 1970s and 1980s, these publications were recommended as collateral readings for college students interested in Asian-American studies. *Amerasia* has since become more academic in the 1980s and 1990s while *Bridge*, for the lack of funds, quietly folded after nearly one decade. In its place, two new academic publications appeared in the 1990s: the *Journal of Asian American Studies*, which is a U.S. East Coast complement (at Cornell University) to *Amerasia*; and the *Journal of Asian American Health*, that serves health research readers as well as the general public. In addition, funded research on health and mental health by the U. S. Department of Health and Human Services has greatly enhanced the research productivities on Asian Americans as well as cumulative bibliographies.

The New Age of Asian-American Research: Emerging Theories and Concepts. Stanley Lyman at the University of California at Berkeley, and S. Frank Miyamoto at the University of Washington, are generally acknowledged as pioneers in Asian-American research. Through his numerous papers and books, Lyman has maintained a theoretical relevance and has demonstrated an historical insight into the origin and growth of Asian-American communities, especially those of the Chinese and Japanese. As a social historian, he based his research, by and large, on archival documents (see Lyman 1970b). Miyamoto, on the other hand, belongs to a founding generation of Japanese-American researchers whose long-time association with the University of Washington and his training under Professor Herbert Blumer at the University of Chicago gave him a mix of symbolic interactionist bend and logical positivist approach to the establishment of sound theoretical propositions in the study of Japanese Americans.

In the 1980s and 1990s, a few well-trained sociologists began to emerge, many of them foreign born and foreign educated, with American postgraduate training—the “first-generation new immigrants”—scholars who arrived at a time when America had become sensitive to diverse cultures. The new breed of Asian-American researchers are increasingly more vocal, questioning traditional sociological theories and concepts based on studies of European immigrants in the early 1920s and 1930s. There is also a reflection of the postmodern and world community perspectives that have become influential intellectual trends of the time. These new studies of Asian-American communities have added much to a field that had been underserved by the social sciences. In addition, as Asian-American studies became a new academic discipline in line with the African-American and other ethnic minority and gender studies, the need grew for more social science information. The lack of usable and more accurate estimates on many attributes of Asian Americans based on adequate sample design and culturally appropriate survey instruments employed in federal surveys has frustrated many Asian-American researchers, in spite of the special publication of information on Asian Americans and Pacific Islanders in the 1980 and 1990 censuses. Asian-American researchers constructively point out how such statistics can

be improved to the advantage of both legislators and research academicians (see Yu and Liu 1992).

Much information on Asian Americans, particularly new immigrants, still depends on small sample backyard research by individual investigators. In the post-civil rights movement decades, studies on ethnic identities and race and ethnic relations continue to flourish, adding new Asian immigrants into the sample of observations and analyses. The newly arrived Korean businessmen and professionals gave birth to fresh topics in the research literature. Publications on Korean professionals and small businesses provided opportunities to support the old "middleman" theory that argued Asians succeeded in finding business opportunities by being middleman between white and black supplier and customer relations; (see Light and Bonacich 1988) and also advanced an argument that newly emerged Asian-American ethnic business communities can best be understood in the context of a global business community (Min 1987, and 1988; Yu, E.Y. 1983, Light and Sanchaz 1987).

Newer research also includes a collection of refugee studies that involved Vietnamese, Cambodians, and Laotian Hmongs. Publications on the Vietnamese community centered largely on the initial movement of refugees after the withdrawal of American troops from Vietnam on April 25, 1975. Liu and his associates made a survey of the first wave of refugees who were brought in directly from Vietnam to Camp Pendleton in California (Liu, Lamanna, and Murata 1979). He directed the reader's attention to the special status of refugees vis-à-vis immigrants, and the pathway to becoming refugees from previously nonrefugee status as a result of both political and military decisions. The distinction between refugees and immigrants was later further elaborated by Haines (1989a, 1989b). Gold (1992) compared Vietnamese with Jewish refugees' adaptive experience, and showed commonalities of refugee experience in general. Freeman (1984) on the other hand, collected life histories and reported refugees' own accounts of flight and adjustment. Taken together, studies on Vietnamese, Cambodians, and Laotians focused more on their cohort experience as refugees, rather than their transition to an emerging new ethnic community.

The smaller number of Cambodian and Laotian Hmong people, relative to the Vietnamese, is a major reason why they remained as a part of the underserved Asian-American population in the Asian-American literature. Much of the writings on the Hmong people were based on clinical interviews by practicing health providers and academic psychiatrists (Beiser 1987, 1988; Boehnlein 1987; Mollicca et al. 1987). There is also the reflection of a time when the concern was on wartime trauma, refugee experience, and cultural adjustment (see Chan 1994). These publications tend to leave an impression that Hmong people had the most difficult time in America, and are psychologically maladjusted. A popular book that portrayed the experience between American physicians and a Hmong child revealed how culture interfered in clinical judgment, no matter how well intentioned (Fadiman 1997)

There remained a scarcity of systematic studies, except for Agarwal's (1991) work on Indian immigrants. Agarwal's survey on immigrant Asian Indians in America was based on a rather small sample of professionals. Available studies on immigrant Americans from the Indian subcontinent, however, remained inadequate and woefully few.

The arrival of voluminous publications on new immigrants from Asia did not slow down studies of prior to 1965 immigrants. A cumulative bibliography began to focus on the aftermath of Japanese nisei resettlement (Ichioka 1989a; Miyamoto 1989; Warren 1989), and sensei scholars began to search for the Japanese identity of their parents' generation (Ichioka 1989b). A well-publicized book by Ronald Tadaki (1989), *Strangers from a Different Shore: A History of Asian Americans*, contained verbatim recorded life histories. The book was well received by the public but was poorly reviewed in the social science literature because it lacks a new conceptual framework for an old topic. However, it did arouse renewed interest in Asian Americans and their American experience, particularly at a time of race consciousness.

While the third-generation Japanese Americans were busy finding their identities, nisei continued to search for the meaning of "being American." In September of 1987, on the campus at the University of California at Berkeley, a group of scholars who belonged to the original Japanese American Evacuation and Resettlement Study

(JERS) at the Berkeley campus convened, and reminisced about lost valuable information of that period (see JERS 1989). Among those who attended include Ichioka, Miyamoto, L.R and J.H. Hirabayashi, Suzuki, Spencer, Kikuchi, Takagi, and Sakoda. Later researchers learned from discussion notes that there was a diary kept by Charles Kikuchi, known as the *Kikuchi Diary*, but it was destroyed. A manuscript entitled *American Betrayed* by Professor Morton Grodzin was suppressed from being published. Furthermore, another manuscript reportedly written by Violet de Christoforo described internees' refusal to leave camps as camps were closed. The book also exposed the harshness of expulsion. The existence of this manuscript, if true, shed additional light on similar experiences reported in Camp Pendelton as the Vietnamese camps were closed, when refugees were labeled as suffering from *campetitis* by the federal administrator in charge of closing all camps that housed refugees from Indochina (see Liu et al. 1979).

Clearly Asian-American research could not be separated from the general field of race and ethnic studies. In the 1980s and 1990s, researchers continued to be fascinated by Asians who had mutual ill feelings in their home countries because of neighboring dominations and the World War II experience, but appeared to be united behind a cause of advancing the status of Asian-Americans as a group. Whether there is a single identity of all Asian-Americans, or multiple subidentities of separate entities depends, of course, on issues. But the persistence of a multiple subidentities seem to be present not only among the first-generation immigrants, which is understandable, it also appears to be real among second- or third-generation ethnics. Fugita and O'Brien's (1991) volume on Japanese Americans is a good illustration; they seemed to have suggested that a single identity of Asian Americans is but an abstract rather than a reality. Among the Asian-American professionals, perhaps this issue is more complex and deep than is commonly expected (see Espirita 1992).

There also had begun some long-awaited new social science contributions to the literature on Filipino immigrants in the 1980s that were absent in the earlier generation. These studies included Filipino-American income levels (Cabezas, Shinagawa, and Kawaguchi 1986-1987), Filipino assimilation (Pido 1986), and Filipino health practices (Montepio 1989).

As more practicing professionals took part in studying Asian immigrants, there appeared in the 1970s and 1980s a bifurcation of writings on Asian Americans: those that catered to an academic audience and those that served as "voices" of the grassroots community (see Radhakrishnan 1996). It is understandable that, when more and more publications contained a whole spectrum of topics, the quality of writings would also vary widely. At the conceptual level, there remained in these writings a contrast between neo-Marxian and neo-classical economic approaches to status attainment, income, and employment opportunities for Asian Americans.

For example, the censuses of 1980 and 1990 confirmed the fact that U.S.-born Japanese and Chinese men came closest to parity with white men with respect to individual income. Japanese and Chinese women have significantly lower income than white women. The rest of those Asian men and women continued to have lower incomes than those of whites, Japanese, and Chinese. One explanation seemed to have suggested that Asians as a group valued education and scholastic achievement or individual effort, known as the *human capital theory* (Becker 1975). But within various Asian subgroups, the disturbing question is why some Asian immigrants attained higher income than others in the same ethnic group. Here both Becker's *human capital* and the *labor market segmentation* explanations are applicable. The Lahei suggests a two tier wage system prevail (see Cabezas, Shinagawa, and Kawaguchi 1986-1987; Bonacich 1975, 1988, 1992).

Perhaps a third explanation of the differential pace of status attainment came from some writings about the Filipino immigrant-labor market structure that related to the manner in which newcomers came to join their kin-relatives. The so-called "network recruitment" tended to form clusters in the same occupation area, resembling the earlier immigration patterns of Chinese in California (who came from four or five villages in Guangdong Province) and Japanese farm workers (who were recruited from southern prefectures of Japan).

Unlike blacks and Native Americans, Asian Americans varied significantly in terms of language proficiency, which had an enormous impact on income and the kinds of occupations in which they tended to cluster together. Barry Chiswick

(1974) has demonstrated that English proficiency is a major factor in income parity. P.G. Min (1986) showed that Filipino and Korean immigrants, an even match for income, engage in quite different occupations. Koreans engage in business but Filipinos do not. Min pointed out that the language barrier forces Koreans to be self-employed, no matter how hazardous their business turns out to be. Furthermore, it was Korean immigrants' linkage to industrial development in Korea that led to the development of some of the Korean communities in the United States. Filipino communities, on the other hand, did not develop similar enterprises to form a visible ethnic enclave in America. Instead, they depended more on ethnic professional societies and trade associations as basis of ethnic cohesion.

The same rationale was also applied in the case of "new" Chinatown studies. The earlier descriptive studies of Chinatown either over-romanticized the exotic quality of an ethnic enclave, or highlighted the worst side of humanity. To see Chinatown as a unique economic system is perhaps a new approach that is not without controversy. Zhou (1992), herself a new immigrant scholar from China, took the conceptual framework of her major advisor A. Portes, and wrote and published her dissertation on New York's Chinatown. She ably showed how a separate economic system had developed and embedded in urban America. Zhou's book on Chinatown is refreshingly different from several other volumes on the same topic published between the latter part of the 1970s to the early part of the 1990s that continued to portray patterns of conflict and cleavage (Wong 1977; Kuo 1977; Kwon 1987; Kinkead 1992).

The rise of Asian-American Studies programs, either as a part of multicultural or ethnic studies, or as an independent program, certainly has been instrumental in the increasing research and number of publications that deal with Asian-American communities. Given the interdisciplinary nature of the field, the multitudes of topics to be covered, and the unusual personal experiences of writers, the uneven quality of these publications is expected and sometimes unavoidable. Among studies on new communities, on income and status attainment, and on racial and ethnic relations, there appeared to be a genuine effort to formulate theoretically applicable concepts, and to use existing theories and models, which compared to fairly

good and important descriptive studies of an earlier era, both before and after World War II. A good example is the analysis of the Korean rotating credit associations in Los Angeles (Light, Kwun, and Zhong 1990), in which the authors examined the functions of financing and savings groups based on informal trust in Korean business communities.

The most noticeable achievement of the Asian-American Studies programs in the 1970s through the 1990s is the abundant effort to compile important bibliographies, by searching for research materials that are normally scattered through scientific journals, unpublished files, doctoral and masters' dissertations, working papers, diaries, and conference proceedings. The federal government is credited with making bibliographies on Indochinese refugees, either through the U.S. Government Printing Office, or at the University of Minnesota Southeast Asian Refugee Studies Project (see references at the end of this section). Finally, the rise of Asian-American Studies programs increased efforts to establish libraries and documentation centers in a number of universities throughout the country.

ATTITUDES

Attitude "is probably the most distinctive and indispensable concept in contemporary American social psychology" (Allport 1985, p. 35). Hundreds

of books and thousands of articles have been published on the topic. A review of this literature may be found in Eagly and Chaiken (1998). Despite this popularity, there is considerable disagreement about such basics as terminology. Several terms are frequently used as synonyms for attitude, including *opinion* and *belief*. Contemporary writers often distinguish attitudes from *cognitions*, which is broader and includes attitudes as well as perceptions of one's environment. Most analysts distinguish attitude from *value*, the latter referring to a person's ultimate concerns or preferred modes of conduct.

An attitude is a learned predisposition to respond to a particular object in a generally favorable or unfavorable way. Every attitude is about an object, and the object may be a person, product, idea, or event. Each attitude has three components: (1) a belief, (2) a favorable or unfavorable evaluation, and (3) a behavioral disposition. This definition is used by most contemporary writers. However, a small minority define attitude as consisting only of the positive or negative evaluation of an object.

A *stereotype* is one type of attitude. Originally, the term referred to a rigid and simplistic "picture in the head." In current usage, a stereotype is a belief about the characteristics of members of some specified social group. A stereotype may be positive (Asian Americans are good at math) or negative (women are bad at math). Most stereotypes are resistant to change.

Attitudes link the person to other individuals, groups, and social organizations and institutions. Each person has literally hundreds of attitudes, one for each significant object in the person's physical and social environment. By implication, the individual's attitudes should reflect his or her location in society. Thus, attitudes are influenced by gender, race, religion, education, and social class. Considerable research on the relationship between social position and attitudes has been carried out; this literature is reviewed by Kiecolt (1988).

ATTITUDE FORMATION

Many attitudes are learned through direct experience with the object. Attitudes toward one's school, job, church, and the groups to which one belongs

are examples. Attitudes toward the significant persons in one's life are also learned in this way. More often, attitudes are learned through interactions with others. Socialization by parents, explicit teaching in educational and religious settings, and interactions with friends are important sources of attitudes. Research shows that children's attitudes toward a variety of objects, including gender roles and political issues, are similar to those held by their parents.

Another source of attitudes is the person's observations of the world. A topic of continuing interest is the impact of mass media on the attitudes (and behavior) of users. A thorough review of the literature on this topic (Roberts and Maccoby 1985) concludes that television viewing affects both children's and adolescents' attitudes about gender roles. Further, the viewing of programs intentionally designed to teach positive attitudes toward racial or ethnic minorities does increase children's acceptance of such persons. With regard to adults, evidence supports the "agenda setting" hypothesis; the amount and quality of coverage by the media (press, radio, and television) of an issue influences the public's perception of the importance of that issue. The effects of mass media exposure on aggression are discussed by Felson (1996) and Geen (1998).

Stereotypes are also learned. A stereotype may arise out of direct experience with a member of the stereotyped group, for example, a person who encounters a musically talented black person may create a stereotype by overgeneralizing, inferring that all African Americans are gifted musically. More often, however, stereotypes are learned from those with whom we interact such as parents. Other stereotypes may be acquired from books, television, or film. Research indicates that television programming portrays women, the elderly, and members of some ethnic minorities in negative ways and that these portrayals create (or reinforce) misperceptions and negative stereotypes in viewers (McGuire 1985).

Social institutions influence the attitudes one learns in several ways. Adults' ties to particular ethnic, religious, and other institutions influence the attitudes they teach their children. The instruction given in schools reflects the perspectives of the dominant political and economic institutions

in society. The amount and quality of media coverage of people and events reflects the interests of particular groups in society. Through these mechanisms, the individual's attitudes reflect the society, institutions, and groups of which she or he is a member.

Each attitude fulfills one or more of four functions for the individual. First, some attitudes serve an instrumental function: An individual develops favorable attitudes toward objects that aid or reward the individual and unfavorable attitudes toward objects that thwart or punish the individual. For example, a person who earns a large salary will have a positive attitude toward the job. Second, attitudes often serve a knowledge function. They provide the person with a meaningful and structured environment. Third, some attitudes express the individual's basic values and reinforce self-image. Whites' attitudes toward black Americans reflect the importance that whites place on the values of freedom and equality. Fourth, some attitudes protect the person from recognizing certain thoughts or feelings that threaten his or her self-image or adjustment.

Stereotypes also serve several functions. The act of classifying oneself as a member of a group (males, Republicans, whites) elicits the image of a contrasting group (females, Democrats, Latinos). Thus, stereotypes contribute to social identity. They also reduce the demands on the perceiver to process information about individual members of a stereotyped group; instead, one can rely on a stereotype. Finally, stereotypes may be used to justify the political and economic status quo.

ATTITUDE MEASUREMENT

Because attitudes are mental states, they cannot be directly observed. Social scientists have developed a variety of methods for measuring attitudes, some direct and some indirect.

Direct Methods. These methods involve asking the person questions and recording the answers. Direct methods include various rating scales and several sophisticated scaling techniques.

The three most frequently used rating scales are single item, Likert scales, and the semantic differential. The *single-item scale* usually consists of

a direct positive or negative statement about the object, and the respondent indicates whether he or she agrees, disagrees, or is unsure. Such a measure is easy to score, but is not precise. A *Likert scale* typically involves several statements, and the respondent is asked to indicate the degree to which she or he agrees or disagrees with each. By analyzing differences in the pattern of responses across respondents, the investigator can order individuals from greatest agreement to greatest disagreement. Whereas Likert scales assess the denotative (literal) meaning of an object to a respondent, the *semantic differential* technique assesses the connotative (personal) meaning of the object. Here, an investigator presents the respondent with a series of bipolar adjective scales. Each of these is a scale whose poles are two adjectives having opposite meanings, for example, good–bad, exciting–boring. The respondent rates the attitude object, such as “my job,” on each scale. After the data are collected, the researcher can analyze them by various statistical techniques.

A variety of more sophisticated scaling techniques have been developed. These typically involve asking a series of questions about a class of objects, for example, occupations, crimes, or political figures, and then applying various statistical techniques to arrive at a summary measure. These include magnitude techniques (e.g., the Thurstone scale), interlocking techniques (e.g., the Guttman scale), proximity techniques (e.g., smallest space analysis), and the unfolding technique developed by Coombs. None of these has been widely used.

Indirect Methods. Direct methods assume that people will report honestly their attitudes toward the object of interest. But when questions deal with sensitive issues, such as attitudes toward members of minority groups or abortion, respondents may not report accurately. In an attempt to avoid such reactivity, investigators have developed various indirect methods.

Some methods involve keeping respondents unaware of what is being measured. The “lost letter” technique involves dropping letters in public areas and observing the behavior of the person who finds it. The researcher can measure attitudes toward abortion by addressing one-half of the letters to a prochoice group and the other half to a prolife group. If a greater percentage of letters to

the latter group are returned, it suggests people have prolife attitudes. Another indirect measure of attitude is pupil dilation, which increases when the person observes an object she or he likes and decreases when the object is disliked.

Some indirect measures involve deceiving respondents. A person may be asked to sort a large number of statements into groups, and the individual’s attitude may be inferred from the number or type of categories used. Similarly, a respondent may be asked to write statements characterizing other people’s beliefs on an issue, and the content and extremity of the respondent’s statements are used to measure his or her own attitude. A third technique is the “bogus pipeline.” This involves attaching the person with electrodes to a device and telling the person that the device measures his or her true attitudes. The respondent is told that some signal, such as a blinking light, pointer, or buzzer, will indicate the person’s real attitude, then the person is asked direct questions.

While these techniques may reduce inaccurate reporting, some of them yield measures whose meaning is not obvious or is of questionable validity. Does mailing a letter reflect one’s attitude toward the addressee or the desire to help? There is also evidence that measures based on these techniques are not reliable. Finally, some researchers believe it is unethical to use techniques that involve deception. Because of the importance of obtaining reliable and valid measures, research has been carried out on how to ask questions. This research is reviewed by Schuman and Presser (1996).

For a comprehensive discussion of attitude measurement techniques and issues, see Dawes and Smith (1985).

ATTITUDE ORGANIZATION

An individual’s attitude toward some object usually is not an isolated psychological unit. It is embedded in a cognitive structure and linked with a variety of other attitudes. Several theories of attitude organization are based on the assumption that individuals prefer consistency among the elements of cognitive structure, that is, among attitudes and perceptions. Two of these are balance theory and dissonance theory.

Balance Theory. Balance theory, developed by Heider, is concerned with cognitive systems composed of two or three elements. The elements can be either persons or objects. Consider the statement “I will vote for Mary Sweeney; she supports parental leave legislation.” This system contains three elements—the speaker, P; another person (candidate Mary Sweeney), O; and an impersonal object (parental leave legislation), X. According to balance theory, two types of relationships may exist between elements. *Sentiment relations* refer to sentiments or evaluations directed toward objects and people; a sentiment may be either positive (liking, endorsing) or negative (disliking, opposing). *Unit relations* refer to the extent of perceived association between elements. For example, a positive unit relation may result from ownership, a relationship (such as friendship or marriage), or causality. A negative relation indicates dissociation, like that between ex-spouses or members of groups with opposing interests. A null relation exists when there is no association between elements.

Balance theory is concerned with the elements and their interrelations from P’s viewpoint. In the example, the speaker favors parental leave legislation, perceives Mary Sweeney as favoring it, and intends to vote for her. This system is balanced. By definition, a *balanced state* is one in which all three relations are positive or in which one is positive and the other two are negative. An *imbalanced state* is one in which two of the relationships between elements are positive and one is negative or in which all three are negative. For example, “I love (+) Jane; Jane loves (+) opera; I hate (-) opera” is imbalanced.

The theory assumes that an imbalanced state is unpleasant and that when one occurs, the person will try to restore balance. There is considerable empirical evidence that people do prefer balanced states and that attitude change often occurs in response to imbalance. Furthermore, people maintain consistency by responding selectively to new information. There is evidence that people accept information consistent with their existing attitudes and reject information inconsistent with their cognitions. This is the major mechanism by which stereotypes are maintained.

Dissonance Theory. Dissonance theory assumes that there are three possible relationships

between any two cognitions. Cognitions are consistent, or *consonant*, if one naturally or logically follows from the other; they are *dissonant* when one implies the opposite of the other. The logic involved is psycho logic—logic as it appears to the individual, not logic in a formal sense. Two cognitive elements may also be irrelevant; one may have nothing to do with the other.

Cognitive dissonance is a state of psychological tension induced by dissonant relationships between cognitive elements. There are three situations in which dissonance commonly occurs. First, dissonance occurs following a decision whenever the decision is dissonant with some cognitive elements. Thus, choice between two (or more) attractive alternatives creates dissonance because knowledge that one chose A is dissonant with the positive features of B. The magnitude of the dissonance experienced is a function of the proportion of elements consonant and dissonant with the choice. Second, if a person engages in a behavior that is dissonant with his or her attitudes, dissonance will be created. Third, when events disconfirm an important belief, dissonance will be created if the person had taken action based on that belief. For example, a person who buys an expensive car in anticipation of a large salary increase will experience dissonance if she or he does not receive the expected raise.

Since dissonance is an unpleasant state, the theory predicts that the person will attempt to reduce it. Usually, dissonance reduction involves changes in the person’s attitudes. Thus, following a decision, the person may evaluate the chosen alternative more favorably and the unchosen one more negatively. Following behavior that is dissonant with his or her prior attitude, the person’s attitude toward the behavior may become more positive. An alternative mode of dissonance reduction is to change the importance one places on one or more of the attitudes. Following a decision, the person may reduce the importance of the cognitions that are dissonant with the choice; this is the well-known “sour grapes” phenomenon. Following disconfirmation of a belief, one may increase the importance attached to the disconfirmed belief. A third way to reduce dissonance is to change behavior. If the dissonance following a choice is great, the person may decide to choose B instead of A. Following disconfirmation, the person may change behaviors that were based on the belief.

Numerous books and hundreds of articles about dissonance theory have been published since it was introduced by Festinger in 1957. There is a substantial body of research evidence that supports various predictions from and elaborations of the theory. Taken together, this literature has produced a detailed taxonomy of situations that produce dissonance and of preferred modes of dissonance reduction in various types of situations.

ATTITUDE STABILITY AND ATTITUDE CHANGE

Both balance and dissonance theories identify the desire for consistency as a major source of stability and change in attitudes. The desire to maintain consistency leads the individual either to interpret new information as congruent with his or her existing cognitions (assimilation) or to reject it if it would challenge existing attitudes (contrast). This process is very important in preserving stability in one's attitudes. At the same time, the desire for consistency will lead to attitude change when imbalance or dissonance occurs. Dissonance theory explicitly considers the link between behavior and attitudes. It predicts that engaging in counterattitudinal behavior may indirectly affect attitudes. This is one mechanism by which social influences on behavior may indirectly affect attitudes. This mechanism comes into play when the person experiences changes in roles and the requirements of the new role are inconsistent with his or her prior attitudes.

The classic perspective in the study of attitude change is the *communication-persuasion paradigm*, which grew out of the work by Hovland and his colleagues at Yale University. *Persuasion* is defined as changing the beliefs or attitudes of a person through the use of information or argument. Attempts at persuasion are widespread in everyday interaction, and the livelihood of advertisers and political consultants. According to the paradigm, each attempt involves source, message, target, and context. Thousands of empirical studies, many of them experiments done in laboratory settings, have investigated the influence of variations in these four components on the outcome of an attempt. In general, if the source is perceived as an expert, trustworthy, or physically attractive, the message is more likely to produce attitude change.

Thus, it is no accident that magazine and television commercials feature young, attractive models. Message variables include the extent of discrepancy from the target's attitude, whether it arouses fear, and whether it presents one or both sides. Under certain conditions, highly discrepant, fear-arousing, and one-sided messages are more effective. Target factors include intelligence, self-esteem, and prior experience and knowledge. The most researched contextual factor is mood. For a review of this research, see Perloff (1993).

In the 1990s considerable work built upon the *elaboration-likelihood model* proposed by Petty and Cacioppo (1986). This model identifies two basic routes through which a message may change a target's attitudes: the central and the peripheral. Persuasion via the *central route* occurs when a target scrutinizes the arguments contained in the message, interprets and evaluates them, and integrates them into a coherent position. This process is termed *elaboration*. In elaboration, attitude change occurs when the arguments are strong, internally coherent, and consistent with known facts. Persuasion via the *peripheral route* occurs when, instead of elaborating the message, the target pays attention primarily to extraneous cues linked to the message. Among these cues are characteristics of the source (expertise, trustworthiness, attractiveness), superficial characteristics of the message such as length, or characteristics of the context such as response of other audience members. Several factors influence whether elaboration occurs. One is the target's involvement with the issue; if the target is highly involved with and cares about the issue addressed by the message, he or she is more likely to elaborate the message. Other factors include whether the target is distracted by noise or some other aspect of the situation, and whether the target is tired. Which route a message elicits in attitude change is important. Attitudes established by the central route tend to be more strongly held and more resistant to change because the target has thought through the issue in more detail.

The literature on attitude change flourished in the 1990s. The effects of many variables have been studied experimentally. A review of the research conducted in 1992 to 1995 concluded that any one variable may have multiple effects, depending upon other aspects of the persuasion attempt (Petty, Wegener, and Fabrigar 1997). For

example, consider the effect of mood on attitude change. Assuming that happy people are more open to new information, one might predict that persuasive messages would lead to greater attitude change in happy persons than in sad ones. However, research indicates that happy people spend less time processing persuasive messages than persons in neutral moods, and so may be less influenced by them. The *hedonic contingency* hypothesis states that the effect of mood depends upon the hedonic tone of the message. Happy people want to maintain their happy mood, so they are likely to scrutinize and process happy messages but not sad ones. Sad people often want to change their mood, and most messages will improve it, so their processing is not affected by messages' hedonic tone. The results of two experiments support the hypothesis (Wegener, Petty, and Smith 1995). Thus, the effect of mood on persuasion depends on whether the message is uplifting or depressing.

ATTITUDE-BEHAVIOR RELATION

The attitude-behavior relation has been the focus of considerable research since the early 1970s. This research has identified a number of variables that influence the extent to which one can predict a person's behavior from his or her attitudes.

Some of these variables involve the measurement of the attitude and of the behavior. The correspondence of the two measures is one such variable: one can predict behavior more accurately if the two measures are at the same level of specificity. An opinion poll can predict the outcome of an election because there is high correspondence between the attitude ("Which candidate do you prefer for mayor in next month's election?") and the behavior (voting for a candidate in that election). The length of time between the measure of attitude and the occurrence and measure of the behavior is also an important variable. The shorter the time, the stronger the relationship. The longer the elapsed time, the more likely the person's attitude will change, although some attitudes are stable over long periods, for example, twenty years.

The characteristics of the attitude also influence the degree to which one can predict behavior from it. In order for an attitude to influence behavior, it must be activated, that is, brought

from memory into conscious awareness. An attitude is usually activated by a person's exposure to the attitude object. Attitudes vary in *accessibility*, the ease with which they are activated. The more accessible an attitude is, the more likely it is to guide future behavior (Kraus 1995). Another variable is the source of the attitude. Attitudes based on direct experience with the object are more predictive of behavior. The certainty or confidence with which the person holds the attitude also moderates the attitude-behavior relationship.

The attitude-behavior relation is also influenced by situational constraints—the social norms governing behavior in a situation. An attitude is more likely to be expressed in behavior when the behavior is consistent with these norms.

An important attempt to specify the relationship between attitude and behavior is the *theory of reasoned action*, developed by Fishbein and Ajzen (1975). According to this theory, behavior is determined by behavioral intention. Behavioral intention is determined by two factors: attitude and subjective norm. Attitude is one's beliefs about the likely consequences of the behavior and one's evaluation—positive or negative—of each of those outcomes. Subjective norm is the person's belief about other important persons' or groups' reactions to the behavior and the person's motivation to comply with the expectations of each. One of the strengths of the theory is this precise specification of the influences on behavioral intention. It is possible to measure quantitatively each of the four components (likely consequences, evaluation, likely reactions, motivation to comply) and use these to make precise predictions of behavior. Many empirical studies report results consistent with such predictions. The theory applies primarily to behavior that is under conscious, volitional control.

On the other hand, researchers have shown that attitudes can affect behavior without being brought into conscious awareness (Bargh 1996). Attitudes toward objects influence our judgments and behavior toward those objects without conscious awareness or intent. Stereotypes of social groups are often activated automatically, as soon as an individual is perceived as a member of the group. Automatic processing is more likely when the individual experiences information overload, time pressures, or is not interested in engaging in effortful processing.

ATTITUDE AS INDICATOR

Increasingly, attitudes are employed as indicators. Some researchers use attitude measures as indicators of concepts, while others study changes in attitudes over time as indicators of social change.

Indicators of Concepts. Measures of specific attitudes are frequently used as indicators of more general concepts. For example, agreement with the following statement is interpreted as an indicator of powerlessness: "This world is run by the few people in power, and there is not much the little guy can do about it." Powerlessness is considered to be a general orientation toward the social world and is a sense that one has little or no control over events. Feelings of powerlessness may be related to such varied behaviors as vandalism, not voting in elections, and chronic unemployment.

Attitude measures have been used to assess many other concepts used in the analysis of political attitudes and behavior. These include the liberalism-conservatism dimension, political tolerance (of radical or unpopular groups), trust in or disaffection with national institutions, and relative deprivation. (For a review of this literature, see Kinder and Sears 1985.) Attitude measures are used to assess many other characteristics of persons. In the realm of work these include occupational values, job satisfaction, and leadership style.

A major concern when attitudes are employed as indicators is *construct validity*, that is, whether the specific items used are valid measures of the underlying concept. In the powerlessness example, the connection between the content of the item and the concept may seem obvious, but even in cases like this it is important to demonstrate validity. A variety of analytic techniques may be used, including interitem correlations, factor analysis, and LISREL.

Indicators of Social Change. Two methodological developments have made it possible to use attitudes to study social change. The first was the development of probability sampling techniques, which allow the investigator to make inferences about the characteristics of a population from the results obtained by surveying a sample of that population. The second is the use of the same attitude measures in surveys of representative samples at two or more points in time.

A major source of such data is the General Social Survey (GSS), an annual survey of a probability sample of adults. The GSS repeats a core set of items on a roughly annual basis, making possible the study of changes over a period of thirty years. Many of these items were drawn directly from earlier surveys, making comparisons over a forty- or fifty-year timespan possible. A published book describes these items and presents the responses obtained each time the item was used (Niemi, Mueller, and Smith 1989). Other sources of such data include the National Election Studies and the Gallup Polls.

This use of attitude items reflects a general concern with social change at the societal level. The investigator uses aggregate measures of attitudes in the population as an index of changes in cultural values and social institutions. Two areas of particular interest are attitudes toward race and gender roles. In both areas, efforts have been made to improve access to educational programs, jobs, and professions, increase wages and salaries, and provide greater opportunity for advancement. The availability of responses to the same attitude items over time allows us to assess the consistency between these social changes and attitudes in the population. Consider the question "Do you think civil rights leaders are trying to push too fast, are going too slowly, or are moving at about the right speed?" This question was asked in surveys of national samples every two years from 1964 to 1976 and in 1980. The percentage of whites replying "too fast" declined from 74 percent in 1964 to 40 percent in 1980 (Bobo 1988), suggesting increased white support for the black movement. In general, research indicates that both racial and gender-role attitudes became more liberal between 1960 and 1990, and this finding is consistent with the social changes in these areas. Other topics that have been studied include attitudes toward abortion, social class identification, and subjective quality of life.

There are several issues involved in this use of attitude items. The first is the problem of "nonattitudes." Respondents may answer survey questions or endorse statements even though they have no attitude toward the object. In fact, when respondents are questioned about fictional objects or organizations, some of them will express an opinion. Schuman and Kalton (1985) discuss

this issue in detail and suggest ways to reduce the extent to which nonattitudes are given by respondents.

The second issue involves the interpretation of responses to items. In the example above, the analyst assumes that white respondents who reply "Too fast" feel threatened by the movement. However, there is evidence that small changes in the wording of survey items can produce substantial changes in aggregate response patterns. This evidence and guidelines for writing survey items are discussed in Schuman and Presser (1996).

Finally, there is the problem of equivalence in meaning over time. In order to make meaningful comparisons across time, the items need to be the same or equivalent. Yet over time the meaning of an item may change. Consider the item "Are you in favor of *desegregation*, strict *segregation*, or something in between?" This question was asked of national samples in 1964 and every two years from 1968 to 1978. From 1964 to 1970, the percentage of white, college-educated adults endorsing desegregation increased; from 1970 to 1978, the percentage decreased steadily. Until 1970, desegregation efforts were focused on the South; after 1970, desegregation efforts focused on school integration in northern cities. Evidence suggests that endorsement of desegregation changed because the meaning of the question for white adults changed (Schuman, Steeh, and Bobo 1985).

JOHN D. DELAMATER

ATTRIBUTION THEORY

Attribution is a cognitive process that entails linking an event to its causes. Attribution is one of a variety of cognitive inferences that are included within social cognition, which is one of several theoretical models within social psychology. Social cognition has been the most dominant social psychological perspective within psychology since the 1960s, and this is evident in the popularity of research on attribution. In the mid-1970s, as much as 50 percent of the articles in major social psychology journals concerned attributional processes, in part because attribution theory is relevant to the study of person perception, event perception, attitude change, the acquisition of self-knowledge, and a host of applied topics including therapeutic interventions, close relationships, legal and medical decision making, and so forth. Although the proportion of published research that focused on this topic declined during the 1980s, attribution remains one of the more popular fields of social psychological research.

DEFINITION

An attribution is an inference about why an event occurred. More generally, "attribution is a process that begins with social perception, progresses through a causal judgment and social inference, and ends with behavioral consequences" (Crittenden 1983, p. 426). Although most theories of and research on attribution focus on causal inference, empirical research has dealt with attributions not

only of cause but also of blame and responsibility. Although these types of attributions are closely related, they are not conceptually identical. Furthermore, because personality characteristics constitute a major category of potential causes of behavior, attributions about individuals' traits (both one's own traits and those of others) have received explicit theoretical attention.

MAJOR THEORIES OF ATTRIBUTION

Even though attribution has been one of the most popular social psychological research topics in the social sciences, only a few theories of attribution have been developed. The study of attribution began with Fritz Heider's (1958) original attempt to provide a systematic, conceptual explanation of "naive" psychology. Heider maintained that people strive to understand, predict, and control events in their everyday lives in much the same way as scientists do in their professional lives. On the basis of observation, individuals form theories about their social worlds, and new observations then serve to support, refute, or modify these theories. Because people act on the basis of their beliefs, Heider argued that it is important to understand this layperson's psychology. Although Heider did not develop an explicit theory of attribution, he did assert several principles that have guided all subsequent theorizing on this topic.

Primary among these principles is the notion that people are inclined to attribute actions to stable or enduring causes rather than to transitory factors. Heider also stressed the importance of distinguishing unintentional from intentional behavior, a distinction that has been particularly influential in theories of the attribution of responsibility. He identified environmental and personal factors as two general classes of factors that produce action and hypothesized that an inverse relationship exists between these two sets of causes. He also suggested that the "covariational principle" is fundamental to attribution: An effect is attributed to a factor that is present when the effect is present and to a factor that is absent when the effect is absent. Heider's early analyses of social perception represent a general conceptual framework about common sense, implicit theories people use in understanding events in their daily lives. The two most influential theories of attribution are based on Heider's work but go beyond it

in the development of more systematic statements about attributional processes.

Covariational model. Harold Kelley's (1967, 1973) covariational model of attribution addresses the question of whether a given behavior is caused by an actor or, alternatively, by an environmental stimulus with which the actor engages. According to this model, the attribution of cause is based on three types of information: consensus, distinctiveness, and consistency. Consensus refers to the similarity between the actor's behavior and the behavior of other people in similar circumstances. Distinctiveness refers to the generality of the actor's behavior: Does she or he behave in this way toward stimuli in general, or is the behavior specific to this stimulus? Consistency refers to the actor's behavior toward this stimulus across time and modality. There are many possible combinations of these three types of information, but Kelley makes explicit predictions about just three. The combination of high consensus, high distinctiveness, and high consistency supports an attribution to the environmental stimulus, whereas a profile of low consensus, low distinctiveness, and high consistency supports an attribution to the actor. When the behavior is inconsistent, regardless of the level of consensus or distinctiveness, an attribution to circumstances is predicted.

Empirical tests of Kelley's model have focused either on the effects of a particular type of information or, more in keeping with his formulation, on the effects of particular patterns of information (McArthur 1972). In an innovative analysis, Miles Hewstone and Jos Jaspars (1987) proposed a different logic (although one consistent with Kelley's model), suggesting that potential attributers consider whether different causal loci are necessary and sufficient conditions for the occurrence of an effect. They conclude that the notion of causality is flexible and thus assert that there may be some advantage to conceiving of situation-specific notions of causality. More recent work has examined the universality and external validity of Kelley's model. Irina Anderson and Geoffrey Beattie (1998), for example, analyzed actual conversations between men and women talking about rape. They found that men tended to use the reasoning outlined in Kelley's model by making reference to consensus, distinctiveness, and consistency, as well as by using these types of information to formulate

attributions for behavior. Women, on the other hand, made less use of these variables and introduced the variable of "foreseeability" into their analyses.

Correspondent inference. The theory of correspondent inference (Jones and Davis 1965; Jones and McGillis 1976) addresses the attribution of personality traits to actors on the basis of their behavior and focuses on attributions about persons in greater depth than does Kelley's covariational model. These two theories thus address different questions. Kelley asks: When do we attribute an event to an actor or to some stimulus in the environment? Edward Jones asks: When do we attribute a trait to an actor on the basis of her or his behavior? The theory of correspondent inference focuses more narrowly on the actor but also yields more information about the actor in that it specifies what it is about the actor that caused the behavior. Jones and his coauthors predict that two factors guide attributions: (1) the attributer's prior expectancies for behavior, specifically, expectancies based either on knowledge of earlier behaviors of the actor (target-based) or on the actor's social category memberships (category-based), and (2) the profile of effects that follow from the behavioral choices available to the actor.

Edward Jones and Daniel McGillis propose that expectancies determine the degree of confidence with which a particular trait is attributed; the lower the expectancy of behavior, the more confident the attribution. The profile of effects helps the attributer identify what trait might have produced the behavior in question. Noncommon effects—effects that follow from only one of the behavioral options—provide information about the particular disposition. The fewer the noncommon effects, the clearer the attribution. Thus, behavior that contradicts prior expectancies and a profile of behavioral choices with few noncommon effects combine to maximize the possibility of attributing a disposition to the actor (a correspondent inference). Empirical research generally has supported these predictions.

These two models share some attributional principles. Expectancy variables (target-based and category-based) are analogous to Kelley's types of information. Although the predicted effects of consensus information and its analogue, category-based expectancies, are compatible, the predicted

effects of consistency and distinctiveness information and their analogue, target-based expectancies, present some incompatibilities. This contradiction has been evaluated both conceptually and empirically (Howard and Allen 1990).

Attribution in achievement situations. Bernard Weiner (1974) and his colleagues have applied attributional principles in the context of achievement situations. According to this model, we make inferences about an individual's success on the basis of the individual's ability to do the task in question, how much effort is expended, how difficult the task is, and to what extent luck may have influenced the outcome. Other possible causal factors have since been added to this list. More important perhaps is Weiner's development of, first, a structure of causal dimensions in terms of which these causal factors can be described and, second, the implications of the dimensional standing of a given causal factor (Weiner, Russell, and Lerman 1978). The major causal dimensions are locus (internal or external to the actor), stability or instability, and intentionality or unintentionality of the factor. Thus, for example, ability is internal, stable, and unintentional. The stability of a causal factor primarily affects judgments about expectancies for future behavior, whereas locus and intentionality primarily affect emotional responses to behavior. This model has been used extensively in educational research and has guided therapeutic educational efforts such as attribution retraining. Cross-cultural research has explored the cultural generalizability of these models. Paul Tuss, Jules Zimmer, and Hsiu-Zu Ho (1995) and Donald Mizokawa and David Rickman (1990) report, for instance, that Asian and Asian American students are more likely to attribute academic failure and success to effort than are European American students, who are more likely to attribute performance to ability. European American students are also more likely to attribute failure to task difficulty. Interestingly, as Asian Americans spend more time in the United States, they place less emphasis on the role of effort in performance.

Attribution biases. The theoretical models described above are based on the assumption that social perceivers follow the dictates of logical or rational models in assessing causality. Empirical research has demonstrated, not surprisingly, that there are systematic patterns in what has been variously conceived of as bias or error in the

attribution process (Ross 1977). Prominent among these is what has been called the "fundamental attribution error," the tendency of perceivers to overestimate the role of dispositional factors in shaping behavior and to underestimate the impact of situational factors. One variant of this bias has particular relevance for sociologists. This is the general tendency to make inadequate allowance for the role-based nature of much social behavior. That is, perceivers fail to recognize that behavior often derives from role memberships rather than from individual idiosyncrasy. Again, cross-cultural research has called into question the generalizability of this bias. Joan Miller (1984) shows that the tendency to attribute behavior to persons is markedly more prominent in the United States, among both adults and children, whereas a tendency to attribute behavior to situational factors is more prominent among Indian Hindus, both adults and children, calling into question the "fundamentality" of this attributional pattern.

A second systematic pattern is the actor-observer difference, in which actors tend to attribute their own behavior to situational factors, whereas observers of the same behavior tend to attribute it to the actor's dispositions. A third pattern concerns what have been called self-serving or egocentric biases, that is, attributions that in some way favor the self. According to the false consensus bias, for example, we tend to see our own behavioral choices and judgments as relatively common and appropriate whereas those that differ from ours are perceived as uncommon and deviant. There has been heated debate about whether these biases derive from truly egotistical motives or reflect simple cognitive and perceptual errors.

METHODOLOGICAL AND MEASUREMENT ISSUES

The prevalent methodologies and measurement strategies within attributional research have been vulnerable to many of the criticisms directed more generally at social cognition and to some directed specifically at attribution. The majority of attributional research has used structured response formats to assess attributions. Heider's original distinction between person and environmental cause has had a major influence on the development of these structured measures. Respondents typically are asked to rate the importance of situational and

dispositional causes of events. These ratings have been obtained on ipsative scales as well as on independent rating scales. Ipsative measures pose these causes as two poles on one dimension; thus, an attribution of cause to the actor's disposition is also a statement that situational factors are not causal. This assumed inverse relationship between situational and dispositional causality has been rejected on conceptual and empirical grounds. In more recent studies, therefore, respondents assign each type of causality separately. (Ipsative measures are appropriate for answering some questions, however, such as whether the attribution of cause to one actor comes at the expense of attribution to another actor or to society.) In theory, then, both dispositional and situational variables could be identified as causal factors.

The breadth of these two categories has also been recognized as a problem. Dispositional causes may include a wide variety of factors such as stable traits and attitudes, unstable moods and emotions, and intentional choices. Situational cause is perhaps an even broader category. It is quite possible that these categories are so broad as to render a single measure of each virtually meaningless. Thus, researchers often include both general and more specific, narrower responses as possible choices (e.g., choices of attributing blame to an assailant or to the situation might be refined to the assailant's use of a weapon, physical size, and psychological state, on the one hand, and the location, time of day, and number of people nearby, on the other).

Structured measures of attributions are vulnerable to the criticism that the categories of causes presented to respondents are not those they use in their everyday attributions. Recognizing this limitation, a few researchers have used open-ended measures. Comparative studies of the relative utility of several different types of measures of causal attributions conclude that scale methods perform somewhat better in terms of their inter-test validity and reliability, although open-ended measures are preferable when researchers are exploring causal attributions in new situations. Some researchers have attempted to overcome some of the limitations of existing scales; Curtis McMillen and Susan Zuravin (1997), for example, have developed and refined "Attributions of Responsibility" and "Blame Scales" for use in clinical research that may be useful for other kinds of attributional situations.

The great majority of attribution studies use stimuli of highly limited social meaning. Generally, the behavior is represented with a brief written vignette, often just a single sentence. Some researchers have shifted to the presentation of visual stimuli, typically with videotaped rather than actual behavioral sequences, in order to ensure comparability across experimental conditions. Recognizing the limitations of brief, noncontextualized stimuli, a few researchers have begun to use a greater variety of more extended stimuli including newspaper reports and published short stories. Most of these stimuli, including the videotaped behavioral sequences, rely heavily on language to convey the meaning of behavior. Conceptual attention has turned recently to how attribution relies on language and to the necessity of considering explicitly what that reliance means. Some researchers (Anderson and Beattie 1998; Antaki and Leudar 1992) have attempted to use more naturalistic approaches, incorporating into the study the analysis of spontaneous conversations among study participants.

WHEN DO WE MAKE ATTRIBUTIONS?

Long after attribution had attained its popularity in social psychology, a question that perhaps should have been raised much earlier began to receive attention: When do we make attributions? To what extent are the attributions in this large body of research elicited by the experimental procedures themselves? This is a question that can be directed to any form of social cognition. It is particularly relevant, however, to attribution. Most people, confronted with a form on which they are to answer the question "Why?," do so. There is no way of knowing, within the typical experimental paradigm, whether respondents would make attributions on their own. In a sense there are two questions: Do people make attributions spontaneously, and if they do, under what circumstances do they do so?

In response to the first question, Weiner (1985) has marshaled impressive evidence that people do indeed make attributions spontaneously. Inventive procedures have been developed for assessing the presence of attributional processing that is not directly elicited. This line of evidence has dealt almost entirely with causal attributions. Research

suggests that trait attributions may be made spontaneously much more often than causal attributions. In response to the second question, a variety of studies suggest that people are most likely to make attributions when they encounter unexpected events or events that have negative implications for them.

SOCIOLOGICAL SIGNIFICANCE OF ATTRIBUTION

Attribution is a cognitive process of individuals; much of the extant research on attribution is, accordingly, highly individualistic. In the 1980s, however, researchers began to pay increasing attention to the sociological relevance of attribution. The process of attribution itself is fundamentally social. Attribution occurs not only within individuals but also at the interpersonal, intergroup, and societal levels. Moreover, the process of attribution may underlie basic sociological phenomena such as labeling and stratification.

Interpersonal attribution. At the interpersonal level, attribution is basic to social interaction. Interpersonal encounters are shaped in many ways by attributional patterns. Behavioral confirmation, or self-fulfilling prophecies, illustrate the behavioral consequences of attribution in social interaction; attribution of specific characteristics to social actors creates the expectancies that are then confirmed in behavior. Considering attribution at this interpersonal level demonstrates the importance of different social roles and perspectives (actors vs. observers) as well as how attribution is related to evaluation. The self is also important to the attribution process; the evidence for attributional egotism (self-esteem enhancing attributional biases), self-presentation biases, and egocentrism is persuasive. Attributions also affect social interaction through a widespread confirmatory attribution bias that leads perceivers to conclude that their expectancies have been confirmed in social interaction.

Research has challenged the universality of egocentric biases by examining differences in attributional styles according to race, class, and gender. Several studies (Reese and Brown 1995; Wiley and Crittenden 1992; Broman 1992; Andrews and Brewin 1990) have shown that women

are less likely than men to make self-serving dispositions. In a study of academics' accounts of their success in the profession, Mary Glenn Wiley and Kathleen Crittenden (1992) argue that women explain their success in a more modest manner in order to preserve a feminine identity, at the expense of their professional identities. This attributional style may make it more likely for women to blame themselves for various types of negative situations. Consistent with this reasoning, Bernice Andrews and Chris Brewin (1990) found that female victims of marital violence tended to blame themselves for their experience of violence. Childhood experiences of physical or sexual abuse increased women's chances of characterological self-blame when, as adults, they found themselves in abusive relationships. (Other research, however, notes that the relationship between attributions and adjustment is complex and not always so straightforward; see McMillen and Zuravin 1997.)

Race and class characteristics also create distinct attributional patterns; research on these factors has been more likely than research on gender to consider possible interactive effects on attributions. In a study conducted by Fathali Moghaddam and colleagues (1995) on attributional styles of whites, blacks, and Cubans in Miami, for example, middle-class black respondents were more likely to blame negative outcomes on discrimination than were lower-class blacks. Lower-class whites were the only group to attribute failure to themselves personally.

The great preponderance of research on social interaction has been based on relationships between strangers in experimental contexts, which may seem to undermine the claim that attribution is significant for interpersonal interaction. The best evidence of this significance, then, is the increasingly large body of research on the role of attribution in the formation, maintenance, and dissolution of close relationships. There is substantial evidence that attributions are linked to relationship satisfaction and behaviors such as conflict resolution strategies. There is also evidence that distressed and nondistressed couples make differing attributions for significant events in their relationships; these patterns may actually serve to maintain marital distress among troubled

couples, thus ultimately influencing marital satisfaction. Attributions also play an important role in relationship dissolution. Attributions are a critical part of the detailed accounts people provide for the dissolution of their relationships, and these accounts go beyond explanation to rationalize and justify the loss of relationships.

Research on interpersonal attribution extends the intrapersonal approach in several ways. When people who interact have substantial knowledge of and feelings about each other, the attribution process involves evaluation as well as cognition. Issues of communication, and hence potential changes in preexisting attributions for recurrent relationship events, also become salient at the interpersonal level. There is very little research on how attributions change through interaction and relationships, but this is clearly a significant topic. Attributions at the interpersonal level also entail greater concern with accountability for action; causality at this level also raises issues of justification.

Intergroup attribution. Intergroup attribution refers to the ways in which members of different social groups explain the behavior of members of their own and other social groups. At this level, social categorization has a direct impact on attribution. Studies using a variety of subjects from different social groups and often different countries show consistent support for an ingroup-serving attributional pattern, for example, a tendency toward more dispositional attributions for positive as opposed to negative behavior for ingroup actors. The evidence for the converse pattern, more dispositional attributions for negative as opposed to positive behavior for outgroup actors, is not as strong. (Moreover, these patterns are stronger in dominant than in dominated groups.) Social desirability biases can counteract this pattern; Steven Little, Robert Sterling, and Daniel Tingstrom (1996), for example, found that white respondents held black actors less responsible for participating in a bar fight than did black respondents. The authors suggest that this finding may be due to the desire of the white sample—undergraduates from a suburban area—to appear racially progressive.

Parallel studies of a group's success and failure show a consistent pattern of ingroup protection. Outgroup failure is attributed more to lack of ability than is ingroup failure. Effects of group

membership on attributions about success are not as strong. Interestingly, there is also some evidence of outgroup-favoring and/or ingroup-derogating attributions among widely recognized lower-status, dominated groups such as migrant labor populations (Hewstone 1989). A third form of evidence of intergroup attribution is provided by studies of attributions about social positions occupied by existing groups. In general, these studies, like those cited above, show higher ratings of ingroup-serving as opposed to outgroup-serving attributions.

Societal attribution. At the societal level, those beliefs shared by the members of a given society form the vocabulary for social attributions. The concept of social representations, which has its origins in Durkheim's concept of "representation collectives," was developed by Serge Moscovici (1976) to represent how knowledge is shared by societal members in the form of common-sense theories about that society. Social representations are intimately connected to the process of attribution. Not only are explanation and accountability part of a system of collective representations, but such representations determine when we seek explanations. Social representations serve as categories that influence the perception and processing of social information; moreover, they underscore the emphasis on shared social beliefs and knowledge. Social representations are useful in interpreting research on laypersons' explanations of societal events such as poverty and wealth, unemployment, and racial inequality. Poverty tends to be attributed to individualistic factors, for example, whereas unemployment tends to be attributed to societal factors. Not surprisingly, these patterns may be qualified by attributors' own class backgrounds; although middle-class people attribute poverty more often to internal factors, those who are themselves poor attribute poverty more often to external factors such as governmental policies (Singh 1989). Gender and racial stereotyping can also shape attributions. Cynthia Willis, Marianne Hallinan, and Jeffrey Melby (1996), for example, found that respondents with a traditional sex-role orientation showed a favorable bias toward the male perpetrator in domestic violence situations. When the female victim was African American and married, both egalitarians and traditionalists were less likely to attribute blame to the man.

Moving away from an emphasis on normative stereotyping, research has considered possible effects of counter-stereotyping on attributional patterns, and of attributions on changes in stereotypes. Portrayals of structurally subordinate groups that counter stereotypical expectations can increase the perceived credibility of members of those groups (Power, Murphy, and Coover 1996). Moreover, an attribution of counterstereotypic behavior to dispositional factors of clearly typical outgroup members can modify outgroup stereotypes (Wildner, Simon, and Faith 1996).

Cross-cultural research illustrates another aspect of societal attributions. This work compares the extent and type of attributional activity across cultures. Although there has been some support for the applicability of Western models of attribution among non-Western cultures, most of this research has demonstrated in a variety of ways the cultural specificity of particular patterns of attribution (Bond 1988). As noted above, for example, Joan Miller (1984) provides cross-cultural empirical evidence that the fundamental attribution error, the tendency to attribute cause more to persons than to situations, is characteristic of Western but not non-Western societies. Attributions about the self also vary across cultures; members of some non-Western cultures attribute performance more to effort than to ability; the opposite pattern has been found in the United States. Cultural patterns also shape responsibility attributions; V. Lee Hamilton and Shigeru Hagiwara (1992) found that U.S. (and male) respondents were more likely to deny responsibility for their own inappropriate behaviors than were Japanese (and female) respondents, who were more likely to apologize for the behaviors. Hamilton and Hagiwara argue that the Japanese (and women) were more concerned with maintaining the quality of the interaction between the accuser and the accused.

SOCIOLOGICAL APPLICATIONS

It may be useful to identify several sociological phenomena to which theories of attribution are relevant. A number of scholars have suggested integrating attribution theory and labeling theory (Crittenden 1983). Attribution occurs within an individual; labels are applied by a group. Judith Howard and Randy Levinson (1985) offer empirical evidence that the process of applying a label is

directly analogous to attribution. They report that the relationships between attribution information and jury verdicts are consistent with predictions based on a labeling perspective.

Richard Della Fave (1980) demonstrates the importance of attribution for understanding a key but neglected aspect of stratification, namely, how it is that stratification systems become legitimated and accepted by those disadvantaged as well as by those advantaged by those systems. He draws heavily on attribution theory in developing a theory of legitimation and in identifying possible sources of delegitimation.

Attribution is a significant social process that ranges widely from cognitive processes to collective beliefs. The field is still imbalanced; more work has been done at the intrapersonal and interpersonal levels. There is evidence for both intergroup and societal attributions, however, and research at these two levels is steadily increasing (Hewstone 1989). Recent research has demonstrated connections across areas as diverse as social cognition, social interaction, intergroup relations, and social representations; these connections provide increasing evidence of the importance of attribution for sociological phenomena. Indeed, in the next decade it may be that the fruits of attribution theories will be evident more in research on these other topics, than in research on attribution alone.

BALANCE THEORY

See Attitudes; Cognitive Consistency Theories.

BANKRUPTCY AND CREDIT

Every society must resolve the tension between debtors and creditors, especially if the debtors cannot pay or cannot pay quickly enough. Many of the world's religions have condemned lending money for interest, at least among co-religionists. In traditional societies, money lenders, although necessary for ordinary commerce, were often viewed as morally suspect. The development of a robust capitalism was based upon raising capital by paying interest or dividends, and so it has been important for capitalist societies to develop institutions and mechanisms for handling debt and credit.

The inherent tension between creditors and debtors turns upon the creditor's claim to justice as the property owner and the debtor's interest in fairness in the terms of repayment. To be sure, lenders sometimes used their position to create social control mechanisms such that debtors often could never work their way out of debt. Such arrangements as sharecropping and the use of the company store often tied laborers to employers through the bonds of debt. With some exceptions, states and legal regimes upheld property rights against the claims of the debtors.

Through the years, societies have sanctioned creditors' use of slavery, debt-prison, transportation to debtors' colonies, debt-peonage, seizure of assets or garnishment of wages to control debtors.

Most such methods, however, work to the advantage only of the first creditor or the most aggressive creditor to demand payment. Bankruptcy, as used in the United States and a number of other countries, provides a means for resolving not only the debtor-creditor conflict but also the potential conflict among creditors.

Bankruptcy is a very old concept. The word itself comes from an Italian phrase meaning "broken bench," because a bankrupt merchant's work bench would be broken by his creditors if he could not repay the debt. In the United States, each state has laws governing debtor-creditor relations, but the enactment of bankruptcy statutes is reserved to the Congress by the U.S. Constitution. United States bankruptcy occurs in the federal courts and is regulated by statutes enacted by Congress. Special bankruptcy courts are located in each federal judicial district, and specially appointed bankruptcy judges oversee the caseload. Bankruptcy decisions may be appealed to the federal district court and subsequently to the federal appeals court and the U.S. Supreme Court.

Bankruptcy is technically different from insolvency. Insolvency refers to a financial situation in which a person or business has liabilities that exceed assets. To be bankrupt, the debtor must file for bankruptcy protection in the federal court. Although the overwhelming majority of individuals filing for bankruptcy are also insolvent, occasionally a solvent business will file for bankruptcy because of anticipated liabilities that will exceed its assets. An example of such a bankruptcy is that of pharmaceutical manufacturer A. H. Robbins, whose

Dalkon Shield intrauterine device (a contraceptive) was judged the cause of many injuries and some deaths among women who used it. As the financial judgments against the company mounted, its management sought the protection of the bankruptcy courts. Bankruptcy allowed the company to hold its creditors at bay for a period of time to allow the company to propose a financial settlement.

THE ROLE OF THE STATES

Although bankruptcy is a federal matter, states also have laws to govern debtor-creditor relations. Each state's debtor-creditor laws are affected by its history and by the debt conventions that are part of its history. Before becoming a state, for example, Georgia was a debtor's colony. Before the Civil War, debtors in such southern states often fled harsh debt-collection laws by going to Texas, indicated by "G.T.T." in sheriffs' records. Texas has traditionally retained pro-debtor statutory provisions, especially its generous exemption.

An exemption is the property that a debtor may keep despite bankruptcy or a judgment for nonpayment. The federal bankruptcy statutes recognize the right of state law to prescribe exemptions. There is also a federal exemption, but state legislatures may require their citizens to claim only the state exemption, which in some states is smaller than the federal exemption. State exemption laws vary widely, with some states allowing a substantial exemption and other states exempting very little property. Even a generous exemption law, however, is not a guarantee that a debtor will keep a lot of property. A home is not exempt if there is a mortgage on the home, and other goods are similarly not protected from a secured creditor if they have been used as collateral for a debt.

The states with a Spanish heritage often followed the Spanish tradition that a bankrupt's family should have the means to continue to make a living. Thus, the state laws of Florida, Texas, and California, for example, have traditionally been liberal in permitting debtors to keep their homesteads and some other assets, such as the tools of their trade and current wages. Other states exempt items that are believed necessary for the family's well being, such as children's school books, certain farm equipment, sewing machines, and

funeral plots. There is a recent trend toward substituting dollar limitations for exemptions instead of listing specific items of property.

The state exemption is the principal determinant of the resources a bankrupt debtor will have following the bankruptcy. The rest of the debtor's postbankruptcy status depends upon the type of bankruptcy the debtor declares.

TYPES OF BANKRUPTCY

Bankruptcy may be entered either on a voluntary or on an involuntary basis. U.S. bankruptcy law arranges several ways by which debtors may voluntarily declare bankruptcy. Either individuals or corporate actors, including incorporated and unincorporated businesses, not-for-profit agencies, and municipalities may declare bankruptcy. The law makes special provision for the bankruptcies of railroads and stockbrokers. Creditors may in some circumstances initiate an involuntary bankruptcy. Only a small proportion of all bankruptcies is involuntary, and nearly all of those cases are targeted toward a business.

The Clerk of the Bankruptcy Court classifies each case filed as a business bankruptcy or a nonbusiness bankruptcy. These distinctions are not always clear-cut. As many as one in every five "nonbusiness" debtors reports currently owning a business or having recently owned a business. Moreover, many of the "business" bankruptcies are small family-owned enterprises. Whether classified as business or nonbusiness, the bankruptcy of a small business owner typically affects the family's welfare as well as that of the business.

Individual, noncorporate debtors typically have two choices in bankruptcy: *Chapter 7 liquidation* or a *Chapter 13 repayment plan*. In a Chapter 7 case, the debtor's assets over and above the exempt property will be sold and the creditors will be paid *pro rata*. Creditors with secured debts (those debts with collateral) will be allowed to have the collateral. All remaining debt will be discharged, or wiped away by the court. The debtor will not be able to file a Chapter 7 bankruptcy again for six years.

The Chapter 13 repayment plan is available only to individual debtors with a regular source of income. There are also other legal limitations,

such as maximum limits on the amount of debt owed. The debtor files with the court a plan for repaying debts over a three-to-five year schedule. The debtor must report all income to the court, and must also include a budget that provides the necessities of rent, food, clothing, medical treatment, and so on. The difference between the budgeted amount and the monthly income is the disposable income, which becomes the amount of the monthly payment.

The Chapter 13 petitioner must pay to a trustee, who is appointed by the court, all disposable income for the period of the plan. The debtor gets to keep all property. The trustee disburses the funds to the creditors. For a judge to confirm a Chapter 13 plan, the unsecured creditors must receive more money through the plan payments than they would have received in a Chapter 7 liquidation. At the conclusion of the plan, any remaining debt is discharged. Following this discharge, the Chapter 13 petitioner is also barred from further Chapter 7 bankruptcies for six years.

About two of every three Chapter 13 filers do not complete the proposed plan. Although the Chapter 13 may provide some benefits to the debtor—for example, he might have time to reorganize his finances—once plan payments are missed the court may dismiss the Chapter 13 and the debtor loses the protection of bankruptcy. Repayment plans such as Chapter 13 were begun by bankruptcy judges in northern Alabama before Congress wrote them into law. Even today, Chapter 13 is disproportionately popular in some judicial districts in the South. About one-third of all nonbusiness bankruptcies are filed in Chapter 13.

Some debts survive bankruptcy, regardless of the chapter in which the bankruptcy is filed. Child support, alimony, federally-backed educational loans, and some kinds of taxes are among those effectively nondischargeable in Chapter 7. Creditors may also object to the discharge of a specific debt if the debt arose from certain misbehavior, including fraud and drunkenness. Creditors may also object to the discharge generally on the grounds of debtor misbehavior, including hiding assets, disposing of assets before the bankruptcy, and lying to the court. A judge may object to a debtor filing in Chapter 7 if the judge believes that the filing represents a “substantial abuse.” A Chapter 13 plan must be filed in “good faith.”

For persons with substantial assets and for businesses there is an additional choice, *Chapter 11*, also called a *reorganization*. In Chapter 11, a debtor business seeks the protection of the court to reorganize itself in such a way that its creditors can be repaid (although perhaps not one hundred cents on the dollar). Creditors are given an opportunity to review the plan and to vote on its acceptability. If a sufficient number of creditors agree, the others may be forced to go along. In large cases, a committee of creditors is often appointed for the duration of the Chapter 11. Reorganizations may provide a means to save jobs while a business reorganizes.

In recent years, critics have charged that undoing business obligations has become an important motive for companies to reorganize under Chapter 11. Various companies have been accused of trying to avoid labor contracts, to avoid product liability, or to insulate management from challenges. These strategic uses of bankruptcy are potentially available to solvent companies. Although strategic uses of bankruptcies by individuals probably occur, most studies have found that the individuals in bankruptcy are in poor financial condition, often with debts in excess of three years' income.

There is also *Chapter 12* bankruptcy, another type of *reorganization* specifically for farmers. It was introduced in 1986 and in most years between one and two thousand cases are filed in Chapter 12.

Federal law permits the fact of a bankruptcy to remain on a credit record for ten years, but the law also prohibits discrimination against bankrupt debtors by governments or private employers.

BANKRUPTCY TRENDS

The number of business bankruptcies remains relatively small, usually fewer than 75,000 in a year, with exceptions in a few years. The number of nonbusiness bankruptcies, however, has generally risen for about two decades, from about 313,000 in 1981 to 811,000 in 1991. Nonbusiness bankruptcies passed the millionmark in 1996, and by 1998 there were more than 1.4 million nonbusiness bankruptcies in the United States.

Embedded within the general increase in bankruptcy are substantial regional variations in filing

rates that seem to follow the business cycle. Some analysts believe that bankruptcy is a lagging indicator; that is, some months after an economic slowdown, bankruptcies begin to rise as laid-off workers run out of resources or small business owners find they cannot remain in business.

Each bankruptcy affects at least one household, and one estimate puts the average number of creditors affected at eighteen. Some creditors, such as credit card issuers, are affected by numerous bankruptcies within a single year. Some bankruptcies initiate a chain of events: The bankruptcy of a single business may lead later to the bankruptcies of employees who lost their jobs, of creditors whose accounts receivable were never received, and of suppliers who could not find new customers. Creditors often argue that the rising numbers of bankruptcies cause them costs that are then passed on to all consumers in the form of higher interest rates.

A bankruptcy may be filed either by a single individual or jointly by a couple. Since the early 1980s, there has been a sharp increase in the proportion of bankruptcies filed by adult women. Several studies indicate between one-third and one-half of bankruptcies are now filed by women. Over half of bankrupt debtors are between the ages of thirty and fifty. Their mean occupational prestige is approximately the same as that of the labor force as a whole, and their educational level is also similar to that of the adult population. The proportion of immigrants in the bankrupt population is approximately the same as their proportion in the general population. There are conflicting findings about the extent to which minority populations are overrepresented or underrepresented in bankruptcy. Despite their educational and occupational levels, however, the median incomes of bankrupt debtors are less than half the median income of the general population.

CAUSES OF BANKRUPTCY

Much of what social scientists know about bankruptcy comes from reviewing the bankruptcy petitions filed in courts, and from interviewing judges, lawyers, clerks, and others who work in the bankruptcy courts. Information about the causes of bankruptcy, however, typically comes from interviews with the debtors themselves. Because many

debtors are ashamed of their bankruptcies, and because American debtor populations are geographically mobile, interview studies often have somewhat low response rates. For learning the cause of a bankruptcy, however, there is probably no substitute for asking the debtor.

Debtors often report “inability to manage money” or “too much debt” as the reason for their bankruptcy. In probing a little deeper, however, researchers have found five major issues involved in a large fraction of all bankruptcies: job problems, divorce and related family problems, medical problems, homeowner problems, and credit card debts.

Many debtors have been laid off completely, lost overtime, or had their hours of work or their pay rates reduced. Some debtors have had long periods of unemployment; others have lost their jobs because of the closure of the plant or the store where they worked. The job loss causes an unplanned loss of income, and this fact in turn often creates a mismatch between the petitioner’s debt obligations and the ability to meet those obligations. During the recession of the early 1990s, when many industries were downsizing and otherwise restructuring their labor forces, about two in every five bankrupt debtors reported a job-related reason for bankruptcy.

Divorce and other family problems may result in lower incomes for the two ex-spouses (especially the ex-wife). Moreover, in most divorce settlements the debts are also divided, and the debt burden may be too great for one of the ex-spouses. Sometimes an ex-spouse will file bankruptcy knowing that any jointly-incurred debts discharged by the bankrupt spouse will have to be paid by the other ex-spouse. Although alimony and child support cannot be discharged as debts, for custodial parents who do not receive the payments the financial consequences may be grave. Similarly, for parents who must make the payments, a reduction in other debts may make the payments more possible. Finally, it is harder to support two households on the income that used to support just one household. For all of these reasons, the recently divorced may find themselves in bankruptcy.

Medical problems may lead to higher debts if the debtor is uninsured or if insurance is insufficient to pay for needed medical procedures, pharmaceuticals, and professional services. Medical

problems may at the same time lead to lower incomes if a person is too ill or injured to work. Either way, a spell of illness or an automobile accident may push a previously solvent person into a situation in which debts are no longer manageable. Medical problems rise in frequency as a reported cause of bankruptcy for adults aged fifty-five to sixty-four, years in which medical problems may increase but before Medicare coverage becomes available.

Earlier efforts to examine medical debts as an indicator of the causes of bankruptcy showed medical debt to be a fairly insignificant cause, whereas direct interviews of debtors are more likely to reveal medical issues as causative. There are reasons to believe that the debt indicators underestimate this reason for bankruptcy. Insurance will often pay medical providers but will not replace income, so that debts to hospitals or physicians might not appear in the records even though the illness or injury is nevertheless the reason that the debtor cannot repay debts. Moreover, some medical providers accept credit cards, so that the medical expenses are hidden within credit card debt. And some debtors will make efforts to pay off their medical creditors first for fear of being denied services. On the other hand, there may be some overestimate of the impact of medical issues in interviews, because respondents may believe a medical reason may be seen as a socially acceptable cause for bankruptcy.

Bankrupt debtors are somewhat less likely to be homeowners than the general population, but a substantial number of homeowners file for bankruptcy, often to prevent the foreclosure of their mortgage. Chapter 13 permits homeowners to pay the arrearages (missed payments) on their mortgage along with their current payments. Home ownership may also be an issue for a worker who is transferred to a different city and buys a second home before the first home is sold. Equity is the portion of the home's value for which the homeowner has made payment. The recent proliferation of home-equity loans, which allow homeowners to use the equity in their homes as collateral, has also put homes at risk even if the payments on the principal mortgage are current. Small business owners are often required to use their homes as collateral for business loans, which means that a failing business may also entail the threat of the family losing its home. Home-equity lending is

being extended to a number of other situations, including college loans and credit cards, with the result that many Americans are risking their homes, often without realizing it.

A final reason for bankruptcy is large credit card debts, often at high rates of interest. All-purpose cards (such as Visa, MasterCard, and American Express) are now used for many consumption purposes, including payment of federal income taxes, payment of college tuition, and many goods and services, with the result that credit card debt is assumed for many different purposes. Most ordinary living expenses can now be charged with a credit card, so that interpreting a high credit card debt is difficult. High rates of interest accelerate the credit card debt quickly. Credit card debt is the fastest-growing reason for bankruptcy being given by debtors.

BANKRUPTCY MYTHS

Empirical studies have refuted a number of myths about bankruptcy. One such myth is that some people file for bankruptcy again and again. Several studies have been unable to confirm this myth, but there are a number of people who are unsuccessful at Chapter 13 who eventually file Chapter 7. These people have not really repeated bankruptcy, because they have never received a discharge from their debts in their Chapter 13 filings.

Another myth is that large numbers of bankrupt debtors have high debts because of alcoholism, drug abuse, and gambling. Although most empirical studies have identified a few isolated cases in which one of these problems plays a role, the great increase in bankruptcy numbers cannot be attributed to a great increase in addictive behavior.

A third myth is that there is widespread abuse of the bankruptcy process because many debtors could allegedly pay all of their debts. Most studies of the repayment possibilities for the debtors find that the debtors are unable to repay their debts, even if their families live on very modest budgets (such as the model low-income budget of the U.S. Bureau of Labor Statistics). The few studies that have found debtors able to repay have often eliminated from repayment whole categories of debt that the debtors themselves cannot eliminate. There are, however, documented cases of fraudulent or

abusive use of bankruptcy, some of which are prosecuted by the government as criminal matters.

STRUCTURAL SOURCES OF BANKRUPTCY

Several changes in American financial life have contributed to the imbalance of debt with income and may have increased the numbers of people who file for bankruptcy.

Consumer credit has been available for decades, principally as a means to help households finance a large purchase over a period of time. Individual sellers extended credit, often on the basis of personal knowledge of the borrower and the borrower's ability to repay. Later, banks, credit unions, and personal finance companies helped finance the purchase of homes, cars, and small appliances. These institutional arrangements offered more protection to the seller and made a personal acquaintanceship less important in the lending decision.

The development of credit cards, with preapproved credit limits, allowed consumers to buy a large variety of goods or services on credit, not just large or expensive items. It was not just the invention of the credit card, however, but some later developments in its use that have changed consumer financial patterns in a way that may have influenced higher bankruptcy rates.

First, beginning in the late 1970s, most states repealed their laws making usury an offense, and Congress made state usury laws largely ineffective. Usury, the charging of excessive interest, was formerly regulated by the states, most of which set limits on the maximum amount of interest that could be charged to borrowers. With the repeal of these laws, high rates of interest—some as high as 20 percent or more—could legally be charged. Prior to this time, such high rates of interest were usually defined as criminal and were associated with loan-sharking and the lending practices of organized crime.

Second, credit cards became a major profit center for many banks, especially because of the high interest rates that could be charged. Marketing of credit cards mushroomed. New markets, including relatively low-income families, became the targets of sophisticated mail and telephone campaigns. Even though many of the families might not be able to repay everything they charged,

the large interest payments made the lending profitable. Credit cards are now extensively marketed to young people, especially college students, who are relatively unfamiliar with financial matters.

Third, credit devices proliferated to include gold and platinum levels, cash advances, and many other features that were both profitable to card issuers and attractive to card holders. Sometimes card holders did not understand how these features worked; for example, many card holders did not realize that there is no grace period for repaying a cash advance, and the interest rate on a cash advance is often higher than the rate for purchases.

Fourth, merchants who accepted credit cards enjoyed increased business because the buyers did not have to carry a large supply of cash. Advertising by stores and restaurants increasingly emphasized the acceptability of credit cards, so that the advertising for goods and services reinforced the advertising of the credit card issuers. Meanwhile, the credit card issuers provided protection against nonpayment to the merchant who accepted a credit card, and they also provided some protection for the card-holder against the fraudulent use of the cards.

Fifth, a major restructuring of the U.S. economy occurred at the beginning of the 1990s, in which millions of workers were laid off or could find only contingent jobs. Many of these workers found credit cards to be a convenient way to maintain consumption levels and their family's lifestyle even though their expected income stream was interrupted.

These trends contributed to an increase in the numbers of people who had high debt-to-income ratios. Some people incurred high levels of debt, often at high interest rates, and simultaneously experienced declining or stagnant income. While not every person with a high debt-to-income ratio filed for bankruptcy, those who did file for bankruptcy had very high ratios. Changes in the American economy during the decade of the 1990s probably influenced the increase in the number of bankruptcies. In particular, the increasing indebtedness of Americans closely tracked the rise in bankruptcies.

Rising Indebtedness. The economic changes of the 1990s, in addition to the well-entrenched borrowing for home mortgages, car purchases,

and college expenses, have resulted in an increase in consumer credit outstanding from 298 billion dollars in 1980 to 1,025 billion in 1995. Thus, while the U.S. population increased by 16 percent, indebtedness increased by 244 percent. These are nominal dollars, but even accounting for inflation (constant dollars) the debt burden doubled. During this same time frame, mortgage lending increased by 223 percent, from 1,463 billion dollars in 1980 to 4,724 billion dollars in 1995. Credit card debt, which was only 81.2 billion dollars in 1980, had increased by 351 percent to 366.4 billion dollars in 1995. Thus, while there was an increase in all forms of indebtedness, credit card debt—which began from a smaller base—showed the largest percentage increase.

Industry sources estimate that in 1990 there were 1.03 billion credit cards in circulation in the United States, and that by 2000 a projected 1.34 billion cards will be in circulation. In 1990, these cards accounted for 466 billion dollars of spending and resulted in 236 billion dollars of debt. By 2000, the projected spending is 1,443 billion dollars, with 661 billion dollars as debt.

In its survey of how consumers use credit cards, the Board of Governors of the Federal Reserve System reported that 54.5 percent of the sample always paid off the balance on their credit cards each month. Another 19.1 percent sometimes pay off the balance, and the remaining 26.4 percent hardly ever pay off the balance. It is from this latter group that the credit card issuers run the greatest risk of eventual nonpayment but also have the possibility of earning the greatest amount of interest. About 30 percent of the consumers earning less than \$50,000 a year “hardly ever” pay off the balance, compared with only 10.5 percent of those who earn more than \$100,000. Over 35 percent of the consumers under the age of thirty-five hardly ever pay off their balance, compared with 10.5 percent of people over the age of seventy-five.

Credit cards alone do not pose a major financial problem for most people, even for those who maintain a balance; the median balance is about \$1,000, with a median charge of \$200 a month. For those people with larger balances, however, and with interest charges and sometimes penalties and late fees added to the principal, indebtedness may

become a serious problem. And although facing this problem can be postponed by making small monthly payments, the balance can quickly become too large ever to be handled on most salaries.

The ubiquity and convenience of credit cards has led to their growing use for additional purposes: as a form of identification, as security for returning rented cars and videotapes, and—perhaps ironically—as an indicator of creditworthiness for additional extensions of credit.

INTERNATIONAL CREDIT ISSUES

Besides the indebtedness of the individuals in a population, there is also growing concern about other forms of indebtedness. Many countries, especially those with less developed economies, have borrowed large sums of money from more developed countries. The repayment of these loans, and the terms that are demanded, have provided a source of tension between the richer nations and the poorer nations. International agencies such as the International Monetary Fund often prescribe austerity measures to help a country meet its repayment obligations.

The development of transnational corporations has also raised issues of which set of debtor-creditor laws govern transactions that may span several countries. Debtor-creditor laws and the laws of insolvency and bankruptcy vary dramatically from country to country, and an important issue in international commerce is how to handle problems of nonpayment. Many of these issues remain highly contested and largely unsettled.

TERESA A. SULLIVAN

BEHAVIORISM

Behaviorism is the conceptual framework underlying the science of behavior. The science itself is often referred to as the *experimental analysis of behavior or behavior analysis*. Modern behaviorism emphasizes the analysis of conditions that maintain and change behavior as well as the factors that influence the acquisition or learning of behavior. Behaviorists also offer concepts and analyses that go well beyond the common-sense understanding of reward and punishment. Contemporary behaviorism provides an integrated framework for the study of human behavior, society, and culture.

Within the social sciences, behaviorism has referred to the social-learning perspective that emphasizes the importance of reinforcement principles in regulating social behavior (McLaughlin 1971). In addition, sociologists such as George Homans and Richard Emerson have incorporated the principles of behavior into their theories of elementary social interaction or exchange (Emerson 1972; Homans 1961). The basic idea in social exchange approaches is that humans exchange valued activities (e.g., giving respect and getting help) and that these transactions are “held together” by the principle of reinforcement. That is,

exchange transactions that involve reciprocal reinforcement by the partners increase in frequency or probability; those transactions that are not mutually reinforcing or are costly to the partners decrease in frequency over time. There is a growing body of research literature supporting social exchange theory as a way of understanding a variety of social relationships.

SOME BASIC ISSUES

The roots of behaviorism lie in its philosophical debate with introspectionism—the belief that the mind can be revealed from a person’s reports of thoughts, feelings, and perceptions. Behaviorists opposed the use of introspective reports as the basic data of psychology. These researchers argued for a natural-science approach and showed how introspective reports of consciousness were inadequate. Reports of internal states and experiences were said to lack objectivity, were available to only one observer, and were prone to error. Some behaviorists used these arguments and also others to reject cognitive explanations of behavior (Skinner 1974; Pierce and Epling 1984; but see Bandura 1986 for an alternative view).

The natural-science approach of behaviorism emphasizes the search for general laws and principles of behavior. For example, the *quantitative law of effect* is a mathematical statement of how the rate of response increases with the rate of reinforcement (Herrnstein 1970). Under controlled conditions, this equation allows the scientist to predict precisely and to regulate the behavior of organisms. Behavior analysts suggest that this law and other behavior principles will eventually account for complex human behavior (McDowell 1988).

Contemporary behaviorists usually restrict themselves to the study of observable responses and events. Observable events are those that are directly sensed or are made available to our senses by instruments. The general strategy is to manipulate aspects of the environment and measure well-defined responses. If behavior reliably changes with a manipulated condition, the researcher has established an environment-behavior relationship. Analysis of such relationships has often resulted in behavioral laws and principles. For example, the principle of discrimination states that an organism

will respond differently to two situations if its behavior is reinforced in one setting but not in the other. You may talk about politics to one person but not to another, because the first person has been interested in such conversation in the past while the second has not. The principle of discrimination and other behavior principles account for many aspects of human behavior.

Although behaviorism usually has been treated as a uniform and consistent philosophy and science, a conceptual reconstruction indicates that there are many branches to the behavioral tree (Zuriff 1985). Most behavior analysts share a set of core assumptions; however, there are internal disputes over less central issues. To illustrate, some behaviorists argue against hypothetical constructs (e.g., memory) while others accept such concepts as an important part of theory construction.

Throughout the intellectual history of behaviorism, a variety of assumptions and concepts has been presented to the scientific community. Some of these ideas have flourished when they were found to further the scientific analysis of behavior. Other formulations were interesting variations of behavioristic ideas, but they became extinct when they served no useful function. For instance, one productive assumption is that a person's knowledge of emotional states is due to a special history of verbal conditioning (Bem 1965, 1972; Skinner 1957). Self-perception and attributional approaches to social psychology have built on this assumption, although researchers in this field seldom acknowledge the impact. In contrast, the assumption that thinking is merely subvocal speech was popular at one time but is now replaced by an analysis of problem solving (Skinner 1953, 1969). In this view, thinking is behavior that precedes and guides the final performance of finding a solution. Generally, it is important to recognize that behaviorism continues to evolve as a philosophy of science, a view of human nature, and an ideology that recommends goals for behavioral science and its applications.

THE STUDY OF BEHAVIOR

Behaviorism requires that a scientist study the behavior of organisms for its own sake. Behaviorists do not study behavior in order to make inferences

about mental states or physiological processes. Although most behaviorists emphasize the importance of biology and physiological processes, they focus on the interplay of behavior and environment.

In order to maintain this focus, behaviorists examine the evolutionary history and physiological status of an organism as part of the context for specific environment-behavior interactions. For example, a biological condition that results in blindness may have profound behavioral effects. For a newly sightless individual, visual events, such as watching television or going to a movie no longer support specific interactions, while other sensory events become salient (e.g., reading by braille). The biological condition limits certain kinds of behavioral interactions and, at the same time, augments the regulation of behavior by other aspects of the environment. Contemporary behaviorism therefore emphasizes what organisms are doing, the environmental conditions that regulate their actions, and how biology and evolution constrain or enhance environment-behavior interactions.

Modern behaviorists are interested in voluntary action, and they have developed a way of talking about purpose, volition, and intention within a natural-science approach. They note that the language of intention was pervasive in biology before Darwin's functional analysis of evolution. Although it appears that giraffes grow long necks in order to obtain food at the tops of trees, Darwin made it clear that the process of evolution involved no plan, strategy of design, or purpose. Natural variation ensures that giraffes vary in neck size. As vegetation declines at lower heights, animals with longer necks obtain food, survive to adulthood, and reproduce; those with shorter necks starve to death. In this environment (niche), the frequency of long-necked giraffes increases over generations. Such an increase is called natural selection. Contemporary behaviorists insist that selection, as a causal mode, also accounts for the form and frequency of behavior during the lifetime of an individual. A person's current behavior is therefore composed of performances that have been selected in the past (Skinner 1987).

An important class of behavior is selected by its consequences. The term *operant* refers to behavior that operates upon the environment to produce effects, outcomes, or consequences. Operant

behavior is said to be emitted because it does not depend on an eliciting stimulus. Examples of operant behavior include manipulation of objects, talking with others, problem solving, drawing, reading, writing, and many other performances. Consequences select this behavior in the sense that specific operants occur at high frequency in a given setting. To illustrate, driving to the store is operant behavior that is likely to occur when there is little food in the house. In this situation, the operant has a high probability if such behavior has previously resulted in obtaining food (i.e. the store is open). Similarly, the conversation of a person also is selected by its social consequences. At the pub, a student shows high probability of talking to his friends about sports. Presumably, this behavior occurs at high frequency because his friends have previously "shown an interest" in such conversation. The behavior of an individual is therefore adapted to a particular setting by its history of consequences.

A specific operant, such as opening a door, includes many performance variations. The door may be opened by turning the handle, pushing with a foot, or even by asking someone to open it. These variations in performance have a common effect upon the environment in the sense that each one results in the door being opened. Because each variation produces similar consequences, behaviorists talk about an operant as a response class. Operants such as opening a door, talking to others, answering questions, and many other actions are each a response class that includes a multitude of forms, both verbal and nonverbal.

In the laboratory, the study of operant behavior requires a basic measure that is sensitive to changes in the environment. Most behaviorists use an operant's rate of occurrence as the basic data for analysis. Operant rate is measured as the frequency of an operant (class) over a specified period of time. Although operant rate is not directly observable, a cumulative recorder is an instrument that shows the rate of occurrence as changes in the slope (or rise) of a line on moving paper. When an operant is selected by its consequences, the operant rate increases and the slope becomes steeper. Operants that are not appropriate to the requirements of the environment decrease in rate of occurrence (i.e., decline in slope). Changes in operant rate therefore reflect the basic causal process of *selection by consequences* (Skinner 1969).

Behavior analysts continue to use the cumulative recorder to provide an immediate report on a subject's behavior in an experimental situation. However, most researchers are interested in complex settings where there are many alternatives and multiple operants. Today, microcomputers collect and record a variety of behavioral measures that are later examined by complex numerical analysis. Researchers also use computers to arrange environmental events for individual behavior and provide these events in complex patterns and sequences.

CONTINGENCIES OF REINFORCEMENT

Behaviorists often focus on the analysis of environment-behavior relationships. The relationship between operant behavior and its consequences defines a *contingency of reinforcement*. In its simplest form, a two-term contingency of reinforcement may be shown as $R(Sr)$. The symbol R represents the operant class, and Sr stands for the reinforcing stimulus or event. The arrow indicates that "if R occurs, then Sr will follow." In the laboratory, the behavior analyst arranges the environment so that a contingency exists between an operant (e.g., pecking a key) and the occurrence of some event (e.g., presentation of food). If the presentation of the event increases operant behavior, the event is defined as a positive reinforcer. The procedure of repeatedly presenting a positive reinforcer contingent on behavior is called positive reinforcement (see Pierce and Epling 1999).

A contingency of reinforcement defines the probability that a reinforcing event will follow operant behavior. When a person turns the ignition key of the car (operant), this behavior usually has resulted in the car starting (reinforcement). Turning the key does not guarantee, however, that the car will start; perhaps it is out of gas, the battery is run down, and so on. Thus, the probability of reinforcement is high for this behavior, but reinforcement is not certain. The behavior analyst is interested in how the probability of reinforcement is related to the rate and form of operant behavior. For example, does the person continue to turn the ignition key even though the car doesn't start? Qualities of behavior such as persistence, depression, and elation reflect the probability of reinforcement.

Reinforcement may depend on the number of responses or the passage of time. A schedule of reinforcement is a procedure that states how consequences are arranged for behavior. When reinforcement is delivered after each response, a continuous schedule of reinforcement is in effect. A child who receives payment each time she mows the lawn is on a continuous schedule of reinforcement. Continuous reinforcement produces a very high and steady rate of response, but as any parent knows, the behavior quickly stops if reinforcement no longer occurs.

Continuous reinforcement is a particular form of ratio schedule. Fixed-ratio schedules state the number of responses per reinforcement. These schedules are called *fixed ratio* since a fixed number of responses are required for reinforcement. In a factory, piece rates of payment are examples of fixed-ratio schedules. Thus, a worker may receive \$1 for sewing twenty pieces of elastic wristband. When the ratio of responses to reinforcement is high (value per unit output is low), fixed-ratio schedules produce long pauses following reinforcement: Overall productivity may be low, leading plant managers to complain about “slacking off” by the workers. The problem, however, is the schedule of reinforcement that fixes a high number of responses to payment.

Reinforcement may be arranged on a variable, rather than fixed, basis. The schedule of payoff for a slot machine is a *variable-ratio* schedule of reinforcement. The operant involves putting in a dollar and pulling the handle, and reinforcement is the jackpot. The jackpot occurs after a variable number of responses. Variable-ratio schedules produce a high rate of response that takes a long time to stop when reinforcement is withdrawn. The gambler may continue to put money in the machine even though the jackpot rarely, if ever, occurs. Behavior on a variable-ratio schedule is said to show *negative utility* since people often invest more than they get back.

Behavior may also be reinforced only after an interval of time has passed. A *fixed-interval* schedule stipulates that the first response following a specified interval is reinforced. Looking for a bus is behavior that is reinforced after a fixed time set by the bus schedule. If you just missed a bus, the probability of looking for the next one is quite low. As time passes, the rate of response increases with

the highest rate occurring just before the bus arrives. Thus, the rate of response is initially zero but gradually rises to a peak at the moment of reinforcement. This response pattern is called *scalloping* and is characteristic of fixed-interval reinforcement. In order to eliminate such patterning, a *variable-interval* schedule may be stipulated. In this case, the first response after a variable amount of time is reinforced. If a person knows by experience that bus arrivals are irregular, looking for the next bus will occur at a moderate and steady rate because the passage of time no longer signals reinforcement (i.e., arrival of the bus).

The schedules of reinforcement that regulate human behavior are complex combinations of ratio and interval contingencies. An *adjusting* schedule is one example of a more complex arrangement between behavior and its consequences (Zeiler 1977). When the ratio (or interval) for reinforcement changes on the basis of performance, the schedule is called adjusting. A math teacher who spends more or less time with a student depending on the student’s competence (i.e., number of correct solutions) provides reinforcement on an adjusting-ratio basis. When reinforcement is arranged by other people (i.e., social reinforcement), the level of reinforcement is often tied to the level of behavior (i.e., the greater the strength of response the less the reward from others). This adjustment between behavior and socially arranged consequences may account for the flexibility and variability that characterize adult human behavior.

Human behavior is regulated not only by its consequences. Contingencies of reinforcement also involve the events that precede operant behavior. The preceding event is said to “set the occasion” for behavior and is called a discriminative stimulus or *Sd*. The ring of a telephone (*Sd*) may set the occasion for answering it (operant), although the ring does not force one to do so. Similarly, a nudge under the table (*Sd*) may prompt a new topic of conversation (operant) or cause the person to stop speaking. Discriminative stimuli may be private as well as public events. Thus, a headache may result in taking a pill or calling a physician. A mild headache may be discriminative stimulus for taking an aspirin, while more severe pain sets the occasion for telephoning a doctor.

Although discriminative stimuli exert a broad range of influences over human behavior, these

events do not stand alone. These stimuli regulate behavior because they are an important part of the contingencies of reinforcement. Behaviorism has therefore emphasized a three-term contingency of reinforcement, symbolized as $Sd:R(r)Sr$. The notation states that a specific event (Sd) sets the occasion for an operant (R) that produces reinforcement (Sr). The discriminative stimulus regulates behavior only because it signals past consequences. Thus, a sign that states “Eat at Joe’s” may set the occasion for your stopping at Joe’s restaurant because of the great meals received in the past. If Joe hires a new cook, and the meals deteriorate in quality, then Joe’s sign will gradually lose its influence. Similarly, posted highway speeds regulate driving on the basis of past consequences. The driver who has been caught by a radar trap is more likely to observe the speed limit.

CONTEXT OF BEHAVIOR

Contingencies of reinforcement, as complex arrangements of discriminative stimuli, operants, and reinforcements, remain a central focus of behavioral research. Contemporary behaviorists are also concerned with the *context of behavior*, and how context affects the regulation of behavior by its consequences (Fantino and Logan 1979). Important aspects of context include the biological and cultural history of an organism, its current physiological status, previous environment–behavior interactions, alternative sources of reinforcement, and a history of deprivation (or satiation) for specific events or stimuli. To illustrate, in the laboratory food is used typically as an effective reinforcer for operant behavior. There are obvious times, however, when food will not function as reinforcement. If a person (or animal) has just eaten a large meal or has an upset stomach, food has little effect upon behavior.

There are less obvious interrelations between reinforcement and context. Recent research indicates that depriving an organism of one reinforcer may increase the effectiveness of a different behavioral consequence. As deprivation for food increased, animals worked harder to obtain an opportunity to run on a wheel. Additionally, animals who were satiated on wheel running no longer pressed a lever to obtain food. These results imply that eating and running are biologically interrelated. Based on this biological history, the supply or

availability of one of these reinforcers alters the effectiveness of the other (Pierce, Epling, and Boer 1986). It is possible that many reinforcers are biologically interrelated. People commonly believe that sex and aggression go together in some unspecified manner. One possibility is that the availability of sexual reinforcement alters the reinforcing effectiveness of an opportunity to inflict harm on others.

CHOICE AND PREFERENCE

The emphasis on context and reinforcement contingencies has allowed modern behaviorists to explore many aspects of behavior that seem to defy a scientific analysis. Most people believe that choice and preference are basic features of human nature. Our customary way of speaking implies that people make decisions on the basis of their knowledge and dispositions. In contrast, behavioral studies of decision making suggest that we choose an option based on its rate of return compared with alternative sources of reinforcement.

Behaviorists have spent the last thirty years studying choice in the laboratory using concurrent schedules of reinforcement. The word *concurrent* means “operating at the same time.” Thus, concurrent schedules are two (or more) schedules operating at the same time, each schedule providing reinforcement independently. The experimental setting is arranged so that an organism is free to alternate between two or more alternatives. Each alternative provides a schedule of reinforcement for choosing it over the other possibilities. A person may choose between two (or more) response buttons that have different rates of monetary payoff. Although the experimental setting is abstract, concurrent schedules of reinforcement provide an analogue of choice in everyday life.

People are often faced with a variety of alternatives, and each alternative has its associated benefits (and costs). When a person puts money in the bank rather than spending it on a new car, television, or refrigerator, we speak of the individual choosing to save rather than spend. In everyday life, choice often involves repeated selection of one alternative (e.g. putting money in the bank) over the other alternatives considered as a single option (e.g. buying goods and services). Similarly, the criminal chooses to take the property of others rather than take the socially acceptable

route of working for a living or accepting social assistance. The arrangement of consequences for crime and legitimate ways of making a living is conceptually the same as concurrent schedules of reinforcement (Hamblin and Crosbie 1977).

Behaviorists are interested in the distribution or allocation of behavior when a person is faced with different rates of reinforcement from two (or more) alternatives. The distribution of behavior is measured as the relative rate of response to, or relative time spent on, a specific option. For example, a student may go to school twelve days and skip eight days each month (not counting weekends). The relative rate of response to school is the proportion of the number of days at school to the total number of days, or $12/20 = 0.60$. Expressed as a percentage, the student allocates 60 percent of her behavior to school. In the laboratory, a person may press the left button twelve times and the right button eight times each minute.

The distribution of reinforcement may also be expressed as a percentage. In everyday life, it is difficult to identify and quantify behavioral consequences, but it is easily accomplished in the laboratory. If the reinforcement schedule on the left button produces \$30 an hour and the right button yields \$20, 60 percent of the reinforcements are on the left. There is a fundamental relationship between relative rate of reinforcement and relative rate of response. This relationship is called the *matching law*. The law states that the distribution of behavior to two (or more) alternatives matches (equals) the distribution of reinforcement from these alternatives (Herrnstein 1961; de Villiers 1977).

Although it is difficult to identify rates of reinforcement for attending school and skipping, the matching law does suggest some practical solutions (Epling and Pierce 1988). For instance, parents and the school may be able to arrange positive consequences when a child goes to school. This means that the rate of reinforcement for going to school has increased, and therefore the relative rate of reinforcement for school has gone up. According to the matching law, a child will now distribute more behavior to the school.

Unfortunately, there is another possibility. A child may receive social reinforcement from friends for skipping, and as the child begins to spend more time at school, friends may increase their rate of reinforcement for cutting classes. Even though the

absolute rate of reinforcement for going to school has increased, the relative rate of reinforcement has remained the same or decreased. The overall effect may be no change in school attendance or even further decline. In order to deal with the problem, the matching law implies that interventions must increase reinforcement for attendance and maintain or reduce reinforcement for skipping, possibly by turning up the cost of this behavior (e.g., withdrawal of privileges).

The matching law has been tested with human and nonhuman subjects under controlled conditions. One interesting study assessed human performance in group discussion sessions. Subjects were assigned to groups discussing attitudes toward drug abuse. Each group was composed of three confederates and a subject. Two confederates acted as listeners and reinforced the subject's talk with brief positive words and phrases, provided on the basis of cue lights. Thus, the rate of reinforcement by each listener could be varied depending on the number of signals arranged by the researchers. A third confederate asked questions but did not reinforce talking. Results were analyzed in terms of the relative time subjects spent talking to the two listeners. Speakers matched their distribution of conversation to the distribution of positive comments from the listeners. Apparently, choosing to speak to others is behavior that is regulated by the matching law (Conger and Kileen 1974).

Researchers have found that exact matching does not always hold between relative rate of reinforcement and relative rate of response. A more general theory of behavioral matching has been tested in order to account for the departures from perfect matching. One source of deviation is called *response bias*. Bias is a systematic preference for an alternative, but the preference is not due to the difference in rate of reinforcement. For example, even though two friends provide similar rates of reinforcement, social characteristics (e.g., status and equity) may affect the distribution of behavior (Sunahara and Pierce 1982). Generalized matching theory is able to address many social factors as sources of bias that affect human choice and preference (Baum 1974; Pierce and Epling 1983; Bradshaw and Szabadi 1988).

A second source of deviation from matching is called *sensitivity to differences* in reinforcement.

Matching implies that an increase of 10 percent (e.g., from 50 to 60 percent) in relative rate of reinforcement for one alternative results in a similar increase in relative rate of response. In many cases, the increase in relative rate of response is less than expected (e.g., only 5 percent). This failure to discriminate changes in relative rate of reinforcement is incorporated within the theory of generalized matching. To illustrate, low sensitivity to changes in rate of reinforcement may occur when an air-traffic controller rapidly switches between two (or more) radar screens. As relative rate of targets increases on one screen, relative rate of detection may be slow to change. Generalized matching theory allows behaviorists to measure the degree of sensitivity and suggests procedures to modify it (e.g., setting a minimal amount of time on a screen before targets can be detected).

Matching theory is an important contribution of modern behaviorism. In contrast to theories of rational choice proposed by economists and other social scientists, matching theory implies that humans may not try to maximize utility (or reinforcement). People (and animals) do not search for the strategy that yields the greatest overall returns; they equalize their behavior to the obtained rates of reinforcement from alternatives. Research suggests that matching (rather than maximizing) occurs because humans focus on the immediate effectiveness of their behavior. A person may receive a per-hour average of \$10 and \$5 respectively from the left and right handles of a slot machine. Although the left side generally pays twice as much, there are local periods when the left option actually pays less than the right. People respond to these changes in *local rate of reinforcement* by switching to the lean alternative (i.e., the right handle), even though they lose money overall. The general implication is that human impulsiveness ensures that choice is not a rational process of getting the most in the long run but a behavioral process of doing the best at the moment (Herrnstein 1990).

MATHEMATICS AND BEHAVIOR MODIFICATION

The matching law suggests that operant behavior is determined by the rate of reinforcement for one alternative relative to all other sources of reinforcement. Even in situations that involve a single

response on a schedule of reinforcement, the behavior of organisms is regulated by alternative sources of reinforcement. A rat that is pressing a lever for food may gain additional reinforcement from exploring the operant chamber, scratching itself, and so on. In a similar fashion, rather than work for teacher attention a pupil may look out the window, talk to a friend, or even daydream. Thus in a single-operant setting, multiple sources of reinforcement are functioning. Herrnstein (1970) argued this point and suggested an equation for the single operant that is now called the *quantitative law of effect*.

Carr and McDowell (1980) applied Herrnstein's equation to a clinically relevant problem. The case involved the treatment of a 10-year-old boy who repeatedly and severely scratched himself. Before treatment the boy had a large number of open sores on his scalp, face, back, arms, and legs. In addition, the boy's body was covered with scabs, scars, and skin discoloration. In their review of this case, Carr and McDowell demonstrated that the boy's scratching was operant behavior. Careful observation showed that the scratching occurred more often when he and other family members were in the living room watching television. This suggested that a specific situation set the occasion for the self-injurious behavior. Further observation showed that family members repeatedly and reliably reprimanded the boy when he engaged in self-injury. Reprimands are seemingly negative events, but adult attention (whether negative or positive) can serve as reinforcement for children's behavior.

In fact, McDowell (1981) showed that the boy's scratching was in accord with Herrnstein's equation (i.e., the quantitative law of effect). He plotted the reprimands per hour on the *x*-axis and scratches per hour on the *y*-axis. When applied to this data, the equation provided an excellent description of the boy's behavior. The quantitative law of effect also suggested how to modify the problem behavior. In order to reduce scratching (or any other problem behavior), one strategy is to increase reinforcement for alternative behavior. As reinforcement is added for alternative behavior, problem behavior must decrease; this is because the reinforcement for problem behavior is decreasing (relative to total reinforcement) as reinforcement is added to other (acceptable) behavior.

APPLIED BEHAVIOR ANALYSIS AND EDUCATION

The application of behavior principles to improve performance and solve social problems is called *applied behavior analysis* (Baer, Wolf, and Risley 1968). Principles of behavior change have been used to improve the performance of university students, increase academic skills in public and high school students, teach self-care to developmentally delayed children, reduce phobic reactions, get people to wear seat belts, prevent industrial accidents, and help individuals stop cocaine abuse, among other things. Behavioral interventions have had an impact on such things as clinical psychology, medicine, education, business, counseling, job effectiveness, sports training, the care and treatment of animals, environmental protection, and so on. Applied behavioral experiments have ranged from investigating the behavior of psychotic individuals to designing contingencies of entire institutions (see Catania and Brigham 1978; Kazdin 1994).

One example of applied behavior analysis in higher education is the method of personalized instruction. Personalized instruction is a self-paced learning system that contrasts with traditional lecture methods that often are used to instruct college students. In a university lecture, a professor stands in front of a number of students and talks about his or her area of expertise. There are variations on this theme (e.g., students are encouraged to be active rather than passive learners), basically the lecture method of teaching is the same as it has been for thousands of years.

Dr. Fred Keller (1968) recognized that the lecture method of teaching was inefficient and in many cases a failure. He reasoned that anyone who had acquired the skills needed to attend college was capable of successfully mastering most or all college courses. Some students might take longer than others to reach expertise in a course, but the overwhelming majority of students would be able to do so. If behavior principles were to be taken seriously, there were no bad students, only ineffective teaching methods.

In a seminal article, titled "Good-bye, teacher. . .," Keller outlined a college teaching method based on principles of operant conditioning (Keller 1968). Keller's personalized system of instruction (PSI) involves arranging the course material in a sequence of graduated steps (units or modules).

Each student moves through the course material at his or her own pace and the modules are set up to ensure that most students have a high rate of success learning the course content. Some students may finish the course in a few weeks, others require a semester or longer.

Course material is broken down into many small units of reading and (if required) laboratory assignments. Students earn points (conditioned reinforcement) for completing unit tests and lab assignments. Mastery of lab assignments and unit tests is required. If test scores are not close to perfect, the test (in different format) must be taken again after a review of the material for that unit. The assignments and tests build on one another so they must be completed in a specified order.

Comparison studies have evaluated student performance on PSI courses against the performance of students given computer-based instruction, audio-tutorial methods, traditional lectures, visual-based instruction, and other programmed instruction methods. College students instructed by PSI outperform students taught by these other methods when given a common final examination (see Lloyd and Lloyd 1992 for a review). Despite this positive outcome, logistical problems in organizing PSI courses such as teaching to mastery level (most students get an A for the course), and allowing students more time than the allotted semester to complete the course, have worked against widespread adoption of PSI in universities and colleges.

SUMMARY

Modern behaviorism emphasizes the context of behavior and reinforcement. The biological history of an organism favors or constrains specific environment-behavior interactions. This interplay of biology and behavior is a central focus of behavioral research. Another aspect of context concerns alternative sources of reinforcement. An individual selects a specific option based on the relative rate of reinforcement. This means that behavior is regulated not only by its consequences but also by the consequences arranged for alternative actions. As we have seen, the matching law and the quantitative law of effect are major areas of basic research that suggest new intervention strategies for behavior modification. Finally, applied behavior

analysis, as a technology of behavior change, is having a wide impact on socially important problems of human behavior. A personalized system of instruction is an example of applied behavior analysis in higher education. Research shows that mastery-based learning is more effective than alternative methods of instruction, but colleges and universities its implementation.

W. DAVID PIERCE

BIRTH AND DEATH RATES

Much of the birth and death information published by governments is in absolute numbers. These raw data are difficult to interpret. For example, a comparison of the 42,087 births in Utah with the 189,392 in Florida in 1996 reveals nothing about the relative levels of fertility because Florida has a larger population (Ventura et al. 1998, p. 42).

To control for the effect of population size, analyses of fertility and mortality usually use rates. A rate measures the number of times an event such as birth occurs in a given period of time divided by the population at risk to that event. The period is usually a year, and the rate is usually expressed per 1,000 people in the population to eliminate the decimal point. Dividing Florida's births by the state's population and multiplying by 1,000 yields a birth rate of 13 per 1,000. A similar calculation for Utah yields 21 per 1,000, evidence that fertility makes a greater contribution to population growth in the state with the large Mormon population.

BIRTH RATES

The crude birth rate calculated in the preceding example,

Crude birth rate per 1,000= (1)

$$\frac{\text{Live births in year } x}{\text{Midyear population in year } x} \times 1,000$$

is the most common measure of fertility because it requires the least amount of data and measures the impact of fertility on population growth. Crude birth rates at the end of the twentieth century range from over 40 per 1,000 in many African countries and a few Asian countries such as Yemen and Afghanistan to less than 12 per 1,000 in the slow-growing or declining countries of Europe and Japan (Population Reference Bureau 1998).

The crude birth rate is aptly named when used to compare childbearing levels between populations. Its estimate of the population at risk to giving birth includes men, children, and postmenopausal women. If women of childbearing age compose different proportions in the populations under consideration or within the same population in a longitudinal analysis, the crude birth rate is an unreliable indicator of the relative level of childbearing. A portion of Utah's 61 percent higher crude birth rate is due to the state's higher proportion of childbearing-age women, 23 percent, versus 20 percent in Florida (U.S. Bureau of the Census 1994). The proportion of childbearing-age women varies more widely between nations, making the crude birth rate a poor choice for international comparisons.

Other rates that more precisely specify the population at risk are better comparative measures of childbearing, although only the crude birth rate measures the impact of fertility on population growth. If the number of women in childbearing ages is known, general fertility rates can be calculated:

General fertility rate per 1,000= (2)

$$\frac{\text{Live births in year } x}{\text{Women 15-44 in year } x} \times 1,000$$

This measure reveals that a thousand women in Utah of childbearing age produce more births in a year than the same number in Florida, 89 versus 64 births per 1,000 women between ages fifteen and forty-four (Ventura et al. 1998, p. 42). The 39 percent difference in the two states' general fertility rates is substantially less than that indicated by

BIRTH AND DEATH RATES

Figure 1. Age-Specific Fertility Rates: Selected Countries, Mid-1990s.

SOURCE: United Nations, *Demographic Yearbook*, 1996.

their crude birth rates which are confounded by age-composition differences.

Although the general fertility rate is a more accurate measure of the relative levels of fertility between populations, it remains sensitive to the distribution of population across women of child-bearing ages. When women are heavily concentrated in the younger, more fecund ages, such as in developing countries today and in the United States in 1980, rather than the less fecund older ages, such as in the United States and other developed countries today, the general fertility rate is not the best choice for fertility analysis. It inflates the relative level of fertility in the former populations and deflates the estimates in the latter populations.

Age-specific fertility rates eliminate potential distortions from age compositions. These rates are calculated for five-year age groups beginning with ages fifteen to nineteen and ending with ages forty-five to forty-nine:

Age-specific fertility rate per 1,000= (3)

$$\frac{\text{Live births in year } x \text{ to women age } a}{\text{Women age } a \text{ in year } x} \times 1,000$$

Age-specific fertility rates also provide a rudimentary measure of the tempo of childbearing. The four countries in Figure 1 have distinct patterns. Zimbabwe, a less-developed country with high fertility, has higher rates at all ages. At the

other extreme, Japan's low fertility is highly concentrated between the ages of twenty-five and thirty-four, even though the Japanese rates are well below those in Zimbabwe. In contrast, teenage women in the United States continue to have much higher fertility than teenage women in Japan and other industrialized countries, despite declines in the 1990s. The younger pattern of American fertility also is evident in the moderately high rates for women in their early twenties. At the other extreme, Irish women have an older pattern of fertility.

More detailed analyses of the tempo of childbearing require extensive information about live birth order to make fertility rates for each age group specific for first births, second births, third births, and so forth (Shryock and Siegel 1976, p. 280). A comparison of these age-order-specific rates between 1975 and 1996 reveals an on-going shift toward later childbearing in the United States (Ventura et al. 1998, p. 6). The first birth rate increased for women over thirty while it decreased for women ages twenty to twenty-four. As a result, 22 percent of all first births in 1996 occurred to women age thirty and over, compared to only 5 percent in 1975.

When the tempo of fertility is not of interest, the advantages of age-specific fertility rates are outweighed by the cumbersome task comparing many rates between populations. As an alternative, each population's age-specific rates can be

condensed in an age–sex adjusted birth rate (Shryock and Siegel 1976, pp. 284–288). The most frequently used age–sex adjusted rate is calculated:

$$\text{Total fertility rate} = \frac{\text{Sum (age-specific fertility rates per 1,000 X 5)}}{1,000} \quad (4)$$

if the age-specific fertility rates are for five-year age groups. Single-year age-specific rates are summed without the five-year adjustment. When expressed per single woman, as in equation (4), the total fertility rate can be interpreted as the average number of births that a hypothetical group would have at the end of their reproduction if they experienced the age-specific fertility observed in a particular year over the course of their childbearing years.

Age-specific rates in real populations that consciously control fertility can be volatile. For example, the fertility rate of American women ages thirty to thirty-four fell to 71 per 1,000 in the middle of the Great Depression and climbed back to 119 during the postwar Baby Boom, only to fall again to 53 in 1975 and rebound to 84 in 1996 (U.S. Bureau of the Census 1975, p. 50; Ventura et al. 1998, p. 32). Consequently, a total fertility rate calculated from one year's observed age-specific rates is not a good estimate of the eventual completed fertility of childbearing-age women. It is, however, an excellent index of the level of fertility observed in a year that is unaffected by age composition.

The total fertility rate also can be interpreted as an estimate of the reproductivity of a population. Reproductivity is the extent to which a generation exactly replaces its eventual deaths. While the total fertility measures the replacement of both sexes, other measures of reproductivity focus only on the replacement of females in the population (Shryock and Siegel 1976, pp. 314–316). The gross reproduction rate is similar to the total fertility rate except that only female births are included in the calculation of the age-specific rates. It is often approximated by multiplying the total fertility rate by the ratio of female births to all births.

Theoretically, women need to average two births, one female and one male, and female newborns need to live long enough to have their own

female births at the same ages that their mothers gave birth to them to maintain a constant population size. In real populations some female newborns die before their mothers' ages at their births and the tempo of fertility fluctuates. As a result, both the total fertility rate and the gross reproduction rate overestimate reproductivity. The net reproduction rate adjusts for mortality, although it remains sensitive to shifts in the tempo of childbearing. This measure of reproductivity is calculated by multiplying the age-specific fertility rates for female births by the corresponding life-table survival rates that measure the probability of female children surviving from birth to the age of their mothers, and summing across childbearing ages. If the tempo of fertility is constant, a net reproduction rate of greater than one indicates population growth; less than one indicates decline; and one indicates a stationary population.

Because of the impact of female mortality, the total fertility rate must exceed two for a generation to replace all of its deaths. In industrialized countries with a low risk of dying before age fifty, the total fertility rate needs to be about 2.1 for replacement. Developing countries with higher mortality need a higher total fertility rate for replacement. Malawi, for example, with an infant mortality rate of 140 per 1,000 live births and a life expectancy of only thirty-six needs a rate of about three births per woman for replacement.

The fertility of most industrialized countries has fallen below replacement (Population Reference Bureau 1998). Some, including the United States (Figure 2), Ireland, Iceland, and New Zealand, are barely below replacement. Others have declined to unprecedented low rates. Spain (Figure 2), Portugal, Italy, Greece, Germany, most Eastern European countries, and Japan have total fertility rates of 1.1 to 1.4 births per woman. Some of these populations are already declining. Without constant, substantial net in-migration, all will decline unless their fertility rates rebound to replacement levels or above.

In contrast, the total fertility rates of most developing countries whose economies are still dependent primarily on agriculture exceed replacement (Population Reference Bureau 1998). The highest rates are found in Africa where most countries have rates greater than five births per

BIRTH AND DEATH RATES

Figure 2. Total Fertility Rates: Selected Countries, 1950–1995.

SOURCE: United Nations, *World Population Prospects*, 1996.

woman. A few, including Ethiopia, Somalia, Niger, and Angola, equal or exceed seven births per woman. As a result, sub-Saharan Africa is growing at about 2.6 percent per year. If unchanged, Africa's population would double in twenty-seven years. Change, however, appears underway in most African countries. The largest fertility declines since 1980 have occurred in North African countries like Egypt (Figure 2) and in Kenya, Zimbabwe, and South Africa. Nevertheless, fertility in all African countries remains well above replacement. The continent's 1998 total fertility rate was 5.6 births per woman.

Fertility has declined to lower levels in other developing regions. Led by three decades of decline in Mexico (Figure 2), Brazil, Ecuador, Peru, and Venezuela, fertility rates for Central and South America have declined to 3.4 and 2.8 births per woman, respectively. Most Caribbean countries have near replacement-level fertility. Haiti, the Dominican Republic, and Jamaica are the major exceptions.

Rapid fertility declines also have occurred throughout much of Asia. China's aggressive birth control policy and nascent economic growth reduced its fertility to 1.8 births per woman (Figure 2), about the same as its Korean and Taiwanese neighbors. A number of other Asian countries, including the large populations of Bangladesh, Iran, Thailand, Vietnam, and Turkey, experienced

more than a 50 percent decline in the last two decades of the twentieth century. The even larger populations of India and Indonesia continued their previous slow downward trend, yielding 1998 rates of 3.4 and 2.7 births per woman, respectively. Only a few Asian countries, other than traditional Moslem societies such as Afghanistan, Iraq, and Pakistan, continue to have more than five births per woman.

The fertility measures discussed up to this point are period rates. They are based on data for a particular year and represent the behavior of a cross-section of age groups in the population in that year. Fertility also can be measured over the lifetime of birth cohorts. Cumulative fertility rates can be calculated for each birth cohort of women by summing the age-specific fertility rates that prevailed as they passed through each age (Shryock and Siegel 1976, p. 289). This calculation yields a completed fertility rate for birth cohorts that have reached the end of their reproductive years. It is the cohort equivalent of the period total fertility rate.

DEATH RATES

The measurement of mortality raises many of the same issues discussed with fertility. Rates are more informative than absolute numbers, and those rates that more precisely define the population at

risk to dying are more accurate. Unlike fertility, however, the entire population is at risk to dying, and this universal experience happens only once to an individual.

The impact of mortality on population growth can be calculated with a crude death rate:

$$\text{Crude death rate per 1,000} = \frac{\text{Deaths in year } x}{\text{Midyear population in year } x} \times 1,000 \quad (5)$$

Crude death rates vary from over 20 per 1,000 in some African countries to as low as 2 per 1,000 (Population Reference Bureau 1998). The lowest crude death rates are not in the developed countries of Europe, North America, and Oceania, which have rates between 7 and 14 per 1,000. Instead, the lowest crude death rates are found in oil-rich Kuwait, Qatar, and United Arab Emirates, where guest workers inflate the proportion of young adults, and in the young populations of developing countries experiencing declining mortality. Developed countries that underwent industrialization and mortality decline before 1950 have old-age compositions. The proportion of people age sixty-five and over ranges between 11 and 17 percent in these countries compared to less than 5 percent in most African, Asian, and Latin American populations. Although there is a risk of dying at every age, the risk rises with age after childhood. Consequently, older populations have higher crude death rates.

To control for the strong influence of age on mortality, age-specific rates can be calculated for five-year age groups:

$$\text{Age-specific mortality rate per 1,000} = \frac{\text{Deaths in year } x \text{ to the population age } a}{\text{Population age } a \text{ in year } x} \times 1,000 \quad (6)$$

Before age five, the age-specific mortality rate usually is subdivided to capture the higher risk of dying immediately after birth. The rate for one- to four-year olds, like other age-specific rates, is based on the midyear estimate of this population. The conventional infant mortality rate, however, is based on the number of live births:

$$\text{Infant mortality rate per 1,000} = \frac{\text{Deaths under age 1 in year } x}{\text{Live births in year } x} \times 1,000 \quad (7)$$

The infant mortality rate is often disaggregated into the neonatal mortality rate for the first month of life and the postneonatal rate for the rest of the year.

$$\text{Neonatal mortality rate per 1,000} = \frac{\text{Deaths under 29 days of life in year } x}{\text{Live births in year } x} \times 1,000 \quad (8)$$

$$\text{Postneonatal mortality rate per 1,000} = \frac{\text{Deaths from 29 days to age 1 in year } x}{\text{Live births in year } x} \times 1,000 \quad (9)$$

Infant mortality varies widely throughout the world. Iraq, Afghanistan, Cambodia, and many African countries have 1998 rates that still exceed 100 per 1,000 live births, although most have declined (Population Reference Bureau 1998). Infant mortality rates in most other African, Asian, and all other Latin American countries have declined as well. They now range in developing countries from 7 in Cuba to 195 in Sierra Leone. In contrast, developed countries have rates at or below 10, led by Japan with under 4 infant deaths per 1,000 live births.

The declining American infant mortality rate, 7 per 1,000 live births in 1998, continues to lag behind Japan, Australia, New Zealand, Canada, and most Northern and Western European countries due to a higher prevalence of prematurity and low-birth-weight babies which are major causes of infant death (Peters et al. 1998, pp. 12–13). The prematurity and low-birth-weight rates for the country's largest minority, African Americans, are double those of non-Hispanic whites (Ventura 1998, pp. 57–58). Not all minority mothers have higher rates than non-Hispanic whites. Low-birth-weight rates are lower for Americans of Chinese, Mexican, Central and South American origin, about the same for Native Americans and those of Cuban origin, and higher for Puerto Rican, Filipino, and Japanese Americans.

BIRTH AND DEATH RATES

Death Rates per 100,000 for the Fourteen Leading Causes of Death in the Population 45-64 Years of Age, by Sex and Selected Race and Ethnic Categories: United States, 1997

	Males			Females

Table 1. Death Rates per 100,000 for the Leading Causes of Death in the Population 45-64 Years of Age, by Sex and Selected Race and Ethnic Categories: United States, 1997.

SOURCE: Hoyert, D. *Deaths: Final Data for 1997*.

Infant mortality also varies by sex. The rate for male infants born to white mothers in the United States is 6.7 per 1,000 live births, compared to 5.4 for female infants (Peters 1998, p. 80). Similarly, the rate for male infants born to African-American mothers is 16 per 1,000 live births, compared to 13 for female infants.

Like race and ethnic differences, the sex difference in mortality is evident at all ages. The greatest gap is among young adults; American males are two and one-half to three times more

likely to die between the ages of fifteen and twenty-nine than females due largely to behavioral causes. These include motor vehicle and other accident fatalities, homicides, and suicides. Higher male death rates from congenital anomalies at younger ages and from heart disease in middle age (Table 1) suggest that biological factors also contribute to the sex difference in mortality. Behavioral causes continue to play a significant role in the sex difference in mortality in middle age with chronic liver disease and cirrhosis and human immunodeficiency virus (HIV) adding premature male mortality.

Figure 4. Life Expectancy for Whites by Sex: United States, 1900-1996.

BIRTH AND DEATH RATES

Figure 3. Life Expectancy at Birth: Selected Countries, 1950–1995.

SOURCE: United Nations, *World Population Prospects*, 1996.

Note that cause-specific death rates are calculated per 100,000 population in a specified group, rather than per 1,000 to avoid working with decimals.

Age-specific mortality rates usually are specific for sex and race or ethnicity because of the large differences evident in Table 1. Using five-year age categories results in thirty-eight rates for each racial or ethnic group. Analyses of such data can be unwieldy. When the age pattern of mortality is not of interest, an age-adjusted composite measure is preferable. The most readily available of these for international comparisons is life expectancy.

Life expectancy is the average number of years that members of an age group would live if they were to experience the age-specific death rates prevailing in a given year. It is calculated for each age group in a life table (Shryock and Siegel 1976, pp. 249–268). Life expectancy has increased since the nineteenth century in developed countries like the United States in tandem with economic growth and public health reforms. Japan has the longest

life expectancy at birth, eighty years, due to extremely low infant mortality. With the exception of Russia and some of the other former Soviet-bloc countries of Eastern Europe that have had declines in life expectancy, all other developed countries have life expectancies at birth that equal or exceed seventy years (Population Reference Bureau 1998).

Figure 3 presents trends in life expectancy since World War II in selected countries. Some of the most rapid increases have been in Asia and Latin America. China, Sri Lanka, Malaysia, Mexico, and Venezuela, for example, have 1998 life expectancies at birth of over seventy years. Increases in life expectancy in African countries, in contrast, where there is a relatively high prevalence of poor nutrition, unsanitary conditions, and infectious diseases, generally have lagged behind Asia and Latin America. Most have 1998 life expectancies in the forties or fifties, similar to those of developed countries at the end of the nineteenth century. The future trend in life expectancy in many African countries is uncertain.

Progress made in some is being undermined by the spread of HIV and political conflict. The drug therapies that have reduced mortality from HIV in developed countries have so far proven too costly for widespread use in Africa and political unrest continues.

Declines in infant and child mortality from infectious diseases have been largely responsible for the historical increase in life expectancy around the world. As a result, life expectancy has increased far more at birth than at age sixty (Figure 4). Heart disease, cancer, and cerebrovascular diseases have become the major causes of death in the United States (Peters et al. 1998, p. 7), other developed countries, and some developing countries. Bringing these chronic diseases under control has proven to be difficult. Research suggests that both genetic composition and unhealthy behaviors affect the development of such chronic diseases over time. In the United States where health education campaigns have stressed the link between these diseases and obesity, use of tobacco, and lack of sufficient physical activity, mortality has declined from heart disease since 1950 and from cancer since 1990. If these trends continue, gains in life expectancy at older ages will accelerate.

BRITISH SOCIOLOGY

In a global age, the concept of British sociology poses an interesting question with regard to the viability of national sociologies. Neither academic disciplines nor the subjects studied fit easily into national boundaries. An academic's closest colleague may be in New York or Delhi rather than in Lancaster or Birmingham. Key figures in British sociology, such as Dahrendorf, Westergaard, and Bauman are not British but have spent some or all of their careers working in British institutions (Halsey 1989). As sociologists working in Britain they were well placed to investigate questions related to British society. Then there are the British sociologists who have left Britain to research and teach elsewhere; John Goldthorpe to Sweden and Germany, and John Hall and Michael Mann to the United States, for example. British sociologists have often studied other nations too: Ronald Dore focuses on Japan, David Lane on Russia, and John Torrance on Austria to name a few. With all of these international influences exemplifying the present status of sociology in Britain, how "British" then is British sociology? This entry briefly explores the range of sociology that has developed in

Britain from its origins to the present day, and ends by noting possible implications for its future.

FOUNDATION

The discipline of sociology in Great Britain has a history that stretches back to the early 1900s. Martin White and the London School of Economics (LSE) figure prominently in the development of British sociology. In 1907, White effectively founded the study of sociology in Britain by investing about £1,000 to fund a series of lectures at the LSE, as well as to establish the Sociological Society. The first annual report of the society indicated 408 members distributed throughout Great Britain, and thirty-two overseas. Early members of the society included an interesting variety of prominent public and literary figures, such as H.H. Asquith, Hilaire Belloc, and the Bishop of Stepney; British academics including Bertrand Russell, Graham Wallas, and Beatrice Webb; as well as international academics such as Emile Durkheim and Ferdinand Tonnies, among others. Also in 1907, White gave the University of London £10,000 for a permanent chair in sociology to be located at LSE. White also donated additional funds for lectureships, bursaries, and scholarships in sociology. Because of White's prominence in supporting these early initiatives, Dahrendorf has argued that "it is not too much to say that one man, Martin White, established the discipline of sociology in Britain. . . . Moreover, sociology came to life at LSE." (Dahrendorf 1995, p. 103).

Despite this promising start, by 1945 the LSE remained the only university with a department of sociology in Britain. Several reasons have been identified for this late development. Among these was the long-standing opposition to the creation of sociology as a university subject by the universities of Oxford and Cambridge, which were at the top of the educational establishment in Britain. In addition, two other disciplines had claims on similar social research that predated the emergence of sociology. Anthropology and political economy both focused on social research that suited the interests of Britain at the time. Studies of foreign shores while Britain was still a major empire was of greater interest than social research focused on issues closer to home. Empirically based scholarship on the political economy was preferable to

the theoretical emphasis of many sociologists because of its perceived lack of application to the real world. The purported lack of credibility of those promoting the study of sociology, many of whom were either located on the outside or on the margins of academe, did not lend a helping hand to the development of sociology either. But, the most persistent obstacle was the hierarchical social structure of British society that prevented the effective interrogation of its social structures (Albrow 1989).

EXPANSION

Following World War II, the fortunes of sociology changed dramatically, in line with the social changes in Britain at this time. In these years there was a general feeling of optimism regarding possible changes in social relationships as well as increasing expectations of education and science to create a better life. In this context the study of sociology represented a commitment to social reorganization. "There was a demand [for sociology]. . . irrespective of what was on offer" (Albrow 1989, p. 202).

Around this same time, Edward Shils moved to London from the University of Chicago. His teaching of classical European sociology has been described "as magnificent a professorial presentation of the social science scenery as could be found in the Western world," and had a great deal to do with shaping and inspiring the first generation of British sociologists (Halsey 1999). This first generation of "career sociologists" in Britain completed their education at the LSE between 1950 and 1952. They included: J.A. Banks, Olive Banks, Michael Banton, Basil Bernstein, Percy Cohen, Norman Dennis, Ralf Dahrendorf, A.H. Halsey, David Lockwood, Cyril Smith, J.H. Smith, Asher Tropp, and John Westergaard. All became prominent sociologists in Britain by the mid-1960s. Members of this cohort have described the sociological analysis they developed as grounded in their own experiences of social inequality and informed by critical reflections on Marx, Parsons, and Popper (Halsey 1985; Dahrendorf 1995). Two of the many publications from members of this group are: David Lockwood's *Some Remarks on The Social System*, published in 1956, and Dahrendorf's *Class*

and *Class Conflict in Industrial Society*, published in 1959. Lockwood's paper is notable because it became the most widely read single paper by a British sociologist at the time. Dahrendorf's book, a critical reflection on Marx and Parsons, argued that Weber's ideas were useful in explaining the positive effects of conflict in Great Britain, and was dedicated to this first cohort at the LSE.

British sociology was further developed in the next decade by the work of John Rex at the University of Leeds. His work *Key Problems in Sociological Theory* (1961) became the most popular British sociological theory textbook in the 1960s. Rex used a Weberian action framework in contrast to the functionalist orthodoxy prominent at the time. In addition to Leeds, departments of sociology had been established at the universities of Leicester, Birmingham, Liverpool, Nottingham, and Hull. In 1967, three important works became available in Britain, Garfinkel's *Studies in Ethnomethodology*, Berger and Luckmann's *The Social Construction of Reality*, and Schutz's *The Phenomenology of the Social World*. These books contained an implicit critique of the kind of sociology that had been pursued in Britain up to this time. They emphasized a qualitative analysis of the ways in which social actors create meaning and acquire social positions in the context of language. The growth of the discipline continued throughout this time with nearly every institution of higher education in Britain housing a department of sociology. This led some to make the observation that it was growing with "explosive force" (Heyworth 1965, p.11). Sociology as a discipline was beginning to come into its own in Britain.

By the 1970s, there were many theoretical currents in British sociology; not only were phenomenological and Marxist arguments being pursued, but also the works of Althusser, the French structuralists, the "Frankfurt School," and Habermas and Gramsci. Links between British sociology and European social theory were becoming stronger. In addition there were important empirical studies being done; the best example is the 1972 Oxford Mobility Studies undertaken by a group of sociologists at Nuffield College, Oxford, and greatly influenced by the work of one of their team, John Goldthorpe. Around this same time a dialogue between the debates in social theory and empirical understanding was initiated by Anthony Giddens

in his analysis of the founders of sociology, *Capitalism and Modern Social Theory* (1971). By 1979 he had developed structuration theory to reconcile the previous theoretical debates. Giddens's systematic analysis of modernity is the most extensive and widely disseminated work of any British sociologist to date.

Starting in the 1980s, the emerging theoretical *zeitgeist* of British sociology was an increasing interest in the study of culture. Cultural studies as developed in the 1960s through the rather different works of Richard Hoggart, E.P. Thompson, and Stuart Hall emphasized the social aspects of culture and led to the specialization in the 1980s and 1990s of the areas of media, feminism, and ethnicity. Cultural analyses were developed as part of an overall analysis of fundamental shifts in modern societies around production, consumption, and social interaction. Influenced by European theories of politics, ideology, and discourse, existing Marxist and functionalist theories were seen as unable to adequately theorize the modern social world.

The work of sociologists based at the Birmingham Centre for Contemporary Cultural Studies represents an example of this analysis. In 1983, the group consisting of John Solomos, Bob Findlay, Simon Jones, and Paul Gilroy outlined a neo-Marxist approach to racism in a series of articles entitled *The Empire Strikes Back*. Gilroy's book, which followed the original articles, *There Ain't No Black in the Union Jack*, developed these themes and stressed the contest over the meaning of "race" that occurs in the public sphere between different social actors. Gilroy's analysis is an example of the wider move in British sociology away from a Marxist analysis of class conflict toward an emphasis on new social movements, such as the women's movement, youth movements, peace movements, green movements, and others they claimed were not easily reducible to class-based politics. There is, of course, a continuing debate between cultural-studies thinkers and Marxists, such as Robert Miles, who argue that class conflict is still far from dead, and remains a central feature in explaining the production of racism. The diversity and pluralism within sociology in Britain at this time has been described as one of its great strengths (Albrow 1989).

CHALLENGES AND OPPORTUNITIES

The growth of sociology in Britain was abruptly impeded by a governmental investigation of higher-education research funding in 1981. One recommendation following the investigation was the withdrawal of funding for any new departments of sociology and those seen as "substandard." Sociologists were also limited in their representation on the Social Science Research Council (SSRC), with only two of the ninety-four members from sociology departments. As a reflection of this change in academic focus, the SSRC was renamed the Economic and Social Research Council in 1984. Albrow (1989) argues that no other academic discipline was singled out in this way.

Governmental scrutiny of sociology programs and departments has become an integral part of British higher education. It is, however, not because it continues to be singled out for special treatment as it was in previous decades but rather it is part of the larger process of fiscal accountability and quality assurance instituted by the government. The first two Research Assessment Exercises (RAE) were conducted in 1992 and 1996 respectively. Each RAE rated every department of every subject on its research output. In 1996, sociology at the universities of Essex and Lancaster received 5* (the highest rank) ratings, while close behind were the universities of Loughborough, Manchester, Oxford, Surrey, Warwick, and Edinburgh, and the college of Goldsmiths, with ratings of 5 each (RAE 1996). Most important about the ratings is that the British government "... funding bodies use the ratings to inform the distribution of grants for research to HEIs" (higher education institutions) (RAE 1996). It has been reported that, "Some 20 percent of funding from the Higher Education Funding Council for England is a reward for research excellence, as a measured by the "research assessment exercise" (Wolf 1999). In fact, these funds are extremely important to the day-to-day running of departments and in some cases make them viable or not.

If research was to be assessed, then teaching could not be far behind. The Teaching Quality Assessment (TQA) exercise was instituted in 1993 with various subjects coming up for review in each country of Britain over an eight-year period. In England, sociology was reviewed between 1995

and 1996. At the time of TQA there were approximately 20,000 students studying sociology in eighty-one institutions of higher education in England alone. The Overview Report of all departments reviewed in England noted that, "The overall picture that emerges from the assessment process of the quality of education in sociology is a positive one. . . . On the other hand there is little room for complacency." It was further noted that, "The majority of institutions use a suitable range and variety of teaching, learning and assessment methods. The assessors found considerable evidence of innovative approaches to teaching, which encouraged and enthused students (HEFCE 1996, p. 14).

Funding does not follow from high TQA scores. Instead, high-scoring departments can bid for money from the Fund for the Development of Teaching and Learning. In sociology five consortium projects were funded to a total of over £1,000,000. The five projects publish a regular newsletter and there are plans to launch an online journal for teaching in 2000 (Middleton 1999).

THE NEXT CENTURY

As British sociology enters a global age it is challenged with the ironies and complexities of understanding the current state of modernity that includes the increasing interconnectedness of the world as a whole, the increasing choices each individual has, and the resilience of national identities as evidenced by the increasing number of nations that emerge year after year. Each of these issues has been the subject of research by British sociologists in the past decade. The 1990s saw an "explosion" of interest in studies of culture informed by debates around the high-modern or postmodern condition, albeit influenced by the works of the French sociologists, Pierre Bourdieu, and Michel Foucault (Swingewood 1998). Both the study of nations and trends toward globalization find British sociology in the lead as well. Ernest Gellner (1983) and Anthony Smith (1986) have claimed the territory of nations and nationalism. At the same time, Anthony Giddens (1990), Roland Robertson (British by birth) (1992), Leslie Sklair (1995), and Martin Albrow (1996) have advanced theories of globalization. Emerging from work on globalization is the sociology of human rights. Two examples include: Anthony Woodiwiss's (1998) work on the compatibilities between Asian

values and human rights discourses, and Kevin Bales's (1999) study of economic globalization and the development of modern slavery. These seem to highlight some important issues to be debated within sociology (worldwide) in this millennium.

The first century of British sociology saw its ups and downs. At times it was a popular subject to study and at other times it faced significant threats to its existence. Probably there was no threat more dramatic than the former Prime Minister Margaret Thatcher's declaration that, "There is no such thing as society." However, despite the attacks and the loss of funding, sociology as a discipline has managed not only to survive but is poised to lead policy making in Britain. Currently there are increasing numbers of Members of Parliament and Lords who have a sociology background and there are nearly a dozen Vice Chancellors of universities who are sociologists. "Indeed, the subject somehow seems in tune with the times. With a government that not only accepts, but explicitly seeks to understand, and manage society, it is surely no coincidence that Tony Blair's favourite academic, Anthony Giddens. . . is another sociologist-cum-VC (or Director as the position is called at the London School of Economics)" (Brown 1999, p. iii). The reference here is to Giddens's latest contribution to British sociology, his book entitled *The Third Way: The Renewal of Social Democracy* (1998). In many ways sociology has come full circle, with LSE academics once again playing an important role in its resurgence. Despite all attempts to deny its value, sociology in Britain can once again try to fulfill the claim made a century ago and an ocean away, that "Sociology has a foremost place in the thought of modern men [and women]" (Small 1895, p.1).

PETER THAYER ROBBINS
VANEETA-MARIE D'ANDREA

BUREAUCRACY

The origin of the term *bureaucracy* can be traced to eighteenth-century French literature (Albrow 1970). The early usage referred to an official workplace (bureau) in which individual activities were routinely determined by explicit rules and regulations. As modern systems of management, supervision, and control, bureaucracies are designed to rationally coordinate the duties and responsibilities of officials and employees of organizations. The delineation of official duties and responsibilities, by means of formal rules and programs of activity (March and Simon 1958), is intended to displace and constrain the otherwise private, idiosyncratic, and uniquely personal interests and actions of individuals. Bureaucratic systems of administration are designed to ensure that the activities of individuals rationally contribute to the goals and interests of the organizations within which they work.

THE CONTRIBUTION OF MAX WEBER

The historical trend toward increasing bureaucratization throughout modern Western Europe, highlighted by the changing structure of military organizations, is documented by the work of Karl

Marx ([1852] 1963) and of Alexis de Tocqueville (1877). Michels' (1949) analysis of the dynamics of power distribution within bureaucratic organizations and the concomitant development of oligarchic tendencies (fundamentally detrimental to democratic principles) provided an understanding of one of the more important unintended consequences of bureaucratic processes. However, the study of bureaucratic structure and processes as a prominent sociological topic is based on the intellectual legacy of Max Weber (1864-1920). Although Weber conducted his studies at the turn of the nineteenth century, wide recognition of his work by English-speaking theorists had to await later translations of his work (Weber 1946, 1947).

Weber's thorough and richly informative work included consideration of Chinese, Egyptian, Roman, Prussian, and French administrative systems. In his comparative analysis of this vast array of diverse cultural systems of administration, Weber recognized an inexorable relationship between power and authority, on the one hand, and differing systems of administration on the other. In Weber's analysis, the bureaucratic form of administration reflects one of three ways in which power can be legitimated. To gain a clear appreciation of the unique features of bureaucratic structure and processes, it is necessary to briefly address Weber's proclaimed relationship between power, authority, and systems of administration. *Power*, for Weber, represents the ability or capacity to have other people behave in accordance with certain orders or dictates, irrespective of whether those affected regard its application as rightful or legitimate. *Authority* represents the legitimation of this power by those individuals whose activities are so ordered such that the application of power and its impact on them are perceived to be proper and acceptable. In Weber's historical analysis, three different types of authority are identified: traditional, charismatic, and rational-legal (Weber 1947, p. 328).

Three Types of Authority. *Traditional authority* represents a system in which the use of power is regarded as legitimate when it is predicated upon belief in the sanctity of time-honored traditions and patterns of behavior. By contrast, *charismatic authority* is based on situationally specific acts of personal devotion. Under these circumstances, authority is conferred upon a specific individual

who is regarded by the devoted followers to exhibit exceptional, sacred, and/or heroic characteristics. Charismatic authority is therefore limited to a specific setting and time. *Rational-legal* authority derives from the belief in the legitimacy of law, specifically in the legality of rules and the authority of officials and employees to perform certain legally sanctioned and mandated duties to which they have been formally assigned. Official rational-legal authority often permits individuals to perform tasks that otherwise would not be permitted. For example, police officers may engage in certain behaviors in the course of their official duties, such as the use of lethal force, that if performed by an ordinary citizen would expose the citizen to legal liability. Thus, it is not the act or set of behaviors per se that is critical to an understanding of rational-legal authority, but rather who performs the act or behavior and whether the individual performing the act is legally authorized to engage in such behavior.

Three Systems of Administration. Each type of authority is associated with a distinctive system of administration. Over the course of premodern social history, traditional authority was the principal means by which social organization was achieved. This type of authority structure resulted in the development of a wide variety of highly stable but nonetheless particularistic systems of administration, in which personal relations of dependence or loyalty provided the bases for authority. In general, these systems of administration are most clearly exemplified by patrimonial and feudal systems of administration. Unlike traditional authority, charismatic authority results in highly unstable systems of administration, because the foundations of these systems, the profoundly personal relationships between charismatic leaders and followers, are decisively limited in both time and circumstance. Given the tenuous foundation of charismatic authority structures, it is not surprising that the systems of administration that arise in such situations encounter difficulties in generating stable administrative practices. In this regard, problems pertaining to the routinization of authority and leadership succession are particularly salient and acute (Weber 1947, pp. 358–373). Thus, administrative systems predicated upon charismatic authority tend to be inherently transitory and most likely arise during periods of crisis or unprecedented change.

In contrast to the personal bases of authority inherent in both traditional and charismatic systems of administration, rational-legal systems of administration rely on impersonal rules and regulations, culminating in the emergence of highly precise and universalistic systems of administration that are most clearly exemplified by the modern rational bureaucracy. Weber clearly regards such administrative practices to be relatively recent in their development: “Bureaucracy . . . is fully developed in political and ecclesiastical communities only in the modern state, and in the private economy only in the most advanced institutions of capitalism” (Weber 1978, p. 956).

THE FORMAL CHARACTERISTICS OF BUREAUCRACIES

The most distinguishing feature of modern rational bureaucracies is the formal control, prescription, and regulation of individual activity through the enforcement of rules. The explicit intent of enforcing these rules is to efficiently achieve specific organizational goals. In orchestrating individual action, a succinct and unambiguous specification of the official duties and responsibilities is provided to minimize, if not to eliminate, the influence of personal interests and ambitions upon the performance of official duties. The official or employee is then able to concentrate exclusively upon the technical aspects of the work, in particular the efficient and rational completion of assigned tasks. In addition to this attempt to separate individuals’ private concerns from their official duties and responsibilities, other distinguishing characteristics of bureaucracies include:

1. The hierarchical ordering of authority relations, limiting the areas of command and responsibility for subordinate as well as superordinate personnel
2. The recruitment and promotion of individuals on the basis of technical expertise and competence
3. A clearly defined division of labor with specialization and training required for assigned tasks
4. A structuring of the work environment to ensure continuous and full-time employment, and the fulfillment of individual career expectations within the organization

5. The impersonality and impartiality of relationships among organization members and with those outside the organization
6. The importance of "official records" in the form of written documents.

THE RATIONALITY OF BUREAUCRATIC RULES

Within a bureaucratic organization, rules serve to direct individual action in ways that promote the technical efficiency of the organization. The distinctive feature of bureaucratic organization is not the use of rules *per se* but, rather, the type of rules employed within an organization as well as the justification for the use of rules. Rules have been, and continue to be, used in other forms of administration to control individual action; however, the rules used in the other administrative forms (such as rules based on tradition in feudal administration or on dependency in a patrimonial system) are not necessarily based on technical knowledge and the rational achievement of specific goals. By contrast, within a modern bureaucracy explicit rules are designed to assure uniformity of performance in accordance with technical requirements. Bureaucracies denote systems of control that attempt to ensure that the technical abilities of individuals are effectively utilized. A concerted effort is made to systematically exclude any factor or element that would reduce the prospect of an official's or employee's performance being anything other than organizationally focused, affectively neutral, and achievement oriented (Parsons and Shils 1951, pp. 76–91).

THE IDEAL TYPE CONSTRUCT

By underscoring the unique features of modern bureaucratic systems of administration, Weber provides an ideal-type characterization of bureaucracies. Despite subsequent confusion as to the value of the ideal-type portrayal of bureaucracies, Weber did not intend the characterization to represent an accurate empirical description of bureaucracies. As noted in the introduction to one of his edited works, "Situations of such pure type have never existed in history. . . . The ideal types of Weber's sociology are simply mental constructs to serve as categories of thought, the use of which will

help us to catch the infinite manifoldness of reality . . . "(Rhinestein 1954, pp. xxix–xxx). The ideal-type characterization is not suggestive of either extreme cases or distinct logical categories of phenomena (Mouzelis 1967). Rather, it provides a simplification and exaggeration of empirical events so that one can appreciate more clearly the features of the phenomena in question. Actual bureaucratic organizations may exhibit only a limited number of these properties or may possess them in varying degrees, a point well understood by Weber.

A GENERAL THEORETICAL PERSPECTIVE ON BUREAUCRATIC ORGANIZATIONS

As a general line of inquiry, the study of bureaucratic structure and processes has tended to represent a "closed" or "rational-system" approach to the study of organizations (Scott 1992). Predicated upon Weber's conception of bureaucracy, the "legal-rational" features of organizations such as the use of formal rules, the creation of specific personnel positions or roles, and personnel policies directed at the efficient achievement of organizational goals have been the focus of study. By directing attention toward the internal properties of bureaucratic organizations, interest in a number of topics has arisen, including the impact of technology on organizational structures (Thompson 1967), the interrelationships among organizational features (Hage et al. 1968), the integration of individuals within organizations (Argyris 1964; Herzberg et al. 1959), and the increase of worker productivity and organizational efficiency (Taylor 1911; Mayo 1933). Across this array of topics, a general theoretical perspective prevails in which the internal properties of bureaucratic organizations are regarded to be of cardinal importance. By directing primary attention toward the internal properties of bureaucratic organizations, the extent to which organizations are embedded in the more global structure and context of society is not fully realized. However, as bureaucratic organizations have grown in function and complexity, assuming an ever-expanding role in society, and displacing previous, more particularistic and personalized forms of administration, management, and control, the vibrant interplay between the internal properties of organizations and the environments in which they are situated has become more salient. Correspondingly, a more "open" theoretical orientation is warranted. Organizations

are viewed as “natural systems” (Scott 1992) in which the interaction between an organization and its environment involves a series of potential two-way relationships. While many of the processes within a bureaucracy are designed to insulate the organization from external influences, invariably environmental influences can appreciably impact an organization and its internal operations. Similarly, the bureaucratic organization, with its expanding role in modern society, has unquestionably had a major impact on society.

EMPIRICAL ASSESSMENT

Stanley Udy (1959) was among the first to propose that, rather than regarding the specification of bureaucracies to be strictly a matter of definition, we need to ascertain empirically the extent to which bureaucratic characteristics are associated with one another in actual organizations. In the subsequent efforts at empirical assessment of the extent to which organizations exhibit bureaucratic properties, the works of Richard Hall (1963) and the Aston University research group (Pugh et al. 1968) are especially noteworthy. Hall’s (1963) findings suggest that among samples of U.S. organizations, bureaucratic features of organizations may vary independently of one another. As is illustrated by the negative relationship between an emphasis on technical qualifications and other bureaucratic features—in particular hierarchy of authority and rule enforcement—Hall’s study suggests that bureaucratic systems of organization may be indicative of multidimensional rather than unitary processes.

The Aston University research group (Pugh et al. 1968) reported similar findings for organizations in Britain. On the basis of their measurements of the bureaucratic characteristics of organizations specified by Weber, these researchers found four mutually independent dimensions of organizational structure rather than a single overarching bureaucratic dimension. With this finding, the authors concluded that bureaucracy is a multidimensional phenomenon and that it “. . . is not unitary, but that organizations may be bureaucratic in any number of ways” (Pugh et al. 1968, p. 101). However, these findings have not been unchallenged. The contentious nature of inquiry into the precise structure of bureaucratic organization is succinctly reflected in the work of

Blau (1970) and of Child (1972), the adoption of a modified position by one of the investigators in the original Aston group (Hickson and McMillan 1981), and the subsequent reply by Pugh (1981).

THE RISE OF BUREAUCRATIC CONTROL

Although bureaucracy existed in imperial Rome and ancient China, as well as in various national monarchies, the complexity of legislative issues arising within the modern state has caused an enormous growth of administrative function within both government and the private sector. Consequently, the power and authority of bureaucratic administrative officials to control policy within an organization as well as the modern state has, over time, increased significantly. The rise to power of bureaucratic officials means that, without expressly intending to achieve power, nonelected officials can and do have a significant impact on a broad spectrum of activities and future developments within society. As Weber noted,

The bureaucratic structure is everywhere a late product of historical development. The further back we trace our steps, the more typical is the absence of bureaucracy and of officialdom in general. Since bureaucracy has a rational character, with rules, means–ends calculus, and matter-of-factness predominating, its rise and expansion has everywhere had revolutionary results. (1978, p. 1002)

Moreover, Weber contended that traditional authority structures have been, and will continue to be, replaced by the rational–legal authority structures of modern bureaucracies, given their “purely technical superiority over any other form of organization” (Weber 1946, p. 214). Regardless of the apparent technical benefit, the increased prominence of bureaucracies in both the public and the private sectors is not without its problems. As Weber acknowledged, certain negative consequences may follow the development of bureaucratic systems of administration to include:

1. The monopolization of information and the creation of “official secrets”
2. The inability to change bureaucratic structure because of vested incentive and reward systems, and the dependency of society on the specialization and expertise provided by the bureaucracy

3. The tendency for bureaucracies to act in an autocratic manner, indifferent to variations or changes not previously articulated or anticipated within the bureaucracy. (Weber 1947, pp. 224–233)

A frequently expressed concern is that bureaucracies are often unresponsive to the individuals and groups they were designed to serve. To exacerbate the situation still further, few, if any, techniques of control are available outside the bureaucracies to make officials more responsive. Additionally, a number of practical problems may arise to potentially undermine bureaucratic efficiency. These difficulties can include the unwarranted application of rules and regulations, the duplication of effort, and an indifferent and even cavalier attitude among officials. Nonetheless, bureaucracies are relatively efficient and technically superior forms of administration proven to be indispensable to large, complex organizations and modern society. As Perrow has noted (1972), criticism of bureaucracies frequently relates to the fact that the actions of officials are not bureaucratic enough and personal interests may not be fully insulated from official duties.

In viewing the operation and function of bureaucracies, it is imperative that the operational efficiency of bureaucratic procedures be recognized but not at the cost of neglecting a more “humanistic” orientation (Kamenka 1989, ch. 5). The situational constraints faced by individuals and groups both within and outside bureaucracies warrant attention. As Martin Albrow has noted, bureaucracy is “a term of strong emotive overtones and elusive connotations” (1970, p. 13), and as such it represents more than a straightforward technical process and deserves an eclectic perspective in order to fully appreciate its complexities.

BUREAUCRATIC DYSFUNCTIONS

The classic works of Merton (1940) and of Gouldner (1954) illustrate how unanticipated developments can adversely impact the intended effectiveness of bureaucratic procedures. Merton notes that, commencing with the need for bureaucratic control, individual compliance with rules is enforced, thereby allowing for the development of routinely prescribed, reliable patterns of activity. However, when

this agenda of rule compliance is implemented in a dynamic and fluctuating environment requiring more spontaneous responses, these prescribed patterns of bureaucratic activity can lead to adverse unintended consequences. Even though the circumstances require a different type of response, prescribed and fixed patterns of response may still be adopted because such responses are legitimated and defensible within the bureaucracy, given the extent to which they enhance individual reliability. Consequently, officials and employees do not accommodate the unique features of the situation, efficiency is undermined, and difficulties with clients and customers may ensue. Eventually, troublesome experiences with customers and clients may contribute to an even greater emphasis on bureaucratically reliable behavior rather than attenuating this encapsulated and counterproductive type of behavior. As Merton (1940) notes, “Adherence to the rules, originally conceived of as a means, becomes transformed into an end in itself; there occurs the familiar process of displacement of goals whereby an instrumental value becomes a terminal value. . .” While more highly adaptive and flexible behavior is required and permitted within a bureaucracy, powerful structural constraints may operate to promote situationally inappropriate rule-bound behavior (Blau and Meyer 1987; Allinson 1984).

Like Merton, Gouldner (1954) is concerned with possible unintended effects of formal rule enforcement. In Gouldner’s model, the implications of using general and impersonal rules as a means of enforcing organizational control are investigated. The intention of using such rules is to mask or partially conceal differential power relations between subordinates and their superiors. In societies with egalitarian norms, such as the United States, this serves to enhance the legitimacy of supervisory positions, thereby reducing the prospect of tension between groups with differing power. However, the use of general and impersonal rules also has the unintended consequence of providing only minimal guidelines regarding acceptable organizational behavior. In turn, if only minimum standards of performance are specified and if individuals conform only to these standards, then a disparity arises between the stated goals of the organization, which require a level of performance beyond minimally acceptable and specified standards, and actual individual performance. Since

a greater level of individual output and performance is required, more personal and closer forms of supervision need to be employed. This closer supervision increases the visibility of power relations, a consequence that may undermine the effect previously achieved by the use of general and impersonal rules.

The satirical, but nonetheless insightful, work of Peter and Hull (1969) indicates that bureaucratic processes may not always reflect the principle of personal expertise. Peter and Hull contend that even though individual talent and expertise are the formal requisites for recruitment and promotion within a bureaucracy, individuals often are promoted to positions that exceed their level of competence. Since the act of promotion often requires the assumption of new duties, an element of uncertainty over whether individuals will be as efficient in their new positions as they were in their previous positions is ever present. Not until an individual has had the position for a period of time is it apparent if he will be able to perform the newly assigned tasks in an efficient and competent manner. Most individuals are able to achieve an acceptable level of competence in their new duties; but what about those individuals who are unable to perform their new duties competently? Peter and Hull contend that, instead of being relocated to more suitable positions, these individuals remain in the elevated positions due, in all likelihood, to the difficulties and organizational costs associated with removing and reassigning them. Consequently, some individuals may be promoted to and remain in positions that exceed their level of competence, a portrayal clearly at variance with the image of operational efficiency.

THE PERVASIVENESS OF BUREAUCRACY IN SOCIETY

Throughout the nineteenth and twentieth centuries, a notable increase occurred in the number and type of functions performed within or regulated by a bureaucratic organization. Bureaucracies have superceded other more personalized, particularistic operations (ostensibly due to the technical superiority of the bureaucratic process) or, as new processes developed, they developed within the context of a bureaucratic structure. The ubiquitous presence of bureaucracies in modern society is indicated by the common usage of the term

“red tape.” The term originally denoted unnecessary and prolonged bureaucratic paperwork and procedures, and has since been expanded to encompass a more generic sense of unproductive effort. The level of everyday exposure to bureaucracies is sufficient such that notions of what a bureaucracy is (or perhaps more importantly, what it is not) have become a part of the popular culture of modern society. Fictional settings in which bureaucratic procedures interfere with the good intentions of people, promote an unproductive or unhealthy outcome, or lead to an uninspired work environment are common themes of movies, novels, syndicated cartoon features, and television shows.

The expansion of bureaucratic procedures has clearly impacted developments in the areas of health care and labor. In the area of health care, changes in the technological base of medicine, the methods by which medical services are financed, the regulatory role of government, as well as efforts to enhance the efficiency and accountability of health care providers has culminated in the bureaucratization of medical care (Mechanic 1976). In contrast to past medical practice settings characterized by a private and dyadic relationship between a doctor and a patient, the delivery of medical care in bureaucratized settings, intended to provide broader and more uniform care, increases the likelihood of conflicts of interest and the diminished salience of individualized care. When medical care is delivered in a bureaucratic setting, the specific features of patient care may be based on a number of nonclinical elements in addition to the clinically pertinent factors. Nonclinical criteria such the determination of what services will be provided and the avoidance of “unnecessary” services, patient case management by nonmedical personnel, a predetermined referral protocol and network, and the disclosure of sensitive patient information within the bureaucratic organization all limit the role of the doctor. Each of these nonclinical, bureaucratically derived elements introduce different and potentially conflicting viewpoints in an evaluation of effective patient care and may direct attention more toward resolving organizational conflicts than enhancing patient care. The issues facing bureaucratic medical care will likely become more acute with the “aging” of society and the need to attend to a greater number of patients suffering from debilitating, protracted, and nonrecoverable medical conditions.

The logic underlying the structure of bureaucratic organization is to control and regulate work routines on the basis of formal rules and regulations. In intending to use formal rules to administer workers' duties and responsibilities, it is assumed that key components of a job can be identified to the extent that rules can effectively monitor and be used to evaluate individual performance. The precise specification of work routines for the purpose of enhancing worker productivity and organizational efficiency has been an ongoing interest throughout the twentieth century, as indicated by the time-motion studies and efficiency "experts" of the early part of the century and process evaluation and quality assessments of the later part of the century. In the course of precisely specifying work responsibilities and routines, the de-skilling of the labor force (Taylor 1911) is, if not an intended outcome, a likely development. If a job can be defined in terms of specific component tasks and if the component tasks are rudimentary enough to be regulated by formal rules, then the skill requirements of job are reduced. As this process continues, the skill levels of workers in the labor force may exhibit similar reduction. Organizations can hire an individual with the nominal skill sets needed to adhere to the formally specified rules instead of hiring someone who is capable of displaying individual judgment working effectively in an environment characterized by job variability and uncertainty.

Bureaucracies have become both indispensable and despised fixtures of modern society. In the drive for overall organizational efficiency and accountability, individuals within and outside the bureaucracy often experience the unsettling feeling that they have no influence over a process that may directly impact them. The aggravation of wanting to have a problem solved or question answered but being unable to find anyone who is in the position to respond to the expressed concern fuels criticism of bureaucracies.

While criticism of bureaucratic procedures (or lack of "appropriate" procedures) is frequent, it is also apparent many of the everyday functions in society are possible only because of the operation of bureaucracies. The major institutions of society, with the multitude of diverse projects performed every day, depend on the administrative and regulatory features of bureaucracies. The

faceless bureaucratic official who may be criticized for indifference is nonetheless an essential element in such consequential areas as national defense, public education and welfare, and communications. The assessment of bureaucratic structure and procedures therefore needs to attend to both the overall scope of bureaucratic functions and the manner in which particular tasks are performed.

"Red tape" and inefficiency are two of the most heavily criticized elements of public bureaucracies, and instigate appropriate calls for reform. However, bureaucracies contain complex structures and multifaceted procedures intended to serve a number of purposes. Criticism often reflects common misperceptions rather than the true workings of bureaucracies. Regarding red tape, the bureaucracy does not necessarily create these protracted procedures in an effort to either insulate the organization from competition or to ensure that little if anything gets done without the organization's official approval. Rather, it is more likely the result of disclosure and accountability requirements imposed on the bureaucracy (Kaufman 1977, p. 29). Similarly, inefficiency needs to be placed in the more global perspective of what in addition to the specific task is being accomplished by the bureaucracy. If the focus is limited to a specific task (e.g., construction of a highway), then the process can reasonably be viewed as inefficient if the task could have been completed sooner or cost less if done by someone else. However, there may be a number of additional goals that the bureaucracy is attempting to achieve while completing the specific task in question. In the public sector, a bureaucracy is often required to be responsive to a number of outside interest groups to ensure that its operation is socially fair, accountable, and impartial, in addition to being technically able to complete a particular task (Wilson 1989, pp.315-325). The determination of efficiency is compounded by this collateral concern regarding the attainment of social goals and specific technical goals. Bureaucracies are thus faced with the dual challenge of being socially responsible and technically proficient and therefore have to be assessed on the basis of the extent to which they concurrently achieve these two sets of goals and not just one set at the exclusion of the other.

C

CAPITALISM

NOTE: *Although the following article has not been revised for this edition of the Encyclopedia, the substantive coverage is currently appropriate. The editors have provided a list of recent works at the end of the article to facilitate research and exploration of the topic.*

Sociology has no complete, formal consensus on a specific definition of capitalism. The discipline of sociology itself arose as an attempt to understand and explain the emergence and nature of modern capitalist societies. Sociology's founding theorists were very much concerned with the development of capitalism. Émile Durkheim sought to find the bases of new forms of morality and social solidarity in the division of labor, which capitalism both expanded and accelerated (Durkheim 1984). Karl Marx, of course, spent his adult life analyzing and criticizing capitalist society. Marx's project was guided by his hope and expectation that capitalism would be displaced as history moved toward a socialist, and then communist, future. Max Weber, too, devoted considerable attention to the origins of modern capitalism and the historically specific character of Western society under capitalist expansion. Contemporary sociology's treatment of capitalism is grounded in the works of these theorists. The works of Marx and Weber, insofar as they more explicitly focused attention on the dynamics of capitalism, provide a point of departure for discussing modern sociology's approaches to capitalism.

The term *capitalism* is sometimes used to refer to the entire social structure of a capitalist society.

Unless otherwise indicated, it is used here with specific reference to a form of economy to which multiple social institutions are effectively bound in relatively compatible ways. Weber used the term *capitalism* in a very general way: "wealth used to gain profit in commerce" (Weber 1976, p. 48). This understanding of capitalism permits the discovery of capitalism in a wide variety of social and historical settings. Weber describes this general form of capitalism in traditional India and China, ancient Babylon, Egypt, and Rome and in medieval and modern Europe. However, Weber also constructs a more specific typology that pertains to the form that capitalism has taken in more contemporary Western society. This form of capitalism is referred to as modern, or Western, capitalism. In *The Protestant Ethic and the Spirit of Capitalism*, Weber (1958 pp. 21–22) contends that this is "a very different form of capitalism which has appeared nowhere else" and that it is unique in its rational "organization of formally free labor." Other important characteristics of modern capitalism, such as the separation of business from the household and rational bookkeeping, derive their significance from this peculiar organization of labor. In this emphasis on the importance of free labor, or the creation of a labor market, Weber's definition of capitalism moves much closer to Marx's use of the term.

For Marx, it is the creation of a market for human labor that is the essence of capitalism. Marx wrote that capitalism can "spring into life only when the owner of the means of production and subsistence meets in the market with the free

laborer selling his labor power” (Marx, quoted in Sweezy 1970 pp. 56–57). The emergence of the free laborer represents the destruction of other noncapitalist economic forms. Feudal or slave economies, for example, are not characterized by the recognized right of laborers to sell their own labor power as a commodity. Simple commodity production, or economies in which laborers own their own means of production (tools, equipment, etc.), are not characterized by the need for laborers to sell their labor power as a commodity. In the latter case, Weber concurs with Marx that this freedom is only formal since such laborers are compelled to sell their labor by the “whip of hunger.”

The sociological conception of capitalism also varies with particular theoretical understandings of the nature of history. Marxists, guided by an evolutionlike vision of history, tend to see capitalism as a stage in humanity’s progressive movement to a communist future. In this manner, Marxist sociology also often refers to various phases of capitalism. Wright (1978 pp. 168–169), for example, describes six stages of capitalist development: primitive accumulation, manufacture, machinofacture, monopoly capital, advanced monopoly capital, and state-directed monopoly capitalism. The implicit assumptions of law-like forces at work in the historical process are evident in the Marxist confidence that capitalism, like all previous socioeconomic orders, will eventually be destroyed by the internal contradictions it generates. References to the current stage of capitalism as “late capitalism” (e.g., Mandel 1978), for instance, reveal a belief in the inevitability of capitalism’s demise.

The Weberian tradition, on the other hand, rejects the assumption of history’s governance by “iron laws.” This leads to a recognition of various types of capitalism but without the presumption that capitalism must eventually be eliminated. The Weberian tradition discovers in the history of Western capitalism a process of rationalization toward depersonalization, improved monetary calculability, increased specialization, and greater technical control over nature as well as over persons (Brubaker 1984). However, while the Weberian tradition can expect the *probability* of continued capitalist rationalization, it does not predict the *inevitability* of such a course for history. It is important to note that, for Weber, a transition from

capitalism to socialism would probably only further this rationalization. Such developments were seen as associated with industrial society and bureaucratic forms of domination rather than with capitalism per se.

This background permits a more detailed examination of contemporary sociology’s treatment of capitalism. Already, it can be seen that sociology’s understanding of capitalism is more specific than popular conceptions of capitalism as simply “free-market” or “free-enterprise” systems. This is especially so insofar as sociology focuses its attention on modern society. It is the emergence of a “free market” in human labor that sociology tends to recognize as the distinguishing characteristic of modern capitalism. For Durkheimian sociology, this market guides the normal division of labor that is the basis of social solidarity. In this view, the absolute freedom of such a market is necessary to generate the conditions of equal opportunity that are required to guarantee norms by which people come to accept capitalism’s highly developed division of labor. Under conditions of a truly free labor market, the stratification system is seen as legitimate since individuals attain their position through their own achievement and not by means of some ascribed status (e.g., caste, gender, race, ethnicity, nepotism) or political patronage. For Marxian sociology, it is in this labor market that the two fundamental and opposing classes of capitalism meet: the owners of the means of production or capitalists (*bourgeoisie*) and the workers (*proletariat*). In this view, the struggle between these two classes is the dynamic force behind capitalist development. For Weberian sociology, this market for human labor is necessary for the development of the advanced and superior calculability of capitalist economic action. This calculability is, in turn, a fundamental component of the rationalization process in modern Western society.

This transformation of human labor into a commodity is the force behind both capitalism’s internal dynamism as well as its outward expansion. On the one hand, capitalism is constantly driven to enhance its productivity. This compulsion of modern capitalism continuously to develop its technical capacity to produce is not driven simply by competition among capitalists but is related to the unique role that human labor plays in capitalist production. Prior to the emergence of a market for human labor, premodern forms of

capitalism exhibited no such pressure constantly to revolutionize the technical means of production. Modern capitalism's dependence on human labor as a commodity, however, demands that this cost of production be kept as low as possible. First, technological development can lower the cost of labor as a commodity by vastly increasing the production of mass consumer goods. The subsequent reduction in the cost of items like food and clothing translates into reductions in the cost of wages to sustain laborers and their families. Another means to this end is automation, the creation of technology that can replace or enhance human labor. Such technological development also permits capitalists to circumvent the natural limits of the human body to labor and the tendency of laborers to organize and demand higher wages, especially important spurs to technological development in capitalist societies characterized by a shortage of labor. However, under such conditions the capitalist's demand for profitability may limit the internal expansion of technology as a means of increasing production (i.e., capital-intensive production) in favor of an outward expansion that draws upon new sources of labor. This expansion of capitalism can take two basic forms. On the one hand, there is a drive toward proletarianization, or the inclusion of more and more of society's population segments that have previously escaped the labor market. On the other hand, there is a tendency to reach outside of the society itself toward other societies, thus incorporating ever larger regions of the world into the sphere of capitalism.

In the early development of capitalist societies, peasants are freed from feudal relations and slaves are freed from slave relations to add to the available pool of labor. This transformation is rarely a smooth one. The great revolutions in Western Europe and the U.S. Civil War forced these precapitalist classes to surrender their workers to the capitalist labor market. Another major source of labor for capitalist expansion has been independent laborers or persons who "work for themselves." Farmers who own their own land and equipment and work without hired labor are a good example of the type of self-employed producer that sociologists commonly refer to as simple commodity producers. There are other occupations in this general classification, of course. Highly skilled laborers have at times been able to

retain independence from capitalist labor markets. However, capitalism has displayed a powerful capacity to bring these laborers into the sphere of capitalist, wage labor relations. For example, carpenters, mechanics, butchers, even doctors and lawyers increasingly find themselves working for wages or a salary in a capitalist firm rather than working for themselves. From time to time, the number of self-employed appears actually to rise in certain capitalist societies (Bechhofer and Elliott 1985). This is usually the result of the introduction of some new technology or new service. Sometimes persons who strongly wish to be their "own bosses" are able to take advantage of specific market conditions or are willing to sacrifice potential income to achieve this status. But clearly, if capitalist societies are examined over the course of the last 200 to 300 years, the tendency is strongly toward increased absorption of persons into the capitalist labor market.

In recent times, labor markets in nations like the United States have found another major source of labor power in women. The traditional role of homemaker impeded the inclusion of women in the labor market. That role of women within the home has changed somewhat, but the role played by women in expanding the pool of labor available to capital has increased tremendously. According to Christensen (1987), for example, in 1960 30 percent of American mothers were employed; in 1986, 62 percent were employed. Ethnic minorities have often performed a similar function in expanding the size of the labor market. Succeeding waves of immigrants have frequently played an initially marginal role in the labor market, only to be gradually absorbed into more routine participation as time passes.

Capitalism's inherent expansionary tendencies also push the capitalist society to reach beyond the borders of the nation. This expansion occurs as capitalism seeks markets for its products but also in the search for raw materials and cheaper labor to produce goods for the home market. Eventually, capitalism may simply seek profitable investment outlets outside the nation of origin. Sociology has analyzed capitalism's transnational expansion with two general but conflicting theoretical approaches. Modernization theory views this expansion in a positive way, seeing it as a means by which undeveloped societies are enabled to begin the process of development that the

developed societies have already achieved. This theoretical orientation has been especially important in shaping development policies directed at the “third world” by many Western governments, the World Bank, and even the United Nations (Giddens 1987).

Sociology’s other basic approach to the emergence of a world-scale capitalist economy involves a more critical interpretation. This view tends to see capitalist expansion as having actually caused underdevelopment. The underdevelopment approach sees the lack of development in less-developed societies (periphery) as a consequence of systematic exploitation of their people and resources by the advanced societies (core). This process of underdevelopment is generally viewed as having occurred in three stages. The first stage, that of merchant capitalism, persisted from the sixteenth century to the late nineteenth century. Merchant capitalism, supported by military force, transferred vast amounts of wealth from the periphery to the European nations to help finance initial industrial development in what are now the advanced capitalist societies. The second stage, colonialism, persisted until about ten to fifteen years after World War II, when many colonial nations were granted formal independence. In the colonial stage, the developed societies organized economic and political institutions in the less-developed nations to serve the needs of industrial capitalism in the advanced nations. In the postcolonial period, formal political independence has been granted, but the persistent economic inequalities between developed and underdeveloped nations strongly favor the more-developed capitalist societies. Even when raw materials and finished products remain in the lesser-developed nation, the profits derived from such production are taken from the periphery and returned to the advanced core societies. Thus, the pattern of underdevelopment continues in the face of formal independence.

Traditionally, much of sociology’s attention to international capitalist expansion has focused on relations between nations. Increasingly, sociology is examining these matters with greater attention to relations between classes. This shift of emphasis reflects the increasing importance of the transnational corporation in recent times. The transnational corporation’s greater capacity to use several international sites for component production and the shift of much industrial production to

underdeveloped regions are generating a process of deindustrialization in the advanced capitalist societies. While capitalism has long been a world system, many sociologists contend that the transnational, or “stateless,” corporation has significantly less commitment or loyalty to any specific nation. Capital flows ever more rapidly throughout the world, seeking the cheapest source of labor. Modern computer technology has facilitated this trend. Asian, European, and North American capital markets are increasingly interdependent. Sociology’s shift of emphasis reflects this tendency for the U.S. capitalist to have more in common, sociologically, with the Japanese or German capitalist than the U.S. investor has in common with the American worker. Sociology’s new attention to the internationalization of capital may present a need for rethinking the usefulness of the nation as the typical boundary of a society. The emergence of the “new Europe” and the demise of state socialism in Eastern Europe and the USSR may also lead to a more flexible notion of what constitutes a society.

The preceding discussion has focused on capitalism as a specific form of economy that is defined by the expansion of a labor market in which propertyless workers sell their labor power for money. Capitalist societies are, of course, far more complex than this. There are a number of distinct economic forms that coexist with capitalism in both complementary and conflictual relations. The capitalist economy itself may be broken down into two basic sectors, one representing big business and one representing small business. Sociologists usually refer to these as the monopoly sector and the competitive sector. This dual economy is reflected in a segmented, or dual, labor market. Monopoly sector workers are more likely to be male, unionized, receive better wages and benefits, have greater job security, and work in a more clearly defined hierarchy of authority based on credentials. Competitive sector workers are less likely to possess strong credentials, more likely to be female, receive lower pay, work under more dangerous conditions, and work without union protection, benefits, or job security.

Noncapitalist economic forms also exist alongside this dual capitalist economy. The self-employed reflect a form distinct from modern capitalism that sociologists commonly refer to as simple

commodity producers or petite bourgeoisie. These people produce goods and services (commodities) for sale on the market, but they work for themselves and use only their own labor in production. Most capitalist societies also contain cooperative economic organizations that are distinct from capitalist enterprises. Cooperatives are commercial, nonprofit enterprises, owned and democratically controlled by the members. The nonprofit status and democratic distribution of control (one member, one vote) set cooperatives apart. The cooperative is an especially important form of economic organization for those simple commodity producers, like farmers, described above. All capitalist societies today also contain elements of socialist economy. Key social services, such as health care, and even some commodity production are provided by the state in many societies commonly recognized as capitalist. The United States is perhaps among the most resistant to this movement toward mixed economy. Yet even the United States has, to some extent, socialized education, mail delivery, libraries, police and fire protection, scientific research and technological development, transportation networks (e.g., highways, airports, urban transit), military production, industrial infrastructure provision, and so on. The mixed character of this economy is further indicated by the common practice of the government contracting capitalist firms to produce many goods and services. In a related way, the development of welfare has influenced the nature of capitalist society. The increased intervention of government into the economy has generated the notion of the welfare state. While popular conceptions of the welfare state tend to focus on the role that government plays in alleviating the impacts of poverty on individuals, sociology also recognizes that welfare reduces the cost of reproducing the commodity-labor. In this sense, welfare functions, in the long run, as a subsidy to capital. Further, many of the socialized sectors of capitalist economies function to ensure a profitable environment for capitalist firms (O'Connor 1973; Offe 1984). In many instances, such subsidization of capital is biased toward the largest corporations.

Some sociologists have contended that the rise of the large capitalist corporation, with its dispersed stock ownership and bureaucratic form of organization, has eroded the power of individual capitalists to control the corporation in which

they have invested their capital. Instead, it is argued, bureaucratic managers have gained control over corporate capital. Such managers are thought to be relatively free of the drive to maximize profits and are willing to accept average rates of profit. In this way, the ruthless character of earlier forms of capitalism are seen as giving way to a capitalism that is managed with broader interests in mind. Further, the dispersal of ownership and control is said to eliminate the misuse of capital in the interests of an elite and wealthy minority. This "managerialist" position complements pluralist political theory by providing greater authority for institutions of representative democracy to control the allocation of society's resources.

This view is challenged in a variety of ways. Other sociologists contend that while management may have gained some formal independence, its job requires devotion to profit maximization, and its performance is assessed on this criteria. In this view, the larger companies' executives and owners are able to use interlocking directorates and their common class background (e.g., elite schools, private clubs, policy-planning organizations) to minimize price competition and thus sustain high profit levels. Others argue that those informal ties are of less consequence than their common dependency on banks. In this view, banks, or finance capital, play a disproportionately powerful role in centralizing control over the allocation of capital resources. This position strongly opposes the managerialist arguments and those who envision an independent corporate elite whose power lies in the control of corporate bureaucracies rather than in personal wealth (Glasberg and Schwartz 1983). Further, to the extent that it is valid, this argument is particularly important given the increasing internationalization of capital discussed above, since a great deal of that development has occurred in the sphere of finance capital.

These sorts of arguments reflect an important shift in sociology's understanding of the relationship between capitalism and democracy. Sociology's Enlightenment roots provided a traditional legacy of viewing capitalism and democracy as intertwined in the process of modernization. While this parallel development is certainly recognizable in early forms of modern capitalism, more recent forms of capitalism call into question the extent to which capitalism and democracy are inevitably bound together. Indeed, recent works suggest that capitalism

and democracy are now opposed to one another (e.g., Piven and Cloward 1982). This view holds that the tremendous inequality of wealth generated by modern capitalism impedes the possibility of political equality. Even conservative writers (e.g., Huntington 1975) have noted the problematic relationship between contemporary capitalism and democracy, suggesting a retrenchment of democratic forms in defense of capitalism. The future of capitalism will be shaped by this tension with democracy, but that tension itself is located in an increasingly global economy. At the moment, the politics of capitalist society seem to lag behind the economic changes. The individual is increasingly pressured to sell his or her labor as a commodity on a world market, yet at the same time that individual remains a citizen, not of the world, but of the nation. The transnational capitalist enterprise and the flow of capital, on the other hand, are ever more free of such national borders.

CASE STUDIES

There is a sense in which virtually every activity that we associate with sociology might be called “case studies.” These activities include the generation of samples (which are made up of individual cases) for statistical analysis, the use of empirical examples (or cases) to illustrate aspects of general sociological theories, and comparative analyses of the interconnected events (again cases) that form historical and cultural patterns. Indeed, Charles Ragin and Howard S. Becker (1992) have edited an anthology dedicated to defining case studies, entitled *What is a Case?* Historically, the answer that sociologists have usually given to this question is that case studies are in-depth analyses of single or a few communities, organizations, or persons’ lives. They involve detailed and often subtle understandings of the social organization of everyday life and persons’ experiences. Because they focus on naturally occurring events and relationships (not laboratory experiments or survey data), case studies are sometimes described as naturalistic. Case studies usually involve extensive interviews about persons’ lives, or direct observation of community or organization members’ activities, or both.

The case-study approach is not unique to sociology but is a general approach to social life that is used by social scientists (especially anthropologists and historians), psychotherapists and family therapists, and journalists. All such uses of case studies involve idiographic interpretation that emphasizes how social action and relationships are influenced by their social contexts. Case studies are unique within sociology because they require that researchers immerse themselves in the lives and concerns of the persons, communities, or organizations they study, or all of these. While case studies are based on the general scientific method and are intended to advance the scientific goals of sociology, they are also humanistic because they offer readers insight into the concerns, values, and relationships of persons making up diverse social worlds.

Social scientists use the understandings developed in case studies to introduce the general

public to the unique ways of life or problems of communities, or both, to apply and build theories, and to develop policy interventions concerned with individual and social problems. Two classic examples of how case studies may be used to achieve these ends are Elliott Liebow’s (1967) *Tally’s Corner* and Helen MacGill Hughes’s (1961) *Fantastic Lodge*. Liebow’s book reports on his experiences as a participant-observer within a poor, male, African-American urban community. Liebow describes the practical problems faced by these men in living their everyday lives, and the practical strategies they used to deal with life’s pressing problems. The study challenged many of the prevailing assumptions held by policy makers and academics during the 1960s, and has been used to reassess how the social service and mental health needs of inner city, minority groups are best addressed.

Hughes’s study, which is subtitled *The Autobiography of a Drug Addict*, details the life experiences of Janet Clark, a young white woman living in a poor urban area. Hughes describes Ms. Clark as speaking from a marginal urban world made up of drugs and drug addicts, arrest and incarceration, and the urban “sporting” life. The book raises themes that were later systematized by Howard S. Becker (1963)—the person who conducted the interviews of Janet Clark—in developing his version of the labeling approach to the sociology of deviance. The labeling perspective emphasizes that deviance is not just a matter of rule breaking, but is always created through the official responses of others. It has had profound and enduring implications for how sociologists define, study, and analyze societal responses to rule-breaking behavior.

CASE STUDIES AND THE DEVELOPMENT OF SOCIOLOGY IN THE UNITED STATES

Sociological case studies are most associated with the ethnographic traditions established at the University of Chicago during the first half of the twentieth century. The Chicago school’s emphasis on case studies partly reflects the influence of Robert E. Park, who joined the Sociology Department in 1916 and later served as department chair. Park taught his students that case studies should emphasize how persons’ lives and the organization of communities are shaped by general social processes and structures. For example, Park analyzed

the ways in which cities develop as interrelated territories involving distinctive ways of life and opportunities. He described such territories as “natural areas” and stressed that they emerged based on social and economic competition.

Many of the best-known and most influential sociological case studies done in the United States were conducted in the 1920s and 1930s by students and faculty members at the University of Chicago who were interested in the distinctive ways of life in diverse natural areas (e.g., Anderson 1923; Cressey 1932; Shaw 1930; Thomas 1923; Wirth 1928; and Zorbaugh 1929). While it was done later, H. M. Hughes’s (1961) study of Janet Clark’s life is also an example of the Chicago approach to case studies and urban life. Perhaps the best-known and most influential case study done in the early Chicago school tradition is William Whyte’s (1943) *Street Corner Society*, a participant-observer study of a poor Italian-American community. The significance of the study is related to Whyte’s use of his observations to identify and explicate some basic sociological issues involving social relations and social control in small groups.

Park’s approach to case studies has been modified and refined over the years, particularly by Everett C. Hughes (1970), who developed a comparative approach to work groups and settings. The approach uses case studies to identify and analyze comparatively generalized aspects of work groups and settings, such as work groups’ definitions of “dirty work” and their interest in controlling the conditions of their work. Becker’s (1963) use of multiple case studies in articulating the labeling perspective is a notable example of how the comparative strategy advocated by E. C. Hughes may be applied to develop sociological theory. Another major contributor to the Chicago school of sociology is Erving Goffman (1959), who used case studies to develop a dramaturgical perspective on social interaction. The perspective treats mundane interactions as quasi-theatrical performances involving scripts, stages, and characters.

Although less influential than the Chicago school, a second source for case studies in American sociology was structural-functionalist theorists who analyzed communities and organizations as stability-seeking social systems. Structural-functional case studies were influenced by anthropological studies of nonindustrial communities and the more

abstract theories of Talcott Parsons and Robert Merton. These studies analyze how social systems are maintained and adapt to changing environmental circumstances. For example, structural functionalists have used case studies to analyze the consequences of organizational activities and relationships for maintaining organizational systems (Blau 1955; Gouldner 1954; Sykes 1958).

An exemplary structural-functionalist case study is Rosabeth Moss Kanter’s (1977) analysis of a multinational corporation, which she calls Indsco. The study examines how social relations in corporations are shaped by social structures which produce feelings of uncertainty and marginality among managers and secretaries. Kanter uses her case study to illustrate how gender segregation is produced and maintained in Indsco as secretaries and managers cope with the practical problems emergent from corporate power and opportunity structures. She also makes some practical suggestions for altering these structures in order to better address the needs of managers and secretaries, and to produce more egalitarian relations between corporate members. Many of Kanter’s suggestions have been adopted by diverse American corporations. This is another way in which case studies may influence social policies.

RECENT DEVELOPMENTS IN CASE-STUDIES RESEARCH

While many qualitative sociologists continue to work within the Chicago school and structural-functional traditions, several important developments have occurred in qualitative sociology in the past twenty-five years. For example, many of the case studies of ethnic communities done by early Chicago school sociologists deal with the problems and social organization of European-American communities. Many more recent case studies, on the other hand, explore these issues within the context of nonEuropean-American communities. Ruth Horowitz’s (1983) case study of a Hispanic community and Elijah Anderson’s (1990) research in an African-American community are major contributions to this development.

Age-based communities have also emerged as subjects for case studies by sociologists. One focus in this literature involves the distinctive life circumstances and coping strategies of communities of older people. Arlie Hochschild’s (1973) study of

a group of widowed women as an “unexpected community” is an important example of this focus, as is Jennie Keith’s (1977) analysis of the social construction of community in a retirement facility in France. Another approach to case-study research is Jaber Gubrium’s (1993) analysis of the life stories told to him by a group of elderly nursing home residents. Equally significant are recent case studies of communities of young people, particularly of communities organized around shared interests in popular culture. A useful example is Sarah Thornton’s (1996) case study of dance clubs and raves in London. Thornton’s analysis extends traditional analysis of communities as subcultures by showing how this community was created and is maintained through the actions of (not so youthful) members of the London mass media.

A related change has been case studies of experiential communities. That is, social groups that share common social experiences, but not a common territory. For example, Richard Majors and Janet Mancini Billson (1992) analyze African-American males as a racial and gender community that is organized around shared practical problems and strategies for managing them. Using a semiotic perspective, Dick Hedbridge (1979) also analyzes an experiential community in using several case studies to show how young people form a subculture that is organized around the expression of cultural styles, which symbolically resist dominant forces in society. Another focus in this literature is on the distinctive life experiences of members of gay and lesbian communities. A notable example is Carol A. B. Warren’s (1974) case study of a gay community in which she raises some important questions about the labeling perspective. Thus, both Warren’s and Hedbridge’s research show how case studies contribute to theoretical development in sociology.

A different, but complementary, use of the case-study research strategy is auto-ethnography. These are case studies conducted within and about one’s own group. The researcher acts as both a sociologist seeking information about a community, and as a subject of the research. A groundbreaking auto-ethnography is David Hayano’s (1982) study of professional card players. This case study provides readers with distinctive access to, and insights into, the experiences of professional card players. Two other notable auto-ethnographies are Helen Rose Fuchs Ebaugh’s (1977) case study

of her own and others’ exit from the social role of Roman Catholic nun, and Thomas Schmid’s and Richard S. Jones’s (1991) analysis of Jones’s and other inmates’ adaptations to prison life.

Auto-ethnographers’ concern for taking account of their own and others’ experiences is extended in another trend in sociological case-studies research. This trend focuses on emotions as a basic and important aspect of social life. Many case studies done by sociologists of emotions deal with other persons’ emotional experiences (Hochschild 1983; Katz 1988). Other sociologists, however, adopt a more auto-ethnographic strategy by treating their own lives and feelings as topics for sociological analysis. The sociologist’s feelings become the case or part of the case under study. An important example of the latter approach to case studies is David Karp’s (1996) discussion of his own experiences with depression, and his linking of them to the emotional experiences reported by other members of this community of sufferers.

In addition to the changes discussed above, three other changes in case-studies research warrant special notice. They are the emergence of radical case studies, a focus on reality construction, and concern for the politics and poetics of writing case studies.

RADICAL CASE STUDIES

While early sociological case studies were sometimes associated with reformist movements, they were seldom intended to advance politically radical causes or to build radical social theory. This orientation may be contrasted with that of radical journalists of the same era (such as Upton Sinclair) who used case studies to highlight social problems and raise questions about the legitimacy of capitalism. Radical sociologists have begun to use case studies to develop their sociological goals. One source for radical case studies is Marxist sociologists concerned with the ways in which worker-management relations are organized in work settings, how social classes are perpetuated, and how capitalism is justified.

Marxist sociologists use their case studies to challenge more conservative case studies that, from the radicals’ standpoint, do not take adequate account of the ways in which persons’ everyday

lives are shaped by political and economic structures. They are also used to analyze historical changes in capitalism and the consequences of the changes for workers. For Marxist theorists, a major change has been the rise of a new of society—monopoly capitalism—dominated by multinational corporations. These theorists use case studies of work settings to illustrate and analyze the effects of monopoly capitalism on workers (Burawoy 1970).

Although it is not as well developed in sociology as in anthropology, another focus of radical case studies involves the social and personal consequences of the international division of labor. The studies are concerned with the ways in which multinational corporations internationalize the production process by exporting aspects of production to Third World countries. Case studies of this trend show the profound impact of global economic changes for gender and family roles in Third World countries (Ong 1987). Finally, radical sociologists have used the case-study method to analyze the ways in which capitalist institutions and relationships are justified and perpetuated by noneconomic institutions such as schools (Willis 1977).

A second source for radical case studies is feminist sociology. While it is diverse and includes members who hold many different political philosophies, all forms of feminist sociology are sensitive to the politics of human relationships. A major theme in feminist case studies involves the ways in which women's contributions to social relationships and institutions go unseen and unacknowledged. Feminist sociologists use case studies to call attention to women's contributions to society and analyze the political implications of their invisibility. A related concern involves analyzing relationships and activities that are typically treated as apolitical and private matters as matters of public concern. One way in which feminist sociologists do so is by treating aspects of their own lives as politically significant and making them matters for sociological analysis (McCall 1993).

The case-study approach is central to the feminist sociology of Dorothy E. Smith (1987). Smith treats case studies as points of entry for studying general social processes that shape persons' experiences and lives. Her approach to case studies emphasizes how the seemingly insignificant activities of everyday life are related by general social

processes (such as patriarchy and market relationships) and how they help to perpetuate the processes. Smith describes, for example, how the commonplace activity of dining in a restaurant is organized within, and perpetuates, capitalist commodity relations. Smith's analysis might also be seen as an example of the general analytic strategy, which Michael Burawoy (1998) calls the "extended case method." This approach to case studies involves four major steps:

- Researcher observations of, and immersion in, a social setting,
- Analysis of the researcher's observations as aspects of general social processes that shape life in diverse contemporary social settings,
- Historicizing the observations and social processes by showing how they are embedded in historical forces that guide and structure the evolution of capitalist society, and
- Linking the observations and analyses to formal sociological theories that explain the researcher's initial observations and their larger social and historical contexts.

This is one way in which case studies may be used as a springboard for developing systematic, general, and formal sociological analyses.

CASE STUDIES OF REALITY CONSTRUCTION

Basic to the case-study method and idiographic interpretation is a concern for human values and culture. Beginning in the 1960s, one focus of this concern has been with the ways in which social realities are produced in social interactions. The new focus is generally based on the social phenomenology of Alfred Schutz and ethnomethodology. While different in some ways, both are concerned with the folk methods that people use to construct meanings (Silverman 1975). For example, Harold Garfinkel (1967), the founder of ethnomethodology, used a case study of a patient seeking a sex-change operation to analyze how we orient to ourselves and others as men and women.

Case studies of reality construction emphasize how social realities are created, sustained, and

changed through language use. The emphasis has given rise to new orientations to traditional areas of sociological research, such as science. Until recently, sociologists of science have treated scientific work as a simple, noninterpretive process centered in scientists' adherence to the rules of the scientific method, which emphasizes how "facts" and "truth" emerge from observations of the "real" world. Viewed this way, scientific facts are not matters of interpretation or social constructions. This view of science has been challenged by case studies of scientific work that focus on the ways in which scientific facts are socially produced based on scientists' interpretations of their experiments (Latour and Woolgar 1979).

A major branch of ethnomethodology is conversation analysis, which focuses on the turn-by-turn organization of social interactions (Sacks, Schegloff, and Jefferson 1974). For conversation analysts, social reality is collaboratively constructed within turn-taking sequences, which may be organized around such linguistic practices as questions and answers or charges and rebuttals. A major contribution of conversation-analytic studies has been to show how IQ and other test results are shaped by the ways in which test-givers and test-takers interact (Marlaire and Maynard 1990). Also, sociologists influenced by conversation analysis theory have considered how power and dominance are interactionally organized and accomplished.

Some qualitative sociologists have extended and reformulated ethnomethodological case studies by analyzing the relationships between the interpretive methods used by interactants in concrete situations and the distinctive meanings they produce in their interactions. This approach to case studies focuses on the practical and political uses of meanings in social institutions. These ethnographers analyze meanings as rhetorics which interactants use to persuade others and to assign identities to themselves and others. An important contribution to this approach to case-study research is Donileen Loseke's (1992) study of decision making and social relations in a shelter for battered women. Loseke details the practical contexts within which shelter workers, shelter residents, and applicants to the shelters encounter each other and manage their social relationships. It is in these encounters, Loseke states, that shelter

workers and residents give concrete meaning to the abstract cultural category of battered women.

Two other important, and related, trends in case studies of reality construction involve comparative analysis of two or more cases, and the use of new theoretical perspectives in analyzing case-study data. One example is Jaber Gubrium's (1992) comparative analysis of two different family therapy sites. Gubrium uses observational data from the sites to show how different therapy approaches are organized to "detect" and remedy different kinds of family and personal problems. He also shows how aspects of Weberian theory may be used in analyzing the sociological significance of family therapy. Gale Miller and David Silverman (1995) have also contributed to this development by comparatively analyzing social interactions in two different counseling centers located in the United States and England. This study is based on the ethnography of institutional discourse perspective (Miller 1994), which is a strategy for developing general theoretical statements from case-study research.

THE POLITICS AND POETICS OF WRITING CASE STUDIES

While some qualitative sociologists focus on the folk methods of description and interpretation used by others in creating realities, other sociologists are reconsidering the reality constructing methods used by sociologists in writing case studies. Their interest centers in the question, How do we do our work? The question raises issues about the relationships between qualitative researchers and the people they study. For example, is it enough that case studies inform the public and sociologists about aspects of contemporary society, or should they also help the persons and communities studied? A related issue involves editorial control over the writing of case studies. That is, should the subjects of case studies have a voice in how they are described and analyzed?

Such questions have given rise to many answers, but most of them involve analyzing case studies as narratives or stories that sociologists tell about themselves and others. For example, John van Maanen (1988) divides ethnographic writing into several types of "tales" involving different

orientations to the persons described, readers, and authorship. Other analyses focus on the various rhetorical devices used by ethnographers to write their case studies (Bruyn 1966). Such rhetorical devices include metaphor, irony, paradox, synecdoche, and metonymy, which ethnographers use both to describe others and to cast their descriptions as objective and authoritative.

Qualitative sociologists' interest in writing case studies may be part of a larger interdisciplinary movement involving social scientists and humanists. The movement is concerned with analyzing the rhetorics of social scientific inquiry (Nelson et al. 1987) as well as how to write better narratives. The latter issue is basic to efforts by British sociologists to develop new forms of writing that better reflect the ways in which their case studies are socially constructed (Woolgar 1988) and other sociologists' interest in developing alternatives to the logico-scientific writing style that better express their theoretical perspectives, political philosophies, and experiences (DeVault 1990; Richardson 1990). A related change in this area is some sociologists' interest in using performance art to represent their research data. For example, Carolyn Ellis and Arthur Bochner (1992) have written a play about the experiences and dilemmas faced by women and their male partners in deciding whether to abort the woman's pregnancy. Ellis and Bochner state that this presentational form allows for a wider range of communication devices than does the usual textual approach to reporting case-study findings.

In sum, the case-study method is a dynamic approach to studying social life, which sociologists modify and use to achieve diverse political and theoretical goals. While the popularity of the case-study method waxes and wanes over time, it is likely to always be a major research strategy of humanistically oriented sociologists.

CASTE AND INHERITED STATUS

The study of social inequalities is one of the most important areas of sociology as inequalities in property, power, and prestige have long-term consequences on access to the basic necessities of life

such as good health, education, and a well-paying job. Unequal resources between groups also influence their interaction with all the basic institutions of society: the economy, the political system, and religion, among others. An understanding of how inequalities arise, their forms and consequences, and the processes that tend to sustain them is essential for the formulation of policies that will improve the well-being of all in society.

All societies in the world are socially stratified (i.e. wealth, power, and honor are unequally distributed among different groups). However, they vary in the ways in which inequality is structured. One of the most frequently used bases for categorizing different forms of stratification systems is the way status is acquired. In some societies, individuals acquire status on the basis of their achievements or merit. In others, status is accorded on the basis of ascribed, not achieved characteristics. One is born into them or inherits them, regardless of individual abilities or skills. A person's position is unalterable during his or her lifetime. The most easily understood example is that of the prince who inherits the status of king because he is the son of a king.

Sociologists who study stratification use the idea of ascribed and achieved status to contrast caste systems with class systems. In class systems one's opportunities in life, at least in theory, are determined by one's actions, allowing a degree of individual mobility that is not possible in caste systems. In caste systems a person's social position is determined by birth, and social intercourse outside one's caste is prohibited.

The term "caste" itself is often used to denote large-scale kinship groups that are hierarchically organized within a rigid system of stratification. Caste systems are to be found among the Hindus in India and among societies where groups are ranked and closed as in South Africa during the apartheid period. Toward the end of this article, examples of caste systems will be given from other non-Hindu societies to illustrate how rigid, ranked systems of inequality, where one's position is fixed for life, are found in other areas that do not share India's religious belief system.

Early Hindu literary classics describe a society divided into four *varnas*: Brahman (poet-priest),

Kshatriya (warrior-chief), Vaishya (traders), and Shudras (menials, servants). The *varnas* formed ranked categories characterized by differential access to spiritual and material privileges. It excluded the Untouchables, who were despised because they engaged in occupations that were considered unclean and polluting.

The *varna* model of social ranking persisted throughout the Hindu subcontinent for over a millennia. The basis of caste ranking was the sacred concept of purity and pollution with Brahmins, because they were engaged in priestly duties considered ritually pure, while those who engaged in manual labor and with ritually polluting objects were regarded as impure. Usually those who had high ritual status also had economic and political power. Beliefs about pollution generally regulated all relations between castes. Members were not allowed to marry outside their caste; there were strict rules about the kind of food and drink one could accept and from what castes; and there were restrictions on approaching and visiting members of another caste. Violations of these rules entailed purifactory rites and sometimes expulsion from the caste (Ghurye 1969).

The *varna* scheme refers only to broad categories of society, for in reality the small endogamous group or subcaste (*jati*) forms the unit of social organization. In each linguistic area there are about two thousand such subcastes. The status of the subcaste, its cultural traditions, and its numerical strength vary from one region to another, often from village to village.

Field studies of local caste structures revealed that the caste system was more dynamic than the earlier works by social scientists had indicated. For example, at the local level, the position of the middle castes, between the Brahmins and the Untouchables, is often not very clear. This is because castes were often able to change their ritual position after they had acquired economic and political power. A low caste would adopt the Brahminic way of life, such as vegetarianism and teetotalism, and in several generations attain a higher position in the hierarchy. Upward mobility occurred for an entire caste, not for an individual or the family. This process of upward mobility, known as Sanskritization (Srinivas 1962), did not however, affect the movement of castes at the

extremes. Brahmans in most parts of the country were found at the top, and Untouchables everywhere occupied a degrading status because of their economic dependency and low ritual status.

The operation of this hierarchical society was justified with reference to traditional Hindu religious beliefs about *samsara* (reincarnation) and *karma* (quality of actions). A person's position in this life was determined by his or her actions in previous lives. Persons who were born in a Brahman family must have performed good deeds in their earlier lives. Being born a Shudra or an Untouchable was punishment for the sinful acts committed in previous lives.

Some scholars (Leach 1960; Dumont 1970) saw the caste system as a cooperative, inclusive arrangement where each caste formed an integral part of the local socioeconomic system and had its special privileges. In a *jajmani* system, as this arrangement between castes was known, a village was controlled by a dominant caste, which used its wealth, numerical majority, and high status to dominate the other castes in the village. Most other castes provided services to this caste. Some worked on the land as laborers and tenants. Others provided goods and services to the landowning households and to other castes. A village would thus have a potter, blacksmith, carpenter, tailor, shoemaker, barber, sweeper, and a washerman, with each caste specializing in different occupations. These were hereditary occupations. In return for their services castes would be paid in kind, usually farm produce. These patron-client relationships continued for generations, and it was the religious duty of the *jajman* (patron) to take care of others.

Although the system did provide security for all, it was essentially exploitative and oppressive (Berreman 1981; Beidelman 1959; Freeman 1986), particularly for the Untouchables, who were confined to menial, despised jobs, working as sweepers, gutter and latrine cleaners, scavengers, watchmen, farm laborers, and curers of hides. They were denied access to Hindu temples; were not allowed to read religious Sanskrit books and remained illiterate; could not use village wells and tanks; were forced to live in settlements outside the village; and were forbidden to enter the residential areas of the upper castes.

CHANGES IN THE CASTE SYSTEM

British rule profoundly affected the Indian social order. The ideas of Western culture; the opening of English educational institutions; the legal system, which introduced the principle of equality before the law; and the new economic activities and the kind of employment they generated all brought new opportunities for greater advancement. Although these new developments resulted in greater mobility and opened doors for even the low castes, those castes that benefited most were the ones already in advantageous positions. Thus, Brahmans with a tradition of literacy were the first to avail themselves of English education and occupy administrative positions in the colonial bureaucracy.

The spread of communications enabled local subcastes to link together and form caste associations. These organizations, although initially concerned with raising the caste status in terms of Brahmanical values, later sought educational, economic, and social benefits from the British (Rudolph and Rudolph 1960). When the colonial authorities widened political participation by allowing elections in some provinces, castes organized to make claims for political representation. In some regions, such as the South, the non-Brahman castes were successful in restricting entry of Brahmans in educational institutions and administrative services.

To assuage the fears of communities about upper-caste Hindu rule in independent India and also to weaken the nationalist movement, the British granted special political representation to some groups such as the Untouchables. They had become politically mobilized under the leadership of Dr. B. R. Ambedkar and had learned, like other castes and communities, the use of political means to secure status and power (Zelliot 1970).

After the country became independent from British rule in 1947, the Indian leaders hoped that legislative and legal measures would reorder an entrenched social structure. A new Constitution was adopted, which abolished untouchability and prohibited discrimination in public places. In addition, special places were reserved for Untouchables in higher educational institutions, government services, and in the lower houses of the central and state legislatures.

What progress has the country made toward improving the lives of the Untouchables, who now form 16.48 percent (according to the 1991 Indian Census) of the population? Has the traditional caste system disintegrated?

The movement from a traditional to a modern economy—increase in educational facilities; expansion of white-collar jobs, especially in the state sector; expansion of the transportation and communication networks; increase in agricultural production (known as the Green Revolution)—has had a significant impact on the institution of caste. However, political factors have been equally if not more important in producing changes in the caste system. One is the democratic electoral system. The other is the state's impact on intercaste relations through its policy of preferences for selected disadvantaged castes.

The close association between caste and traditional occupation is breaking down because of the expansion of modern education and the urban-industrial sector. In India, an urban middle class has formed whose members are drawn from various caste groups. This has reduced the structural and cultural differences between castes, as divisions based on income, education, and occupation become more important than caste cleavages for social and economic purposes. However, the reduction is most prominent among the upper socioeconomic strata—the urban, Western-educated, professional, and higher-income groups, whose members share a common lifestyle (Beteille 1969).

For most Indians, especially those who live in rural areas (73 percent of the Indian population is still rural), caste factors are an integral part of their daily lives. In many parts of the country Dalits (the term means “oppressed” and is now preferred by the members of the Untouchable community rather than the government-assigned label “Scheduled Castes”) are not allowed inside temples and cannot use village water wells. Marriages are generally arranged between persons of the same caste.

With the support of government scholarships and reservation benefits, a small proportion of Dalits has managed to gain entry into the middle class—as school teachers, clerks, bank tellers, typists, and government officials. Reservation of seats in the legislature has made the political arena

somewhat more accessible, although most politicians belonging to the Dalit community have little say in party matters and government policymaking. The majority of Dalits remain landless agricultural laborers, powerless, desperately poor, and illiterate.

Modern economic forces are changing the rural landscape. The increase in cash-crop production, which has made grain payments in exchange for services unprofitable; the introduction of mechanized farming which has displaced manual labor; the preference for manufactured goods to handmade ones; and the migration to cities and to prosperous agricultural areas for work and better wages have all weakened the traditional patron-client ties and the security it provided. The Dalits and other low castes have been particularly affected as the other sectors of the economy have not grown fast enough to absorb them.

The rural social structure has been transformed in yet another way. The dominant castes are no longer from the higher castes but belong to the middle and lower peasant castes—the profit maximizing “bullock capitalists” (Rudolph and Rudolph 1987) who were the chief beneficiaries of land reform and state subsidies to the agricultural sector (Blair 1980; Brass 1985). They have displaced the high-caste absentee landlords who have moved to cities and taken up modern occupations.

Modern political institutions have also brought about changes in the traditional leadership and power structure of local communities. Relations between castes are now governed by rules of competitive politics, and leaders are selected for their political skills and not because they are members of a particular caste. The role of caste varies at different levels of political action. At the village and district levels caste loyalties are effectively used for political mobilization. But at the state and national levels, caste factors become less important for political parties because one caste rarely commands a majority at these levels. The rise of a Dalit political party, the Bahujan Samaj Party, is evidence that Dalits are finally gaining some political power. They are particularly strong in the northern Indian state of Uttar Pradesh where they received 20.61 percent of the votes in the 1996 general elections. However, at the national level they have fared poorly, capturing only 11 seats (and 3.64 percent of the votes) in the 1996 general elections.

In the 1990s there were numerous instances of confrontations between the middle peasant castes and Dalits in rural areas. Violence and repression against Dalits has increased as they have begun to assert themselves. With the support of Communist and Dalit movements, they are demanding better wages, the right to till government-granted land, and the use of village wells.

In urban areas, caste conflict has mainly centered around the issue of "reservation." The other backward castes (who belong mainly to the Shudra caste and form about 50 percent of the country's population) have demanded from the government benefits similar to those available to Dalits in government service and educational institutions. Under electoral pressures the state governments have extended these reservation benefits to the other backward castes, leading to discontent among the upper castes.

Extension of preferential treatment from Dalits to the more numerous and in some states somewhat better-off backward castes has not only created great resentment among the upper castes but also has reduced public support for the policy of special benefits for the Dalits. In cities they have often been victims during anti-reservation agitations. That this is happening at the very time when the preferential programs have gradually succeeded in improving the educational and economic conditions for Dalits is not accidental (Sheth 1987).

As education and the meaning of the vote and the ideas of equality and justice spread, the rural and urban areas will witness severe intercaste conflicts. What is significant, however, is that these conflicts are not over caste beliefs and values, but like conflicts elsewhere between ethnic groups, have to do with control over political and economic resources.

CASTE IN OTHER SOCIETIES

Do castes exist outside India? Is it a unique social phenomenon distinct from other systems of social stratification? Opinion among scholars is divided over this issue. Castelike systems have been observed in the South Asian subcontinent and beyond (in Japan, Africa, Iran, and Polynesia). Caste has also been used to describe the systems of racial stratification in South Africa and the southern United States.

Whether the term "caste" is applicable to societies outside the South Asian region depends on how the term is defined. Those who focus on its religious foundations argue that caste is a particular species of structural organization found only in the Indian world. Louis Dumont (1970), for example, contends that caste systems are noncomparable to systems of racial stratification because of the differences in ideology—one based on the ideology of hierarchy, the other on an equalitarian ideology.

Cultural differences notwithstanding, caste as a ranked system exists in many societies. In fact, wherever ethnic groups stand in a hierarchical or ranked relationship to each other they resemble castes (Weber 1958; Horowitz 1985; Berreman 1981). As in caste systems, the identity of an ethnic group is regarded as being a consequence of birth or ancestry and hence immutable; mobility opportunities are restricted; and members of the subordinate group retain their low social position in all sectors of society—political, economic, and social. Social interactions between groups remain limited and are suffused with deference. Given these similarities in their social structures and social processes, caste stratification is congruent with race stratification and ranked ethnic systems. Below are some examples of castelike systems in countries outside South Asia.

In Japan, during the Tokugawa period (from the early 1600s to the middle 1800s), the Shogun rulers established a very rigid, hierarchical system that was maintained by force of law and other means. At the top were the *shogunate* warrior-bureaucrats, their *samurai* military elite, and the higher aristocracy. This was followed by peasants, then artisans, and then merchants. At the bottom and separated from the rest of the populace there was a group of outcasts called *eta* (meaning heavily polluted) or *hinin* (meaning nonhuman) who were treated much like the Indian Untouchables described above. Eta were legally barred from marrying outside their group or from living outside their designated hamlets. These hamlets were called *buraku*, and their residents known as *Burakumins*.

Burakumins are indistinguishable in appearance from other Japanese. They faced discrimination because they inherited their status from people whose jobs were considered polluting and undesirable like butchering animals, tanning skins,

digging graves, handling corpses, and guarding tombs.

The outcasts were formally emancipated in 1871, by the Meiji government (1868–1912). The descendants of *Burakumins* were identified as “new common people.” However, they continued to face discrimination as their identity could be revealed through the household register system that included the ancestry of all Japanese families. Although now the household register is not made available to the public without the permission of the family, the identity of individuals is frequently revealed when families and employers conduct investigations for marriage purposes and hiring (Ishida 1992).

Rwanda, a country just south of the Equator in Africa and which has witnessed violent ethnic conflict is another example of a system of caste stratification. Before European colonization, political power was concentrated in the hands of the king and the pastoral aristocracy (Tutsi). The Tutsis constituted only about 10 percent of the population. Hutus, the lower caste of agriculturalists, formed the vast majority of the population. The lowest caste, known as Twa, were a small minority and worked as potters, court jesters, and hunters. No intermarriage was permitted between the groups. The Tutsis used their political and military power to maintain the hierarchical system (Southall 1970), particularly in central parts of the country. This hierarchical relationship was later reinforced under colonial rule and lasted until it was brought to an end in the 1950s (Newbury 1988).

As Gerald Berreman (1981) has argued, the blacks in America and South Africa, the Burakumin of Japan, the Dalit of India, and the Hutu and Twa of Rwanda, all live in societies that are alike in their structure and in their effect on the life experiences of those most oppressed. However, those at the bottom do not accept their condition willingly. Often too powerless to revolt openly, structurally similar forms of domination create common forms of *infrapolitics*—of surreptitious resistance. Rituals of aggression, tales of revenge, use of carnival symbolism, gossip, and rumor are all examples of the strategic form of resistance the subordinates use for open defiance under severely repressive conditions (Scott 1990). Finally, similarities also exist in the political consequences of preferential policies that culturally distinct societies such as the

United States and India have adopted to reduce group disparities (Weiner 1983).

RITA JALALI

CAUSAL INFERENCE MODELS

NOTE: *Although the following article has not been revised for this edition of the Encyclopedia, the substantive coverage is currently appropriate. The editors have provided a list of recent works at the end of the article to facilitate research and exploration of the topic.*

The notion of causality has been controversial for a very long time, and yet neither scientists, social scientists, nor laypeople have been able to think constructively without using a set of explanatory concepts that, either explicitly or not, have

implied causes and effects. Sometimes other words have been substituted, for example, *consequences*, *results*, or *influences*. Even worse, there are vague terms such as *leads to*, *reflects*, *stems from*, *derives from*, *articulates with*, or *follows from*, which are often used in sentences that are almost deliberately ambiguous in avoiding causal terminology. Whenever such vague phrases are used throughout a theoretical work, or whenever one merely states that two variables are correlated with one another, it may not be recognized that what purports to be an "explanation" is really not a genuine theoretical explanation at all.

It is, of course, possible to provide a very narrow definition of causation and then to argue that such a notion is totally inadequate in terms of scientific explanations. If, for example, one defines causation in such a way that there can be only a single cause of a given phenomenon, or that a necessary condition, a sufficient condition, or both must be satisfied, or that absolute certainty is required to establish causation, then indeed very few persons would ever be willing to use the term. Indeed, in sociology, causal terminology was almost deliberately avoided before the 1960s, except in reports of experimental research. Since that time, however, the notion of *multivariate causation*, combined with the explicit allowance for impacts of neglected factors, has gradually replaced these more restrictive usages.

There is general agreement that causation can never be proven, and of course in a strict sense *no* statements about the real world can ever be "proven" correct, if only because of indeterminacies produced by measurement errors and the necessity of relying on evidence that has been filtered through imperfect sense organs or fallible measuring instruments. One may accept the fact that, strictly speaking, one is always dealing with causal *models* of real-world processes and that one's inferences concerning the adequacy of such models must inevitably be based on a combination of *empirical evidence* and *untested assumptions*, some of which are about underlying causal processes that can never be subject to empirical verification. This is basically true for all scientific evidence, though the assumptions one may require in making interpretations or explanations of the underlying reality may be more or less plausible in view of

supplementary information that may be available. Unfortunately, in the social sciences such supplementary information is likely to be of questionable quality, thereby reducing the degree of faith one has in whatever causal assertions have been made.

In the causal modeling literature, which is basically compatible with the so-called structural equation modeling in econometrics, equation systems are constructed so as to represent as well as possible a presumed real-world situation, given whatever limitations have been imposed in terms of omitted variables that produce unknown biases, possibly incorrect functional forms for one's equations, measurement errors, or in general what are termed *specification errors* in the equations. Since such limitations are always present, any particular equation will contain a disturbance term that is assumed to behave in a certain fashion. One's assumptions about such disturbances are both critical for one's inferences and also (for the most part) inherently untestable with the data at hand. This in turn means that such inferences must always be tentative. One never "finds" effects, for example, but only infers them on the basis of findings about covariances and temporal sequences *and* a set of untested theoretical assumptions. To the degree that such assumptions are hidden from view, both the social scientist and one's readers may therefore be seriously misled to the degree that these assumptions are also incorrect.

In the recursive models commonly in use in sociology, it is assumed that causal influences can be ordered, such that one may designate an X_1 that does not depend on any of the remaining variables in the system but, presumably, varies as a result of exogenous causes that have been ignored in the theory. A second variable, X_2 , may then be found that may depend upon X_1 as well as a different set of exogenous factors, but the assumption is that X_2 does *not* affect X_1 , either directly or through any other mechanism. One then builds up the system, equation by equation, by locating an X_3 that may depend on either or both of X_1 or X_2 , plus still another set of independent variables (referred to as exogenous factors), but with the assumption that neither of the first two X 's is affected by X_3 . Adding still more variables in this recursive fashion, and for the time being assuming linear and additive relationships, one arrives at the system of equations shown in equation system 1,

$$\begin{aligned} X_1 &= \varepsilon_1 \\ X_2 &= \beta_{21}X_1 + \varepsilon_2 \\ X_3 &= \beta_{31}X_1 + \beta_{32}X_2 + \varepsilon_3 \\ &\vdots \\ X_k &= \beta_{k1}X_1 + \beta_{k2}X_2 + \beta_{k3}X_3 + \cdots + \beta_{k,k-1}X_{k-1} + \varepsilon_k \end{aligned} \tag{1}$$

in which the disturbance terms are represented by the ε_i and where for the sake of simplicity the constant terms have been omitted.

The essential property of recursive equations that provides a simple causal interpretation is that changes made in any given equation may affect subsequent ones but will *not* affect any of the prior equations. Thus, if a mysterious demon were to change one of the parameters in the equation for X_3 , this would undoubtedly affect not only X_3 but also X_4 , X_5 , through X_k , but could have no effect on either of the first two equations, which do not depend on X_3 or any of the later variables in the system. As will be discussed below, this special property of recursive systems does not hold in the more general setup involving variables that may be reciprocally interrelated. Indeed, it is this recursive property that justifies one's dealing with the equations separately and sequentially as single equations. The assumptions required for such a system are therefore implicit in all data analyses (e.g., log-linear modeling, analysis of variance, or comparisons among means) that are typically discussed in first and second courses in applied statistics.

Assumptions are always critical in causal analyses or—what is often not recognized—in *any* kind of theoretical interpretation of empirical data. Some such assumptions are implied by the forms of one's equations, in this case linearity and additivity. Fortunately, these types of assumptions can be rather simply modified by, for example, introducing second- or higher-degree terms, log functions, or interaction terms. It is a mistake to claim—as some critics have done—that causal modeling requires one to assume such restrictive functional forms.

Far more important are two other kinds of assumptions—those about measurement errors and those concerning the disturbance terms representing the effects of all omitted variables. Simple causal modeling of the type represented by

equation system 1 requires the naive assumption that all variables have been perfectly measured, an assumption that is, unfortunately, frequently ignored in many empirical investigations using path analyses based on exactly this same type of causal system. Measurement errors require one to make an auxiliary set of assumptions regarding both the sources of measurement-error bias and the causal connections between so-called true scores and measured indicators. In principle, however, such measurement-error assumptions can be explicitly built into the equation system and empirical estimates obtained, provided there are a sufficient number of multiple indicators to solve for the unknowns produced by these measurement errors, a possibility that will be discussed in the final section.

In many instances, assumptions about one's disturbance terms are even more problematic but equally critical. In verbal statements of theoretical arguments one often comes across the phrase "other things being equal," or the notion that in the ideal experimental design all causes except one must be literally held constant if causal inferences are to be made. Yet both the phrase "other things being equal" and the restrictive assumption of the perfect experiment beg the question of how one can possibly know that "other things" are in fact equal, that all "relevant" variables have been held constant, or that there are no possible sources of measurement bias. Obviously, an alert critic may always suggest another variable that indeed does vary across settings studied or that has not been held constant in an experiment.

In recursive causal models this highly restrictive notion concerning the constancy of all possible alternative causes is relaxed by allowing for a disturbance term that varies precisely because they are *not* all constant. But if so, can one get by without requiring any other assumptions about their effects? Indeed not. One must assume, essentially, that the omitted variables affecting any one of the X 's are uncorrelated with those that affect the others. If so, it can then be shown that the disturbance term in each equation will be uncorrelated with each of the independent variables appearing on the right-hand side, thus justifying the use of ordinary least-squares estimating procedures. In practical terms, this means that if one has had to omit any important causes of a

given variable, one must also be willing to assume that they do not systematically affect any of its presumed causes that have been explicitly included in our model. A skeptic may, of course, be able to identify one or more such disturbing influences, in which case a modified model may need to be constructed and tested. For example, if ϵ_3 and ϵ_4 contain a common cause that can be identified and measured, such a variable needs to be introduced explicitly into the model as a cause of both X_3 and X_4 .

Perhaps the five-variable model of Figure 1 will help the reader visualize what is involved. To be specific, suppose X_5 , the ultimate dependent variable, represents some behavior, say, the actual number of delinquent acts a youth has perpetrated. Let X_3 and X_4 , respectively, represent two internal states, say, guilt and self-esteem. Finally, suppose X_1 and X_2 are two setting variables, parental education and delinquency rates within the youth's neighborhood, with the latter variable being influenced by the former through the parents' ability to select among residential areas.

The fact that the disturbance term arrows are unconnected in Figure 1 represents the assumption that they are mutually uncorrelated, or that the omitted variables affecting any given X_i are uncorrelated with any of its explicitly included causes among the remaining X 's. If ordinary least squares is used to estimate the parameters in this model, then the empirically obtained residuals e_i will indeed be uncorrelated with the independent X 's in their respective equations, but since this automatically occurs as a property of least-squares estimation, it cannot be used as the basis for a test of our a priori assumptions about the true disturbances.

If one is unwilling to accept these assumptions about the behavior of omitted variables, the only way out of this situation is to reformulate the model and to introduce further complexities in the form of additional measured variables. At some point, however, one must stop and make the (untestable) assumption that the revised causal model is "closed" in the sense that omitted variables do not disturb the patterning of relationships among the included variables.

Assuming such theoretical closure, then, one is in a position to estimate the parameters, attach

Figure 1. Simple Recursive Model

their numerical values to the diagram, and also evaluate the model in terms of its consistency with the data. In the model of Figure 1, for instance, there are no direct arrows between X_2 and X_3 , between X_4 and both X_1 and X_2 , and between X_5 and both X_1 and X_3 . This means that with controls for all prior or intervening variables, the respective partial correlations can be predicted to be zero, apart from sampling errors. One arrives at the predictions in equation system 2.

$$\begin{aligned}
 r_{23.1} &= 0 & r_{14.23} &= 0 & r_{24.13} &= 0 \\
 r_{15.234} &= 0 & r_{35.124} &= 0 & &
 \end{aligned}
 \tag{2}$$

Thus, for each omitted arrow one may write out a specific “zero” prediction. Where arrows have been drawn in, it may have been possible to predict the signs of direct links, and these directional predictions may also be used to evaluate the model. Notice a very important property of recursive models. In relating any pair of variables, say, X_2 and X_3 , one expects to control for antecedent or intervening variables, but it is *not* appropriate to introduce as controls any variables that appear as subsequent variables in the model (e.g., X_4 or X_5). The simple phrase “controlling for all relevant variables” should therefore not be construed to mean variables that are presumed to depend on both of the variables being studied. In an experimental setup, one would presumably be unable to

carry out such an absurd operation, but in statistical calculations, which involve pencil-and-paper controlling only, there is nothing to prevent one from doing so.

It is unfortunately the case that controls for dependent variables can sometimes be made inadvertently through one’s research design (Blalock 1985). For example, one may select respondents from a list that is based on a dependent variable such as committing a particular crime, entering a given hospital, living in a certain residential area, or being employed in a particular factory. Whenever such improper controls are introduced, whether recognized explicitly or not, our inferences regarding relationships among causally prior variables are likely to be incorrect. If, for example, X_1 and X_2 are totally uncorrelated, but one controls for their common effect, X_3 , then even though $r_{12} = 0$, it will turn out that $r_{12.3} \neq 0$.

Recursive models also provide justifications for common-sense rules of thumb regarding the conditions under which it is *not* necessary to control for prior or intervening variables. In the model of Figure 1, for example, it can be shown that although $r_{24.13} = 0$, it would be sufficient to control for *either* X_1 or X_3 but not both in order for the partial to disappear. Similarly, in relating X_3 to X_5 , the partial will be reduced to zero if one controls for either X_2 and X_4 or X_1 and X_4 . It is not necessary

Figure 2. Model of Figure 1, with Path Coefficients and Standardized Variables

to control for all three simultaneously. More generally, a number of simplifications become possible, depending on the patterning of omitted arrows, and these simplifications can be used to justify the omission of certain variables if these cannot be measured. If, for example, one could not measure X_3 , one could draw in a direct arrow from X_1 to X_4 without altering the remainder of the model. Without such an explicit causal model in front of us, however, the omission of variables must be justified on completely ad hoc grounds. The important point is that pragmatic reasons for such omissions should not be accepted without *theoretical* justifications.

PATH ANALYSIS AND AN EXAMPLE

Sewall Wright (1934, 1960) introduced a form of causal modeling long before it became fashionable among sociologists. Wright, a population geneticist, worked in terms of standardized variables with unit variances and zero means. Expressing any given equation in terms of what he referred to as path coefficients, which in recursive modeling are equivalent to beta weights, Wright was able to derive a simple formula for decomposing the correlation between any pair of variables x_i and x_j . The equation for any given variable can be written as $x_i = p_{i1}x_1 + p_{i2}x_2 + \dots + p_{ik}x_k + u_i$, where the p_{ij} represent standardized regression coefficients and where

the lower-case x 's refer to the standardized variables. One may then multiply both sides of the equation by x_j , the variable that is to be correlated with x_i . Therefore, $x_i x_j = p_{i1}x_1 x_j + p_{i2}x_2 x_j + \dots + p_{ik}x_k x_j + u_i x_j$. Summing over all cases and dividing by the number of cases N , one has the results in equation system 3.

$$r_{ij} = \frac{\sum x_i x_j}{N} = p_{i1} \frac{\sum x_1 x_j}{N} + p_{i2} \frac{\sum x_2 x_j}{N} + \dots + p_{ik} \frac{\sum x_k x_j}{N} + \frac{\sum u_i x_j}{N}$$

$$= p_{i1} r_{1j} + p_{i2} r_{2j} + \dots + p_{ik} r_{kj} + 0 = \sum_k p_{ik} r_{kj} \quad (3)$$

The expression in equation system 3 enables one to decompose or partition any total correlation into a sum of terms, each of which consists of a path coefficient multiplied by a correlation coefficient, which itself may be decomposed in a similar way. In Wright's notation the path coefficients are written without any dots that indicate control variables but are indeed merely the (partial) regression coefficients for the standardized variables. Any given path coefficient, say p_{54} , can be interpreted as the change that would be imparted in the dependent variable x_5 , in its standard deviation units, if the other variable x_4 were to change by one of its standard deviation units, with the remaining explicitly included independent variables (here x_1 , x_2 , and x_3) all held constant. In working with standardized variables one is able to simplify these expressions owing to the fact that r_{ij}

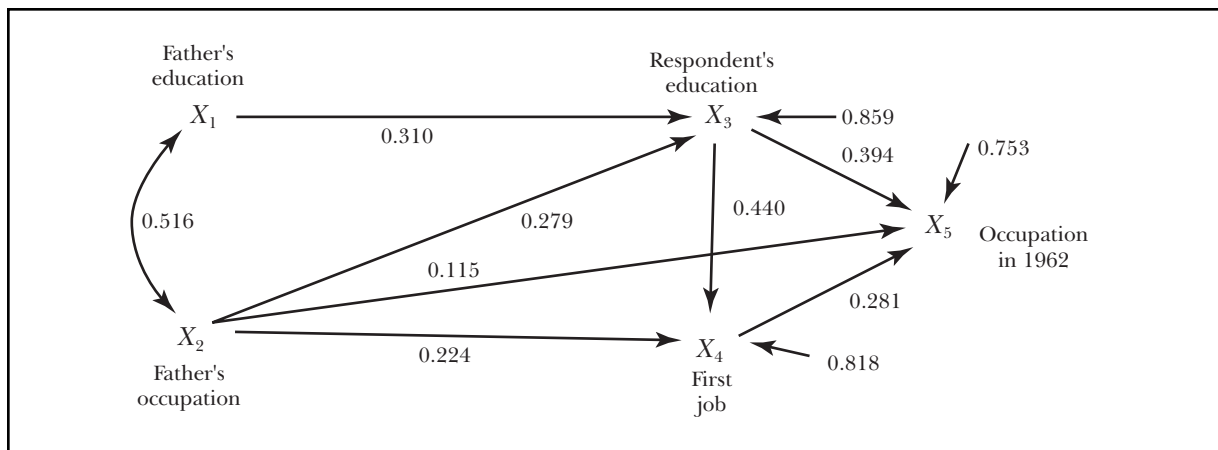

Figure 3. Path Diagram for Blau-Duncan Model

$= \sum x_i x_j / N$, but one must pay the price of then having to work with standard deviation units that may vary across samples or populations. This, in turn, means that two sets of path coefficients for different samples, say men and women, cannot easily be compared since the standard deviations (say, in income earned) may be different.

In the case of the model of Figure 2, which is the same causal diagram as Figure 1, but with the relevant p_{ij} inserted, one may write out expressions for each of the r_{ij} as shown in equation system 4.

$$\begin{aligned}
 r_{12} &= p_{21}r_{11} = p_{21}(1) = p_{21} \\
 r_{13} &= p_{31}r_{11} = p_{31} \\
 r_{23} &= p_{31}r_{12} = p_{31}p_{21} = r_{13}r_{12} \quad (\text{or } r_{23.1} = 0) \\
 r_{14} &= p_{43}r_{13} = p_{43}p_{31} \\
 r_{24} &= p_{43}r_{23} = p_{43}p_{31}p_{21} \\
 r_{34} &= p_{43}r_{33} = p_{43} \\
 r_{15} &= p_{52}r_{21} + p_{54}r_{41} = p_{52}p_{21} + p_{54}p_{43}p_{31} \\
 r_{25} &= p_{52}r_{22} + p_{54}r_{42} = p_{52}p_{54}p_{43}p_{31}p_{21} \\
 r_{35} &= p_{52}r_{23} + p_{54}r_{43} = p_{52}p_{31}p_{21} + p_{54}p_{43} \\
 r_{45} &= p_{52}r_{24} + p_{54}r_{44} = p_{52}p_{43}p_{31}p_{21} + p_{54}
 \end{aligned}
 \tag{4}$$

In decomposing each of the total correlations, one takes the path coefficients for each of the arrows coming into the appropriate dependent variable and multiplies each of these by the total correlation between the variable at the source of

the arrow and the “independent” variable in which one is interested. In the case of r_{12} , this involves multiplying p_{21} by the correlation of x_1 with itself, namely $r_{11} = 1.0$. Therefore one obtains the simple result that $r_{12} = p_{21}$. Similar results obtain for r_{13} and r_{34} . The decomposition of r_{23} , however, results in the expression $r_{23} = p_{31}r_{12} = p_{31}p_{21} = r_{12}r_{13}$, which also of course implies that $r_{23.1} = 0$.

When one comes to the decomposition of correlations with x_5 , which has two direct paths into it, the expressions become more complex but also demonstrate the heuristic value of path analysis. For example, in the case of r_{35} , this total correlation can be decomposed into two terms, one representing the indirect effects of x_3 via the intervening variable x_4 , namely the product $p_{54}p_{43}$, and the other the spurious association produced by the common cause x_1 , namely the more complex product $p_{52}p_{31}p_{21}$. In the case of the correlation between x_4 and x_5 one obtains a similar result except that there is a direct effect term represented by the single coefficient p_{54} .

As a numerical substantive example consider the path model of Figure 3, which represents the basic model in Blau and Duncan’s classic study, *The American Occupational Structure* (1967, p. 17). Two additional features of the Blau-Duncan model may be noted. A curved, double-headed arrow has been drawn between father’s education and father’s occupation, indicating that the causal paths between these two exogenous or independent variables have not been specified. This means that

there is no p_{21} in the model, so that r_{12} cannot be decomposed. Its value of 0.516 has been inserted into the diagram, however. The implication of a failure to commit oneself on the direction of causation between these two variables is that decompositions of subsequent r_{ij} will involve expressions that are sometimes combinations of the relevant p 's and the unexplained association between father's education and occupation. This, in turn, means that the indirect effects of one of these variables "through" the other cannot be assessed. One can determine the direct effects of, say, father's occupation on respondent's education, or its indirect effects on occupation in 1962 through first job, but not "through" father's education. If one had, instead, committed oneself to the directional flow from father's education to father's occupation, a not unreasonable assumption, then all indirect effects and spurious connections could be evaluated. Sometimes it is indeed necessary to make use of double-headed arrows when the direction of causation among the most causally prior variables cannot be specified, but one then gives up the ability to trace out those indirect effects or spurious associations that involve these unexplained correlations.

The second feature of the Blau-Duncan diagram worth noting involves the small, unattached arrows coming into each of the "dependent" variables in the model. These of course represent the disturbance terms, which in a correctly specified model are taken to be uncorrelated. But the *magnitudes* of these effects of outside variables are also provided in the diagram to indicate just how much variance remains unexplained by the model. Each of the numerical values of path coefficients coming in from these outside variables, when squared, turns out to be the equivalent of $1 - R^2$, or the variances that remain unexplained by *all* of the included explanatory variables. Thus there is considerable unexplained variance in respondent's education (0.738), first job (0.669), and occupation in 1962 (0.567), indicating, of course, plenty of room for other factors to operate. The challenge then becomes that of locating additional variables to improve the explanatory value of the model. This has, indeed, been an important stimulus to the development of the status attainment literature that the Blau-Duncan study subsequently spawned.

The placement of numerical values in such path diagrams enables the reader to assess, rather easily, the relative magnitudes of the several direct effects. Thus, father's education is inferred to have a moderately strong direct effect on respondent's education, but none on the respondent's occupational status. Father's occupation is estimated to have somewhat weaker direct effects on both respondent's education and first job but a much weaker direct effect on his later occupation. The direct effects of respondent's education on first job are estimated to be only somewhat stronger than those on the subsequent occupation, with first job controlled. In evaluating these numerical values, however, one must keep in mind that all variables have been expressed in standard deviation units rather than some "natural" unit such as years of schooling. This in turn means that if variances for, say, men and women or blacks and whites are not the same, then comparisons across samples should be made in terms of unstandardized, rather than standardized, coefficients.

SIMULTANEOUS EQUATION MODELS

Recursive modeling requires one to make rather strong assumptions about temporal sequences. This does not, in itself, rule out the possibility of reciprocal causation provided that lag periods can be specified. For example, the actions of party A may affect the later behaviors of party B, which in turn affect still later reactions of the first party. Ideally, if one could watch a dynamic interaction process such as that among family members, and accurately record the temporal sequences, one could specify a recursive model in which the behaviors of the same individual could be represented by distinct variables that have been temporally ordered. Indeed Strotz and Wold (1960) have cogently argued that many simultaneous equation models appearing in the econometric literature have been misspecified precisely because they do not capture such dynamic features, which in causal models should ideally involve specified lag periods. For example, prices and quantities of goods do not simply "seek equilibrium." Instead, there are at least three kinds of autonomous actors—producers, customers, and retailers or wholesalers—who react to one another's behaviors with varying lag periods.

In many instances, however, one cannot collect the kinds of data necessary to ascertain these lag periods. Furthermore, especially in the case of aggregated data, the lag periods for different actors may not coincide, so that macro-level changes are for all practical purposes continuous rather than discrete. Population size, literacy levels, urbanization, industrialization, political alienation, and so forth are all changing at once. How can such situations be modeled and what additional complications do they introduce?

In the general case there will be k mutually interdependent variables X_i that may possibly each directly affect the others. These are referred to as endogenous variables, with the entire set having the property that there is no single dependent variable that does not feed back to affect at least one of the others. Given this situation, it turns out that it is not legitimate to break the equations apart in order to estimate the parameters, one equation at a time, as one does in the case of a recursive setup. Since any given variable may affect the others, this also means that its omitted causes, represented by the disturbance terms ε_i , will also directly or indirectly affect the remaining endogenous variables, so that it becomes totally unreasonable to assume these disturbances to be uncorrelated with the “independent” variables in their respective equations. Thus, one of the critical assumptions required to justify the use of ordinary least squares cannot legitimately be made, meaning that a wide variety of single equation techniques discussed in the statistical literature must be modified.

There is an even more serious problem, however, which can be seen more readily if one writes out the set of equations, one for each of the k endogenous variables. To this set are added another set of what are called predetermined variables, Z_j , that will play an essential role to be discussed below. Our equation set now becomes as shown in equation system 5.

The regression coefficients (called “structural parameters”) that connect the several endogenous variables in equation system 5 are designated as β_{ij} and are distinguished from the γ_{ij} representing the direct effects of the predetermined Z_j on the relevant X_i . This notational distinction is made because the two kinds of variables play different roles

$$\begin{aligned}
 x_1 &= \beta_{12}x_2 + \beta_{13}x_3 + \cdots + \beta_{1k}x_k + \gamma_{11}z_1 + \gamma_{12}z_2 \\
 &\quad + \cdots + \gamma_{1m}z_m + \varepsilon_1 \\
 x_2 &= \beta_{21}x_1 + \beta_{23}x_3 + \cdots + \beta_{2k}x_k + \gamma_{21}z_1 + \gamma_{22}z_2 \\
 &\quad + \cdots + \gamma_{2m}z_m + \varepsilon_2 \\
 x_3 &= \beta_{31}x_1 + \beta_{32}x_2 + \cdots + \beta_{3k}x_k + \gamma_{31}z_1 + \gamma_{32}z_2 \\
 &\quad + \cdots + \gamma_{3m}z_m + \varepsilon_3 \\
 &\vdots \\
 x_k &= \beta_{k1}x_1 + \beta_{k2}x_2 + \cdots + \beta_{k,k-1}x_{k-1} + \gamma_{k1}z_1 + \\
 &\quad \gamma_{k2}z_2 + \cdots + \gamma_{km}z_m + \varepsilon_k
 \end{aligned} \tag{5}$$

in the model. Although it cannot be assumed that the disturbances ε_i are uncorrelated with the endogenous X 's that appear on the right-hand sides of their respective equations, one may make the somewhat less restrictive assumption that these disturbances are uncorrelated with the predetermined Z 's.

Some Z 's may be truly exogenous, or distinct independent variables, that are assumed not to be affected by any of the endogenous variables in the model. Others, however, may be lagged endogenous variables, or prior levels of some of the X 's. In a sense, the defining characteristic of these predetermined variables is that they be uncorrelated with any of the omitted causes of the endogenous variables. Such an assumption may be difficult to accept in the case of lagged endogenous variables, given the likelihood of autocorrelated disturbances, but we shall not consider this complication further. The basic assumption regarding the truly exogenous variables, however, is that these are uncorrelated with all omitted causes of the X 's, though they may of course be correlated with the X 's and also possibly each other.

Clearly, there are more unknown parameters than was the case for the original recursive equation system (1). Turning attention back to the simple recursive system represented in equation system 1, one sees that the matrix of betas in that equation system is triangular, with all such coefficients above the main diagonal being set equal to zero on a priori grounds. That is, in equation system 1, half of the possible betas have been set equal to zero, the remainder being estimated using ordinary least squares. It turns out that in the more general equation system 5, there will be too

Figure 4. Nonrecursive Modification of Figure 1

many unknowns unless additional restrictive assumptions are made. In particular, in each of the k equations one will have to make a priori assumptions that at least $k - 1$ coefficients have been set equal to zero or some other known value (which cannot be estimated from the data). This is why one needs the predetermined Z_i and the relevant gammas. If one is willing to assume that, for any given endogenous X_j , certain direct arrows are missing, meaning that there are no *direct* effects coming from the relevant X_j or Z variable, then one may indeed estimate the remaining parameters. One does not have to make the very restrictive assumptions required under the recursive setup, namely that if X_j affects X_i , then the reverse cannot hold. As long as one assumes that *some* of the coefficients are zero, there is a chance of being able to identify or estimate the others.

It turns out that the *necessary* condition for identification can be easily specified, as implied in the above discussion. For any given equation, one must leave out at least $k - 1$ of the remaining variables. The *necessary and sufficient* condition is far more complicated to state. In many instances, when the necessary condition has been met, so will the sufficient one as well, unless some of the

equations contain exactly the same sets of variables (i.e., exactly the same combination of omitted variables). But since this will not always be the case, the reader should consult textbooks in econometrics for more complete treatments.

Returning to the substantive example of delinquency, as represented in Figure 1, one may revise the model somewhat by allowing for a feedback from delinquent behavior to guilt, as well as a reciprocal relationship between the two internal states, guilt and self-esteem. One may also relabel parental education as Z_1 and neighborhood delinquency as Z_2 because there is no feedback from any of the three endogenous variables to either of these predetermined ones. Renumbering the endogenous variables as X_1 , X_2 , and X_3 , one may represent the revised model as in Figure 4.

In this kind of application one may question whether a behavior can ever influence an internal state. Keeping in mind, however, that the concern is with *repeated* acts of delinquency, it is entirely reasonable to assume that earlier acts feed back to affect subsequent guilt levels, which in turn affect future acts of delinquency. It is precisely this very frequent type of causal process that is ignored whenever behaviors are taken, rather simply, as “dependent” variables.

Figure 5. Simple Measurement-Error Model, with Two Unmeasured Variables X and Y , Two Indicators of Each, and Source of Bias W

Here, $k = 3$, so that at least two variables must be left out of each equation, meaning that their respective coefficients have been set equal to zero. One can rather simply check on the necessary condition by counting arrowheads coming to each variable. In this instance there can be no more than two arrows into each variable, whereas in the case of guilt X_1 there are three. The equation for X_1 is referred to as being “underidentified,” meaning that the situation is empirically hopeless. The coefficients simply cannot be estimated by *any* empirical means. There are exactly two arrows coming into delinquency X_3 , and one refers to this as a situation in which the equation is “exactly identified.” With only a single arrow coming into self-esteem X_2 , one has an “overidentified” equation for which one actually has an excess of empirical information compared to the number of unknowns to be estimated. It turns out that overidentified equations provide criteria for evaluating goodness of fit, or a test of the model, in much the same way that, for recursive models, one obtains an empirical test of a null hypothesis for each causal arrow that has been deleted.

Since the equation for X_1 is underidentified, one must either remove one of the arrows, on a priori grounds, or search for at least one more predetermined variable that does *not* belong in this equation, that is, a predetermined variable that is assumed not to be a direct cause of level of

guilt. Perhaps school performance can be introduced as Z_3 by making the assumption that Z_3 directly affects both self-esteem and delinquency but not guilt level. A check of this revised model indicates that all equations are properly identified, and one may proceed to estimation. Although space does not permit a discussion of alternative estimation methods that enable one to get around the violated assumption required by ordinary least squares, there are various computer programs available to accomplish this task. The simplest such alternative, two-stage least squares (2SLS), will ordinarily be adequate for nearly all sociological applications and turns out to be less sensitive to other kinds of specification errors than many of the more sophisticated alternatives that have been proposed.

CAUSAL APPROACH TO MEASUREMENT ERRORS

Finally, brief mention should be made of a growing body of literature—closely linked to factor analysis—that has been developed in order to attach measurement-error models to structural-equation approaches that presume perfect measurement. The fundamental philosophical starting point of such models involves the assumption that in many if not most instances, measurement errors can be conceived in causal terms. Most often, the indicator or measured variables are taken as *effects*

of underlying or “true” variables, plus additional factors that may produce combinations of random measurement errors, which are unrelated to all other variables in the theoretical system, and systematic biases that are explainable in causal terms. Thus, measures of “true guilt” or “true self-esteem” will consist of responses, usually to paper-and-pencil tests, that may be subject to distortions produced by other variables, including some of the variables in the causal system. Perhaps distortions in the guilt measure may be a function of amount of delinquent behavior or parental education. Similarly, measures of behaviors are likely to overestimate or underestimate true frequencies, with biases dependent on qualities of the observer, inaccuracies in official records, or perhaps the ability of the actor to evade detection.

In all such instances, we may be able to construct an “auxiliary measurement theory” (Blalock 1968; Costner 1969) that is itself a causal model that contains a mixture of measured and unmeasured variables, the latter of which constitute the “true” or underlying variables of theoretical interest. The existence of such unmeasured variables, however, may introduce identification problems by using more unknowns than can be estimated from one’s data. If so, the situation will once more be hopeless empirically. But if one has available *several* indicators of each of the imperfectly measured constructs, *and* if one is willing to make a sufficient number of simplifying assumptions strategically placed within the overall model, estimates may be obtainable.

Consider the model of Figure 5 (borrowed from Costner 1969), which contains only two theoretical variables of interest, namely, the unmeasured variables X and Y . Suppose one has two indicators each for both X and Y and that one is willing to make the simplifying assumption that X does not affect either of Y ’s indicators, Y_1 and Y_2 , and that Y does not affect either of X ’s indicators, X_1 and X_2 . For the time being ignore the variable W as well as the two dashed arrows drawn from it to the indicators X_2 and Y_1 . Without W , the nonexistence of other arrows implies that the remaining causes of the four indicators are assumed to be uncorrelated with all other variables in the system, so that one may assume measurement errors to be strictly random.

If one labels the path coefficients (which all connect measured variables to unmeasured ones) by the simple letters a, b, c, d , and, e , then with $4(3)/2 = 6$ correlations among the four indicators, there will be six pieces of empirical information (equation system 5) with which to estimate the five unknown path coefficients.

$$\begin{aligned} r_{x_1x_2} &= ab & r_{x_1y_2} &= ace \\ r_{y_1y_2} &= de & r_{x_2y_1} &= bcd \\ r_{x_1y_1} &= acd & r_{x_2y_2} &= bce \end{aligned} \tag{6}$$

One may now estimate the correlation or path coefficient c between X and Y by an equation derived from equation system 6.

$$c^2 = \frac{abc^2de}{(ab)(de)} = \frac{r_{x_1y_1}r_{x_2y_2}}{r_{x_1x_2}r_{x_1y_2}} = \frac{r_{x_1y_2}r_{x_2y_1}}{r_{x_1x_2}r_{y_1y_2}} \tag{7}$$

Also notice that there is an excess equation that may be used to check on the consistency of the model with the data, namely the prediction that $r_{x_1y_1}r_{x_2y_2} = r_{x_1x_2}r_{x_1y_2} = abc^2de$.

Suppose next that there is a source of measurement error bias W that is a common cause of one of X ’s indicators (namely X_2) and one of Y ’s (namely Y_1). Perhaps these two items have similar wordings based on a social survey, whereas the remaining two indicators involve very different kinds of measures. There is now a different expression for the correlation between X_2 and Y_1 , namely $r_{x_2y_1} = bcd + fg$. If one were to use this particular correlation in the estimate of c^2 , without being aware of the impact of W , one would obtain a biased estimate. In this instance one would be able to detect this particular kind of departure from randomness because the consistency criterion would no longer be met. That is, $(acd)(bce) \neq (ace)(bcd + fg)$. Had W been a common cause of the two indicators of either X or Y alone, however, it can be seen that one would have been unable to detect the bias even though it would have been present.

Obviously, most of one’s measurement-error models will be far more complex than this, with several (usually unmeasured) sources of bias, possible nonlinearities, and linkages between some of the important variables and indicators of *other* variables in the substantive theory. Also, some indicators may be taken as *causes* of the conceptual variables, as for example often occurs when one is

attempting to get at experience variables (e.g., exposure to discrimination) by using simple objective indicators such as race, sex, or age. Furthermore, one's substantive models may involve feedback relationships so that simultaneous equation systems must be joined to one's measurement-error models.

In all such instances, there will undoubtedly be numerous specification errors in one's models, so that it becomes necessary to evaluate alternative models in terms of their goodness of fit to the data. Simple path-analytic methods, although heuristically helpful, will no longer be adequate. Fortunately, there are several highly sophisticated computer programs, such as LISREL, that enable social scientists to carry out sophisticated data analyses designed to evaluate these more complex models and to estimate their parameters once it has been decided that the fit to reality is reasonably close. (See Joreskog and Sorbom 1981; Long 1983; and Herting 1985.)

In closing, what needs to be stressed is that causal modeling tools are highly flexible. They may be modified to handle additional complications such as interactions and nonlinearities. Causal modeling in terms of attribute data has been given a firm theoretical underpinning by Suppes (1970), and even ordinal data may be used in an exploratory fashion, provided that one is willing to assume that dichotomization or categorization has not introduced substantial measurement errors that cannot be modeled.

Like all other approaches, however, causal modeling is heavily dependent on the assumptions one is willing to make. Such assumptions need to be made as explicit as possible—a procedure that is unfortunately often not taken sufficiently seriously in the empirical literature. In short, this set of tools, properly used, has been designed to provide precise meaning to the assertion that neither theory nor data can stand alone and that any interpretations of research findings one wishes to provide must inevitably also be based on a set of assumptions, many of which cannot be tested with the data in hand.

Finally, it should be stressed that causal modeling can be very useful in the process of theory construction, even in instances where many of the variables contained in the model will remain unmeasured in any given study. It is certainly a

mistake to throw out portions of one's theory merely because data to test it are not currently available. Indeed, without a theory as to how missing variables are assumed to operate, it will be impossible to justify one's assumptions regarding the behavior of disturbance terms that will contain such variables, whether explicitly recognized or not. Causal modeling may thus be an important tool for guiding future research and for providing guidelines as to what kinds of neglected variables need to be measured.

CENSORSHIP AND THE REGULATION OF EXPRESSION

Modern discussions of censorship center on the legitimacy of the regulatory structures and actions through which expression and communication are governed, and the extent to which these structures meet the requirements of democratic societies. In this entry, we first survey prominent historical examples of centralized censorship systems in the West. This history provides a context for a discussion of modern conceptions of censorship and issues associated with the term itself. We then turn to legal structures regulating speech and press in the United States, to government control of political speech, and to some modern-day controversies over the regulation of expression.

EARLY SYSTEMS OF GOVERNMENT CENSORSHIP

Traditional conceptions of censorship are rooted in rigid systems of ecclesiastic and governmental control over discourse and printing. The term itself derives from the office of the census in early Rome, where the censor served as both census taker and as supervisor of public conduct and morals. Before the advent of the printing press in the fifteenth century, most manuscripts in Europe were produced in monasteries, which controlled their production. Centralized systems of control over books developed largely in response to the invention of the printing press, which both church and state perceived as threats to their authority. In the mid-sixteenth century the Catholic Church issued the Index of Forbidden Books, which was enforced through compliance of the faithful, pre-publication screening of books, the burning of heretical tracts, and the persecution of heretics. In Protestant countries, the State generally assumed control over the publication of books. The English monarchy published its first list of prohibited books in 1529 and exercised its control through a contractual arrangement with the Stationers' Company, which, in 1557, was granted a monopoly on the production and distribution of printed materials. This charter remained in effect until 1694 when it was allowed to expire, primarily because of difficulties in its administration. These centralized mechanisms of control were replaced by less systematic methods, such as laws against seditious libel, through which speech that merely criticized government policies could be punished.

Although systems similar to these proliferated worldwide and continue to exist in modern-day authoritarian regimes, they are consensually viewed as incompatible with the practice of democracy. The history of free speech principles in the West coincides with the rise of democratic thought, as expressed in the writings of the eighteenth-century Enlightenment philosophers in France and in the influential political philosophies of John Locke, John Milton, and John Stuart Mill in England. The turn of mind that gripped Europe during this period is reflected in Locke's dictum that governments are the servants of the people, not the reverse, and in the insistence by each of these philosophers that self-governance cannot function under regimes where the circulation of ideas is dependent upon the whims of rulers. In modern

political theory, Habermas (1989) considers the demise of systematic state censorship to be a precondition of the rise of a “public sphere,” an admittedly idealized realm of discourse—independent of both state and market—in which public issues can be deliberated in an environment where reason, not the status of speakers is honored.

THE RHETORIC OF “CENSORSHIP”

The use of language plays a critical role in framing thought and discussion about the legitimate control of speech. The term “censorship” most frequently arises in debates over the desirability of restricting access to one or another form of communicative content. However, the term is fraught with the complexities of multiple meanings, uses, and understandings. These complexities arise from the historical baggage it carries, the multiple contexts—popular, legal, and scholarly—in which it is used, and the highly contested nature of the debates in which it is invoked. Although systematic empirical analyses of the term have yet to be conducted, its meanings appear to differ along two dimensions, connotative and descriptive. Underlying the connotative force of the term is the strong conviction that suppression of speech is at best a necessary evil. As such, the term typically carries with it a highly pejorative connotation and a strong air of illegitimacy. Although First Amendment scholar Smolla (1991) informs us that “censorship was not always a dirty word,” this facet of the term is now found in Webster’s Dictionary, which states that it refers especially to control that is “exercised repressively.”

Descriptive uses of the term differ according to the breadth of the domain covered. Under strict uses of the term, censorship means the prior restraint of information by government. It is this meaning that enables the Federal Communications Commission (FCC) to enact regulations that impose post hoc penalties for some forms of speech while at the same time declaring that “nothing in the Act [that governs the FCC] shall be . . . construed to give the Commission the power of censorship.” In a second form of use, censorship refers to any form of government regulations that restrict or disable speech. Fines imposed by the FCC for “indecent” speech on radio fit this use, as the intent is to deter further indecency. In a third, less conventional usage, the term is modified to

refer to nongovernmental restrictions on speech. For example, in one of the few instances in which the Supreme Court has applied the term to private concerns (*Red Lion v. FCC*, 395 U.S. 367, 1969), the Court stated that “The First Amendment does not protect private censorship by broadcasters who are licensed by the Government to use a scarce resource which is denied to others.”

In each of these three descriptive domains the term “censorship” almost invariably carries its pejorative inflection. In its broadest sense, censorship signifies control over the means of expression; the determination of what content will not be communicated. This sense of the term is found in the work of Bourdieu (1991), for whom censorship is located not only in explicit prohibitions, but also in the everyday practices and power relationships that determine what is and is not said. It includes not only the sixteenth-century Inquisitor who decides which books will be burned, but also the twentieth-century film editor who leaves a scene on the cutting room floor. It includes both the intentional actions of individuals and, as importantly, the de facto results of impersonal forces that lead some ideas not to be expressed. This expansive meaning, which has yet to make significant inroads into popular discourse, is incompatible with the pejorative connotation found in everyday usage: If censorship is an integral part of everyday life, it cannot always, or even typically, be evil.

The prototypical understanding of “censorship” is firmly anchored at the point where the term’s pejorative connotation intersects with governmental restrictions on speech. This can be seen in how the term is and is not used in legal and popular discourse. First, there are numerous forms of government restrictions that tend not to be thought of as censorship at all. Examples include punishment for perjury, threats, and libel, and prohibitions on misleading advertising. The core meaning of the term “censorship” tends to be applied to restrictions that are consensually deemed to be illegitimate; it tends not to be applied to restrictions that are consensually deemed to be legitimate, although they fall within the descriptive scope of the term. As such, the term typically serves to label those policies and actions that have been deemed undesirable rather than to describe a set of activities whose legitimacy could then be judged. A thorough sociological understanding of

“censorship” would require a mapping of the shifting boundaries around which this legitimacy is withheld or conferred. For example, punishment for blasphemy was once considered legitimate, whereas penalties for inciting hatred against ethnic groups may not be thought of as “censorship” in the future. Second, in areas where the legitimacy of a restriction is under dispute, those who oppose the restriction tend to label it as censorship, whereas those who support the restriction attempt to distance themselves from the term.

This core understanding of the term—as illegitimate government action—leads to a number of consequences, two of which will be mentioned here. First, discussions of the legitimate control of expression are typically framed as battles between censorship, on the one hand, and Free speech, on the other: Free speech is the absence of governmental control. This framing of the communicative needs of a democracy—codified in the First Amendment—places a wholesome burden on governments to justify regulatory action. On the other hand, this framing excludes from discussion the positive role that governments can (and do) play in supporting these needs. It also excludes consideration of the instances in which private concerns and impersonal market forces can produce deleterious effects; ones that exclude particular viewpoints from the marketplace of ideas. The restrictions placed by health maintenance organizations (HMOs) upon what physicians can say to their patients (i.e., “gag rules”) are but one of countless areas in which private institutions “censor” valuable speech.

Research is needed to uncover the role that the rhetoric of “censorship” plays in maintaining the conception of free speech as the absence of government regulation. It is apparently with the goal of disabling this entrenched dichotomy that some theorists have used the term—e.g., “soft censorship,” “de facto censorship” “private censorship”—to refer to those private and impersonal forces that lead some forms of expression to be systematically excluded from the marketplace of ideas (e.g., Barbur 1996; cf. Post 1998). Barbur, for example, argues that “monopoly is a polite word for uniformity, which is a polite word for virtual censorship—censorship not as a consequence of political choices, but as a consequence of inelastic markets, imperfect competition, and economies of scale . . .” (1996, pp. 137–138). Similarly, theorists

like Baker (1998) use the term “structural regulation” to refer to government interventions designed to increase viewpoint diversity in the public forum. The goal of such rhetorical interventions is to reframe the discussion of “free speech” in a way that is meticulously sensitive to the threats of government incursions on speech, yet, that at the same time allow this discussion to incorporate both the speech-restricting characteristics of private action and the speech-expanding possibilities of government.

The second consequence of our core understanding of “censorship” is linked primarily to the distaste the term evokes. This pejorative connotation renders the term useful in singling out illegitimate expressive restrictions, and as a persuasive device in popular and legal debate. However, the pejorative nature of the term also disables it as a useful construct in discussions that aim to present a balanced account of contemporary debates over the control of expression. For example, to frame a controversy concerning the legitimacy of restrictions on hate speech as a debate over whether such speech should be censored is to ask, in effect, whether the illegitimate suppression of hate speech is or is not legitimate. This framing, though a popular one, clearly biases the discussion toward one side of the debate.

In this entry we attempt to use less loaded terms to describe the concerns that the term “censorship” evokes and the underlying controversies in which the term is typically used. Correspondingly, we strive to reserve the term “censorship” for those uses in which it is integral to the viewpoint being expressed.

LEGAL PRINCIPLES GOVERNING THE REGULATION OF EXPRESSION IN THE UNITED STATES

The legal principles governing freedom of expression in the United States are based largely on interpretations of the First Amendment to the Constitution, whose “speech” and “press” clauses are combined in the statement that “Congress shall make no law . . . abridging the freedom of speech, or of the press.” The amendment refers only to actions taken by the U.S. Congress, and it was not held to apply to laws made by the individual states until 1925 (*Gitlow v. New York*, 2688 U.S.

652, 1925) when the Court ruled that the fourteenth Amendment required that state laws not be in conflict with federal law. In addition to state and constitutional law, other major sources of legal regulation originate in common law (e.g., sedition, privacy) and administrative law (e.g., rulemaking of the FCC).

Despite the apparent clarity of the First Amendment language, both Congress and the states have crafted many laws that regulate freedoms of speech and press. These regulations stem primarily from three sources. First, the First Amendment is subject to widely varying interpretations. Some constitutional scholars conclude that at time the Bill of Rights was drafted, conceptions of freedom of expression referred only to prior restraints on speech. Others note ambiguities in the words “abridge” and “speech,” and further question the intent of the framers of the Constitution. For example, do regulation of defamatory tracts, false commercial advertising, perjury, threats, violent obscenity, or nude dancing necessarily count as abridgments of speech (Sunstein 1993)? Some have also argued that the speech clause governs only political speech or that the press clause should not be interpreted to apply to tabloid entertainment that masquerades as news.

Second, the modern world differs from the world of the late eighteenth century. The framers could not have foreseen the technological advances that have brought us telephones, television, and the Internet. Neither could they have had in mind the concentrated corporate ownership or the advertising-driven programming that characterizes today’s media. Some argue that government regulation is required in order to achieve the principles embodied in the Constitution.

Third, speech rights do not stand alone. For example, the rights of some to speak may conflict with the rights of others to be let alone or to be treated with dignity and equality. Also, the speech rights asserted by some inevitably conflict with the speech rights claimed by others.

In light of such issues, the clarity and simplicity that at first seem to characterize the First Amendment turn out to be illusory. As a result, scholars have developed theories of the underlying values that they believe free speech should promote in a democracy and should govern interpretation of

the First Amendment. Although no theory is universally accepted as dominant, most agree with the judgment of constitutional scholar Emerson (1973) that the value of free expression lies in its ability to promote participation in the decision-making process by all members of society; to advance knowledge and the pursuit of truth; to promote individual self-fulfillment; and, by allowing dissent to be publicly vented, to promote a balance between stability and change.

Disputes over the role of government in regulating speech turn, in part, on which of these values is given precedence. Those who emphasize the role of speech in promoting deliberative democracy often favor an affirmative role of government to promote viewpoint diversity or to ensure that the distribution of viewpoints in the public sphere is somewhat reflective of their distribution in the community. In practical terms, this may lead to restrictions on the amount of money that corporations can contribute to political campaigns, to the enforcement of rights of access to media by citizens, to the strategic placement of “public forum” spaces on the Internet, to stricter enforcement of the antitrust laws as they pertain to media, or to government subsidies for valued forms of speech (Baker 1998). In many instances, the promotion of viewpoint diversity and balance may require the government to regulate or infringe upon the speech or property rights of some in order to advance the needs of deliberative democracy.

DIFFERENTIAL JUDICIAL TREATMENT OF DIFFERENT FORMS OF EXPRESSION

The corpus of First Amendment decisions shows that all speech is not equal in the protections it is afforded. Political discourse—broadly defined to include speech about social, cultural, and religious issues—is considered speech of the highest value. As a result, the government must demonstrate a “compelling” interest to warrant its restriction. Particularly, political speech cannot be directly restricted unless it is “directed to inciting or producing imminent lawless action and is likely to incite or produce such action.” Advertising was long considered outside the purview of First Amendment protections and was subject to strict regulation. Commercial speech has experienced tremendous leaps in its status under the Court as

many local restrictions have been declared unconstitutional. Obscenity lies at the lowest rung of speech and receives no protection under the First Amendment. Although the requirements for demonstrating that speech is obscene have become progressively more demanding, Congress and the states are permitted to ban the public dissemination of speech that meets these criteria (see below). Depending upon how they are classified in terms of value to society, other forms of speech receive greater or lesser protection. For example, unlicensed medical advice and misleading advertising can be restricted through a “balancing test” which shows that the harm that stems from suppressing them are fewer than the harm they cause. A “balancing test” which shows that the harm that stems from suppressing them are less than the harm they cause.

Current First Amendment doctrine also reflects a second, cross-cutting mode of classification according to which proposed regulations are categorized as content neutral, content based, or viewpoint based. Of the three, content neutral regulations must pass the lowest constitutional hurdle whereas viewpoint-based regulations must pass the highest. An example of content-neutral regulations might include rules that designate sound-level restrictions on expressive activities, such as music in Central Park. Examples of viewpoint-based restrictions might include a ban on a gay parade or on either Democrat or Republican billboards. Regulations on expression that are content based, but viewpoint neutral face a high, but not insurmountable, constitutional hurdle. For example, in their contractual relations with cable companies, municipalities have been allowed to require the companies to provide local news and sports, and the federal government has been allowed to prohibit all partisan political campaigning on army bases.

The application of First Amendment law is also a function of the technological environment, or medium, in which expression is conveyed. Except through the sporadic use of antitrust laws, the Court has been least likely to permit regulations of print-based news and most likely to allow regulations of broadcast media. Cable television has fallen somewhere in between, with regulations reflecting the monopolistic control that companies exert over cable access to individual households and the fact that municipalities own the

property through which television cables are distributed. Telephone companies are classified as “common carriers,” which interdicts their editorial control over the information that passes through their wires. The newest form of communication, the Internet, has so far been granted the highest rung of protection from government regulation.

The willingness of the Court to allow government regulation of broadcast media lies largely on three rationales: public ownership of the airwaves, scarcity of the broadcast spectrum, and “pervasiveness” of the broadcast signal. First, the airwaves through which broadcast signals are transmitted are owned by the public and licensed on a renewable basis to radio and television broadcasters. Second, only a limited number of broadcast signals can coexist in any given segment of airspace (scarcity principle). In other words, the broadcast spectrum is a scarce resource, one that has historically required some regulatory body to decide which of the many interested broadcasters will be allotted the frequencies that exist. The management of these tasks is the function of the FCC, which was authorized to regulate broadcasters in the “public convenience, interest, or necessity.” In interpreting the “public-interest” clause, the FCC has issued a number of requirements, including, for example, a modicum of public-interest programming such as local news, rights of reply to those attacked in political editorials, and requirements to air political advertisements. Regulations governing the latter are governed by a “no censorship” clause, whereby the FCC deprives stations of editorial rights over political advertisements. Although most of these regulations are aimed to increase viewpoint diversity, broadcasters often argue that FCC rules infringe upon their rights to free speech. Finally, the Supreme Court’s judgment that radio and television broadcasts are “pervasive” refers to the assumed inability of viewers and listeners to fully control their own access, or that of their children, to unexpected program content. The susceptibility of audience members to be caught unawares by programming that offends them, or that they deem harmful to their children, has led the court to characterize such broadcasts as an “uninvited intruder” into the privacy of a viewer’s abode. Primarily to provide a “safe haven,” for children, the Court has allowed time restrictions on the broadcast of “indecent” or “patently offensive” programming.

Given the different levels of protection afforded by the First Amendment for different forms of expression, the determination of which category of speech, which kind of regulation, and which form of media a given case will be deemed to embody, is of critical importance. Levels of protection for different forms of speech have changed over time and there is no reason to think that they will not continue to do so. Movies were long considered a form of crass entertainment, outside of First Amendment protections, and birth control information was once classified as obscene. In the not-distant future, the plethora of programming opportunities on the Internet is likely to result in Supreme Court challenges of the scarcity principle upon which public-interest broadcast regulations are based. Particularly in the area of new media, the difficulties inherent in determining how to categorize a particular speech situation often leads the categorical approach to cede to an approach in which the harms of competing outcomes are less formally “balanced” against each other. Projects for sociology might include examination of the social underpinnings of the origin of these categories, of the application of these categories to different forms of speech, and of the evidentiary criteria used to assess both the harms of speech and the harms of regulation. For instance, a near consensus has been reached in the scientific community that media violence leads to social aggression and violence (e.g., Donnerstein and Smith 1997), whereas evidence of harms done by “indecent” broadcasts is anecdotal. What then are the social and political processes that lead one and not the other to be regulated?

PUBLIC SPEECH, PRIVATE SPACES

As can be seen in the language of the First Amendment, the central concern of the framers of the Constitution was to protect the private realm from domination by the state. The First Amendment itself has little to say about the control that private organizations exert over the expressive rights of individuals, or the control that private media companies exert over the communication of public issues. Examples of private-domain controversies include disputes over the “gag rules” that prohibit physicians from discussing alternate, more expensive treatments; corporate contracts that prevent employees from publicizing questionable employer practices; and control over the correspondence

that employees send over company e-mail systems. An evolving legal controversy surrounds the growing replacement of public forums—sidewalks, streets, and public parks—by private ones, such as shopping malls, condominiums, and gated communities. Should the political protesters who once convened in front of the local store be barred from entry to the shopping mall where the store now stands? Should those gathering signatures for political initiatives be excluded from gated communities? These issues pit the property rights of owners against the expressive needs of communities. Supreme Court decisions have given individual states some leeway in deciding which and when one of these interests is the more compelling. Related issues arise in the domain of media, where some point to the growing concentration of media ownership (Bagdikian 1997), the presence of only one daily newspaper in most U.S. cities, and the “skewing” of media content away from the interests of the poor (Baker 1998) as evidence that the marketplace of ideas is not fully served by unregulated economic markets (Sunstein 1993).

A strict reading of the First Amendment suggests that the government has no right to intercede to regulate communication between a corporation and its employees (harassment rules provide an exception) or to intervene when privately owned media fail to meet the needs of a community. Many argue that this is as it should be: employees can always seek employment elsewhere and those whose speech is barred in one forum can always seek another. Others insist that differences between the conditions of modern society and those at the time the Constitution was drafted warrant the extension of communicative rights beyond those provided in the First Amendment.

THE LEGAL SUPPRESSION OF SPEECH DEEMED TO THREATEN THE ESTABLISHED ORDER

A central rationale for laws restricting the expressive activities of people and press is to preserve national security. The chief mechanisms of enforcement under democratic governments have been restrictions on governmentally controlled information, laws prohibiting seditious libel, and, in times of war, systems of prepublication clearance of press dispatches. Most agree that there are some circumstances, particularly in times of war,

in which some national security restrictions are necessary. However, a strong proclivity exists to abuse these laws to protect policies or governments that are losing, or have lost, their base of popular support.

The prototypical conception of censorship is firmly rooted in governmental restrictions on speech that is critical of government, yet poses significant threats to security. The law of seditious libel was imported to the United States from England, where, during the eighteenth century, it served as a principal vehicle through which governments attempted to stave off criticism and to control public opinion. The power of seditious libel laws lay largely in their breadth—advocacy of an “ill opinion” of government was considered actionable—and from the selectivity with which they could be enforced. During most of the eighteenth century, these cases were decided by judges rather than juries, and the truth of a charge was not a defense until the nineteenth century.

The climate in which the Constitution’s press clause was drafted was one in which a central threat to viewpoint diversity was posed by governments who could use their monopolies on legitimized force to control the marketplace of ideas. The most noted illustration of this in colonial America was the case of John Peter Zenger, whose newspaper, the *New York Weekly* was launched in 1734 as the only voice of opposition to the widely reviled colonial Governor, William Cosby. When the newspaper’s opening salvo attacked Cosby’s arbitrary exercise of power, Zenger was promptly charged with seditious libel. After spending eight months in jail, Zenger was acquitted by a jury (reluctantly allowed in this case), who ignored the judge’s instructions that the truth of a charge was irrelevant. Although many thought the First Amendment would change such abuse, Congress soon passed the Sedition Act, which was used by President John Adams, a Federalist, to silence criticism launched by Republican supporters of Thomas Jefferson.

The Sedition Act was allowed to lapse when Jefferson took the Presidency and would not return until World War I. However, in the years during which the Constitution did not apply to the states, statutory attacks on specific viewpoints could be fierce at the state level. Louisiana’s pre-Civil

War statute prosecuting speech that sowed “discontent among the free population or insubordination among the slaves” provides just one example of how law could be enlisted in the service of majoritarian prejudices. When the federal government returned to the sedition business with passage of the Espionage and Sedition Acts, the country was characterized by a climate of isolationism and a receptive ear to the tenets of Socialists, who opposed the entry of the United States into World War I. The Sedition Act rendered it illegal to speak against the draft or to advocate strikes that might hinder wartime production. It resulted in more than 800 convictions, including that of Socialist presidential candidate Eugene Debs. Prosecutions for political speech continued after World War II, when provisions of the 1940 Smith Act were used as the legal arm of an extensive and popularly backed campaign to suppress Communist viewpoints in the press, the workplace, and the entertainment media.

A significant judicial outcome of cases stemming from the enforcement of these acts was the evolution of the criteria used to determine whether political speech warrants conviction. Whereas it had previously sufficed that expression result in only a “bad tendency” to cause harm, these cases eventually produced today’s criterion of “imminent lawlessness.” Had the expressive restrictions of the first part of the century been in place during the civil rights movement and the Vietnam War, much of what was said and written during these periods would have resulted in federally sanctioned jail sentences.

National security interests have also been invoked to justify secrecy classification systems, the labeling of foreign “propaganda,” and the use of contract law by agencies including the Central Intelligence Agency and the Voice of America to require prepublication clearance of communications by both current and former employees.

WARTIME RESTRICTIONS

Compulsory systems of prepublication clearance during wartime were first used during the Civil War and, with the notable exception of Vietnam, have continued to be used in all major military conflicts. The exception of Vietnam was prompted

by the government's fear that prior review systems would alienate the press and by the fact that readily available nonmilitary air transportation in the area would have rendered enforcement difficult. However, there is credible evidence that military officials systematically misrepresented progress by the United States during the war and that media routines and practices rendered them susceptible to this manipulation (Hallin 1986).

Despite the consensus on the need for some form of press management system to protect the lives of soldiers during wartime, controversies arise over the scope and mechanisms of enforcement. Of particular concern to press and public is the fear that controls ostensibly designed to protect the lives of soldiers are used instead to manage public opinion at home.

PORNOGRAPHY

The term pornography comes from the Greek words for "prostitute" and "write," and originally referred to writings about prostitutes and their activities. Today, pornography is broadly used to mean material with explicit sexual content. Like the word censorship itself, however, the definition of pornographic or obscene material is often contested. For example, feminist writers often draw a distinction between pornography, which combines sexuality with abuse or degradation, and erotica, which is sexually arousing material that respects the human dignity of the participants. A distinction is also sometimes drawn between hard-core pornography, which shows actual sexual intercourse or penetration, and soft-core pornography, which may be only suggestive of these activities. Child pornography is prohibited in most nations, and restrictions on its production and distribution tend to be noncontroversial.

In the United States, the Commission on Obscenity and Pornography (1970) and the Attorney General's Commission on Pornography (1986) have provided recommendations for government action regarding pornography. The first report suggested that pornography should not be regulated by law, while the second rejected the claims that pornographic material was harmless and urged prosecution especially for materials that contained violence or degradation. These differing conclusions highlight the ongoing tensions between individual rights and perceived community needs, as

well as changes in the progress and interpretation of research on the effects of pornography. The uses of the conclusions drawn in these and other social-scientific reports are of particular sociological interest. For example, the Nixon Administration was quick to dismiss the conclusions of a report (which it had itself commissioned) that were contrary to its political goals. Here, as in other contested areas of expression, the political climate in which research findings are interpreted is often the deciding factor in how research is used.

Regarding the related question of obscenity, in 1973 the Supreme Court (*Miller v. California*, 413, U.S. 15, 1973) established three criteria for determining whether a given work was obscene: An average person, applying contemporary local community standards, finds that the work, taken as a whole, appeals to prurient interest; the work depicts in a patently offensive way sexual conduct specifically defined by applicable state law; and the work in question lacks serious literary, artistic, political, or scientific value.

Political struggles over the regulation of pornography have been especially intriguing because they have brought together conservatives and feminists, groups traditionally on opposite sides of the ideological spectrum. Although both sides may support banning pornography, they have different reasons for doing so, and the scope of the material they wish to have regulated differs as well. Feminists focus on the degrading character of pornography, whereas conservatives view pornography as morally corrosive. Antipornography activists such as Catherine MacKinnon have defined pornography as a civil rights issue, arguing that pornography itself is a form of sexual discrimination; by presenting women in dehumanizing ways, pornography subordinates them.

Although there is wide variation in pornographic content, pornography often presents what many consider to be an unrealistic view of sexual relations. Encounters take place most often between strangers, not in the context of enduring relationships; participants are sex objects rather than complete individuals. Sexual activity always results in ecstasy, and consequences (such as pregnancy or disease) are nonexistent.

Empirical research on the effects of pornography has shown a range of negative effects. In

typical experimental studies, participants are randomly assigned to pornographic stimuli or nonpornographic stimuli, and their attitudes, behaviors, or physiological reactions are then assessed. There are also paradigms assessing prolonged exposure, including ones in which participants return to the laboratory for multiple sessions of exposure to pornography, to better simulate real-life consumption patterns. Among other effects, studies have shown that after exposure to pornography, participants viewed rape as a less serious crime, overestimated the popularity of less common sexual practices, and showed greater callousness toward women. Furthermore, pornography consumers have shown weaker beliefs in the desirability of marriage and having children, and stronger beliefs in the normality of sexual promiscuity. Ironically, pornography has also been shown to reduce viewers' satisfaction with their own sex lives and partners.

Although these outcomes have been found in a variety of studies using different research procedures, not all studies have confirmed these findings. Some critics of this research argue that rape and other antisocial sexual behavior existed even before pornography became widely available, and that forces besides pornography play a greater causal role in antisocial behavior. Others argue that the increased levels of aggression, hostility, or bias often found in experimental studies of pornography might be traced to differences between the experimental and naturalistic environments in which pornography is viewed: particularly, it is argued that these effects may be due to the lack of opportunity for men to ejaculate in the experimental setting. They also caution that the political biases of investigators may influence the interpretation of results. Others believe that even if the effects research is accurate, the costs of suppressing pornographic material—as measured in state encroachment on individual autonomy—outweigh any benefits that might be gained.

An argument sometimes raised for controlling or eliminating pornography in the form of images (rather than words) is that the individuals pictured in the pornographic photos and films suffered harm or coercion during the creation of the materials. A counterpoint to this argument is provided by Stoller and Levine (1993), who have

conducted in-depth ethnographic style interviews with producers, performers, and other employees in the pornography industry. In this work, the researchers allowed the people who create pornography to speak in their own words, providing both defenses of pornography and insight into why individuals choose, for better or for worse, to work in the pornography industry.

HATE SPEECH

From the advent of the printing press onward, most efforts to legally regulate expression have focused on various forms of mass communication. Efforts to restrict speech can also target communication in interpersonal settings. One such example can be found in attempts to place legal limits on hate speech; defined as harassing or intimidating remarks that derogate the hearer's race, gender, religion, or sexual orientation.

Those who support regulating hate speech compare it to "fighting words," a category of speech not protected by the First Amendment, or argue that it creates a "hostile environment," which violates provisions of the Civil Rights Acts of 1964 and 1990. Champions of hate speech regulations cite the harms its victims suffer: these may range from feelings of exclusion from a community, to the experience of debasement that leads students to skip classes or distress that leads them to leave school. In short, the liberty of a speaker to harass may deny the hearer's right to equality. Critics of hate speech codes cite the administrative excesses they allow. For example, the student guide to the University of Michigan code stated that students could be punished for making a comment "in a derogatory way about someone's appearance."

Following an increase in reported incidents of hate speech in the late 1980s and early 1990s, many universities in the United States adopted policies forbidding discriminatory verbal harassment. However, as they affect public institutions, these rules have been declared unconstitutional in the courts, in part for being either too broad—affecting too many forms of speech—or for being viewpoint based (see above).

The problems inherent in drafting laws that affect only the speech these rules target can be

seen in comparing the provisions of the University of Michigan code with provisions in the bill advanced by Senator Jesse Helms to limit what kinds of works could receive funding from the National Endowment for the Arts. Among the Helms bill's other planks (aimed at homoerotic art, for example), it sought to prohibit funding of "material which denigrates . . . a person, group, or class of citizens on the basis of race, creed, sex, age . . ." Similarly, the Michigan code sought to bar speech that "stigmatizes or victimizes an individual on the basis of race, ethnicity, religion, sex . . ." and also "creates a hostile environment." The projects targeted by the Helms bill included one with a crucifix immersed in a bottle of urine. This work could also be a violation of the Michigan code if it were to be hung in an area frequented by offended Christians. Difficulties of this sort have prompted those supporting hate speech codes to argue that this is one area in which viewpoint-based speech regulations should be allowed: that, similar to laws in Germany that selectively ban Holocaust denial, speech laws in the United States should be allowed to account for the history of discrimination experienced by some groups, but not others. Critics say that viewpoint discrimination of this sort would open the floodgates for future laws that selectively target viewpoints that happen to be deemed undesirable.

The hate speech debates highlight a fundamental dilemma faced by modern democracies: to what extent are we willing to tolerate speech whose very goal is to silence the speech of others, or to deny their rights to equal education or employment? Efforts continue to craft codes that are narrow in scope and that meet constitutional muster, with even staunch civil libertarians favoring prosecution when hate speech poses a clear and present danger of violence (e.g., Smolla 1992). The hate speech debates also mark a significant turn in the rhetoric of "censorship," one in which advocates of speech codes have attempted to enlist the power of this term in their favor. This rhetorical strategy is exemplified by the argument of Catharine MacKinnon, one of the staunchest code supporters, that "the operative definition of censorship . . . shifts from government silencing what powerless people say, to powerful people violating powerless people into silence and hiding behind state power to do it" (1993, p. 10).

BATTLES FOR CONTROL OVER SCHOOL CURRICULA

Schools are the arena in which the values of open deliberation and the constructive exchange of ideas are most prized in democratic societies. It is with some irony, then, that schools are also the domain in which some of the most concerted efforts to limit the scope of deliberation have been focused. The content of textbooks used by most students in the United States has been selectively tailored to the ideological viewpoints of organized pressure groups, and at least one-third of high school students are not exposed to books and films that parents and pressure groups have successfully purged from their educational experience (Davis 1979).

From the vantage point of most teachers, parental and school board mandates to omit works of literature from the curriculum are viewed as illegitimate challenges to their expertise and infringements on their rights as professionals. In effect, teachers believe that they are in the best positions to judge the educational needs of the students they teach. However, the tradition of academic freedom that characterizes both public and private universities is rarely present in elementary and secondary education. Public school curricula are generally approved by the state or by school boards that actively regulate what is taught and what students read. School board members tend to be elected to their positions and are particularly responsive to what teachers view as unreasonable censorial demands.

Parents, on the other hand, see their interventions in the school curricula as a legitimate exercise of control over what their children read in school. They justify their decision, in part, with respect to the compulsory nature of early schooling, where they see their children as captive audiences. A number of well-funded organizations have exerted strong influences on both school boards and textbook adoption processes to influence what does and does not gain entry to the schoolroom.

In money terms, the largest impact of pressure groups has been on textbook publication and adoptions. Most states place orders for textbooks for schools in the entire state. Because publishers cannot provide multiple versions for different regions or states, texts are geared to the largest

markets, usually Texas and California (Del Fattore 1992). As a result, publishers provide their writers with guidelines that govern topics and viewpoints that are currently deemed objectionable (or desirable) in the largest states that engage in statewide adoptions. In this way, pressure groups in one state, such as Texas, often exercise veto power over the entire country's textbook market. Local communities in small and mid-size states exercise a relatively small influence on content.

Community protest and lawsuits are the principal vehicles used to challenge textbooks and reading lists in literature, social studies, and health education. An illustrative controversy—at McClintock High School in Tempe, Arizona in 1996—highlights the susceptibility of teachers and schools to parental and community demands. In this case, a parent of a McClintock High student protested the assignment of Mark Twain's classic *The Adventures of Huckleberry Finn* because the word "nigger" is included in its dialogue. In the ensuing controversy, some held that if schools were forced to shield students from exposure to the term, such intervention would undermine the legitimate authority of teachers and would endorse ignorance of American history and the practice of censorship.

We may ask whether the students grasp the distinctions among Twain's stance on racism, the use of the term "nigger" by a character in the novel, and societal endorsement of the term then and today. Of course the crux of such conflicts also rests upon the educational and social contexts in which sensitive, taboo, or potentially affronting topics that appear in the world of fiction are discussed. For instance, if *The Adventures of Huckleberry Finn* or any other literature is misused to communicate racism, the problem is larger than the choice of which books are read in the classroom.

Unfortunately, the social context of this controversy added complexity. School benches at the same high school were etched with the words "I hate niggers." Of course, there is an important distinction between eliminating the word "nigger" from *The Adventures of Huckleberry Finn* and removing "I hate niggers" from a school bench. The etching creates a hostile educational and social environment in a way that the assignment of book should not do, as long as teachers and schools are doing their jobs well. In controversy after controversy, these distinctions are as important as

they have been difficult to establish. Often teachers simply capitulate to perceptions of the most conservative or protective community elements and use readings that are sure to be "safe" (Davis 1979).

In 1990s most lawsuits were mounted by fundamentalists who condemned many books on school lists as anti-Christian, antiparent, antigovernment, immoral, and obscene. The challenged books change from year to year, but frequently banned books have included *Of Mice and Men* (Steinbeck), *Catch 22* (Heller), and *Catcher in the Rye* (Salinger). Fundamentalists are effective out of all proportion to their numbers because of the intense dedication they bring to their cause.

Research has yet to provide a sound basis for confidently assessing the effects of reading on school children's beliefs. When a story contains a character's arguments against the existence of God, might students question their faith? Qualitative research, particularly, has shown that students take widely divergent readings from stories and that these understandings are frequently critical of the viewpoints adopted by both characters and writers.

Can we maintain that literature gives readers insights into life? That it can change lives? Parents—former pupils, after all—have been encouraged to believe that great works contain great truths. It is not surprising that some of those parents who discern arguments against the social order in their children's readings seek to eliminate the threat from children's lives. Eventually, these ongoing and recurring controversies may be illuminated by scientifically grounded understanding of the social and cognitive foundations of narrative impact (Green, Strange, and Brock 2000).

One of the strongest arguments for keeping school curricula open to ideas to which we currently object or to heinous artifacts of historical prejudices is that one of the important functions of education is the development of critical inquiry. From this perspective, to turn the schoolhouse into an environment where only "safe" ideas are encountered is to do students and society a disservice. This position is rendered more compelling in the context of the current media landscape which makes it certain that students will also encounter these ideas outside the context of a critical learning environment. This argument, of course,

rests on the assumption that schools are, in fact, places where critical inquiry is fostered.

THE SOCIAL PSYCHOLOGY OF “CENSORSHIP”

When information (e.g. a book, a film, a speech, etc.) is explicitly “censored” do people desire that information much less—in accordance with the presumed intention of the censoring agents? Are people less likely to be influenced by a point of view when its expression has been prohibited by those in authority? To answer such questions, the impact of the label “censored” can be studied experimentally by exposing people to a communication (or a “taste” of a communication) to which “censored” is affixed and by then observing the consequences of such a juxtaposition of label and communication on their values and beliefs. When this careful experimental work has been done, the answer to both of these questions is “no.” Numerous experiments have shown that explicit censorship often *backfires*: the prohibition of communications leads people to covet them and to change their attitudes in the directions the censored material advocates.

A social-commodity theory (Brock 1968) accounts for the backfire effect of censorship in terms of the psychology of supply and demand. All public communications are perceived to have some limits on their distribution, and message recipients usually have some dim awareness of the extent of these limits. However, if the distribution is explicitly limited by government statute, or other overt interventions, awareness of scarcity is sharply heightened and the desirability and impact of the communication are consequently increased. When some information becomes less available, this unavailability augments the information’s value. A decrease in supply causes an increase in demand, and perceived censorship invariably entails a perceived decrease in supply.

Experimental social psychology has illuminated the impact of censorship by showing that (a) an individual can be influenced by a censored communication, even without actually receiving it, (b) the backfire effect increases as the penalties for violating censorship are increased; and, somewhat paradoxically, (c) the backfire effect is greater when the prohibition applies selectively to one group of people. For example, for a seventeen

year old, a film that was prohibited to persons under eighteen years of age would be more desirable than a film that was prohibited to all persons. In the former case, the censorship has more impact because it is viewed as violating a personal freedom; freedom to view a film is more threatened if there are many other people (all persons over eighteen years, say) who do have that freedom.

The experimentally grounded insights from social psychology—that explicit censorship usually doesn’t work as planned, and that it often backfires—is often not factored into the planning and interventions of censoring agents. In some instances this may be good, as it reduces the effectiveness of those who attempt to limit information that is vital to public deliberation. In some instances, public information officers appear to have become aware that perceptions of censorship can hamper their efforts. In the 1970s, the Department of Defense directed that the term be completely dropped. This seemingly cosmetic change affects the way news coverage labels the sources of news reports: what was once attributed to the Office of Censorship, became, during the Gulf War, a report from the Joint Information Bureau.

Research on related forms of content advisory labels, such as “parental discretion advised,” “viewer discretion advised,” and the more specific codes signaling levels of violence, nudity, sex, and profanity on television, has begun to reveal the extent to which different kinds of labels affect the selection choices of boys and girls of different ages (Cantor and Harrison, 1994–1995). In several cases, these studies have revealed a “backfire” or “forbidden fruit” effect similar to the pattern found in reactions to the censorship label. The finding that restricted materials become more attracted—which depended on age, gender, and the kinds of labels used—have been extended to video game and music advisories.

Advocates of requiring such labels argue that their goal is not to limit communication at its source, but rather to provide parents and children a greater degree of control over their communication choices. Some critics argue that, regardless of intent, these labels lead producers to alter their productions in order to avoid undesirable labeling. As with the “censored” label, the effects on consumption of the targeted content will depend not only on how the label affects desirability of the

materials, but also on the ultimate availability of the labeled content. If parents use advisory labels to preselect their children's television viewing choices, these labels will effectively place greater selective control in the hands of parents. The probability that parents will do so is heightened by technologies like the "V-chip," through which parental choices can be automated. Similar labels may have a much different effect on the selection of music and video games, where children are more likely to make their own media selections.

Research has also begun to examine the social and psychological origins of calls to restrict deemed harmful to children or to society at large. Studies of the "third person effect" suggest that support for restrictions on such content may sometimes be grounded in systematic overestimates of the effects of media on other persons. Sociological treatments of the rise of public alarm are particularly relevant here. Nicola Beisel's (1992) account of the late-nineteenth-century attack on obscenity that resulted in the highly suppressive Comstock Laws is one example of a fruitful direction that research might take.

INTERNATIONAL ISSUES

Whereas most democratic nations have codified and enforced protections against the most blatant forms of government suppression of sociopolitical speech, governments around the world continue to engage in harsh repression. The bounty placed on the life of Salman Rushdie in retribution for his book, *The Satanic Verses*, is a well-publicized instance of the most egregious form of government-sanctioned repression. However, a variety of both legal and extra-legal tactics continue to be used worldwide to protect those in power. To cite just two typical examples from 1999: A court in Kazakhstan suspended publication of an opposition newspaper for the three months preceding presidential elections on the pretext that it failed to indicate the place of printing on its masthead; and, shortly after the director of the Cameroon newspaper *Le Messager-Populi* was released from a ten-month prison sentence for spreading "false information," the paper's founder was driven from the country upon threats to his life (see generally, Webb and Bell 1998). Typical extra-legal means of suppressing speech critical of the government include awarding and withdrawing governmental

advertising contracts, the licensing of journalists, controls on distribution of newsprint, and, more generally, government ownership and control of broadcast media.

Controls at the site of reception provide another means of suppressing viewpoints that lack the official stamp of approval. For example, a number of countries pose outright bans on ownership of satellite receiving dishes. However, new technologies, particularly the Internet, pose serious threats to the control of political information by authoritarian regimes. The Internet's impending threat is linked to the growing dependency upon computer-based communications in the marketplace. Authoritarian governments appear to be faced with a Hobson's choice: allow connections to the vast and diverse information resources of the Internet or face economic stagnation.

Particularly when looking beyond suppressive controls on political speech, it is important to recognize the distinction between government-controlled media and government-funded media. The BBC is but one example of the government-funded, public television stations that have developed reputations for independent news coverage that gives voice to diverse perspectives of both majority and minority interests. Publicly-subsidized television in Holland instantiates an intriguing model of "free speech" through a system that allots television channels and channel space on a proportional basis to key institutions and sociocultural groups. Public television stations in many European nations seek independence from the demands of both government and marketplace through nongovernmental boards of trustees and through stable funding mechanisms not subject to annual tampering by politically driven legislatures.

INTERNATIONAL INFORMATION FLOW

A handful of news agencies, led by the Associated Press (AP), Reuters, and Agence-France Presse dominate the news that people around the world read about issues and events originating outside their borders. The dominance of both print and broadcast news by a small group of companies is particularly felt in developing nations, ones lacking the capital to compete with the economies of scale enjoyed by entrenched foreign corporations. The concern generated in developing nations focuses not only on the news they receive from

abroad, but also on the images that news agencies project about them. This concern is compounded by news agency values that typically stress large-scale violence and disruption—"coups and earthquakes" as the saying goes—and ignore the cultural achievements and developmental efforts for which these countries would like to be known.

Those who control international news flows view their position of dominance as a desirable and natural outcome of free-market practice. Those in developing nations view the imbalances as a form of de facto neo-imperialism. This view finds its historical roots in the late-nineteenth and early-twentieth centuries, when three European news agencies, Havas (France), Wolff (Germany), and Reuters (England) carved the world into three areas of monopoly control, ones that built upon their respective colonial empires. Some insight into the present-day perspective of developing nations can be gained by examining how news about the United States was communicated in the early part of the century. During those years, the "Ring Cartel" prevented AP from sending news about the United States beyond its borders. According to Kent Cooper, the AP manager who fought to dismantle it, the cartel decided "what the people of each nation would be allowed to know of the people of other nations and in what shade of meaning the news was to be presented." It was Reuters who "told the world about Indians on the war path in the West, lynchings in the South, and bizarre crimes in the North. . . . The charge for years was that nothing credible to America was ever sent" (cited in Frederik 1993, p.39). To those in developing nations, it is the AP who now plays the role of cartel.

Several proposals have been advanced to correct the imbalance in international news flows. Notable are those advanced through the United Nations Educational, Scientific, and Cultural Organization (UNESCO) during the late 1970s and early 1980s. These calls for a "New World Information Order" (NWIO) generated immediate and prolonged controversy, and provoked the United States to withdraw from UNESCO in 1985. The contours of these debates are as intriguing as they are complex, reflecting sharp differences in news values, international economic principles, and the very definition of "free speech." Whereas NWIO supporters liken the values of developmental journalism to current trends in the United States, such

as "civic" journalism, its detractors suggest that the values of developmental journalism cater to the needs of local authority. And whereas NWIO critics argue for a "free flow" of information across international boundaries, NWIO supporters advocate a "balanced flow." Although these issues remain unresolved, promising developments include the rise of regional news agencies, programs such as CNN's World Report, in which locally produced broadcasts gain worldwide exposure; and prospects that the Internet will facilitate the international communication of locally produced news.

The increasing global dominance of U.S. movies and television programming have prompted the European Economic Community and Canada, among other regional and national entities, to seek ceilings on imported cultural goods as exceptions to free trade principles in international trade agreements. These demands reflect the belief that when applied to the area of expression, free market principles support forms of "soft" or "de facto censorship" in which locally produced speech is driven from the marketplace of ideas (cf. Frederik 1993). More generally, these demands reflect the growing tension between the ongoing course of globalization and the threats to cultural sovereignty it entails.

CENSUS

A national census of population is “the total process of collecting, compiling, evaluating, analysing and publishing or otherwise disseminating demographic, economic, and social data pertaining, at a specified time, to all persons in a country” (United Nations 1988, p. 3). The United Nations encourages its members to take regular censuses and provides technical assistance. It also publishes an annual demographic yearbook and maintains a web site with selected census data and other population information for most countries.

A nation may conduct censuses on other subjects such as housing, business firms, agriculture, and local governments. Because of the close link between families and housing units, censuses of population and housing are usually combined.

The actual enumeration for a national population census is usually spread over a period of weeks

or months, but an attempt is made to record circumstances as of a designated census day (April 1 for the 2000 U.S. census). In some censuses, persons are reported in their legal or usual place of residence (*a de jure enumeration*). According to the Bible, a census decree issued by the government in Rome ordered that persons be counted and taxed in their home towns. In response, Joseph and his pregnant wife, Mary, traveled from Nazareth to Bethlehem, where Mary gave birth to Jesus. Other censuses record people where they are on the census day (*a de facto enumeration*). Whatever residency rule is followed, all conceivable special circumstances must be anticipated, questionnaires well designed, and census staff thoroughly trained.

The U.S. census uses the concept of “usual residence,” where the person lives and sleeps most of the time, but some exceptions are made. A few examples from the 2000 U.S. census illustrate the range of circumstances. Some persons staying in hotels and rooming houses are transients temporarily absent from their usual homes; they completed special census forms that were later compared to the census forms received from their home addresses to confirm that they were properly reported by other household members. An operation called “Service-Based Enumeration” was designed to locate homeless persons and others with no usual residence. College students were presumed to be residents at the place they lived while attending college, even if they were at home on spring break on census day. Efforts were made to avoid having an away-at-college child erroneously double-counted as a member of the home household. Pre-college students at away-from-home schools were assigned to the parental household. Citizens working in another country for the U.S. government, and their families, were enumerated (primarily through the use of administrative records), but other citizens living abroad at the census date were not counted. Short-term tourists, however, were supposed to be reported by other members of their households, or by late enumeration upon their return home. Persons not legally resident in the United States were supposed to be counted, but many feared all contact with authorities and took steps to avoid detection by census procedures.

The total population count is only one result of a modern census. Information is also obtained

on many characteristics, such as age, sex, and relationship to others living in the same household, educational level, and occupation. The census then reports on population size and characteristics for provinces, states, counties, cities, villages, and other administrative units. To obtain all this information, the 2000 U.S. census (U.S. Census Bureau 1999) asked every household to complete a “short form” with six questions about each person and one question about each housing unit. A carefully selected sample of one of every six households received a “long form” that included additional questions on fourteen topics for each person and thirteen topics for each housing unit.

Reporting information for the entire country and for the thousands of cities and other subareas results in many volumes of printed reports. Many nations issue additional data on computer-readable files designed for convenient use by national and local governments, organizations, and individuals. Increasing quantities of data are available to anyone with access to the Internet.

In the United States, the idea for a regular census emerged during debates about the problems of creating a representative form of government. The U.S. Constitution (Article I, Section 2) directs that membership in the House of Representatives be based on population: “The actual enumeration shall be made within three years after the first meeting of the Congress of the United States, and within every subsequent term of ten years, in such manner as they shall by law direct.”

The questions asked in a census reflect political and social issues of the day and often provoke spirited debates. For example, slavery was a recurrent divisive issue for the Constitutional Convention. One of the two newly created legislative bodies, the House of Representatives, was to have the number of legislators from each state proportional to the population of the state. Including slaves in the population count would increase the legislative power of southern states. A compromise (Article I, Section 2) provided that: “Representatives. . . shall be apportioned among the several states. . . according to their respective numbers, which shall be determined by adding to the whole number of free persons, excluding Indians not taxed, three-fifths of all other persons.” The distinction between “free persons” and “all other

persons” (slaves) was eliminated after the Civil War (Amendment 14, Section 2).

The 1790 census was modest in scope. Assistants to federal marshals made lists of households, recording for each household the number of persons in five categories: free white males over sixteen and under sixteen, free white females, other free persons, and slaves (Anderson 1988, p. 13).

Censuses from 1790 through 1840 were conducted with little central organization or statistical expertise. A temporary federal census office was established to conduct the 1850 census. The individual rather than the household became the focus of the enumeration, and the content of the census was expanded to include occupation, country or state of birth, and other items. Experienced statisticians were consulted, and the United States participated in the first International Statistical Congress in 1853.

The temporary office for the 1890 census became one of the largest federal agencies, employing 47,000 enumerators and 3,000 clerical workers. To help with the enormous task of tallying data, census officials supported the development by a young inventor, Herman Hollerith, of an electrical tabulating machine. His punched-card system proved effective in census operations and later contributed to the growth of the IBM corporation.

A permanent census office was established in 1902. An increasingly professional staff assumed responsibility for the population censuses and a broad range of other statistical activities. Deficiencies in the federal statistical system became apparent during the 1930s as the nation tried to assess the effects of the Great Depression and to analyze an array of new programs and policies. Several federal agencies successfully advocated expansion of the social and economic content of the 1940 census. New questions in 1940 asked about participation in the labor force, earnings, education, migration (place of residence in 1935), and fertility. A housing census was paired with the population census to provide information about housing values and rents, mortgages, condition of dwellings, water supply, and other property issues. The practice of providing population and housing information for subareas of large cities was greatly expanded.

Governmental statistical agencies are often set in their ways, concerned with continuity rather than innovation and removed from the higher levels of policymaking. For several decades beginning in the late 1930s, the U.S. Census Bureau was extraordinarily creative. Social scientists and statisticians employed by the Census Bureau were active in research and scholarly publication and played leadership roles in professional organizations. Census Bureau personnel pioneered in development of the theory and practice of population sampling. To accommodate large increases in content and geographic scope, the 1940 census questionnaire was divided into two parts. A set of basic questions was asked of everyone, while a set of supplementary questions was asked of a one-in-twenty sample. Subsequent U.S. censuses have continued to use sampling, as with the “long-form” versions of the 1990 and 2000 questionnaires that went to one of every six households. Sampling theory was also applied to the development of periodic sample surveys to provide timely information between censuses and to provide information on additional topics.

For the 1950 census, the Bureau participated actively in the development and utilization of another new technology, the computer. In later censuses, the schedules were microfilmed and optically scanned for direct input of information (without names and addresses) into a computer for error-checking, coding, and tabulating.

Through 1950, census enumeration in the United States was accomplished almost entirely by having an enumerator conduct a personal interview with one or more members of each household and write the information on a special form. By 1990, most census questionnaires were distributed and returned to the Census Bureau by mail, with telephone follow-up replacing many personal visits. Large-scale use of the Internet and other innovative response technologies may be practicable for widespread use in the 2010 census.

National censuses have so far been the best method for obtaining detailed information about the entire population. Only censuses provide counts and characteristics for small administrative and statistical areas, such as villages, voting districts, city blocks, and census tracts. Only censuses provide reliable information on small population

groups, such as the income distribution of female plumbers. Only censuses provide the large numbers of cases needed for complex multivariate analyses. But censuses are so large and difficult to process that by the time the data are released they are, for some purposes, out of date, and this problem increases throughout the interval, commonly ten years, until the next census.

To address the timeliness problem, most national statistical agencies conduct a series of large sample surveys that provide select information on key topics at timely intervals. In the United States, for example, the latest unemployment rate, released on the first Friday of each month, is headline news. It is based on the Current Population Survey, a monthly sample survey that provides current information on many social and economic characteristics.

A few countries keep population registers, continuous records of where people live along with some of their characteristics. If reasonably complete and accurate, these may be used to supplement and update some census information. In many nations, administrative records such as social security, national health, tax, and utility company files, may be adapted to provide periodic estimates of population size and a few characteristics, but difficult questions arise about data quality and comparability with census- and survey-based information. Citizens of many nations are wary about letting the government and corporations compile extensive personal data. Legislative restrictions are increasingly being placed on what information may be gathered and stored and how it may be used.

The questions asked in successive censuses typically change more slowly than the procedures. Keeping the same topics and the same wordings of questions help a government measure change from one census to the next. This appeals to researchers and policy analysts, but policymakers and administrators, whose attention is focused mainly on current programs and next year's budget, often plead for new wording to better serve current concepts. Another reason tending to stifle innovation is that the census is an expensive and visible tool. A lengthy review process confronts any agency that seeks to add, delete, or alter a question. In the United States, both the executive branch and the

Congress must approve the final census schedule. A question on pet ownership has been regularly proposed but rejected because there is no compelling governmental interest in such a question and private sample surveys can provide the desired information. A third reason the content of the questionnaire changes little is that proponents of new topics and questions must compete for questionnaire space, while questions previously asked tend to already have a network of users who have a vested interest in retaining the topic. This competition spurs extensive lobbying and mobilization of support from federal agencies, congressional committees, and interest groups.

An innovative approach to providing timely data is "continuous measurement" using a "rolling-sample" survey. The *American Community Survey* has been implemented by the U.S. Census Bureau (1999), with plans to expand to three million households a year in 2003. Because the survey uses a small, permanent, well-trained and supervised staff (as compared to the large, temporary, briefly trained staff utilized for a census), data quality may be higher than in a census. Another advantage of a monthly survey over a decennial census is the ease of introducing new topics and testing the effects of changes in the wording of questions.

American Community survey results will be cumulated over a year to provide estimates of numbers and characteristics for the nation, states, and places or groups of 65,000 or more people. For smaller places and groups, or for more reliable and detailed data for larger places, data will be cumulated for periods of up to five years. The five-year cumulated sample is designed to be approximately equivalent to the census "long-form" sample and may eliminate the need for a "long form" in the 2010 census. Moving averages could provide annual updates and be used for time series. There are many issues to be worked through in developing and evaluating this type of survey and in determining how well information averaged over a long period compares to standard statistical measures based on time-specific censuses and surveys.

In many nations, questions on race and ethnicity are a sensitive and contentious topic. In the United States, the groups recognized have changed

from each census to the next. For example, special tallies were made from the 1950 and 1960 censuses of persons with Spanish surnames, but only for five southwestern states. Beginning in 1970, and elaborated in later censuses, persons were asked if they were of Spanish/Hispanic origin. Many responses to this question have seemed to be inconsistent with responses to the separate question on race. The Bureau has conducted sample surveys to test various question wordings, and has sponsored field research and in-depth interviews to provide insights into how people interpret and respond to questions about ethnicity. For the 2000 census the basic concepts were retained, but the wording of each was adjusted, provision was made for individuals to report more than one race, and the question on Hispanic ethnicity was placed before the question on race.

In recent decades, extensive social science research has been conducted in many parts of the world on issues of racial and ethnic identity. These identities are almost always more flexible and more complex than can be captured with simple questions. A further complication is that many persons have ancestral or personal links to two or more racial and ethnic groups; how they respond depends on how they perceive the legitimacy and purposes of the census or survey.

In the 1990s, the U.S. Office of Management and Budget conducted an extensive review of its policy statement that specifies the standard race and ethnic classifications to be used by all government agencies, including the Census Bureau (Edmonston and Schulze 1995). Serious methodological problems have arisen as a result of inconsistencies among classifications of individuals on repeated interviews and in different records. A dramatic example occurs with infant mortality rates for race and ethnic groups, which are based on the ratio of counts based on birth registration to counts based on death registration of infants less than one year old. Comparing birth and death certificates for the same person, recorded less than one year apart, revealed large numbers for whom the race/ethnic classification reported at birth differed from that reported at death. The high-level government review also heard from many interest groups, such as Arab-Americans, multiracial persons, and the indigenous people of Hawaii,

who were anxious for the government to enumerate and classify their group appropriately.

In the United Kingdom, controversy about a proposed question on ethnic identity led to the question's omission from the 1981 census schedule, thus hindering analyses of an increasingly diverse population.

The most politically intense and litigious controversy about recent U.S. censuses is not that of content but of accuracy. States, localities, and many interest groups have a stake in the many billions of dollars of government funds that are distributed annually based in part on census numbers.

President George Washington commented about the first census that "our real numbers will exceed, greatly, the official returns of them; because the religious scruples of some would not allow them to give in their lists; the fears of others that it was intended as the foundation of a tax induced them to conceal or diminish theirs; and through the indolence of the people and the negligence of many of the Officers, numbers are omitted" (quoted in Scott 1968, p. 20).

A perfect census of a school, church, or other local organization is sometimes possible, if membership is clearly defined and the organization has up-to-date and accurate records, or if a quick and easily monitored enumeration is feasible. A national census, however, is a large-scale social process that utilizes many organizations and depends on cooperation from masses of individuals. Planning, execution, and tabulation of the 2000 U.S. Census of Population extended over more than ten years. Hundreds of thousands of people were employed at a cost of several billion dollars. A discrepancy between the results of a national census and "our real numbers" is inevitable.

Statisticians, recognizing that error is ubiquitous, have developed many models for identifying, measuring, and adjusting or compensating for error. Census statisticians and demographers around the world have participated in these developments and in trying to put professional insights to practical use.

Following the 1940 U.S. census, studies comparing birth certificates and selective service records to census results documented a sizable net

undercount. To provide more information on census coverage and accuracy, a post-enumeration survey was conducted following the 1950 census using specially selected and closely supervised enumerators. One finding from the survey was that the undercount of infants in the census did not arise, as first thought, from a tendency for new parents to forget to mention a new baby to the census enumerator. The problem, rather, was that many young couples and single parents had irregular and difficult-to-find living arrangements, and entire households were missed by census enumerators. Based on this and related findings, much effort was given in subsequent censuses to precensus and postcensus review of lists of dwelling units.

Special surveys preceding, accompanying, and following censuses are increasingly used to provide evidence on magnitude of error, location of error in specific groups or places, and procedural means for reducing error. Techniques of “demographic analysis” have also been developed and continually refined to provide evidence of census error. The basic technique is to analyze the numbers of persons of each age, sex, and race in successive censuses. For example, the number of twenty-eight year-old white women in the 1990 census should be consistent with the number of eighteen-year-olds in 1980 and eight-year-olds in 1970. Information on births, deaths, immigration, and emigration is taken into account. Based on demographic analysis, the estimated net undercount for the total U.S. population was about 5.6 percent in 1940, 1.4 percent in 1980 (Fay, Passel, and Robinson 1988, Table 3.2) and 1.8 percent in 1990. Estimates of net undercount have also been made for specific age, sex, and race groupings.

If the net undercount were uniform for all population groups and geographic regions, it would not affect equity in the distribution of seats in Congress or public funds. But census errors are not uniform. The estimates for 1990 show net undercounts exceeding 10 percent of adult black males and small net overcounts for some age and race groups.

In 1980, the mayor of Detroit, the City of Detroit, New York City, and others sued the federal government, alleging violation of their constitutional rights to equal representation and fair distribution of federal funds (Mitroff, Mason, and

Barabba 1983). More litigation occurred with respect to the 1990 census. In neither case were the initially reported census counts adjusted to reflect estimated errors in enumeration, although in the case of the 1990 census the Census Bureau technical staff and director thought their methodology would improve the accuracy of the counts.

The Census Bureau developed innovative plans for the 2000 census to integrate an evaluation survey with the census, to use sampling to increase quality and reduce costs of enumerating nonresponsive households, and to produce official counts that already incorporate the best available procedures for minimizing error.

These Census Bureau plans engendered major political and budgetary battles between the Republican-controlled Congress and the Democratic administration. Many of the persons hardest to reach using traditional census methods are poor, often minorities. Many members of Congress assumed that a census with near-zero undercount would increase the population reported for states and localities that tend to vote more for Democrats, and hence reduce, relatively, the representation for states and localities that tend to vote more for Republicans. At the national level, this could alter the reapportionment among states of seats in the House of Representatives. Legislatures in states, counties, and cities are also subject to decennial redistricting according to the “one-person, one-vote” rule, and similar shifts in relative political power could occur.

The controversy between legislative and administrative branches over methods for the 2000 census was taken to the Supreme Court, with plaintiffs seeking a ruling that the Bureau’s plans to use sample-based estimates would be unconstitutional. The Supreme Court avoided the constitutional argument, but ruled that current law did not permit such use of sampling. The Democrats lacked the power to rewrite that part of the basic census law. The two parties compromised by appropriating additional dollars to cover the extra costs of complete enumeration while retaining funds for many of the methodological innovations that permit preparation of improved estimates. Reapportionment among states of seats in Congress could therefore use the results of traditional complete enumeration. Most scholars, analysts, and other

users of census data are likely to consider the adjusted estimates more accurate and hence more useful.

The percentage net undercount understates the total coverage error in the census. If one person is omitted and another person counted twice, the total count is correct but there are two “gross” errors that may affect the counts for specific places and characteristics. Identification of gross errors is receiving increased attention, to improve information on the nature of census error and potential error-reducing methods, and to facilitate development of techniques of data analysis that compensate for known and unknown errors.

One of the difficulties in debates about undercount and other census error arises from confusion between the idea of a knowable true count and the reality that there is no feasible method for determining with perfect accuracy the size and characteristics of any large population. A national census is a set of procedures adopted in a political, economic, and social context to produce population estimates. It is politically convenient if all parties accept these results as the common basis for further action, much as sports contests use decisions by umpires or referees. The more that policy and budgets depend on census results and the more aware that politicians and citizens become of the importance of the census, the more contentious census taking will be.

Every nation confronts political and social problems with its censuses. Regularly scheduled censuses are often postponed or abandoned because of international conflict. The United States and the United Kingdom canceled plans for mid-decade censuses because of national budget constraints. West Germany was unable to take a census for several years because of citizen fears about invasions of privacy. Ethnic conflict has interfered with census taking in India, Lebanon, and other nations.

The processes by which census procedures are determined, the ways in which census figures are used, and the conflicts that occur about these procedures and numbers are not merely “technical” but are embedded in a broader social process. The character of a nation’s census and the conflicts that surround it are core topics for the “sociology of official statistics” (Starr 1987).

CHILDHOOD SEXUAL ABUSE

Although child abuse is probably as old as childhood itself, serious research into child abuse arguably began in 1962 with the publication of Kempe and colleagues' seminal paper, "The Battered Child Syndrome" (Kempe, Silverman, Steele, Droegemuller, and Silver 1962). Not long afterwards, health care professionals began to direct their attention to the specific problem of childhood sexual abuse (Cosentino and Collins 1996). In the past few decades, numerous instances have been documented in detailed case histories, and important research into the causes and consequences of childhood sexual abuse has been initiated.

Numerous extensive reviews have been published that summarize what is presently known about childhood sexual abuse, focusing on the following domains.

- Short-term effects (Beitchman et al. 1991; Beitchman et al. 1992; Briere and Elliott 1994; Browne and Finkelhor 1986; Finkelhor 1990; Gomes-Schwartz et al. 1990; Green 1993; Kelley 1995; Kendall-Tackett et al. 1993; Trickett and McBride-Chang, 1995).
- Long-term consequences (Beitchman et al. 1991; Briere 1988; Briere and Elliott 1994; Briere and Runtz 1991; Cahill et al. 1991a; Collings 1995; Ferguson 1997; Finkelhor 1987; Gibbons 1996; Glod 1993; Green 1993; Murray 1993; Polusny and Follette 1995; Trickett and McBride-Chang 1995; Wolfe and Birt, 1995).
- Prevention of abuse (Adler and McCain 1994; Berrick and Barth 1992; MacMillan et al. 1994; Olsen and Widom 1993; Wolfe et al. 1995).
- Treatment of both survivors and abusers (Cahill et al. 1991b; Cosentino and Collins 1996; Faller 1993; Finkelhor and Berliner 1995; O'Donohue and Elliot 1993).

Consequently, this chapter is not intended to provide a detailed analysis and review of the literature on childhood sexual abuse. Rather, it is meant to serve as a brief overview of, and introduction to, this area of inquiry.

DEFINITION OF THE PROBLEM

Before delving into the field of childhood sexual abuse, one must first understand what is meant by the term. Indeed, the lack of a standard definition has been a major criticism of the field and controversies abound (Finkelhor 1994a; Gibbons 1996; Gough 1996a; Green 1993). In general, the legal and practical research definitions of child sexual abuse require the following two elements: (1) sexual activities involving a child (sometimes construed as including adolescence), and (2) the existence of an "abuse condition" indicating lack of consensuality (Faller 1993; Finkelhor 1994a). "Sexual activities" refer to behaviors intended for sexual stimulation; such activities need not involve physical contact, however, leading to separate definitions for "contact sexual abuse" and "noncontact sexual abuse." Contact sexual abuse includes both penetrative (e.g., insertion of penis or other object into the vagina or anus) and nonpenetrative (e.g., unwanted touching of genitals) acts. Noncontact sexual abuse refers to activities such as exhibitionism, voyeurism, and child pornography (see Faller 1993 and Finkelhor 1994a for reviews on definitions of childhood sexual abuse).

An abuse condition is said to exist when there is reason to believe that the child either did not, or was incapable of, consenting to sexual activity. Three main conditions can be distinguished: (1) the perpetrator has a large age or maturational advantage over the child; or (2) the perpetrator is in a position of authority or in a caretaking relationship with the child; or (3) activities are carried out against the child's will using force or trickery. As evident from this brief summary, "Childhood Sexual Abuse" covers a wide range of acts and situations, and therefore is open to considerable subjective interpretation.

INCIDENCE AND PREVALENCE OF CHILDHOOD SEXUAL ABUSE

Increasing attention has been directed toward childhood sexual abuse not only because of the psychosocial sequelae associated with its occurrence, but also because it now appears to be more widespread than previously thought (Adler and McCain 1994). However, accurate estimates of the occurrence of childhood sexual abuse are difficult

to obtain because many cases are never reported. Thus, available statistics represent only those cases reported to child protection agencies or to law enforcement, and therefore underestimate the true magnitude of the problem.

There are two official sources of incidence data for cases in the United States: The National Incidence Study of Child Abuse and Neglect (NIS), a federally funded research project; and statistics from state child protection agencies (Finkelhor 1994a). The NIS conducted in 1993 documented over 300,000 cases of sexual abuse among children known to professionals in the course of a year, or a rate of approximately forty-five cases per 10,000 children (Sedlak and Broadhurst 1996). Child protective services data suggest that approximately 140,000 cases of childhood sexual abuse occur annually, or twenty-one cases per 10,000 children (Leventhal 1998). An editorial by Finkelhor (1998) suggested that the incidence may be declining. However, this remains to be substantiated. In general, reports suggest that the rate of childhood sexual abuse has increased substantially over the past decades (Sedlak and Broadhurst 1996).

Retrospective surveys provide a second source of information on the occurrence of childhood sexual abuse. Reported rates depend upon how it is defined and operationalized in any given survey. When childhood sexual abuse has been assessed with a single item that narrowly defines it as rape or sexual intercourse, reported prevalence rates tend to be low (e.g., less than 12 percent). Conversely, when it is defined more broadly (e.g., touching genitalia) and assessed using multiple items, prevalence rates tend to be much higher, but with a wide range. The discrepancies observed in the estimated prevalence of childhood sexual abuse points to the need for increased standardization and the use of better assessment instruments in this research.

Because rates of childhood sexual abuse are substantially greater among females than males (e.g., Cosentino and Collins 1996; Finkelhor et al. 1990; Sedlak and Broadhurst 1996), the majority of this research has focused on women. Surveys suggest that anywhere from 18 percent to 30 percent of college women and 8 percent to 33 percent of male and female high school students report having experienced this abuse at some point in

their lives (Ferguson 1997; Finkelhor 1994a; Gibbons 1996; Green 1993; Gorey and Leslie 1997). Among the general adult female population, prevalence rates range from 2 percent to 62 percent (Finkelhor 1987; Finkelhor et al. 1990; Saunders et al. 1992). Rates are even higher within various clinical populations, with 35 percent to 75 percent of female clients reporting a history of some form of sexual abuse during childhood (Gibbons 1996; Wurr and Partridge 1996).

The number of males who have been sexually abused is difficult to estimate because it has been the subject of fewer high-quality studies (Holmes and Slap 1998; Watkins and Bentovim 1992). Nonetheless, a few studies have examined this issue among men and estimate that approximately 3 percent to 16 percent of all men in the United States were sexually abused during childhood (Finkelhor et al. 1990; Gibbons 1996; Holmes and Slap 1998). As is the case for women, rates are higher when studying clinical populations, with estimates ranging from 13 percent to 23 percent (Holmes and Slap 1998; Metcalfe et al. 1990).

In sum, based on the evidence available in the literature, Finkelhor (1994a) estimates that 20 percent of adult women and 5 percent to 10 percent of adult men are survivors of childhood sexual abuse. Similarly, a synthesis of sixteen cross-sectional surveys on the prevalence of it among nonclinical populations reported unadjusted estimates of 22.3 percent for women and 8.5 percent for men (Gorey and Leslie 1997).

SEQUELAE

Research conducted over the past decade indicates that a wide range of psychological and interpersonal problems are more prevalent among those people who have been sexually abused than among those who have not been sexually abused. Although a definitive casual relationship between such problems and sexual abuse cannot be established using retrospective or cross-sectional research methodologies (Briere 1992a; Plunkett and Oates 1990), the aggregate of consistent findings in this literature has led many investigators and health care providers to conclude that childhood sexual abuse is a major risk factor for a variety of problems, both in the short-term and in later

adulthood (Briere and Elliott 1994; Faller 1993). The various problems and symptoms described in the literature can be categorized as follows: (1) posttraumatic stress; (2) cognitive distortions; (3) emotional distress; (4) impaired sense of self; (5) avoidance phenomena; (6) personality disorders; and (7) interpersonal difficulties. In the remainder of this section, each of these categories is defined and illustrated using examples from the research literature.

Posttraumatic stress refers to certain enduring psychological symptoms that occur in reaction to a highly distressing, psychiatric disruptive event. To be diagnosed with posttraumatic stress disorder (PTSD) an individual must experience not only a traumatic event, but also the following problems: (1) frequent re-experiencing of the event through nightmares or intrusive thoughts; (2) a numbing of general responsiveness to, or avoidance of, current events; and (3) persistent symptoms of increased arousal, such as jumpiness, sleep disturbances, or poor concentration (American Psychiatric Association (APA) 1994). In general, researchers have found that children and adults who have been sexually abused are significantly more likely to receive a PTSD diagnosis than their nonabused peers (McLeer et al. 1992; Murray 1993; Rowan and Foy 1993; Saunders et al. 1992; Wolfe and Birt 1995).

Cognitive distortions are negative perceptions and beliefs held with respect to oneself, others, the environment, and the future. In the abused individual, this type of thought process is reflected in his or her tendency to overestimate the amount of danger or adversity in the world and to underestimate his or her worth (Briere and Elliott 1994; Dutton et al. 1994; Janoff-Bulman 1992). Numerous studies document such feelings and perceptions such as helplessness and hopelessness, impaired trust, self-blame, and low self-esteem among children who have been sexually abused (Oates et al. 1985). Moreover, these cognitive distortions often continue on into adolescence and adulthood (Gold 1986; Shapiro and Dominiak 1990).

Emotional distress or pain, which typically manifests itself as depression, anxiety, anger, or all of these, is reported by many survivors of childhood sexual abuse. Depression is the most commonly reported symptom among adults with a

history of childhood sexual abuse (Beitchman et al. 1992; Browne and Finkelhor 1986; Cahill et al. 1991a; Polusny and Follette 1995). Greater depressive symptomatology is also found among children who have been abused (Lipovsky et al. 1989; Yama et al. 1993).

Similarly, elevated anxiety levels have been documented in child victims of sexual abuse and adults who have a history of it (Gomes-Schwartz et al. 1990; Mancini et al. 1995; Yama et al. 1993). Adults with a history of childhood sexual abuse are more likely than their nonabused counterparts to meet the criteria for generalized anxiety disorder, phobias, panic disorder, obsessive compulsive disorder, or all of these (Mancini et al. 1995; Mulder et al. 1998; Saunders et al. 1992).

Another common emotional sequel of childhood sexual abuse is anger; specifically, chronic irritability, unexpected or uncontrollable feelings of anger, difficulties associated with expressing anger, or all of these (Briere and Elliott 1994; Van der Kolk et al. 1994). During childhood and adolescence, anger is most likely to be reflected in behavioral problems such as fighting, bullying, or attacking other children (Chaffin et al. 1997; Garnefski and Diekstra 1997).

Sexual abuse also can damage a child's developing sense of self, with adverse long-term consequences. The development of a sense of self is thought to be one of the earliest developmental tasks of the infant and young child, typically unfolding in the context of early relationships (Alexander 1992). Thus, how a child is treated early in life critically influences his or her growing self-awareness. Childhood sexual abuse can interfere with this process, preventing the child from establishing a strong self image (Cole and Putnam 1992). Without a healthy sense of self, the person is unable to soothe or comfort himself or herself adequately, which may lead to overreactions to stressful or painful situations, and to an increased likelihood of re-victimization (Messman and Long 1996). Indeed, numerous studies have found high rates of sexual re-victimization (e.g., rape, coercive sexual experience) among individuals reporting a history of childhood sexual abuse (Fergusson et al. 1997; Urquiza and Goodlin-Jones 1994; Wyatt et al. 1992).

Avoidance is another major response to having been sexually abused. Avoiding activities among

victims may be viewed as attempts to cope with the chronic trauma and dysphoria induced by the abuse. Among the dysfunctional activities associated with efforts to avoid recalling or reliving specific memories are: dissociative phenomena, such as losing time, repression of unpleasant memories, detachment, or body numbing (APA 1994; Cloitre et al. 1997; Mulder et al. 1998; Nash et al. 1993); substance abuse and addiction (Arellano 1996; Briere 1988; Wilsnack et al. 1997); suicide or suicidal ideation (Briere and Runtz 1991; Saunders et al. 1992; Van der Kolk et al. 1991); inappropriate, indiscriminate, and/or compulsive sexual behavior (McClellan et al. 1996; Widom and Kuhns, 1996), (for reviews see Friedrich 1993; Kendall-Tackett et al. 1993; Tharinger 1990); eating disorders (Connors and Morse 1993; Douzinas et al. 1994; Schwartz and Cohn 1996; Wonderlich et al. 1997); and self-mutilation (Briere 1988; Briere and Elliott 1994). Each of these behaviors serve to prevent the individual from experiencing the considerable pain of abuse-specific awareness and thus reduces the distress associated with remembrance. However, avoidance and self-destructive methods of coping with the abuse may ultimately lead to higher levels of symptomatology, lower self-esteem, and greater feelings of guilt and anger (Leitenberg et al. 1992).

Numerous investigations have found a greater rate of borderline personality and dissociative identity (formerly multiple personality disorder) disorders among adult female survivors of childhood sexual abuse (Green 1993; Polusny and Follette 1995; Silk et al. 1997). Borderline personality disorder includes symptoms of impulsiveness associated with intense anger or suicidal, self-mutilating behavior, and affective instability with depression which are typical sequelae in sexually abused children and in adult survivors of sexual abuse (APA 1994). Childhood trauma, especially continued sexual abuse, is an important etiological factor in many cases of dissociative identity disorder, the most extreme type of dissociative reaction (APA 1994).

Finally, interpersonal difficulties and deficient social functioning often are observed among individuals who have been sexually abused (Briere 1992b; Cloitre et al. 1997). Such difficulties stem from the immediate cognitive and conditioned responses to victimization that extend into the longer term (e.g., distrust of others), as well as the

accommodation responses to ongoing abuse (e.g., passivity). Often, victims of childhood sexual abuse know the perpetrator, who might be a family member, clergy, or friend of the family. The abuse is thus a violation and betrayal of both personal and interpersonal (relationship) boundaries. Hence, it is not surprising that many children and adults with a history of childhood sexual abuse are found to be less socially competent, more aggressive, and more socially withdrawn than their nonabused peers (Cloitre et al. 1997; Mannarino et al. 1991; Mullen et al. 1994).

Among adults, interpersonal difficulties are manifested in difficulties in establishing and maintaining relationships (Finkelhor et al. 1989; Liem et al. 1996) and in achieving sexual intimacy (Browne and Finkelhor 1986; Mullen et al. 1994). Children who have been sexually abused are more likely to exhibit increased or precocious sexual behavior, such as kissing and inappropriate genital touching (Cosentino et al. 1995).

The consequences of childhood sexual abuse can be quite severe and harmful. However, it is important to note that an estimated 10 to 28 percent of persons with a history of it report no psychological distress (Briere and Elliott 1994; Kendall-Tackett et al. 1993). This raises the question of why some persons exhibit difficulties while others do not. Research addressing this question has found the following to be important mediators of individual reactions to childhood sexual abuse:

- *Age at onset of abuse.* Although further elucidation is needed, the available evidence suggests that postpubertal abuse is associated with greater trauma and more severe adverse sequelae than is prepubertal abuse (Beitchman et al. 1992; Browne and Finkelhor 1986; McClellan et al. 1996; Nash et al. 1993);
- *Gender of the victim.* One of the main findings in this area is that male victims appear to show greater disturbances of adult sexual functioning (Beitchman et al. 1992; Dube and Herbert 1988; Garnefski and Diekstra 1997);
- *Relationship to perpetrator.* Abuse involving a father or father figure (e.g., stepfather), which accounts for an estimated 25 percent of all cases (Sedlak and Broadhurst

1996), is associated with greater long-term harm (Browne and Finkelhor 1986; Gold 1986);

- *Duration and frequency of abuse.* In general, the greater the frequency and duration of abuse, the greater the impact on later psychological and social functioning (Nash et al. 1993);
- *Use of force.* The use of force or threat of force is associated with more negative outcomes (Kendall-Tackett et al. 1993);
- *Penetration or invasiveness.* Penetrative abuse is generally associated with greater long-term harm than are most other forms of abuse (Kendall-Tackett et al. 1993); and
- *Family characteristics and response to abuse disclosure.* Individuals who have been abused are more likely to originate from single-parent families, families with a high level of marital conflict, and families with pathology (e.g., parent is an alcoholic, violence between parents, maternal disbelief, and lack of support); all of which are associated with a poorer outcome and greater levels of distress (Beitchman et al. 1992; Draucker 1996; Green 1996; Romans et al. 1995).

CROSS-CULTURAL ISSUES

This review has focused exclusively on studies done in the United States. This is important to keep in mind because the nature of abuse varies according to one's cultural belief system (Gough 1996). As a result, attempts to compare societies on the basis of their care of children or the extent of violence in family relations are fraught with problems (Gough 1996b; Levinson 1989). In addition, methodological factors, such as the questions asked and how childhood sexual abuse is defined and measured, hamper the ability to make direct comparisons among the rates across different countries. All that can be surmised, to date, is that it is not a phenomena just of the United States, but is an international problem (Finkelhor 1994b). Finkelhor's synthesis indicates that most countries have rates similar to those found in the United States and that females are abused at a greater rater than males.

Nonetheless, cross-cultural studies can shed new light on the origins and impact of sexual abuse (Leventhal 1998; Runyan 1998). Such investigations may enable us to understand better the relative importance of different factors that influence the occurrence of abuse and teach us about societies that have been successful at protecting children. Intercultural comparative investigations can also help us appreciate the range of sexual behaviors that are, or can be considered "normal," and thereby contribute to a better understanding of abnormality in childhood sexual behavior and adult behaviors toward children.

It is not surprising that definitions of abuse not only vary within a culture, but also between cultures. The meaning of "abuse," especially, depends upon ideas of individual rights and roles and responsibilities between people and groups within society (Gough 1996a). How a child is viewed will influence what is evaluated as abuse. Definitions of child abuse would be quite different, for example, in a feudal state in which children are considered to be their parents' possessions. Cultural expectations about sexual interactions among adolescents and between different age groups will also affect whether particular practices are defined as abuse (Abramson and Pinkerton 1995). Among the Sambia people of the highlands of Papua, New Guinea, for example, all young boys are expected to participate in ritualized fellatio with older boys as part of their initiation into manhood (Abramson and Pinkerton 1995). In essence, the younger boys are forced to submit; thus, this practice fulfills the two main criteria for childhood sexual abuse as defined above (coercive sex with a child or adolescent). Nevertheless, the Sambia consider ritualized fellatio to be critical for survival (they believe that semen is the source of manly strength and that it must be obtained through ingestion).

Definitions of abuse can also be expected to change over time to reflect societal changes. For instance, anecdotal evidence suggests that in Victorian England it was considered acceptable for a nurse or nanny to quiet a male infant by putting his penis in her mouth (Abramson and Pinkerton 1995). Today, this practice would clearly be considered childhood sexual abuse. The recent broadening of definitions of abuse has been accompanied by a greater sensitivity to signs of abuse that fit these changing definitions, and a greater willingness for professionals and others to intervene

into the private family lives of others, or beyond the walls of institutional life, and so to offer greater visibility of children's experiences (Gough 1996a).

DIRECTIONS FOR FUTURE RESEARCH

Perusal of the literature in this domain suggests several avenues for future studies. First and foremost, large-scale, longitudinal investigations of child victims are needed that examine global functioning, abuse-specific functioning, and attributional and coping strategies along with abuse, child, family, and community factors. Such studies could provide information about both the initial effects of sexual abuse and the factors that influence adjustment at later developmental stages and into adulthood. Because not all victims of childhood sexual abuse develop adjustment problems, a better understanding of who is likely to experience such problems is needed.

Second, further research is needed regarding the efficacy of various approaches for the treatment of related problems (see Cosentino and Collins 1996; O'Donohue and Elliot 1993 for reviews). The utility or effectiveness of any particular treatment modality has yet to be demonstrated using a large-scale, randomized study in which treatment outcomes are measured using standardized instruments and untreated control groups. Consequently, treatment decisions often are made by clinicians without empirically tested guidelines.

Third, greater attention needs to be paid to methodological rigor in the conduct of childhood sexual abuse studies (Green 1993; Plunkett and Oates 1990; Trickett and McBride-Change 1995). In particular, investigators need to: (1) define it clearly and consistently; (2) use instruments with documented psychometric properties; (3) use control or comparison groups, when appropriate; and (4) employ large sample sizes whenever this is feasible. Studies of treatment modalities should also conduct multiple follow-up assessments to determine whether intervention effects are sustained over time. Finally, studies are needed that clearly disentangle the effects of sexual abuse from other forms of abuse or maltreatment.

SUMMARY

Childhood sexual abuse is a significant and widespread problem in our society, no matter how it is

defined. Since it was first brought to the public's attention in the 1960s, a vast amount of research has been conducted in an effort to understand its impact on victims. From the various reviews on the topic, several conclusions can be drawn. First, despite the considerable heterogeneity among sexual abuse victims, as a group, sexually abused children and adolescents tend to display significantly higher levels of symptomatology than their nonabused, nonclinic-referred peers. Second, compared to other clinic-referred children, two problem areas appear to differentiate sexually abused children and adolescents: post-traumatic stress disorder symptomatology and sexuality problems. Third, the type and severity of sequelae experienced by victims depends on the specific characteristics of the abuse situation and the perpetrator. Fourth, research on adult survivors suggest that abuse-related problems tend to persist into adulthood. Indeed, childhood sexual abuse histories are common among several clinical populations, including patients initially diagnosed as depressed or as having a borderline personality disorder.

Taken together, these findings suggest that clinicians and health care providers should screen for sexual abuse among children, adolescents, and adults. For instance, questions about childhood sexual abuse could become part of routine intake procedures. Moreover, it is important that a wide range of service providers are sensitive to, and have staff trained to deal with, issues of childhood sexual abuse when it emerges. Service providers' policy and practice guidelines should explicitly acknowledge the prevalence and impact of it on women, men, and children.

Schools also need to have greater involvement in the prevention and diagnosis of childhood sexual abuse, especially since it generally occurs between the ages of six and twelve (Finkelhor 1994a; Sedlak and Broadhurst 1996). School-based education programs may be a useful vehicle for intervention and prevention. Teachers need to be educated and trained about their role in recognizing and reporting suspected cases.

Finally, further community awareness is needed to help prevent it from occurring. Greater community efforts toward providing treatment services for persons with a history of childhood sexual abuse are needed as are programs targeting

potential perpetrators. Society must work together to stamp out this abhorrence and to assist its survivors.

Preparation of this article was supported in part by a training grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services (MCJ 9040). The author thanks Steven D. Pinkerton, Ph.D. for his helpful comments on this manuscript.

CHINA STUDIES

The sociological study of China has a complex history. It could be argued that Confucian thought embodied a native tradition of sociological thinking about such things as the family, bureaucracy, and deviant behavior. However, modern Chinese sociology initially had foreign origins and inspiration. The appearance of the field in China might be dated from the translation of parts of Herbert Spencer's *The Study of Sociology* into Chinese in 1897. The earliest sociology courses and departments in China were established in private, missionary colleges, and Western sociologists such as D. H. Kulp, J. S. Burgess, and Sidney Gamble played central roles in initiating sociology courses and research programs within China (see Wong 1979).

The Chinese Sociological Association was established in 1930, and in the following two decades a process of Sinification progressed. Chinese sociologists, trained both at home and in the West, emerged. Sociology courses and departments began to proliferate in government-run, public colleges. Increasingly, texts using material from Chinese towns and villages displaced ones that focused on Chicago gangs and the assimilation of Polish immigrants into America. As this process of setting down domestic roots continued, Chinese sociology developed some distinctive contours. Inspiration for the field came as much from British social anthropology as from sociology. The crisis atmosphere of the 1930s and 1940s fostered a strong emphasis on applied, problem-solving research. As a result of these developments, Chinese sociology in those years came to include what in the United States might be considered social anthropology and social work. Within these broad contours, Chinese sociologists/anthropologists produced some of the finest early ethnographies of

“nonprimitive” communities—Chinese peasant villages (see Fei 1939; Yang 1944; Lin 1948).

Although many of the earliest leaders in establishing Chinese sociology were foreigners, by the time of the Chinese communist victory in 1949, its leading practitioners were Chinese. There were only a small number of Western sociologists who concentrated their research on Chinese society (see Lang 1946; Levy 1949), and their methods, problems, and data were not distinctive from those being employed by their Chinese counterparts. Originally a foreign transplant, Chinese sociology had become a thriving enterprise with increasingly strong domestic roots.

When the Chinese Communist Party (CCP) swept to national power in 1949, some Chinese sociologists left the country but most remained. (The development of sociology in the Republic of China on Taiwan after 1949 will not be dealt with here.) Initially, those who remained were optimistic that their skills would be useful to the new government. Experience in community fieldwork and an orientation toward studying social problems seemed to make Chinese sociologists natural allies of those constructing a planned social order. These hopes were dashed in 1952 when the CCP abolished the field of sociology. That decision was motivated by the CCP’s desire to follow the Soviet model. Joseph Stalin had earlier denounced sociology as a “bourgeois pseudo-science” and banned the field from Soviet academe. More to the point, there was no room in the People’s Republic of China (PRC) for two rival sciences of society, Marxism-Leninism-Maoism and sociology. The CCP argued that it had developed its own methods of “social investigations” during the revolutionary process, with Mao Zedong playing a leading role in this development (see Mao [1927] 1971; Thompson 1990). This approach stressed grass roots investigations designed to further official revolutionary or economic goals of the CCP rather than any sort of attempted value-free search for objective truth. Chinese sociologists, trained in a different tradition and able to use professional claims to raise questions about CCP policies, were seen as a threat to the ideological hegemony of the new regime.

The ban on sociology in China was to last twenty-seven years, until 1979. One major attempt was made by Chinese sociologists in 1956 and

1957 to get the ban lifted. In the more relaxed political atmosphere prevailing at that time, ushered in by the CCP’s slogan “let 100 flowers bloom and 100 schools of thought contend” and encouraged by the revival of sociology in the Soviet Union, leading figures such as Fei Xiaotong, Pan Guangdan, Wu Jingchao, and Chen Da wrote articles and made speeches arguing that sociology could be useful to socialist China in the study of social change and social problems—precisely the same rationale used prior to 1952. When the political atmosphere turned harsh again in the latter part of 1957, with the launching of the “anti-rightist campaign,” Fei and many of the other leaders of this revival effort were branded “rightist elements” and disappeared from view.

From 1952 to 1979 some of those trained in sociology were assigned to work that had some links to their abolished field. Throughout this period ethnology remained an established discipline, devoted to the study of China’s various ethnic minorities. When Fei Xiaotong emerged from his political purgatory in 1972, it was as a leading figure in ethnology. But Fei and others could not do research on the 94 percent of the population that is Han Chinese, and they also had to renounce publicly all their former work and ideas as “bourgeois.” Psychology survived better than sociology by becoming defined as a natural, rather than a social, science. Some areas of social psychology (for example, educational psychology) remained at least somewhat active through the 1960s and 1970s (see Chin and Chin 1969). Other components of sociology disappeared in 1952 but reappeared prior to 1979. Demography was established as a separate field in the early 1970s and remains a separate discipline in Chinese academe today. With these partial exceptions, however, Chinese sociology ceased to exist for these twenty-seven years.

While sociology was banned in China, the sociological study of that society developed gradually in the West. Starting in the late 1950s, American foundations and government agencies, and to some extent their European and Japanese counterparts, provided funds for the development of the study of contemporary China—for fellowships, research centers, journals, language training facilities, and other basic infrastructure for the field. Within this developmental effort, sociology was

targeted as an underdeveloped discipline (compared to, say, history, literature, and political science) deserving of special priority. Stimulated by this developmental effort, during the 1960s and 1970s the number of Western sociologists active in the study of China increased from a handful to perhaps two dozen.

Prior to the early 1970s, with a few minor exceptions (e.g., Geddes 1963), it was impossible for foreign sociologists to travel to China, much less to do research there. Even when such travel became possible during the 1970s, it was initially restricted to very superficial “academic tourism.” In this highly constrained situation, foreign sociologists studying China developed distinctive research methods.

Much research was based on detailed culling of Chinese mass media reports. Special translation series of Chinese newspapers and magazines and of monitored radio broadcasts developed in the 1950s and became the mainstays of such research. The Chinese media provided fairly clear statements about official policy and social change campaigns. By conveying details about local “positive and negative models” in the implementation of official goals, the media also provided some clues about the difficulties and resistance being encountered in introducing social change. In a few instances the media even yielded apparently “hard” statistical data about social trends. A minor industry developed around scanning local press and radio reports for population totals, and these were pieced together to yield national population estimates (typically plus or minus 100 million).

Some researchers developed elaborate schemes to code and subject to content analysis such media reports (see, for example, Andors 1977; Cell 1977). However, this reliance on media reports to study Chinese social trends had severe limits. Such reports revealed much more about official goals than they did about social reality, and the researcher might erroneously conclude that an effort to produce major changes was actually producing them. The sorts of unanticipated consequences that sociologists love to uncover were for the most part invisible in the highly didactic Chinese media. It was also very difficult to use media reports to analyze variations across individuals and communities, the staple of sociological analysis elsewhere. Studies based on media reports tended to convey

an unrealistic impression of uniformity, thus reinforcing the prevailing stereotype of China as a totalitarian society.

Partly in reaction to these limitations, a second primary method of research on China from the outside developed—the refugee interview. Scholars in sociology and related fields spent extended periods of time in Hong Kong interviewing individuals who had left the PRC for the British colony. Typically, these individuals were used not as respondents in a survey but as ethnographic informants “at a distance” about the corners of the Chinese social world from which they had come. Although the individuals interviewed obviously were not typical of the population remaining in the PRC, for some topics these refugees provided a rich and textured picture of social reality that contrasted with the unidimensional view conveyed by Chinese mass media. Elaborate techniques were developed by researchers to cope with the problems of atypicality and potential bias among refugee informants (see Whyte 1983).

By combining these methods with brief visits to China, sociologists and others produced a large number of useful studies of contemporary mainland society (Whyte, Vogel, and Parish 1977). Even though the arcane methods they used often seemed to nonspecialists akin to Chinese tea-leaf reading, the best of these studies have stood the test of time and have been confirmed by new research made possible by changes in China since 1979. However, the exclusion from meaningful field research in China did have unfortunate effects on the intellectual agendas of researchers. Much energy was focused on examining the “Maoist model” of development and whether or not China was succeeding in becoming a revolutionary new type of social order. Since the reality of Chinese social organizations in the Maoist period was quite different from the slogans and ideals upon which such constructions were based, this effort appears to have been a waste of scarce intellectual resources. Both this unusual intellectual agenda and the distinctive research methods sociologists studying China were forced to use reinforced the isolation of these researchers from “mainstream” work in sociology.

The year 1979 was significant in two ways for the sociological study of China. First, as already noted, that was the year in which China’s leaders

gave approval for the “rehabilitation” of sociology. After the death of Mao Zedong in 1976, and given the authority crisis that followed in the wake of the Cultural Revolution, the post-Mao leadership reopened many issues. China faced a number of serious social problems that had been ignored previously, and in this situation long-standing arguments about the utility of sociology for the study of social problems could be raised once again.

The second major change that occurred in 1979 was the “normalization” of diplomatic relations between the United States and China. That development led to approval for American and other Western researchers to conduct extended field research in China for the first time since 1949. The days of frustrating confinement to research from outside and academic tourism were over. It also became possible for U.S. sociologists to meet Chinese counterparts and to begin to discuss common research interests and plans for collaboration. Westerners began coming to China to teach sociology courses, Chinese began to be sent abroad for training in sociology, and collaborative conferences and publications were initiated. Leading figures in the West, including Peter Blau, Alex Inkeles, Nan Lin, W. J. Goode, Hubert Blalock, and Jeffrey Alexander, lectured in China and recruited Chinese counterparts for collaborative research and for training in their home institutions. All of the kinds of intellectual interchange between Chinese sociologists and their foreign counterparts that had been impossible for a generation were resumed.

The dangerous political aura surrounding sociology in the Mao era and the lesson of the abortive 1957 attempt to revive the field might have been expected to make it difficult to attract talented people to Chinese sociology after 1979. However, the field revived very rapidly and showed surprising intellectual vigor. A number of surviving pre-1949 sociologists reappeared to play leading roles in the revival, considerable numbers of middle-aged individuals trained in related fields were recruited (or ordered) to become sociologists, and many young people expressed eagerness to be selected for training in the field. The Chinese Sociological Association was formally revived, with Fei Xiaotong as its head. (Fei “unrenounced” his pre-1949 works, weakened his ties with ethnology, and resumed advocacy of the program of Chinese

rural development he had championed a generation earlier.) A number of departments of sociology were established in leading universities, and new sociological journals and a large number of monographs and textbooks began to appear. Institutes of sociology were established within the Chinese Academy of Social Science in Peking as well as in many provincial and city academies. Apparently, the novelty of the field, the chance to make a place for oneself, and perhaps even the chance to study abroad without having to face competition from layers of senior people more than compensated for the checkered political past of sociology. In any case, the speed and vigor with which the field revived surprised the skeptics (see Whyte and Pasternak 1980).

The intellectual focus of the revived sociology was fairly broad. Social problems and the sociology of development were two major foci. Within these and other realms, two sets of issues loomed large. One was the study of the after-effects of the Cultural Revolution and the radical policies pursued under Mao Zedong in the period 1966 to 1976. The other major issue concerned the impact of the opening to the outside world, decollectivization of agriculture, and the market-oriented reforms launched in 1978. A large number of studies began on these and other issues, and by the end of the 1980s the problem facing foreign sociologists studying China was not so much the scarcity of data on their object of study but its abundance. The publication of large amounts of statistical material, the availability of census and survey data dealing with demographic and other matters, and the mushrooming of social science publications threatened to overwhelm those who tried to keep track of Chinese social trends.

In pursuing their new intellectual agendas, Chinese sociologists easily found common ground with Western specialists. The latter were no longer so entranced with the Maoist model and shared a fascination with the social impact of the post-Mao changes. Many Western specialists readily adapted to the chance to conduct research in China and to collaborate with Chinese colleagues. Hong Kong did not die out as a research site and remained vital for some topics, but work from outside China was increasingly seen as supplementary to research conducted within the country. (After 1997 and Hong Kong’s reversion to China this was still the

case, as the special autonomy enjoyed by the former British colony produced a freer research atmosphere than in the rest of the country.) China specialists now had to share the stage with many sociologists who did not have area studies training. With data more readily available and collaboration with Chinese counterparts possible, area studies training and familiarity with the arcane techniques developed in the 1960s and 1970s were no longer so important. Many non-China specialists found the opportunity to study the world's most populous society increasingly attractive. These changes have been beneficial for China specialists within sociology. Given their small numbers and the complexity of Chinese society, there is more than enough "turf" to be shared with sociologists not trained in China studies. And these changes have reduced the intellectual isolation of the specialists, from both colleagues in China and those in their own departments.

As a result of these changes, Chinese sociologists ended their isolation from world sociology, and Western sociologists conducting research on China escaped from a highly constrained environment and began to produce work that was less idiosyncratic. It should be noted, however, that sociological research in China is not without limits, either for foreign researchers or for Chinese. Even in the most liberal phases of the initial reform decade from 1979 to 1989, some topics remained taboo, some locales were off limits, and bureaucratic obstruction and interference were constant facts of life. Nonetheless, even for foreigners it became possible to conduct extended ethnographic studies, carry out probability sample surveys, and gain access for secondary analysis to the raw data from census and survey studies conducted by Chinese, experiences that those who were studying the Soviet Union before its collapse could only envy. The result was a new spurt of research activity and publication that enriched our knowledge of Chinese social life immensely. (For a review of Western research during the decade after 1979, see Walder 1989. For an overview of developments within Chinese sociology during that period, see Lu 1989.)

However, the political fallout from the 1989 Tiananmen massacre raised new problems for the sociological study of China. At least some conservatives within the Chinese leadership used the

crackdown following the massacre to attack sociology and other newly revived social sciences in terms reminiscent of 1952 and 1957. The field was once again accused of being an ideological Trojan horse designed to spread doubts about socialist orthodoxy. Some sociology departments were not allowed to enroll new students, while others had their enrollment targets cut. While these restrictions eased after a year or two, new and serious threats to collaborative research projects continued through the 1990s. Edicts designed to restrict and maintain strict political control over survey projects involving foreign collaboration were passed in secret in 1990 and 1995, resulting in the confiscation of survey data already collected in one instance and delays and torpedoing of projects in others. (The data confiscated after the 1990 secret edict were eventually released to the researchers involved, and other stalled projects resumed, but only after several years of tense negotiations.) In 1998 an international collaborative survey project in social gerontology was publicly attacked within China for allegedly endangering the health of China's elderly and having a concealed aim of enabling foreigners to profit from the "genetic secrets" of the Chinese people. Only after a vigorous public defense from both foreign and Chinese researchers was the disputed project saved. These developments mean that researchers who embark on sociological research within China on even quite nonpolitical topics face some risk that they will not be able to complete their projects due to political interference.

Despite the unpredictable political environment, Chinese and foreign sociologists pressed ahead with a wide-ranging variety of research activities during the 1990s. The success of this effort is a testament to the increasingly robust ties linking Chinese and foreign sociologists. During the 1980s large numbers of aspiring young Chinese sociologists were sent abroad for doctoral training, primarily to the United States. By the latter part of that decade and into the 1990s, a majority of the Western sociology doctoral theses dealing with China were being produced by students from China. After the 1989 Tiananmen massacre most of these newly minted specialists on Chinese society did not return to China, but instead embarked on research careers in the West. However, mindful of the desirability of leaving the door open for their eventual return, China did not treat this

decision as disloyalty, but instead in most instances encouraged and invited these foreign-based Chinese sociologists to visit China to assist in the development of the discipline there and to undertake collaborative research projects. These young, foreign-trained sociologists are able to come and go and to navigate the complex political and bureaucratic terrain surrounding sociological research within China much more easily than their non-Chinese counterparts. Furthermore, the relatively smaller number of Chinese sociologists trained abroad who have returned to the PRC usually have found their new skills and contacts valued and rewarded, rather than treated with envy and suspicion. Many of these individuals are moving up rapidly into positions of responsibility and leadership within Chinese research institutes and universities, where they are generally able to keep research projects moving ahead despite bureaucratic obstacles. As a result of these trends, an increasing share of the new sociological research initiatives and publications that are having an impact on China studies in the West involve sociologists from China, whether currently based abroad or within China.

The changing sources of funding for research on Chinese society also are having an impact. Whereas in the past most research by Chinese social scientists was funded by the Chinese government and was responsive to state priorities and concerns, in the reform era Chinese sociologists and others in China face increasing constraints on government funding of research. New competitive peer review procedures are being introduced to determine who gets scarce research funds, and Chinese authorities encourage research institutes and researchers to find ways to raise or obtain funds on their own to support their research. In this altered environment a variety of Western and international sources of funding—from United Nations agencies, the World Bank, the Ford Foundation, foreign nongovernmental organizations, etc.—have become important in financing research that Chinese sociologists otherwise could not carry out. This changed funding picture thus reinforces other trends that are strengthening the links between sociology within China and abroad.

While the topics pursued within the sociological study of China in the 1990s were varied, the dominant focus was still on the process of market reforms. Some of the impetus for this focus came

from a comparison with developments in the former Soviet Union and its satellites. Sociologists have joined others in trying to understand why to date the dismantling of central planning and the introduction of market reforms have generally been much more successful in China than in Eastern Europe (see, for example, Rozman 1992; Walder 1996a). The bulk of this research, however, looks not at the causes, but at the social consequences of the reforms, and here the concerns are varied and wide-ranging. For example, spirited debates have arisen about whether or in what respects the reforms are contributing to increased inequality within China, and about whether prereform political elites are largely monopolizing the gains produced by the reforms or are being displaced increasingly by new elites (see, for example, Nee 1996; Xie and Hannum 1996; Walder 1996b; Bian and Logan 1996; Zhou, Tuma, and Moen 1996; Buckley 1997). Sociologists and others are also examining the new entrepreneurial class arising within China as a result of market reforms to determine what sorts of social origins they have, and researchers on this topic debate whether these entrepreneurs are a force for political change or are, instead, co-opted and controlled as a result of their dependence upon the state (see, for example, Unger 1996; Nevitt 1999). Research on the latter theme is part of a larger exploration of whether China's reforms are leading to the development of institutions of a "civil society" that might eventually lead to the democratization of China's political system (see Whyte 1992; White 1993). Within research on Chinese stratification there is also a growing body of work considering whether, on balance, the reforms have been harmful or beneficial in terms of the quest for gender equality (see Bauer et al. 1992; Croll 1994; Lee 1998; Entwisle and Henderson forthcoming). Another major focus of research concerns changes in Chinese family life, with the investigation of topics such as rising divorce and premarital sex rates and whether such trends indicate that Chinese family patterns are increasingly "converging" toward the patterns found in other societies (e.g. Xu and Whyte 1990; Davis and Harrell 1993; Logan, Bian, and Bian forthcoming). Still another major focus is on tracing the impact of particular reform changes—for example, the relaxation of migration restrictions that have allowed tens of millions of rural migrants to flood into China's cities, the attempt to revive labor markets as a way of

distributing jobs, and the layoffs and unemployment being generated by reforms of China's inefficient state-owned enterprises (e.g. Bian 1994; Guthrie 1997; Matthews 1998) Solinger 1995; Sensenbrenner 1996.

Another primary research focus of China sociologists, in addition to the causes and consequences of the post-1978 economic reforms, involves China's dramatic fertility decline and its social consequences. The transformation of China from a society with moderately high fertility (total fertility rates of 5+) to extraordinarily low rates (total fertility rates under 2) has occurred in roughly the same time period as China's economic reforms (from the 1970s through the 1990s), but these two fundamental changes have been produced by contradictory processes. Whereas in economic affairs the state has increasingly withdrawn from bureaucratic management and has allowed markets to govern distribution, in regard to population the state has shifted away from indirect management and persuasion in favor of direct bureaucratic mandating of fertility quotas. The high national priority of this fertility reduction program has complex implications, in terms of sociological research. High priority, combined with recurring foreign criticism of China's human rights record in the realm of family planning (see Whyte 1998), produce political sensitivities that often obstruct and constrain research on this topic. However, that same priority has made research on topics related to fertility so important that foreign as well as Chinese demographers and others have been recruited to help plan and carry out a large number of high-quality surveys of China's demographic dynamics. These data have also in most instances been made available for examination by foreign as well as Chinese researchers. On balance the result has been a boom in research on China's population and a much better understanding of current trends in fertility, mortality, and other demographic domains than existed prior to the 1980s (see, for example, Banister 1987; Coale 1984; Feeney and Yuan 1994; Riley and Riley 1997).

In sum, recurring political turbulence in China has in some cases obstructed and delayed sociological research, but both the field and its practitioners have continued to forge ahead despite the uncertainties involved. The rapid and complex social changes that have occurred in China in the

1980s and 1990s have provided many new research questions for sociologists to explore, and a maturing network of Chinese sociologists and foreign China specialists (and nonspecialist sociologists interested in studying the world's most populous and most rapidly developing society) have taken advantage of new research opportunities. As a result of these changes the sociological study of China at the end of the 1990s was much better established than it was two decades earlier, with a wide variety of social processes and trends better studied and more fully understood.

CITIES

A *city* is a relatively large, dense, permanent, heterogeneous, and politically autonomous settlement whose population engages in a range of nonagricultural occupations. Definitions of cities and their associated phenomena vary by time and place, and by population size, area, and function (Shryock, Siegel, and associates 1976, pp. 85–104). The city is often defined in terms of administrative area, which may be larger than, smaller than, or equal to the area of relatively dense settlement that comprises what is otherwise known as the city proper. The suburb is a less dense but permanent settlement that is located outside the city proper and contains populations that usually have social and economic ties to the city.

Definitions of urban vary by nation; in the United States the term refers to populations of 2,500 or more living in towns or cities and to populations living in urbanized areas, including suburbs. In other nations, the lower limits for settlements defined as urban vary between 200 and 50,000 persons. United Nations definitions of urban areas emphasize a population of 20,000 or more, and cities a population of 100,000 or more. *Urbanization* refers to the economic and social changes that accompany population concentration in urban areas and the growth of cities and their surrounding areas.

Cities reflect other areas with which they are linked and the civilizations of which they are a part. Cities are centers of markets, governments, religion, and culture (Weber 1958, pp. 65–89). A *community* is a population sharing a physical environment and leading a common and interdependent life. The size, density, and heterogeneity of the urban community have been described as leading to “urbanism as a way of life,” which includes organizational, attitudinal, and ecological components different from those of rural areas (Wirth 1938).

THE CITY IN HISTORY

Town and city development has been described as tied to a technological revolution in agriculture that increased food production, thereby freeing agriculturalists to engage in nonagricultural occupations. This resulted in an evolution to urban

living and eventually to industrial production (Childe 1950). A second view is that some towns and cities first developed as trade centers, and were then nourished by agricultural activity in their hinterlands (Jacobs 1970).

Increasing complexity of social organization, environmental adaptation, and technology led to the emergence of cities (Child 1950; Duncan 1964). Excluding preagricultural settlements, towns and then cities were first established in the fourth to third millennium B.C. in ancient Mesopotamia within the Tigris and Euphrates river valleys, in the Harappa civilization in the valleys of the Indus River and its tributaries, and in the Egyptian Old Kingdom in the lower Nile valley. Other centers appeared in the Huang Ho basin on the east coast of China and the Peruvian Andes in the second to first millennium B.C., and in Mesoamerica in the first millennium B.C. (Phillips 1997, pp. 82–85).

Small agricultural surpluses and limits on transportation meant that the first towns were small and few in number, and contained only a small proportion of the populations of their regions. Economic activities of the earliest towns were tied largely to their surrounding areas. After the rise of towns in the Middle East, trading centers appeared on the shores and islands of the Mediterranean; some, such as Athens, became city-states. After developing more effective communication and social organization, some Western city-states expanded and acquired empires, such as those of Alexander the Great and of Rome. Following the decline of Rome, complex city life continued in the East and in the West in the Byzantine and Muslim empires, while the population of Europe declined and reverted, for the most part, to subsistence agriculture and organized into small territories held together by the Catholic Church (Hawley 1981, pp. 1–35).

Sjoberg (1960) has described preindustrial cities as feudal in nature and sharing social, ecological, economic, family, class, political, religious, and educational characteristics different from those in modern industrial cities. In the former, the city center, with its government and religious and economic activities, dominated the remainder of the city and was the locale of the upper social classes. Homogeneous residential areas were found throughout the city, but nonresidential activities

were not confined to distinct neighborhoods (Sjoberg 1960).

Beginning in the tenth century, further town development in the West was facilitated by increases in agricultural technology, population, trade, and communication; the rise of an entrepreneurial class; and an expanding web of social norms regarding economic activity. Communication and manufacturing were revived, which led to the growth of towns with local autonomy and public administration, and eventually to networks of cities. Surplus rural populations migrated to towns and cities, which grew because of their specialization and larger markets, becoming focal points of European societies (Hawley 1981, pp. 37–83).

The emergence of a global economy structured city development (Lo and Yeung 1996, pp. 1–13). In the thirteenth and fourteenth centuries, some European central place and port cities, such as those of the Hanseatic League of Northern Europe, established commercial links with others. Meanwhile, other cities in the Eastern Hemisphere and some cities in the Western Hemisphere were linked together by long-distance trade routes transcending the boundaries of empires and states (Wolfe 1982, p. 250). Military-commercial alliances facilitated the incorporation of territories into states. Commercial ties expanded during the late-fifteenth and the sixteenth centuries, as Europeans developed merchant capitalism, and traded with and colonized peoples on other continents. European and North American states developed more complex economies during the next three centuries, facilitating development of a “European world economy” with a global market, a global division of labor, and a global system of cities (Wallerstein 1974).

WESTERN CITIES SINCE THE INDUSTRIAL REVOLUTION

In most regions of the more developed world, urban growth and urbanization have occurred at an increasing rate since the beginning of the Industrial Revolution. After 1820, the numbers and sizes of urban areas and cities in the United States increased as a result of employment concentration in construction and manufacturing, so urban areas began to grow more rapidly than rural ones.

The population classified as urban by the U.S. Census Bureau (based on aggregations of 2,500 or more and including the surrounding densely populated territories) increased from 5 percent in 1790 to 75 percent in 1990. In 1790 the largest urban place in the United States had fewer than 50,000 inhabitants. As late as 1840, not a single urban place in the United States had more than half a million inhabitants. There were four such places in 1890, fourteen in 1940, twenty-two in 1980, and twenty-three in 1990 (U.S. Bureau of the Census 1997, p. 44).

City growth in the United States during the nineteenth century was driven by migration, since there were sometimes excesses of urban deaths over births in the early part of that century and lower birthrates in the last part of that century. Population concentration facilitated greater divisions of labor within and among families and individuals, as well as increasing numbers of voluntary associations centered on new urban interests and problems. At first, cities were compact, growth was vertical, and workers resided near their workplaces. The outward expansion of the residential population was facilitated in the last part of the century by steam and electric railways, the outward expansion of industry, and the increasing role of the central business district in integrating economic activities (Hawley 1981, pp. 61–145).

The increasing scale of production in the United States led to the development of a system of cities that organized activities in their hinterlands. Cities were differentiated from each other by their degree of dominance over or subordination to other cities, some of which were engaged in centralized manufacturing, others of which depended on transportation, commercial, administrative, or other functions. According to Hawley (1986), cities may have certain key functions that dominate other cities, that is, integrating, controlling, or coordinating activities with these cities. Examples of key functions are administration, commerce, finance, transportation, and communication (Duncan et al. 1960). Since each city exists within its own organizational environment, the expansion of linkages of urban organizations has accompanied the development of a system of cities (Turk 1977).

In the United States, the nature of key functions in city systems changed with the expansion of

settlements westward, as colonial seaports, river ports, Midwestern railway towns, central places on the Great Plains, extractive centers, and government centers were integrated into an urban system. A nationwide manufacturing base was established by 1900, as were commercial and financial centers. By 1960 a fully developed system of differentiated urban centers existed within the United States (Duncan and Lieberman 1970).

METROPOLITAN AREAS

In the United States, metropolitan areas are defined as being of two kinds. *Metropolitan statistical areas* (MSAs) are areas including one or more central cities with a population of 50,000 or more, or areas with a less densely populated central city but with a combined urban population of at least 100,000 (75,000 in New England), including surrounding counties or towns. *Consolidated metropolitan statistical areas* (CMSAs) contain at least one million population and may have subareas called *primary metropolitan statistical areas* (PMSAs) (Frey 1990, p. 6). In 1990 a majority of the population of the United States resided in the thirty-nine major metropolitan areas: those with more than one million population (Frey 1995, p. 276).

New urban-population-density patterns appeared in the United States with the development of metropolitan areas. Growth was characterized by increases in population density in central cities, followed by increases in density in the metropolitan ring. Transport and communication technologies facilitated linkages of diverse neighborhoods into metropolitan communities dominated by more densely populated central cities. These linkages in turn organized relationships between central cities and less densely populated hinterlands and subcenters. Older metropolitan areas became the centers of CMSAs, while newer areas were the frontiers of expansion, growing by natural increase and especially by net migration. Metropolitan sprawl extended beyond many former nonurban functions, as well as more centrally located older features of the cityscape.

The interior of large Western metropolitan areas represents a merging of urban neighborhoods into complex overlapping spatial patterns, which reflect to some extent the dates when urban neighborhoods were settled and built-up. The blurring of neighborhood distinctions, facilitated by

freeway and mass transit networks, facilitate interaction among “social circles” of people who are not neighborhood-based. Meanwhile, urban neighborhoods organized around such factors as status, ethnicity, or lifestyle, also persist. As the city ages, so does suburban as well as centrally located housing—a delayed consequence of the spread of urban settlement.

Kasarda (1995, p. 239) states that major cities in the United States have been transformed from centers of manufacturing and wholesale and retail trade, to centers of finance, administration, and information processing. Frey (1995, p.272) indicates that during the 1970s and 1980s populations concentrated in metropolitan areas with diverse economies that emphasized service and knowledge industries, as well as in recreation and retirement areas. In the 1970s there was a metropolitan and nonmetropolitan population turnaround. Populations in smaller metropolitan areas grew more rapidly than did those in larger metropolitan areas and population in developing countries grew more rapidly than in developed countries. In the 1980s, metropolitan population shifts, enhanced by international and internal migration, led to an urban revival, increasing regional racial, skill, and age divisions, the suburban dominance of growth and employment and more isolation of the urban core (Frey 1995, pp. 272–275).

Residential moves—the individual counterpart of population redistribution processes—are affected by population characteristics and other factors. Elements that influence mobility decisions are socioeconomic and psychological factors pertaining to the family and the family life cycle, housing and the local environment, and occupational and social mobility (Sabagh et al. 1969). For each of these factors, conditions may restrain persons from moving, or push or pull them to new locations. Information concerning new housing opportunities, the state of the housing market, and the availability of resources may impede or facilitate moves; subsequent moves may stem from recent migration or residential turnover in the metropolitan areas (Long 1988, pp. 219–224).

TRADITIONAL EXPLANATIONS OF CITIES

During the nineteenth century the character of the Western city was seen as different from that of

noncity areas. Beginning with the public-health movement and concerns with urban housing, social scientists documented “pathologies” of urban life through the use of social surveys, the purpose of which was to provide policy-relevant findings. But since “urbanism as a way of life” has permeated the United States, many of the social and economic problems of cities have spread into smaller towns and rural areas, thus rendering the notion of unique urban pathologies less valid than when it was formulated.

In the first six decades of the twentieth century, explanations of city development were based largely on Western human ecology perspectives, and disagreements have arisen (Sjoberg 1968, p. 455). Theories based on Social Darwinism (Park [1916–1939] 1952) and economics (Burgess 1925, pp. 47–52) were first used to explain the internal structures of cities. “Subsocial” aspects of social and economic organization—which did not involve direct interpersonal interaction—were viewed as generating population aggregation and expansion. Market related competitive-cooperative processes—including aggregation-thinning out, expansion-contraction, centralization, displacement, segregation, migration, and mobility—were believed to determine the structures and patterns of urban neighborhoods (Quinn 1950). The competition of differing urban populations and activities for optimal locations was described as creating relatively homogeneous communities, labeled “natural areas,” which display gradient patterns of decreasing densities of social and economic activities and problems with increasing distance from the city center.

On the basis of competitive-cooperative processes, city growth was assumed to result in characteristic urban shapes. The Burgess hypothesis specifies that in the absence of countervailing factors, the American city takes the form of a series of concentric zones, ranging from the organizing central business district to a commuters’ zone (Burgess 1925, pp. 47–52). Other scholars emphasized star-shaped, multiple-nuclei, or cluster patterns of development. These views were descriptive rather than theoretical; assumed a Western capitalist commercial-industrial city; were distorted by topography, and street and transportation networks; and generally failed to take into account use of land for industrial purposes, which is found in most city zones.

Theodorson (1982) and Michaelson (1976, pp. 3–32) have described research on American cities as reflecting neo-orthodox, social-area analysis, and sociocultural approaches, each with its own frame of reference and methods. Neo-orthodox approaches have emphasized the interdependence of components of an ecological system, including population, organization, technology, and environment (Duncan 1964). This view has been applied to larger ecological systems that can extend beyond the urban community. Sustenance organization is an important focus of study (Hawley 1986). While neo-orthodox ecologists did not integrate the notion of Social Darwinism into their work, the economic aspects of their approach have helped to guide studies of population phenomena, including population shifts and urban differentiation (Frey 1995, pp. 271–336; White 1987), residence changes (Long 1988, pp. 189–251), racial and ethnic diversity (Harrison and Bennett 1995, pp. 141–210), segregation (Farley and Allen 1987, pp. 103–159; Lieberman and Waters 1988, pp. 51–93), housing status (Myers and Wolch 1995, pp. 269–334), and industrial restructuring and the changing locations of jobs (Kasarda 1995, pp. 215–268).

Social-area analysis, in contrast, regards modern industrial society as based on increasing scale, which represents “increased rates and intensities of social relation,” “increased functional differentiation,” and “increased complexity of social organization” (Shevky and Bell 1955). These concepts are related to neighborhood dimensions of social rank, urbanization, and segregation, which are delimited by the factor analysis of neighborhood or census tract measures. “Factorial ecology” has been widely used for classifying census tracts, sometimes for planning purposes. There are disagreements concerning whether factor-analysis studies of urban neighborhood social structure, which are associated with social-area analysis and similar approaches, result in theoretically useful generalizations (Janson 1980, p. 454; White 1987, pp. 64–66)

Sociocultural ecology has used social values such as sentiment and symbolism to explain land use in central Boston (Firey 1947) and other aspects of city life. While values and culture are relevant to explanations of city phenomena, this perspective has not led to a fully developed line of investigation.

Michaelson (1976, pp. 17–32) has argued that none of these aforementioned ecological approaches to the city explicitly study the relationship between the physical and the social environment, for the following reasons: (1) their incomplete view of the environment; (2) their focus on population aggregates; (3) their failure to consider contributions of other fields of study; and (4) the newness of the field. Since Michaelson wrote his critique, sociologists have given more attention to the urban environment.

NEW EXPLANATIONS OF CITIES

Traditional explanations of cities did not adequately account for the economic, political, racial and social upheavals in U.S. cities during the 1960s. Further, urbanization in less developed regions does not necessarily follow the Western pattern. City growth may absorb national population increments and reflect a lack of rural employment, a migration of the rural unemployed to the city, and a lack of urban industrial development. Increasing concentration of population in larger cities in less developed regions may be followed by the emergence of more “Western-style” hierarchies of cities, functions, and interorganizational relationships. Many cities in less developed regions experience the environmental hazards of Western cities, a compartmentalization of life, persistent poverty and unemployment, a rapidly worsening housing situation, and other symptoms of Western social disorganization. The juxtaposition of local urbanism and some degree of Western urbanization may vitiate a number of traditional Western solutions to urban problems.

Kasarda and Crenshaw (1991, pp. 467–500) have summarized and compared theoretical perspectives concerning how urbanization occurs in less developed regions. Modernization-human ecology perspectives portray city building as the result of changes in social organization and applications of technology. Rural-urban migration, resulting from urban industrialization and excess rural fertility, can eventually lead to the reduction of rural-urban economic and social differences (Hawley 1981). Dependency-world-system perspectives describe the capitalist world-system as guiding change in the less developed regions so as to maintain the dominance of the more developed core (Wallerstein 1974). Urban bias perspectives

emphasize the role of the state, sometimes governed by urban elites, which relies on urban resources, and favors urban over rural development (Lipton 1977). Kasarda and Crenshaw (1991) regard these perspectives as underspecified and as lacking empirical confirmation.

Political economy perspectives explain city growth in more developed as well as less developed regions as a product of globalization, including capital accumulation and nation-state formation (Tilly 1975). Europe and the United States colonized non-European peoples and obtained raw materials from the colonies which they processed and exchanged with their colonies as manufactured products. Colonial areas gained political independence after World War II. Economic restructuring then resulted in the globalization of economic and cultural life, and changes in the international division of labor between cities.

Sassen (1991) indicates that following World War II communications technology facilitated the dispersion of manufacturing by multinational corporations to low-wage cities, some in former colonial areas. A globally integrated organization of economic activity then supplanted world economic domination by the United States. Economic activities were integrated beyond national urban hierarchies into a small number of key global cities, which are now international banking centers, with transnational corporate headquarters, sophisticated business services, information processing, and telecommunications. These cities (London, New York, and to a lesser degree Tokyo) command the global economy and are supported by worldwide hierarchies of decentralized specialized cities (Sassen 1991). International networks of cities sometimes provide opportunities for multinational corporations from less developed regions to penetrate more developed regions (Lo and Yeung 1998, p. 2).

Feagan and Smith (1987, pp. 3–33) describe economic restructuring in U.S. cities in the 1980’s as including plant closures and start-ups, the development and expansion of corporate centers, and corporate movement to outlying areas, all of which impact different groupings of cities. They portray economic restructuring as a product of interactions between governmental components of nation-states; multinational, national, and local corporations and businesses; and nongovernment

organizations. These interactions guide policies affecting local taxation, regulation, implementation, and public-private partnerships. Some city neighborhoods have become expendable locations for rapidly shifting economic activity. Policies to accommodate to shifting sites of economic activity influence international and intranational migration, family life, as well as the use of urban, suburban, and rural space.

Aspects of political-economy perspectives have been taken into account in more traditional studies of cities (Frey 1995, pp. 271–336; Kasarda 1995, pp. 215–268). Walton (1993, pp. 301–320) maintains that political-economy perspectives have made the following contributions to the study of cities: (1) showing that urbanization and urbanism are contingent upon the development of social and economic systems; (2) generating comparative studies, particularly in developing countries; (3) elucidating the operation of the informal economy in cities; (4) outlining a political economy of place; (5) showing how globalization relates to ethnicity and community; and (6) relating urban political movements to changes in the global economy.

RETROSPECT AND PROSPECT

Globalization of economic and cultural life is associated with new urban trends. While cities in less developed regions lack resources when compared with those in more developed regions, cities in both types of regions are becoming more responsive to changes in worldwide conditions.

During the twenty-first century the majority of human population is expected to be urban residents (United Nations 1998). In 1995 approximately 46 percent (2.6 billion) of the world's population lived in urban areas. By the year 2005, approximately half of the population is projected to be urban, compared with fewer than one of every three persons in 1950. By 2030 approximately six-tenths (5.1 billion) of the population is projected to be urban.

Urban areas in less developed areas are projected to dominate the growth of the less developed regions and of the world during the twenty-first century. Reasons are the high population growth rates and high numerical population growth of less developed regions, and high rural-urban migration to cities in these regions. In 1995, only

38 percent of the populations in the less developed regions were urban dwellers, compared with 75 percent of the populations in the more developed regions. Urban areas in less developed areas are expected to account for approximately 90 percent (2.4 billion) of the total of 2.7 billion persons that the United Nations projects will be added to the earth's population from 1995 to 2030 (United Nations 1998). (Cities in more developed regions are expected to account for only 140 million of the population increase in the same period.)

There will continue to be significant differences in urbanization between the less developed regions. About three fourths of Latin-American population was urban in 1995, roughly the average level of industrialized regions in Europe, Japan, Australia, New Zealand, the United States and Canada. The most extensive future urban growth will be in Asia and Africa, which are now only about one-third urban (O'Mera 1999; United Nations 1998).

An increasing portion of urban population is residing in giant urban agglomerations. An *urban agglomeration*, according to the United Nations (1998), is the population within a contiguous territory inhabited at urban levels without regard to administered boundaries. In 1995 the fifteen largest ranged in size from 27 million (Tokyo) to 9.9 million (Delhi). Less developed countries are sometimes characterized by primate cities, that is, the largest city in a country dominates other cities and are larger than would be expected on the basis of a "rank-size" rule, which indicates that the rank of a population aggregation times its size equals a constant (Shryock, Siegel, and associates 1976), thus resulting in an inadequate supporting hierarchy of smaller cities. Primate cities often appear in small countries, and in countries with a dual economy, but are not as apparent in large countries or those with long urban histories (Berry 1964).

Megacities, defined by the United Nations (1998) as those cities with 10 million or more inhabitants, are increasing in number and are concentrated in less developed regions. There were fourteen megacities in 1995, including ten in less developed regions. Twenty-six megacities are projected in 2015, including twenty-two in less developed regions, of which sixteen will be in Asia. Megacities have both assets and liabilities. Brockerhoff and

Brennan (1998, pp. 75–114) have suggested that cities' size and rates of population growth are inversely related to welfare. Kasarda and Crenshaw (1991, pp. 471–474) note that megacities, which may have serious social and economic problems, can be driving engines for industrial production in developing regions, and contribute disproportionately to their countries' economies (Kasarda and Crenshaw 1991, pp. 467–501).

Berry (1978) indicates that urbanization may be accompanied by “counter-urbanization” or decreasing city size and density. City growth sometimes occurs in cycles, which begin with rapid growth in the urban core, followed by rapid growth in the suburban ring, a decline in growth in both the core and the ring, and then rapid growth in the core (United Nations 1998). These cycles—of urbanization, suburbanization, counter-urbanization, and reurbanization—appear to be associated with concentrations of services in city centers, followed by improvements in commuting by the labor force and increased suburban home ownership by urban labor forces. The 1970s deurbanization (metropolitan turnaround) in the United States was followed by reurbanization in the 1980s, and the start of another period of deurbanization in the 1990s (United Nations 1998). During the 1970s and 1980s counter-urbanization occurred in other more developed regions and in less developed regions, including a slow-down of population growth rates in some megacities in developing regions, particularly in Latin America (United Nations 1998).

Changes in the global economy and in the aforementioned city growth cycles are associated with new forms of urban land use in the United States, which are laid over preexisting urban patterns. Businesses, which provide the economic base for cities, move between optimum locations in different cities (Wilson 1997, p. 8). Globalization has enhanced the growth of suburbs and “edge cities” organized around outlying business and high-technology centers linked by telecommunications networks to other cities (Castells, 1989; Muller 1997). Unregulated informal sectors of the economy develop in a variety of intraurban locations. High-income native and immigrant populations, which profit from the new global economy, sometimes cluster in protected enclaves. Low-income immigrant and ethnic populations often occupy areas inhabited by earlier cohorts of the

urban poor. Such trends may be related to a spread of ghetto-underclass neighborhoods and to increasingly polarized intracity neighborhood differences of poverty and affluence (Morenoff and Tienda 1997, pp. 59–72).

Trans-border cities are new urban forms that transcend the boundaries of nation-states and reflect increasingly borderless economies. They result from globalization trends, including the economic integration of regions, reductions of trade barriers, and the establishment of multinational free trade zones. They link cities adjacent to a border, and sometimes metamorphose into trans-border systems, complete with specialized functions and populations, and extensive cross-border social and economic ties (Rubin-Kurtzman et al. 1993). Examples are Southern California (U.S.)-Baja California (Mexico), the Singapore-Johore (Malaysia)-Riau (Indonesia) region, and the Beijing (China)-Pyongyang (North Korea)-Seoul (South Korea)-Tokyo (Japan) urban corridor. Trans-border cities pose questions regarding the limits of national sovereignty, but can also integrate human and economic resources and thus enhance international stability.

Cities will continue to exhibit extremes of affluence and poverty, but the extent and consequences of these extremes are unclear. Massey (1996, pp. 395–412) has argued that both the affluent and the poor are concentrating in cities in the United States; consequences may include increased densities of crime, addictions, diseases, and environmental degradation, the emergence of oppositional subcultures, and enhanced violence. Massey assumes these trends apply to less developed regions as well as to the United States. Farley (1996, pp. 417–420) has advanced a counterargument that while economic inequality is increasing in the United States, as may be the geographic segregation of the poor, the continuing (1996) rise in prosperity increases welfare at all income levels. Firebaugh and Beck (1994, pp. 631–653) maintain that economic growth, even in dependent less developed countries, may eventually increase welfare. Hout et al. (1998) state that political institutions, which are partially responsible for growing inequality, can provide appropriate remedies.

As cities account for increasing shares of the earth's population, they will consume increasing shares of the earth's resources, produce increasing

shares of pollution, and their populations will be more subject to negative feedbacks from human impacts on the environment. O'Mera (1999, p. 137) estimates that populations of cities, while occupying only two percent of the earth's surface, consume 75 percent of the earth's resources. Cities are often sited on areas that contain prime agricultural land; urban expansion then inhibits and degrades crop production. Conversion of rural land to urban use intensifies natural hazards including floods, forest and brush fires, and earth slides. Further development concentrates and then disbursts to outlying locations such artificial hazards as air pollution, land and water pollution, and motor vehicle and air traffic noise. Cities are also sited on the shorelines of oceans, thus increasing numbers of city residents are subject to the impacts of storm surges and erosion. Lowry (1992) argues that environmental impacts attributed to cities reflect population growth, industrialization and prosperity rather than city growth itself.

Some of the aforementioned trends are apparent, for example, in Los Angeles and Mexico City, which ranked seventh and second in size, respectively, among the world's largest megacities in 1995. After World War II and until the 1970s, Los Angeles's industrial and population growth and suburban sprawl made it a prototype for urban development that brought with it many inner-city, energy, suburban, environmental, state-management, ethnic, and capital-accumulation problems.

Since the early 1970s, Los Angeles has become a radically changed global megacity based on accumulation of global capital, economic restructuring, communications, and access to new international markets. The reorganization of Los Angeles has affected labor-force demands and the character of both native and immigrant populations. Immigration transformed Los Angeles into a multicultural metropolis (Waldinger and Bozorgmehr 1996, pp. 3-37). The area's economy emphasizes high-income service-sector jobs and low-income service-sector and industrial-sector jobs. Los Angeles has a great concentration of industrial technology and great international cultural importance, is dependent on the private automobile, has environmental hazards (earthquakes, brush fires, and air pollution), limited water supplies, housing shortages, crime, and has experienced uncontrolled intergroup conflicts in 1965 and 1992.

Mexico City, while not commanding the same global economic stature as Los Angeles, is the primate city of Mexico. Mexico City shares many of Los Angeles's problems, including environmental hazards (earthquakes, and air pollution), water shortages, lack of housing and services, expansion of low-income settlements, dependence on the private automobile, lack of sufficient transportation, earthquakes, crime, and rising ethnic violence. Effects of policy responses to these problems have been dampened by economic reversals (Ward 1998).

These illustrations suggest that cities at somewhat similar levels of influence within their respective countries share similar characteristics, whether in the more developed or in the less developed regions. This would support a view that determinants of city development are rooted in the global economy and are influenced by similar trends, but vary according to the city's place in the system.

CIVIL LIBERTIES

Civil liberties and associated controversies reflect the basic sociological issue of what may comprise the requirements of a free yet sustainable society. Classical interests of social thought directly or indirectly concern civil liberties because they address the degree to which individuals may exercise autonomy within the bounds of enduring social relations and community needs. Some of sociology's most venerable research has focused directly on civil liberties. Stouffer's *Communism, Conformity, and Civil Liberties* (1955) served as an intellectual punctuation mark on the McCarthy era, the period during which public discord over civil liberties reached its most intense state in the post-World War II world. Sociological thinking and research has helped American intellectuals and policy makers frame the issues associated with civil liberties and understand the implications of decisions regarding civil liberties for the well-being of society.

Civil liberties may be understood as legally protected areas in which the individual may function without interference by the state or the broader community of citizens. “Civil liberties” are analytically distinct from “civil rights.” Civil liberties concern the individual’s freedom from the broader society and its laws. Civil rights derive from the individual’s claim on society and the state to give him or her equal protection through the state’s police power and equal rights regarding public facilities, services, and largesse. Civil liberties concern the individual’s rights to think, speak, and act outside the state’s apparatus and jurisdiction. Civil rights address the individual’s claim on equal access to public resources such as buses and schools, protection from harm by state agencies, and participation in government and politics.

Sociology offers several core capabilities to promote the citizens’ and policy makers’ understanding of civil liberties and the implications of related public decisions. Classical and contemporary work by sociologists has pertinence in three areas. First, sociological theory and commentary informed by theory helps specify the central dilemmas raised by civil liberties. Second, sociological research enables observers to discover the state of public opinion regarding civil liberties, the dynamics by which public opinion has developed and changed in the past, and the manner in which public opinion may unfold in the future. Finally, sociological thinking and research serves as a resource for understanding the potential consequences of public decisions regarding civil liberties in the years to come. This last capability can aid public decision making and help lay groundwork for achieving the broadest range of civil liberty in society while maintaining the social cohesion necessary to ensure stability, continuity, and affirmation of individual life by core social institutions.

Debate regarding civil liberties has traditionally concerned freedom of expression and due process. Positions regarding freedom of expression have sought to protect the right of individuals to publicly support politically unpopular causes or to display or publish material others may view as objectionable (e.g., pornography). Due process issues have focused on the rights of defendants in criminal cases and claimants in civil and administrative proceedings. Civil liberties advocates have drawn core support from the Bill of Rights and subsequent amendments to the U.S. Constitution

safeguarding free speech, prohibiting unreasonable search and seizure, and limiting the criminal justice system’s ability to require citizens to give self-incriminating testimony. Civil liberties advocates depend heavily on legal doctrines and devices derivative of the Bill of Rights such as fairness, equal protection of the law, and the right of privacy.

The late twentieth century saw a vast extension of activities to which the status of a civil liberty was applied. The 1998 edition of the American Civil Liberties Union’s (ACLU) *The Year in Civil Liberties*, for example, reports challenges by ACLU units to practices and policies such as:

- Religious celebration in public settings (viz. school prayer and holiday displays),
- Youth curfews,
- Prohibition of marijuana use for medical purposes,
- School vouchers,
- Wrongful dismissal from employment due to politics or sexual preference,
- Restraint and corporal punishment of prisoners and “high-risk” legal defendants,
- The death penalty,
- Prohibition of public funding for abortions,
- Legal barriers to adoption of children by lesbian or gay individuals or couples,
- Restriction of legal marriage to heterosexuals only,
- “Sodomy” laws.

According to the ACLU document, these laws and policies belong to a common category of threats to “fairness, freedom of expression, equality, and keeping the government out of our private lives.”

The ACLU does not unilaterally speak for those concerned with civil liberties. But controversy surrounding the ACLU’s extended definition of civil liberties recapitulates central issues in sociological theory, social thought, and public policy. Early social theorists emerging from free-market economics and utilitarianism encountered (wittingly or by implication) the question of what

holds society together, given that individuals “naturally” behave in an atomized manner. Modern participants in civil liberties controversies confront (again wittingly or by implication) a tension between unrestricted individual liberty and the needs of the community and requirements for viable social institutions.

Etzioni, in an essay commenting on the ACLU’s expansion of concerns, emphasizes contradictions between individual liberties and community needs (Etzioni 1991). He stresses the necessity of modifying constitutionally protected individual rights in instances of compelling social exigency. Examples of such modification in the late twentieth century included x-raying of luggage at airports, conducting voluntary fingerprinting of children to facilitate their identification if kidnapped, contact-tracking for people infected with HIV, and mandatory drug testing of workers whose impairment endangers others, such as train engineers. Although these measures have enjoyed public support and none has materially affected the basic rights of the general population, each has been the focus of civil liberties controversies and actions.

Etzioni characterizes opposition to measures such as these as “radical individualism,” encouraged at late century by an imbalance between “excessive individual rights and insufficient social responsibility.” His analysis characterizes the U.S. Constitution as broader than a code of legal provisions to protect the individual from government. The law of the land is also a reflection of “public morality, social values, and civic virtue.” Eclipse of these elements of civil society, Etzioni implies, precludes even marginal modification of legal traditions in the face of compelling social need. He warns that resulting governmental paralysis may ultimately give rise to popular disillusionment, social distress, and abandonment of safeguards to personal liberty on a far greater scale than the marginal modifications initially proposed.

Another critic of ACLU positions alleges that the imbalance between one-sided civil liberties protection and community needs has already affected American social institutions adversely and to a significant degree. Siegel (1991) writes that “the libertarians and their allies in the courts have . . . reshaped virtually every American public institution in the light of their understanding of due

process and equal protection under the Fourteenth Amendment.” This reshaping has had an “elitist” quality, proceeding through abstract legal reasoning and argument but materially harmful, particularly to the economically disadvantaged. According to Siegel’s argument, civil liberties victories in court place burdens on social institutions and prevent them from responding to social reality. Siegel writes:

Civil liberties have become an economic issue as those who can afford it either flee the cities or buy out of public institutions. For those who can’t afford to pay for private school, or private vacations, and are left with junkie infested parks, who can’t afford the private buses which compete with public transportation, and are unable to pay for private police protection, the rights revolution has become a hollow victory. The imposition of formal equality, the sort that makes it almost impossible, for instance, to expel violent high school students, has produced great substantive inequality as would-be achievers are left stranded in procedurally purified, but failing institutions. (Siegel 1991)

Both Etzioni’s and Siegel’s critique of the civil liberties movement reflect sociology’s core perspective and concern, the essential tension between individualistic and social forces. More concretely, sociology’s traditional concern with civil liberties has focused on the citizen’s thinking regarding tolerance of deviation. Survey research has served as the primary source of such information.

Stouffer’s above-referenced classic sounded an optimistic note at the conclusion of the McCarthy era. His study focused on tolerance of people espousing communism and atheism, “nonconformist” ideologies that excited widespread public hostility at the time. In separate surveys conducted by the National Opinion Research Center (NORC) and the Gallup organization, Stouffer asked respondents whether communists and atheists should be allowed to speak in their communities, whether they should be allowed to teach in colleges or universities, and whether their books should be removed from public libraries.

The Stouffer study is remembered largely for reporting relationships between two focuses of

social distinction and tolerance for the nonconformist ideologies. Community leaders and people with advanced education were more likely to score in the “more tolerant” range than the national cross section. On this basis, Stouffer concluded that Americans would become more tolerant of nonconformity in the decades to follow, since the average American was receiving more years of education than his or her parents. Level of education correlated strongly with tolerance in every age group except sixty and over.

A subtheme in the heritage left by Stouffer was evidence for personality-based causes of intolerance regarding civil liberties for deviants. Experience with European totalitarianism had led psychologists to develop the theory of the “authoritarian personality.” Measured according to a device known as the “F scale,” personalities of this kind were distinguished by a simplistic world view, respect for power, and obedience to authority (Adorno 1950). Statistically significant relationships were found between F scale items and intolerance in the Stouffer data. Consistent with these findings, sociologists such as Lipset (1981) claimed that authoritarianism was more likely to be found in the working rather than the middle or upper classes. It is tempting to conclude that a negative relationship between education and basic authoritarianism explains the greater willingness of educated people to extend civil liberties to the politically unpopular, and to speculate that greater education will reduce, if it has not reduced already, personality-related proclivities toward intolerance.

Later research, though, has shown the sociology of public opinion regarding civil liberties to be more complex. Early critics pointed out technical flaws in the F scale. The scale’s items, for example, were all worded in the same direction, encouraging positive responses. Critics raised the possibility that reported relationships between F scale scores and education merely reflected a positive response bias which was particularly strong among working-class respondents. Members of the working class, it was theorized, have a tendency to acquiesce to strong, positive assertions, particularly when these are presented by higher-status individuals such as pollsters.

Reanalysis of the Stouffer data and analysis of data from NORC’s 1990 General Social Survey (GSS) by Schuman, Bobo, and Krysan (1992) casts

doubt upon the causal chain implied above: that low social status (indicated by education) “causes” authoritarian personality, and that authoritarian personality subsequently “causes” intolerance of civil liberties for nonconformists and deviates. Reanalyzing Stouffer’s data, these investigators found relationships between authoritarianism and intolerance of communists and atheists only among the more highly educated. In the 1990 GSS data, they found relationships between authoritarianism and intolerance for blacks and Jews again confined to the educated. The investigators conclude that there is no substantive relationship between class and authoritarianism. Evidence does emerge for a relationship between personality factors and both support for civil liberties for nonconformists and tolerance of minorities. But the roots of these personality factors are unknown and presumably much more complex than class-based socialization.

Changes in public concerns since the 1950s make it risky to apply the findings of Adorno, Stouffer, and others of their era to today’s citizens and social issues. By the end of the twentieth century, communism and atheism had ceased to be mainstream public concerns in the United States. Analysis of civil liberties issues regarding crime had risen to prominence. Remedies such as permanent incarceration of habitual criminals and community notification regarding sex offenders (“Megan’s Law”) had been widely adopted. Increased latitude by police for searching and surveillance of citizens was widely discussed.

Public attitudes favoring compromise of civil liberties in the interests of aggressive law enforcement seemed stable during the 1980s and 1990s. Comparison over time of poll results on the trade-off between aggressive policing and civil liberties indicates growing support for warrantless police searches of cars and drivers. Decided majorities of respondents to Roper and Gallup polls in 1985 and 1986 approved of school officials’ searching students’ belongings for drugs or weapons, again without a warrant. The late twentieth century, though, saw no large-scale support for abandonment of civil liberties in pursuit of greater security. One trend showed a modest rise in support for surveillance of citizens, but another indicated just the opposite: the public did not think it was necessary to “give up some civil liberties” to prevent terrorism (Shaw 1998).

Civil libertarians might feel more alarmed by the polls' findings regarding public ignorance about constitutional rights. According to one survey, only 56 percent of Americans were aware of the innocent-until-proven-guilty principle (Parisi 1979). In another study, only one-third of the respondents correctly indicated the truth or falsehood of a statement regarding double jeopardy (McGarrell and Flanagan 1985).

Review of the studies cited above implies two major conclusions about public opinion regarding civil liberties. First, social determinants of support for civil liberties are likely to be complex and to change over time. Second, the specific focus of concern surrounding civil liberties—for example, the rights of communists versus those of crooks—may predominantly affect their support among citizens. Continual exercise of pertinent sociological research tools is required to maintain awareness of civil liberties-related attitudes and trends; associated theories appear in periodic need of reconstruction.

There is good evidence that sociological thinking and research techniques can promote understanding of the consequences of public decisions regarding civil liberties and help balance civil liberties and community needs. Etzioni's critique includes a recommendation for "limited adjustment" of civil liberties in the interests of society. Criteria for activation of limited adjustment include a "clear and present danger" of sufficient gravity to "endanger large numbers of lives, if not the very existence of our society," and a "direct link between cause and effect." As illustrations, Etzioni cites nuclear weapons, crack cocaine, and AIDS. He recommends minimal interference with constitutional rights, seeking remedies whenever possible that do not actually involve civil liberties.

Even the most measured approach to "adjustment" of civil liberties, though, raises issues for social theory and research. Designation of "clear and present danger" is as much a social fact as one of nuclear physics, pharmacology, and epidemiology. Civil libertarians may justifiably ask what makes crack cocaine a potential threat to society while other narcotics, while causing significant human misery, have not brought society down. Similar issues may be raised regarding AIDS, a biologically less-contagious disease than the traditional scourges

of syphilis and gonorrhea. To what extent, researchers should ask, may the objective significance of these threats have been exaggerated by public emotion?

The impacts of small modifications of civil liberties on the problems these measures are intended to ameliorate should also be viewed as empirical issues. Does contact-tracking of people with AIDS actually drive some underground, making their disease invisible to society and hence more dangerous? If so, how many go underground, for how long, and by what means? Research on likely behavior of people with AIDS and other stigmatized diseases is an essential adjunct to related public decision making.

Finally, the degree to which minor adjustment may ultimately weaken the fabric of civil liberties is a necessary direction for research. Etzioni puts aside the notion that minor modification may initiate a slide down the "slippery slope" toward government or communitarian domination by citing the innocuous nature of procedures such as child fingerprinting. But systematic examination of many seemingly small adjustments may indicate that some indeed result in cascades of increasingly pernicious modifications. Study of the conditions under which the minor modification of traditions has in fact led to their eventual collapse could form the basis of a relevant theory.

CLASS AND RACE

There is considerable debate in the sociology of race relations over how social inequality based on class and that based on race intertwine or intersect. Are these separate dimensions of inequality that simply coexist? Or are they part of the same reality?

Efforts to develop an understanding of the relationship between class and race have a long history in sociology. In the 1930s and 1940s it was common to conceptualize the issue as "caste and class" (Davis, Gardner, and Gardner 1941). Studies were conducted in southern towns of the United States, and a parallel was drawn between the southern racial order and the Indian caste system. Class differentiation was observed within each of the two racial "castes," but a caste line divided them, severely limiting the social status of upper-class African Americans. This view, while descriptively illuminating, was challenged by Cox (1948), who saw U.S. race relations as only superficially similar to caste and based on a very different dynamic.

The relationship between class and race remains hotly debated today. Wilson (1980, 1987) has argued that class has superceded race as a factor in the continuing disadvantage of black

inner-city communities. Wilson argues that economic forces, including the exodus of major industries, have more to do with the social problems of the inner city than do race-based feelings and actions. On the other hand, Omi and Winant (1986) assert the independence of race from class and resist the reduction of race to class forces. They claim that the United States is organized along racial lines from top to bottom and that race is a more primary category than class.

For most Marxist sociologists of race relations, class and race cannot be treated as separate dimensions of inequality that somehow intersect. Rather, they argue that race and class are both part of the same system and need to be understood through an analysis of the system as a whole. Modern race relations are seen as distinctive products of the development of world capitalism. Both racism and capitalism developed together reinforcing one another in a single, exploitative system. The central question then becomes: How has capitalism, as a system based on class exploitation, shaped the phenomena of race and racism?

CAPITALISM AND RACISM

Conventional thinking tends to follow the line that the development of capitalism should eliminate racism. People holding this position argue that racism is an unfortunate leftover from more traditional social systems. Capitalism, based on rational criteria such as efficiency, should gradually eliminate the irrational features of the past. The market is "colorblind," it should only select on the basis of merit. For example, in the area of job allocation, selecting on the basis of such irrelevant criteria as skin color or the race of one's great grandparents, would lead those firms that so choose to perform less well than those that select purely on the basis of ability, and they would go out of business. Only the rational, colorblind firms would survive and racism would disappear in the labor market.

Unfortunately, this idealized theoretical model of the way capitalism works has not proved true in practice. We continue to live in a highly segregated society, with a continuing racial division of labor, and with a high degree of racial inequality on every social and economic dimension. White families, on average, control much higher levels of wealth than African-American families, for example (Oliver and Shapiro 1995). The continuation

of racism within advanced capitalist societies requires further explanation.

Whereas cultural differences have served as a basis for intergroup conflicts for the entire history of humanity, the expansion of Europe, starting in the sixteenth century, set the stage for a new form of intergroup relations. Never before was conquest so widespread and thorough. Nor was it ever associated with such a total ideology of biological and cultural inferiority. Modern racism, with its pseudoscientific claims of inferiority, is a unique phenomenon.

An understanding of European expansion, and its impact on people of color, begins with an analysis of capitalism as it developed in Europe. Capitalism is a system that depends on the private ownership of productive property. In order to earn profits on property, the owners depend on the existence of a nonowning class that has no alternative but to sell its labor-power to the owners. The owners accumulate wealth through profit, that is, the surplus they extract from labor. Hence, a class struggle develops between capitalists and workers over the rights of capitalists to the surplus.

In Europe, labor came to be “free,” that is, people were no longer bound by serfdom or other forms of servitude but were free to sell their labor-power on an open market to the highest bidder. Being free in this sense gave European workers a certain political capacity, even though they were often driven to conditions of poverty and misery.

Capitalism is an expansionary system. Not only does it unleash great economic growth, but it also tends to move beyond national boundaries. The expansionist tendencies lie in a need for new markets and raw materials, a search for investment opportunities, and a pursuit of cheaper labor in the face of political advances by national labor forces. European capitalism thus developed into an imperialistic system (Lenin 1939).

European imperialism led to a virtually total conquest of the globe. Europe carved up the entire world into spheres of influence and colonial domination. The idea and ideology of race and racism emerged from this cauldron. Europeans constructed a kind of folk-scientific view of human differences, dividing the world’s human population into semi-species or “races.” Of course, this division

has no basis in fact, and racial categorization has been completely discredited. Nevertheless, the idea of race, and its use in structuring societies along hierarchical lines, remains exceedingly robust. In sum, race is strictly a social construction, but one with profound implications for the way society is organized.

European domination took multiple forms, from unequal treaties, unfair trade relations, conquest, and the establishment of alien rule to annihilation and white settlement in places where once other peoples had thrived. Imperialism received ideological justification in beliefs that non-European cultures were primitive, uncivilized, barbaric, and savage, and their religions were pagan and superstitious. Europeans were convinced that they had the true religion in Christianity and that all other peoples needed to be “saved.” The denigration of other cultures was accompanied by beliefs in natural, biological inferiority. Dark skin color was a mark of such inferiority, while white skin was viewed as more highly evolved. Africans, in particular, were seen as closer to the apes. These kinds of ideas received pseudoscientific support in the form of studies of cranial capacity and culturally biased intelligence tests (Gould 1981). The totalizing oppression and dehumanization of colonial domination is well captured in Memmi’s *The Colonizer and the Colonized* (1967).

European economic domination had many aspects, but a major feature was the exploitation of colonized workers. Unlike white labor, which was free (in the sense of unbound), colonial labor was typically subjected to various forms of coercion. As conquered peoples, colonized nations could be denied any political rights and were treated openly as beings whose sole purpose was to enhance white wealth. Throughout the colonial world, various forms of slavery, serfdom, forced migrant labor, indentured servitude, and contract labor were common.

Not only did European imperialists exploit colonized workers in their homelands, but they also moved many people around to other areas of the colonial world where they were needed. The most notorious instance was the African slave trade, under which Africans were brought in bondage to the Caribbean area and sections of North and South America. However, other examples

include the movement of contract workers from China and India all over the colonial world. Britain, as the chief imperialist power, moved Indians to southern Africa, Fiji, Trinidad, Mauritius, and other places to serve as laborers in remote areas of the British Empire. These movements created “internal colonies” (Blauner 1972), where workers of color were again subject to special coercion.

Even seemingly free immigrants of color have been subject to special constraints. For example, Chinese immigrants to the United States in the late nineteenth century were denied naturalization rights, in contrast to European immigrants, and as a result, were subjected to special legal disabilities. In the United States, Australia, Canada, and elsewhere, Chinese were singled out for “exclusion” legislation, limiting their access as free immigrants.

African slavery had the most profound effects on the shaping of racial thought and racial oppression. Even though slavery contradicted the basic premise of capitalism as based on a free labor market, it nevertheless flourished within world capitalism, and was an essential feature of it. In a seminal book, Williams (1944; 1966) argued that capitalism could not have developed without slavery, a position elaborated upon by Blackburn (1997). The coerced labor of African slaves enabled the western European nations to accumulate capital and import cheap raw materials that served as a basis for industrialization.

WORKING CLASS DIVISIONS

Within the United States, the coexistence of free labor in the North and slavery in the South, proved to be disastrous, drawing an especially harsh race line between blacks and whites. The very concept of whiteness became associated with the notion of freedom and free labor, while blacks were seen as naturally servile (Roediger 1991). White workers divided themselves from blacks (and other racially defined workers), believing that capitalists could use coerced and politically disabled workers to undermine their interests. Thus a deep division emerged in the working class, along racial lines. The racism of the white working class can be seen as a secondary phenomenon, arising from the ability of capitalists to engage in the super-exploitation of workers of color.

The sections of the world with the worst racial conflicts are the “white settler colonies.” In the British Empire, these include the United States, South Africa, Zimbabwe (Rhodesia), Canada, Australia, and New Zealand. These societies established large white working classes that came into conflict with colonial capitalists over the use of coerced labor (Harris 1964).

From the point of view of workers of color, the distinction between white property owners and white workers seems minimal. Although class conflict raged within the white community, people of color experienced the effects as a uniform system of white domination. All whites appeared to benefit from racism, and all whites appeared to collude in maintaining segregation, job discrimination, and the disenfranchisement of people of color. In this sense, race appears to override class. Nevertheless, it should be recognized that people of color were and are exploited as *labor*, in order to enhance capitalist profits. Thus their relationship to capital includes both race and class elements. Racial oppression intensifies their class oppression as workers.

MIDDLE CLASSES

So far we have talked only of the relations between white capital, white labor, and colonized labor. The colonial world was, of course, more complex than this. Not only did colonized people have their own middle or upper classes, but sometimes outside peoples immigrated or were brought in and served as indirect rulers of the colonized.

Middle strata from among the colonized peoples can play a dualistic role in the system. On the one hand, they can help the imperialists exploit more effectively. Examples include labor contractors, police, or small business owners who make use of ethnic ties to exploit members of their own group. In these types of situations, the dominant white group can benefit by having members of the colonized population help to control the workers primarily for the dominant whites while taking a cut of the surplus for themselves. On the other hand, middle strata can also be the leaders of nationalist movements to rid their people of the colonial yoke.

Outside middle strata, sometimes known as middleman minorities, can be invaluable to the

colonial ruling class. As strangers to the colonized, they have no ambivalence about the aspirations of the colonized for self-determination. They take their cut of profits while not seriously threatening to take over from the Europeans. Because middleman groups tend to serve as the chief interactors with the colonized, they often become a major butt of hostility, deflecting the hostility that would otherwise be directed at the colonial elite. Thus the class and race relations resulting from the development of European capitalism and imperialism have been complex and world-shaping.

CONTEMPORARY RACE RELATIONS

Even though formal colonialism as outright political domination has been successfully challenged by national liberation movements, and even though the most oppressive forms of coerced labor have been legally banned in most of the world, neocolonialism and racial oppression continue in various guises.

For example, African Americans in the United States remain a relatively disenfranchised and impoverished population. Although illegal, racial discrimination persists in everyday practice, and racist ideology and attitudes pervade the society. Many whites continue to believe that blacks are innately inferior and object to social integration in the schools or through intermarriage. African Americans are almost totally absent from positions of power in any of the major political, economic, and social institutions of the society. Meanwhile, they suffer from every imaginable social deprivation in such areas as housing, health care, and education.

The capitalist system maintains racism in part because racially oppressed populations are profitable. Racial oppression is a mechanism for obtaining cheap labor. It allows private owners of capital to reduce labor costs and increase their share of the surplus derived from social production. This is very evident in Southern California today, where the large, immigrant Latino population provides virtually all the hard labor at exceptionally low wages. Their political status as noncitizens, a typical feature of racist social systems, makes them especially vulnerable to the dehumanization of sweatshops and other forms of super-exploitation.

With an increasingly globalized world capitalism, these processes have taken an international dimension. Not only do capitalists take advantage of oppressed groups in their own nation-states, but they seek them out wherever in the world they can be found. Such people are, once again, of color. Of course, the rise of Japan as a major capitalist power has changed the complexion of the ruling capitalist elite, but the oppressed remain primarily African, Latin American, and Asian.

It is common today for people to assume that racism goes both ways and that everyone is equally racist, that African Americans have just as much animosity toward whites as whites have toward blacks. According to this thinking, whites should not be singled out for special blame because racism against those who are different is a universal human trait: We are all equally guilty of racism. This view denies the importance of the history described above. To the extent that peoples of color are antiwhite, it is a reaction to a long history of abuse. Claiming that the antiwhite sentiments of blacks are equally racist and on the same level as white racism is an attempt to negate the responsibility of Europeans and their descendents for a system of domination that has tried to crush many peoples.

At the foundation of the problem of race and class lies the value system of capitalism, which asserts that pursuit of self-interest in a competitive marketplace will lead to social enhancement for all and that therefore the social welfare need not be attended to directly. This assumption is patently untrue. The United States, perhaps the worst offender, has let this social philosophy run amok, resulting in the creation of a vast chasm between excessive wealth and grinding poverty, both heavily correlated with color. Without severe intervention in "free market" processes, the United States is heading toward increased racial polarization and even possible violence.

Movements for social change need to address racial oppression and disadvantage directly. Changing the system of capitalist exploitation will not eliminate racism, since the power and resources available to white workers are so much greater than those of workers of color. The whole system of inequality based on appropriation of surplus wealth by a few, mainly white, private property

owners needs to be challenged, along with its racial aspects. Major redistribution, based on racial disadvantage, would be required. Neither class-based nor racial inequality can be attacked alone. They are linked with each other and must be overthrown together.

CLINICAL SOCIOLOGY

Clinical sociology is a humanistic, multidisciplinary specialization that seeks to improve the quality of people's lives. Clinical sociologists assess situations and reduce problems through analysis and intervention. Clinical analysis is the critical assessment of beliefs, policies, and/or practices with an interest in improving a situation. Intervention, the creation of new systems as well as the change of existing systems, is based on continuing analysis.

Clinical sociologists have different areas of expertise—such as health promotion, sustainable communities, social conflict, or cultural competence—and work in many capacities. They are, for example, community organizers, sociotherapists, mediators, focus group facilitators, social policy implementers, action researchers, and administrators. Many clinical sociologists are full-time or part-time university professors, and these clinical sociologists undertake intervention work in addition to their teaching and research.

The role of the clinical sociologist can be at one or more levels of focus from the individual to the intersocietal. Even though the clinical sociologist specializes in one or two levels of intervention (e.g., marriage counseling, community consulting), the practitioner will move among a number of levels (e.g., individual, organization, community) in order to analyze or intervene or both.

THE HISTORY OF AMERICAN CLINICAL SOCIOLOGY

When sociology emerged as a discipline in the 1890s, the nation was struggling with issues of democracy and social justice. There was rural and urban poverty, women were still without the vote, and there were lynchings. Farmers and workers in the late 1800s were frustrated because they could see the centralization of economic and political power in the hands of limited groups of people. This kind of frustration led to public protests and the development of reform organizations. In this climate, it is not surprising that many of the early sociologists were scholar-practitioners interested in reducing or solving the pressing social problems that confronted their communities.

The First University Courses . While many of the early sociologists were interested in practice,

the earliest known proposal using the words “clinical sociology” was by Milton C. Winternitz (1885–1959), a physician who was dean of the Yale School of Medicine from 1920 through 1935. At least as early as 1929, Winternitz began developing a plan to establish a department of clinical sociology within Yale’s medical school. Winternitz wanted each medical student to have a chance to analyze cases based on a medical specialty as well as a specialty in clinical sociology.

Winternitz vigorously sought financial support for his proposal from the Rosenwald Fund, but he was unable to obtain the necessary funds for a department of clinical sociology. He did note, however, the success of a course in the medical school’s section on public health that was based on the clinical sociology plan.

The first course using the words “clinical sociology” in the title was taught by Ernest W. Burgess (1886–1966) at the University of Chicago. Burgess taught the course in 1928 and then offered it twice in 1929. During these years, the course was considered to be a “special” course and did not appear in the university’s catalog. Burgess offered the clinical sociology course, as a regular course, five times from 1931 through 1933. The course continued to be listed in the catalog for the next several years but was not taught after 1933.

The University of Chicago catalogs did not include a description of the clinical sociology course, but the course always was listed under the social pathology grouping. All courses in this section dealt with topics such as criminality, punishment, criminal law, organized crime, and personal disorganization. Several of the students enrolled in these first clinical sociology courses were placed in child guidance clinics. Clarence E. Glick, for instance, was the staff sociologist at Chicago’s Lower North Side Child Guidance Clinic and Leonard Cottrell was the clinical sociologist at the South Side Child Guidance Clinic.

Two other universities offered clinical courses in the 1930s—Tulane University in Louisiana and New York University. The Tulane University course was designed to give students the opportunity to learn about behavior problems and social therapy by conferences and fieldwork in a child guidance clinic. Louis Wirth (1897–1952), a full-time faculty member and director of the New Orleans Child Guidance Clinic, was scheduled to teach the course

in the spring of 1930. Wirth was unable to teach the course because he accepted a one-year Social Science Research Council Fellowship to work in Europe. The course was taught in his absence, but the university’s course information does not identify the professor who took Wirth’s place.

When Wirth returned to the United States in 1931, he joined the faculty of the University of Chicago. In the spring of 1932 he taught a “minor” course in clinical sociology but by then he no longer was working with child guidance clinics.

New York University also offered clinical sociology courses in the early 1930s. Harvey Warren Zorbaugh (1896–1965) was a faculty member there in the School of Education which provided undergraduate and graduate preparation for visiting teachers, educational counselors, clinicians, social workers, and school guidance administrators. The major focus of the program was the solution of educational problems and other social dilemmas.

Zorbaugh, along with Agnes Conklin, offered “Seminar in Clinical Practice” in 1930. The course was intended to qualify students as counselors or advisers to deal with behavioral difficulties in schools. From 1931 through 1933 the clinical practice course was called “Seminar in Clinical Sociology.” The course was one of the highest numbered courses in educational sociology and was offered both terms of each year. The course was open to graduate students who were writing theses or engaged in research projects in the fields of educational guidance and social work.

Zorbaugh, author of *The Gold Coast and the Slum: A Sociological Study of Chicago’s Near North Side*, had been involved with clinics at least since 1924. That was the year Zorbaugh and Clifford Shaw organized two sociological clinics in Chicago—the Lower North and South Side Child Guidance Clinics. Zorbaugh was associate director of the Lower North Side Child Guidance Clinic in 1925.

Zorbaugh was a founder, in 1928, of the Clinic for the Social Adjustment of the Gifted at New York University. He was director of this clinic at its inception and was actively involved in its work for over fifteen years. The clinic was for intellectually gifted and talented preadolescents. The clinic gave graduate students the opportunity to have supervised experiences in teaching, clinical diagnosing and treating of children with behavioral problems.

During the 1953–54 academic year, Alvin W. Gouldner (1920–1980) was teaching in the Department of Sociology and Anthropology at Antioch College in Ohio. Before joining the faculty, Gouldner had been a university teacher for four years and then worked, for one year, as a consultant to Standard Oil of New Jersey.

Gouldner offered “Foundations of Clinical Sociology” at Antioch. The course was taught at the highest undergraduate level, and students who enrolled in the course were expected to have completed the department’s course in social pathology. The college bulletin provided the following description of the course:

A sociological counterpart to clinical psychology with the group as the unit of diagnosis and therapy. Emphasis on developing skills useful in the diagnosis and therapy of group tensions. Principles of functional analysis, group dynamics, and organizational and small group analysis examined and applied to case histories. Representative research in the area assessed.

The term “clinical sociology” first appears in print. The first known published linking of the words *clinical* and *sociology* was in 1930 when Milton C. Winternitz, a pathologist and dean of the Yale Medical School, wanted to establish a department of clinical sociology. After working on the idea at least as early as 1929, he wrote about it in a report to the president of the Yale Medical School and the report was published in the 1930 Yale University *Bulletin*. That same year saw the publication of a speech Winternitz had given at the dedication of the University of Chicago’s new social science building. The speech also mentioned clinical sociology.

Abraham Flexner, a prominent critic of medical education and director of the Institute for Advanced Study at Princeton, mentioned clinical sociology in 1930 in his *Universities: American, English, German*. Flexner did not approve of the Institute of Human Relations that Winternitz was establishing at Yale. In the pages of criticism devoted to the institute, Flexner briefly mentioned clinical sociology: “Only one apparent novelty is proposed: a professor of clinical sociology” (Flexner 1930).

Winternitz continued to write about the value of clinical sociology until 1936 when his last report

as dean was filed. One of Winternitz’s (1932) most forceful statements in support of the field was the contemporary-sounding statement that appeared in his 1930–1931 annual report:

The field for clinical sociology does not seem by any means to be confined to medicine. Within the year it has become more and more evident that a similar development may well be the means of bringing about aid so sorely needed to change the basis of court action in relation to crime. . .

Not only in medicine and in law, but probably in many other fields of activity, the broad preparation of the clinical sociologist is essential. . .

The first discussion of clinical sociology by a sociologist was Louis Wirth’s 1931 article, “Clinical Sociology,” in *The American Journal of Sociology*. Wirth wrote at length about the possibility of sociologists working in child development clinics, though he did not specifically mention his own clinical work in New Orleans. Wirth wrote “it may not be an exaggeration of the facts to speak of the genesis of a new division of sociology in the form of clinical sociology” (Wirth 1930).

In 1931, Wirth also wrote a career development pamphlet, which stated:

The various activities that have grown up around child-guidance clinics, penal and correctional institutions, the courts, police systems, and similar facilities designed to deal with problems of misconduct have increasingly turned to sociologists to become members of their professional staffs (Wirth 1931).

Wirth “urged (sociology students) to become specialists in one of the major divisions of sociology, such as social psychology, urban sociology. . . or clinical sociology” (Wirth 1931).

In 1931, Saul Alinsky was a University of Chicago student who was enrolled in Burgess’s clinical sociology course. Three years later, Alinsky’s article, “A Sociological Technique in Clinical Criminology,” appeared in the *Proceedings of the Sixty-Fourth Annual Congress of the American Prison Association*. Alinsky, best known now for his work in community organizing, was, in 1934, a staff sociologist and member of the classification board of the Illinois State Penitentiary.

In 1944 the first formal definition of clinical sociology appeared in H.P. Fairchild's *Dictionary of Sociology*. Alfred McClung Lee, the author of that definition, was known as one of the founders of the Society for the Study of Social Problems, the Association for Humanist Sociology, and the Sociological Practice Association. Lee later used the word "clinical" in the title of two articles—his 1945 "Analysis of Propaganda: A Clinical Summary" and the 1955 article "The Clinical Study of Society."

Also appearing in 1944 was Edward McDonagh's "An Approach to Clinical Sociology." McDonagh had read Lee's definition of clinical sociology but had not seen Wirth's 1931 article. McDonagh, in his *Sociology and Social Research* article, proposed establishing social research clinics that had "a group way of studying and solving problems" (McDonagh 1944).

In 1946 George Edmund Haynes's "Clinical Methods in Interracial and Intercultural Relations" appeared in *The Journal of Educational Sociology*. Haynes was a cofounder of the National Urban League (1910) and the first African American to hold a U.S. government subcabinet post. His 1946 article, written while he was executive secretary of the Department of Race Relations at the Federal Council of the Churches of Christ in America, discussed the department's urban clinics. The clinics were designed to deal with interracial tensions and conflicts by developing limited, concrete programs of action.

Contemporary contributions. While publications mentioning clinical sociology appeared at least every few years after the 1930s, the number of publications increased substantially after the founding of the Clinical Sociology Association in 1978. The association, now called the Sociological Practice Association, made publications a high priority. Individuals were encouraged to publish and identify their work as clinical sociology, and the association established publication possibilities for its members. The *Clinical Sociology Review* and the theme journal *Sociological Practice* were published by the association beginning in the early 1980s. These annual journals were replaced in the 1990's by *Sociological Practice: A Journal of Clinical and Applied Sociology*, a quarterly publication.

The Sociological Practice Association has had a central role in the development of American

clinical sociology. The association helped make available the world's most extensive collection of teaching, research, and intervention literature under the label of clinical sociology and it introduced the only clinical sociology certification process.

The Sociological Practice Association's rigorous certification process for clinical sociologists is available at the Ph.D. and M.A. levels. The Ph.D.-level process was adopted in 1983 and certification was first awarded in 1984. The association began to offer M.A.-level certification in 1986. Successful candidates at both the doctoral and master's level are awarded the same designation—C.C.S. (Certified Clinical Sociologist).

Experienced clinical sociologists are encouraged to apply for certification, which is given for intervention work (assessing and changing social systems). As part of the application process, a candidate is required to identify her or his area of specialization (e.g., community, family counseling) and level of intervention (e.g., organization, individual). The certification process requires membership in the Sociological Practice Association, documentation of appropriate education and supervised training, documentation of interdisciplinary training, essays about ethics and theory, and a demonstration before peers and a reviewing committee.

The Sociological Practice Association, along with the Society for Applied Sociology, also has put in place a Commission on Applied and Clinical Sociology. The commission has set standards for the accreditation of clinical and applied sociology programs at the baccalaureate level and intends to do the same for graduate programs.

CLINICAL SOCIOLOGY AND SOCIOLOGICAL PRACTICE

The practical sociology of the 1890s and early 1900s is now referred to as sociological practice. This general term *sociological practice* involves two areas, clinical sociology and applied sociology. Clinical sociology emphasizes hands-on intervention while applied sociology emphasizes research for practical purposes. Both specialties require different kinds of specialized training.

Some sociological practitioners are "clinical" in that they only or primarily do intervention

work; others are “applied” in that they only or primarily conduct research that is of practical interest. Some practitioners do both. Clinical sociologists, for instance, may conduct research before beginning an intervention project to assess the existing state of affairs, during an intervention (e.g., to study the process of adaptation), and/or after the completion of the intervention to evaluate the outcome of that intervention. For some clinical sociologists, the research activity is an important part of their own clinical work. These sociologists have appropriate research training and look for opportunities to conduct research. Other clinical sociologists prefer to concentrate on the interventions and leave any research to other team members. Those clinical sociologists who decide not to engage in research may have research skills but prefer to conduct interventions, may not have enough expertise in the conduct of research, or may know that other team members have more expertise in research.

THEORIES, METHODS, AND INTERVENTION STRATEGIES

Clinical sociologists are expected to have education and training in at least one area in addition to sociology. This means that not only are clinical sociologists exposed to the range of theories (e.g., symbolic interaction, structural-functionalism, conflict, social exchange) and quantitative and qualitative research methods generally taught in sociology programs, but they also have additional influences from outside of their own programs. The result is that clinical sociologists integrate and use a broad range of theoretical and methodological approaches.

Clinical sociologists use existing theory to formulate models that will be helpful in identifying and understanding problems and also to identify strategies to reduce or solve these problems. Clinical sociologists also have shown that practice can have an influence on existing theories and help in the development of new ones.

While clinical sociologists use a wide variety of research methods and techniques (e.g., participatory action research, geographic information systems, focus group analysis, surveys), they probably are best known for their case studies. Case studies involve systematically assembling and analyzing

detailed, in-depth information about a person, place, event, or group. This methodological approach involves many data-gathering techniques such as document analysis, life histories, in-depth interviews, and participant observation.

Clinical sociologists who have been in the field for ten or twenty years probably learned about intervention strategies primarily through courses and workshops given outside of sociology departments as well as through their work and community experiences. Clinical sociologists who have more recently entered the field also may have learned intervention techniques as part of their sociology programs. These sociology programs might include courses, for instance, on focus groups, mediation, or administration, as well as require supervised residencies or internships.

CLINICAL SOCIOLOGY IN INTERNATIONAL SETTINGS

Clinical sociology is as old as the field of sociology and its roots are found in many parts of the world. The clinical sociology specialization, for instance, often is traced back to the fourteenth-century work of the Arab scholar and statesperson Abd-al-Rahman ibn Khaldun (1332–1406). Ibn Khaldun provided numerous clinical observations based on his varied work experiences such as Secretary of State to the rule of Morocco and Chief Judge of Egypt.

Auguste Comte (1798–1857) and Emile Durkheim (1858–1917) are among those whose work frequently is mentioned as precursors to the field. Comte, the French scholar who coined the term “sociology”, believed that the scientific study of societies would provide the basis for social action. Emile Durkheim’s work on the relation between levels of influence (e.g., social compared to individual factors) led Alvin Gouldner (1965, p.19) to write that “more than any other classical sociologist (he) used a clinical model.”

Interest in clinical sociology has been growing in a number of countries. For example, French is the predominant language of many, if not most, of the current international clinical sociology conferences, and books and articles have appeared with clinical sociology in the title in France and French-speaking Canada. The French-language clinical

sociologists emphasize clinical analysis. They have a solid international network and have done an excellent job of attracting nonsociologists to that network. Their literature is substantial. Particularly notable is the work of Jacques van Bockstaele and Maria van Bockstaele; Robert Sevigny, Eugene Enriquez, Vincent de Gaulejac, and Jacques Rheaume.

Beginning in the mid-1990's, Italians hosted clinical sociology conferences, published clinical sociology books and articles and ran numerous clinical sociology training workshops. If one is interested in learning about clinical sociology in Italy, one would want to review the work of Michelina Tosi, Francesco Battisti, and Lucio Luisson. Luisson's 1998 book, *Introduzione alla Sociologia clinica* (Introduction to Clinical Sociology), contains thirteen articles written by Americans. One is an original article written for the volume but all the others are translations of articles that appeared in the Sociological Practice Association's *Clinical Sociology Review* or *Sociological Practice*. The volume concludes with the Sociological Practice Association's code of ethics.

Clinical sociology also is found in other parts of the world. Of particular interest would be developments in Greece, Brazil, Mexico, Uruguay, and South Africa. In South Africa, for instance, one university's sociology department has put a sociological clinic in place and another sociology department has developed a graduate specialization in counseling.

The international development of clinical sociology has been supported primarily by two organizations. The clinical sociology division of the International Sociological Association (ISA) was organized in 1982 at the ISA World Congress in Mexico City. The other major influence is the clinical sociology section of the Association internationale des Sociologues de Langue Francaise (International Association of French Language Sociologists).

It is clear that a global clinical sociology is beginning to emerge. American clinical sociology had a strong role in the early development of the global specialization but now it is only one of many influences. It will be interesting to see if the thrust of the international field will be as explicitly humanistic and intervention-oriented as American clinical sociology.

CLUSTER ANALYSIS

See Correlation and Regression Analysis; Factor Analysis.

COALITIONS

Originally a word for union or fusion, the term *coalition* came in the eighteenth century to mean a temporary alliance of political parties. In modern social science, the meaning has broadened to include any combination of two or more social

actors formed for mutual advantage in contention with other actors in the same social system. In most contemporary theories of coalition formation, it is taken for granted that the principles governing coalition formation are not much affected by the size of the actors, who may be small children or large nations, but are significantly affected by the number of actors in the system. In the sociological and social-psychological literature, interest has focused on coalition formation in social systems containing three actors, commonly known as *triads*, and on the factors that influence the formation of coalitions in that configuration. Coalitions in triads have certain properties that are very useful in the analysis of power relationships in and among organizations. Moreover, tetrads, pentads, and higher-order social systems can be viewed for analytical purposes as clusters of linked triads. In the literature of political science, the principal topic has been the formation of electoral and legislative coalitions in multi-party and two-party systems.

The social science perspective on coalitions derives from two major sources: the formal sociology of Georg Simmel (1902) and the *n*-person game theory of John Von Neumann and Oskar Morgenstern (1944). Simmel had the fundamental insight that conflict and cooperation are opposite sides of the same coin so that no functioning social system can be free of internal conflicts or of internal coalitions. Simmel also proposed that the geometry of social relationships is independent of the size of the actors in a social system but heavily influenced by their number; that social systems are held together by internal differentiation; that relationships between superiors and subordinates are intrinsically ambivalent; that groups of three tend to develop coalitions of two against one; and that, in stable social systems, coalitions shift continually from one situation to another.

While the basic ideas are attributable to Simmel, the analytical framework for most of the empirical research on coalitions that has been undertaken so far is that of Von Neumann (and his collaborator Oskar Morgenstern). Any social interaction involving costs and rewards can be described as an *n*-person game. In two-person games, the problem for each player is to find a winning strategy, but in games with three or more players, the formation of a winning coalition is likely to be the major

strategic objective. The theory distinguishes between zero-sum games, in which one side loses whatever the other side gains, and non-zero-sum games with more complex payoff schedules. And it provides a mathematical argument for the equal division of gains among coalition partners, the gist of which is that any essential member of a winning coalition who is offered less than an equal share of the joint winnings can be induced to desert the coalition and join an adversary who offers more favorable terms. In the various experimental and real-life settings in which coalitions are studied, this solution has only limited application, but game theory continues to furnish the vocabulary of observation.

Some recent writers identify coalition theory as that branch of game theory involving zero-sum games with more than two players and game theory as a branch of rational choice theory (Wood and McLean 1995). The basic assumption of rational choice—by voters, lobbyists, legislators, and managers—has been vigorously attacked (see Green and Shapiro 1994) and as strongly defended (Nicholson 1992, among many others). The critics argue that rational choice theory is essentially self-contained; its elaborate intellectual apparatus does not provide a clear view of political action. The defenders say, in effect, that judgment should be withheld.

Meanwhile, game theory (and its coalition branch) have been developing new ideas, largely based on the key concept of equilibrium. Equilibrium in a game is that condition in which none of the players have incentives to deviate from their chosen strategies. It is called *Nash equilibrium*, after its formulator (Nash 1951), and has been extended to include two interesting varieties: subgame perfect equilibrium and Bayesian equilibrium. The former requires that rational players refrain from incredible threats. The latter replaces the players' initial knowledge about payoff schedules with a set of probabilistic statements, subject to change by additional information. Another interesting innovation is the concept of *nested games* (Tsebelis 1990), in which the apparent irrationality of players' moves in a given game is a rational consequence of their concurrent involvement in other games.

Modern empirical work on coalitions falls into two major categories: (1) experimental studies of

outcomes in games played by small groups—games that have been devised by the experimenter to test hypotheses about the choice of coalition partners and the division of coalition winnings under specified conditions, and (2) observational studies of coalitions in the real world. Stimulated by the publication of divergent theories of coalition formation (Mills 1953; Caplow 1956; Gamson 1961) in the *American Sociological Review*, coalition experiments became part of the standard repertory of social psychology in the 1960s and continue to be so to this day (Bottom, Eavey, and Miller 1996). A great deal has been learned about how the choice of coalition partners and the division of coalition winnings are affected by variations in game rules and player attributes. Much, although by no means all, of this work has focused on three-player games in which the players have unequal resources and any coalition is a winning coalition, the distribution of resources falling into one of three types: (1) $A > B > C$, $A < B + C$; (2) $A = B$, $B > C$, $A < B + C$; and (3) $A > B$, $B = C$, $A < B + C$. With respect to the choice of coalition partners, the central question has been whether subjects will consistently choose the partner with whom they can form the minimum winning coalition, or the stronger partner, or the partner who offers the more favorable terms, or the partner who resembles themselves in attributes or ideology. The general finding is that each of these results can be produced with fair consistency by varying the rules of the experimental game. The division of winnings between coalition partners has attracted even more attention than the choice of partners. The question has been whether winnings will be divided on the principle of *equality*, as suggested by game theory; or of *parity*, proportionate to the contribution of each partner, as suggested by exchange theory; or at an intermediate ratio established by *bargaining*. Although many experimenters have claimed that one or the other of these principles is primary, their collective results seem to show that all three modes of division occur spontaneously and that subjects may be tilted one way or another by appropriate instructions. Additional nuances of coalition formation have been explored in games having more than three players, variable payoffs, or incomplete information. Non-zero-sum games and sequential games with continually changing weights have been particularly instructive. The findings readily lend themselves to mathematical

expression (Kahan and Rapoport 1984; Prasnika and Roth 1992).

The explicit application of coalition analysis to real-life situations began with William Riker's (1962) study of political coalitions in legislative bodies; he discerned a consistent preference for minimal winning coalitions and emphasized the pivotal role of weak factions. Theodore Caplow (1968) showed how the developing theory of coalitions in triads could be used to analyze conflict and competition in nuclear and extended families, organizational hierarchies, primate groups, revolutionary movements, international relations, and other contexts. The initial development of observational studies was relatively slow, compared with the proliferation of laboratory studies, but there were some notable achievements, particularly in family dynamics and international relations, where coalition models fit gracefully into earlier lines of investigation. Coalition theory was also applied, albeit in a more tentative way, to work groups, intra- and interorganizational relationships, litigation and criminal justice, class and ethnic conflict, and military strategy. However, the bulk of empirical research after 1980 was undertaken by political scientists and focused on international relations, with particular emphasis on nuclear deterrence (Powell 1990) and on the formation of legislative coalitions (Laver and Schofield 1990; Shepsle 1991; Krebbiel 1991; Cox and McCubbins 1993). Some investigators have shifted their focus from coalition formation to coalition breaking (Lupia and Strom 1995; Horowitz and Just 1995; Mershon 1996), which appears to follow a quite different dynamic. Economists have studied customs unions, trading blocs, and other forms of economic combination (Burbidge et al. 1995; Yi 1996). But with a few notable exceptions (e. g. Lemieux 1997), sociologists have tended to neglect the study of coalitions since the promising beginnings of the 1970s.

Whatever the field of application, the examination of coalitions, especially the simple coalition of two against one, provides a key to the social geometry of innumerable situations involving conflict, competition, and cooperation. In nearly every conflict, each of the contending parties seeks the support of relevant third parties, and the side that gains that support is likely to prevail. In very many competitive situations, the outcome is eventually decided by the formation of a winning coalition. And any system of cooperation that involves

a status order must rely on the routine formation of coalitions of superiors against subordinates and be able to counter coalitions of subordinates against superiors.

All of these situations are susceptible to coalitions of two against one, which tend to transform strength into weakness and weakness into strength. Under many conditions, in the first of the triads mentioned above ($A > B > C$, $A < B + C$), both A and B will prefer C as a coalition partner; his initial weakness ensures his inclusion in the winning coalition. When $A > B$, $B = C$, $A < B + C$, B and C will often prefer each other as coalition partners; A's initial strength ensures his exclusion from the winning coalition. When $A = B$, $A > C$, C's initial weakness again makes him a likely winner. The first purpose of any hierarchy must be to restrain in one way or another the inherent tendency of subordinates to combine against superiors. Although force and ritual are often deployed for this purpose, the stability of complex status orders depends on certain interactive effects that appear in triads with overlapping membership, called *linked triads*. In such clusters, the choice of coalition partners in one triad influences the choices made in other triads. The natural rules that seem to govern the formation of coalitions in linked hierarchical triads are that a coalition adversary in one triad may not be chosen as a coalition partner in another triad, and that actors offered a choice between incompatible winning coalitions will choose the one in the higher-ranking triad. The net effect favors conservative coalitions of superiors against subordinates without entirely suppressing revolutionary coalitions of subordinates against superiors.

Cross-cutting the coalition preferences that arise from unequal distributions of power and resources are preferences based on affinity, compatibility, and prior experience with potential partners. These other bases of coalition formation are conspicuous in intimate groups such as the family, where same-sex coalitions alternate with same-generation coalitions.

The study of coalitions in nuclear families is particularly rewarding because the distribution of power in the triad of mother-father-child changes so dramatically as the child grows, and because same-sex coalitions are differently valued than

cross-sex coalitions. The initial distribution of power between husband and wife is always transformed by the arrival of children; most cultures encourage certain patterns, such as the Oedipus and Electra complexes dear to Freudians: coalitions of mother and son against father and of father and daughter against mother. Research on the contemporary American family suggests that parental coalitions are quite durable, both mother-daughter and mother-son coalitions against the father are very common, father-daughter coalitions against the mother much less so, and father-son coalitions against the mother comparatively rare. Sibling coalitions are most likely among same-sex siblings adjacent in age. Sibling aggression is endemic in families of this type, especially in the presence of parents. An interesting study by Richard Felson and Natalie Russo (1988) suggests that parents usually take side with the weaker child in these incidents, and this leads to more frequent aggression by the excluded child. There are very few family conflicts that cannot be instructively described by a coalition model.

The application of coalition theory to international relations was particularly rewarding with respect to the “strategic triangle” of the United States, China, and the Soviet Union during the Cold War era of 1950–1985. In one of the many studies that have examined the internal dynamics of this triad, James Hsiung (1987) concluded that China as the weak player in this triad benefitted much more than either of the superpowers from the various coalitional shifts that occurred over time, as would be theoretically expected in a triad of this type ($A=B$, $B>C$, $A<B+C$). A study by Caplow (1989) explained the failure of peace planning in 1815, 1919, and 1945, by showing how efforts to put an end to the international war system were undermined by the formation of coalitions to prevent the domination of the peacekeeping organization by the strongest of the victorious powers. Many older studies of international balances of power visualize international relations as a game in which the first priority of every major player is to block the domination of the entire system by any other player. Frank C. Zagare’s (1984) analysis of the Geneva Conference on Vietnam in 1954 as a three-player game compared the preference schedules of the three players and showed how they combined to produce the unexpected outcome of the negotiations.

Both family dynamics and international relations in peacetime exemplify situations of continuous conflict, wherein relationships have long histories and are expected to persist indefinitely, and the opposition of interests is qualified by the necessity for cooperation. The choice of coalition partners and the division of winnings is strongly influenced by the past transactions of the parties and by the fact that payoffs are not completely predictable. Continuous conflict triads with $A>B>C$, $A<B+C$ often alternate the three possible coalitions according to circumstances: the *conservative coalition* AB reinforces the existing status order; the *revolutionary coalition* BC challenges it; and the *improper coalition* AC subverts it.

Episodic conflicts, by contrast, involve discrete zero-sum games played under strict rules. The passage of any measure in a legislative body necessarily involves the formation of a coalition. Even when one party has a solid majority, its members will seldom be in complete agreement on an issue. The formation of a coalition for the passage of a specific measure usually involves hard bargaining and payoffs negotiated in advance. Under these conditions, the tendency to minimize costs by forming the minimal winning coalitions is very strong. When $A>B>C$, $A<B+C$, a BC coalition is highly probable. Empirical studies of legislative voting bear this out, although more than minimal coalitions also occur, for various reasons.

The resolution of disputes by civil and criminal litigation is another variety of episodic conflict that can be studied as a coalition process. Donald Black (1989) explored the triad of judge and courtroom adversaries and discovered a clear tendency for judges to favor the litigant to whom they are socially closer, ordinarily the litigant of higher status—a tacit conservative coalition. But in forms of dispute resolution where the third party is less authoritative, the weaker adversary may be favored. Marital counselors, for example, often side with wives against husbands, and ombudsmen and other relatively powerless mediators normally incline toward the weaker party.

In terminal conflicts, the object is the permanent destruction of adversaries, and the formation of coalitions is a delicate matter. In the triad where $A>B>C$, $A<B+C$, a successful BC coalition that destroys A leaves C at the mercy of B . Indeed, any winning coalition is hazardous for the weaker

partner. A fragile peace can be maintained if $A > B > C$ and $A = B + C$; the BC coalition forms as a matter of course, creating what is known as a balance of power. This has been the key configuration in European affairs for the past several centuries. The balance breaks down with any significant shift in the relative power of the parties; for example, if A grows stronger than the BC coalition, it will be tempted to conquer them. If B becomes equal to A, an AB coalition may be tempted to attack and partition C. If C grows stronger and the triad assumes the form $A > B$, $B = C$, $B + C > A$, the formation of a BC coalition to overthrow A is likely. In the eighteenth century, the breakdown of a balance of power led to war without delay. Under current conditions, the breakdown of a balance of power among major industrialized states does not involve an automatic resort to arms, but in several regional arenas, such as the Middle East, the old mechanism is still intact.

Terminal conflicts occur also within nations as coups, resistance movements, and revolutions. One common pattern is the urban uprising against a dictatorial regime, in which the players are the government, the army, and the populace. If the army continues to support the government and is willing to fire on the populace, the uprising fails, as in China in 1989. If the army sides with the populace, the government is overthrown, as in Indonesia in 1998. Often the issue is undecided until the moment when the troops confront the demonstrators. At a more fundamental level, successful revolutions require a coalition of formerly separate factions against the ruling group.

Every organization generates both internal and boundary coalitions. Internal coalitions are activated whenever persons or groups of unequal status interact before witnesses. In general, the presence of a high-status witness reinforces the authority of a superior, while the presence of a low-status witness reduces it; examined in detail, these catalytic effects are delicate and precise. Boundary coalitions occur whenever one organization has permanent relations with another. Their respective agents must form a coalition with each other to perform their functions, and that coalition pits them both against their own colleagues, always with interesting consequences.

In a long-term perspective, the three bodies of coalition studies, theoretical, experimental, and

observational, have developed unevenly. The theories are elaborate and elegant. The experimental studies have explored nearly every possibility suggested by the theories, run down every lead, manipulated every variable. But in sociology, as distinct from political science and economics, the observational studies have scarcely tapped the rich possibilities suggested by the available theories. The most important work remains to be done.

THEODORE CAPLOW

COGNITIVE CONSISTENCY THEORIES

Cognitive consistency theories have their origins in the principles of Gestalt psychology, which suggests that people seek to perceive the environment in ways that are simple and coherent (Köhler 1929). Cognitive consistency theories have their beginnings in a number of seemingly unrelated research areas (Eagly and Chaiken 1993). Early consistency theorists drew upon theories of conflict (Lewin 1935; Miller 1944), memory (Miller 1956), and the intolerance for ambiguity by those with an authoritarian personality (Adorno, Frenkel-Brunswick, Levinson, and Stanford 1950). According to Newcomb (1968a), social scientists should not have been surprised at the rise of cognitive consistency theories. He points to a truism that in any field of scientific inquiry, there is an inevitable movement from description of the elements of the field, to understanding the relationships between them. At the heart of cognitive consistency theories is the assumption that people are motivated to seek coherent attitudes, thoughts, beliefs, values, behaviors, and feelings. If these are inconsistent, they will produce a "tension state" in the individual, and motivate the individual to reduce this tension. Individuals reduce this tension, according

to consistency theories, by making their relevant cognitions consistent.

Cognitive consistency theories gained tremendous popularity in the social sciences in the 1950s, and generated hundreds of studies. Toward the end of the 1960s, however, research interest waned. In 1968, Abelson and colleagues published a massive handbook, entitled *Theories of Cognitive Consistency: A Sourcebook*. The book was a thorough chronicle of cognitive consistency theories, and it addressed these theories from virtually any angle the reader could imagine. Ironically, the scholarly detail in which the editors and authors carefully described their research seemed to have been the death knell of cognitive consistency theories. Virtually no research on cognitive consistency theories took place during the 1970s.

With the end of the 1960s, theories of behavior that centered around motivational and affective forces (which certainly described cognitive consistency theories) were “out of vogue” with researchers. Many point to the simultaneous rise of social cognition approaches in general, and attribution theory in particular as helping to divert interest from cognitive consistency theories. Research on cognitive consistency theories was supplanted by more complex (some believed) “cold cognition” approaches that strictly dealt with how cognitive processes work together, not accounting for “hot” forces such as feelings and motivation.

Theories of cognitive consistency theory did not die, they just went away for a while. Abelson (1983) noted the reemergence of cognitive consistency theories in the early 1980s with the observation that authors were beginning to write about social cognition theories in light of the renewed interest in the nature of affect (e.g., Fiske 1982; Hamilton 1981). Toward the end of the 1980s, researchers began to take a closer look at the influence of affect on cognitive processes (e.g., Forgas 1990; Isen 1987; Schwarz 1990). This change was precipitated by the development of several theoretical perspectives concerning the nature and structure of emotion (e.g., Frijda 1988; Ortony, Clore, and Collins 1988). In an influential article, Zanna and Rempel (1988) argued that attitudes toward different attitude objects may be more or less determined by affective, rather than cognitive, sources. Consistency theories were not only back, they were thriving (Harary 1983).

This chapter will discuss five major theories of cognitive consistency that have had the most impact on the behavioral sciences. They are (in no particular order) balance theory (Heider 1946, 1958), strain toward symmetry (Newcomb 1953, 1968b), congruency theory (Osgood and Tannenbaum 1955), affective-cognitive consistency model (Rosenberg 1956), and finally, what Eagly and Chaiken (1993) refer to as the “jewel in the consistency family crown,” (p. 456) cognitive dissonance theory (Festinger 1957).

BALANCE THEORY

The earliest consistency theory is Heider’s balance theory (1946, 1958). This approach is concerned with an individual’s perceptions of the relationships between himself (*p*) and (typically) two other elements in a triadic structure. In Heider’s formulation, the other elements are often another person (*o*) and another object (e.g., an issue, object, a value). The attitudes in the structure are designated as either positive or negative. The goal of assessing the structure of a triad is to ascertain whether the relationships (attitudes) between the actors and the other elements are balanced, or consistent. According to Heider (1958), a balanced triad occurs when all the relationships are positive, or two are negative and one is positive (i.e., two people have a negative attitude toward an issue, but they like each other), and the elements in the triad fit together with no stress. Imbalance occurs when these outcomes are not achieved (i.e., all three relationships are negative, or you have a negative attitude toward an issue that your friend favors). Heider assumed that people prefer balanced states to imbalanced ones, because imbalance results in tension and feelings of unpleasantness. Balance, according to Heider, is rewarding.

Interestingly, imbalanced states can also be rewarding and exciting. Heider said that sometimes balance can be “boring” and that “The tension produced by unbalanced situations often has a pleasing effect on our thinking and aesthetic feelings” (1958, p. 180). In other words, imbalance stimulates us to think further, to solve the problem, to imagine, and to understand the mystery of the imbalance. According to balance theory, there are three ways to restore balance to an imbalanced triad: (1) one may change one’s attitude toward either the object or the other person, in order to

restore balance; (2) one might distort reality to perceive that the relationships are balanced (e.g., your friend doesn't really favor something you dislike, she really dislikes it); and (3) one might cognitively differentiate the relationship one has with a friend, so that the friend's opposing attitude toward something one favors is separated from one's positive attitude toward the friend as a person (e.g., you might compartmentalize a friend's opposite political views apart from your attitude toward her, in order to maintain your friendship and maintain balance, in most other areas where she is concerned) (Eagly and Chaiken 1993).

A limitation of Heider's balance theory is that it did not account for the strength of attitudes between persons and objects in the triad. It merely categorized the relationships as either positive or negative, and it therefore assumed that tension that is produced by imbalance was objectively of the same strength and effect on the individuals in the triad. Because some attitudes are held with more conviction and are more meaningful and important to us, it stands to reason that triads that involve imbalance with such strongly-held attitudes ought to evoke more tension (Eagly and Chaiken 1993). Another shortcoming of the theory is that it only deals with relationships between three entities. To address this latter concern, Cartwright and Harary (1956) published a paper that nicely generalized Heider's theory to account for structures of any size.

STRAIN TOWARD SYMMETRY MODEL

Newcomb (1953, 1968b) suggested that there are three, rather than two types of balance relationships in a triad. First, a structure that does not motivate modification (or acceptance) is termed a "nonbalanced" structure. These situations are characterized by indifference. Here, disagreement with another individual about an issue or object does not arouse tension if that other individual is devalued (or otherwise not important). However, when the other person is valued (i.e., a friend or significant other), then agreement with him or her about an object results in a "positively balanced" structure, while disagreement results in a "positively imbalanced" structure. The term "positive" in the latter two types of structure denotes the valence of the relationship between p and o , who is a valued other. The important focus in Newcomb's

approach is the relationship of o to p , and p 's view of o as a valued person, and "suitability as a source of information, or support, or of influence concerning the object" (Newcomb 1968b, p. 50). Newcomb's experiments supported his idea that the tension that is aroused when p and o have strong attitudes in the structure is much greater than when their attitudes are held with little conviction. He also found that positively balanced situations are the most preferred structures, followed by nonbalanced structures, with the positively imbalanced situations being the least preferred.

CONGRUENCY THEORY

A particular advantage of Osgood and Tannenbaum's (1955; Tannenbaum 1968) congruency theory is its precision in assessing: 1) the strength of the relationships between p and o , 2) the strength of the motivation to change an incongruent triad, and 3) the degree of attitude change that is necessary to balance a triad. Another advantage of this theory is that, like Newcomb's approach, it takes into account the strength of the attitudes of p and o in evaluating the degree of incongruity in the structure. Osgood and Tannenbaum discuss the Heider triad in terms of p , another individual, termed the source (s) and s 's attitude (termed an "assertion") toward another object or concept (x). According to the theory, attitudes can be quantified along a seven-unit evaluative scale, from extremely negative (-3) to neutral (0) to extremely positive (+3).

When p 's attitude toward s and x are positive, and s 's assertion is equally strong and of the same valence, there is a "congruous" structure to the triad. There is no motivation to change one's attitude toward the object or toward the source. When p 's attitude toward s is positive, and p has an equally positive attitude toward x that s later negatively evaluates, an incongruous structure is established. In this situation, p is motivated to change his or her attitude toward s , or x , or both, in the direction of congruity. Consider the following example. If p 's attitude toward s is a +2, and p 's attitude toward x is a -2, the structure would be congruent if s 's assessment is a -2. If, however, the assessment is a +2, the structure is imbalanced. In this case, p 's attitude toward either x or s needs to change four units to make the triad congruent. Of course, if the relationships are weaker, the degree

of attitude change to make the triad congruent is that much less (by the exact amount denoted in the quantitative calculation of all the relations of p , s , and x). Osgood and Tannenbaum also argued that strongly held attitudes would be less likely to be modified in incongruent triads. This was supported in subsequent research (Tannenbaum 1968).

AFFECTIVE-COGNITIVE CONSISTENCY MODEL

This approach suggests that people seek consistency in order to satisfy a general motivation toward simplicity in cognition, and/or to adhere to norms, traditions, customs, or values that reinforce consistency in one's cognitions and behavior (Rosenberg 1956, 1968). Another interesting twist on the consistency approach is that in the affective-cognitive consistency model, Rosenberg (1956, 1968) proposed that people are more motivated to maintain cognitive consistency so that *other people* perceive that they are consistent. In other words, while the individual may occasionally feel some tension as a result of inconsistency, other people find the inconsistency more aversive, because it represents a conflict for those around the individual. Specifically, if o has a positive attitude toward p , but p dislikes x , which o likes, o is caught between being friendly with, and avoiding, p . In this model, o feels tension at this conflict, and must reduce the tension by changing attitudes toward p (e.g., increasing attraction toward p , which would thereby outweigh any conflict with p 's negative attitude toward x) or toward x (e.g., o devalues x , so that p 's dislike of x does not result in o feeling conflicted).

Rosenberg's model also considers the relationship between the individual, his or her values, and an attitude object. For example, consider that p also has various other important values, denoted as y_1 , y_2 , y_3 , etc. Rosenberg suggests that the p - x - y triad is just as important in understanding cognitive consistency as the traditional p - o - x triad. In the affective-cognitive consistency approach, we must consider p 's attitudes toward each of his or her values, how p feels about x , and p 's perception of the relationship between x and each of the values. When all or most of the p - x - y triads are consistent, the individual has achieved cognitive consistency. When most or all of the p - x - y triads are inconsistent, the individual experiences cognitive inconsistency.

The reason Rosenberg's approach is called the affective-cognitive consistency model is that it proposes that inconsistency results when one's feelings are inconsistent with one's beliefs. That is, when the way we think and feel about an object or person are at odds, we will modify one or both to make the attitude consistent. Thus, this model attempts to address consistency within one's own attitudes toward other people and objects, but also consistency in how one's value system relates to other people and objects. The model is also unique in suggesting that other people experience more tension as a result of one's own inconsistency. Generally speaking, the model has been supported by experiments (Rosenberg 1964), and is considered a very useful addition to the family of cognitive consistency theories.

COGNITIVE DISSONANCE THEORY

Of all the cognitive consistency theories, none has had more influence on researchers and subsequent theories than cognitive dissonance theory (Festinger 1957). A conservative estimate suggests that at least 1,000 articles have been published in which researchers present data bearing upon the theory and their own revisions of the theory (Cooper and Fazio 1984). Many agree with Jones's (1976) assessment that cognitive dissonance theory is "the most important development in social psychology to date" (p. x). Along the way, the theory has been hailed for its elegant simplicity, and its powerful range of utility (Collins 1992). It has also been criticized for its lack of specificity (Lord 1992; Schlenker 1992).

In formal terms, Festinger's theory states that two elements (behaviors or thoughts, or both) "...are in a dissonant relation if, considering these two alone, the obverse of one element would follow from the other" (1957, p. 13). Dissonance, then, refers to a negative arousal brought about by one's inconsistent thoughts or actions, or both. Essentially, this translates into the following assumptions. If one has opposing thoughts or behaviors, or both, this brings about an aversive state of tension, akin to a drive state like hunger or thirst. This tension motivates the individual to seek relief by eliminating the tension. The tension can be dissipated by changing: 1) either a thought or attitude to make it consonant with the opposing thought or behavior, or 2) one's behavior, to make

it consonant with the opposing behavior or thought. Because it is often much easier to change one's thoughts rather than one's behaviors, these are typically the elements that get modified by the person in dissonance reduction.

As an example, Festinger (1957) talked about the dissonance experienced by most smokers at some point in their lives. Smokers engage in behavior (smoking) that is harmful to their health. This is at odds with our desire to avoid harming ourselves. This arouses tension in the individual. The smoker could reduce it by changing his or her behavior (quit smoking) or changing the way he or she thinks about the smoking behavior. As mentioned above, changing behavior is often more difficult than changing cognitions, and, as most smokers will affirm, quitting smoking is certainly no exception to this axiom. In this instance, Festinger suggests, smokers eliminate their dissonance by changing their thoughts about smoking. They may: 1) disbelieve the validity of the health consequences of smoking, or distort the information about smoking by thinking that smoking is only harmful if you smoke so many packs a day, or if you inhale cigar smoke, etc., or more fatalistically, 2) convince themselves that "we all die of something, and I might as well die doing something I enjoy." All of these changes in thoughts eliminate the dissonance for the smoker.

It should be noted that Festinger was not talking about logical inconsistencies. There are certainly conditions under which people think and do logically inconsistent things, yet feel no dissonance, or they feel dissonance, yet are not in a situation where a logical inconsistency is present. Festinger recognized what has become a truism in psychology, that a person's reaction to a stimulus is not a function of the objective properties of the stimulus itself, but rather the individual's *construal*, or *perception of*, that stimulus. This explains why the presence or absence of logical inconsistencies may or may not be accompanied by dissonance in an individual. The most important and reliable way to predict a person's behavior in a dissonance situation is to understand how he or she construes the potential dissonance arousing thoughts or behaviors, or both.

History. Cognitive dissonance theory came onto the scene in the 1950s when reinforcement

theories of behavior were very dominant in virtually all areas of inquiry in psychology. According to reinforcement principles, behavior that is followed by a reward is more likely to be repeated. Behavior that is followed by a strong reward should be more likely to be learned and repeated than behavior followed by a weak (or no) reward. Reinforcement theory was such a simple yet very powerful principle that it seemed to explain virtually all behavior in any context. For that reason, it was extremely popular among behavioral scientists. An experiment by Festinger and Carlsmith (1959) showed that reinforcement theory was not the all-purpose theory it appeared to be. In their experiment, Festinger and Carlsmith (1959) had participants do boring tasks (i.e., turning pegs one-quarter turn on a cribbage board) for an hour. Participants randomly assigned to a control group were then given a short questionnaire in which they were asked to rate how much they enjoyed the task. In other conditions, the experimenter then told participants that his research assistant had not yet arrived for a different version of the experiment, and he asked the participant if he would do the research assistant's job of telling the next participant (in the hall, who was in reality a confederate) that he enjoyed the experiment tasks. This was, of course, a lie, because the tasks were boring. These participants were assigned to one of two conditions. Some were given \$1 to tell the lie, and others were given \$20 to tell the lie. After participants had told the lie and were leaving, the experimenter ran up to the participant, explaining that he forgot to have the participant complete the ratings of the attitudes toward the experiment tasks.

The experiment pitted reinforcement theory against the predictions made from dissonance theory. Reinforcement theory suggests that the participants who were given \$20 should find the tasks more rewarding (pleasant), and should have a more positive attitude toward the tasks (and the experiment) than those only given a weak (or no) reward. Dissonance theory suggests that those in the control condition would feel no dissonance because they did a boring task, and would rate the tasks as such on the questionnaire. However, counter to intuition (and reinforcement theory) those in the \$20 condition should feel little (or no) dissonance, because although they did boring tasks, and disliked the tasks, saying that the tasks were fun is not an inconsistent behavior if one has

adequate justification (\$20) for doing so. They could attribute their lying to the incentive, and they would not feel hypocritical. The \$1 participants experienced significant dissonance because they did boring tasks, but yet they said they thought the tasks were fun. As Festinger and Carlsmith predicted, the \$1 was an insufficient justification for the lie, so the dissonance remained unless the participants changed their attitudes toward the task, and convinced themselves (as shown in their ratings of the tasks) that maybe the tasks were *not* boring, and in fact, they rather enjoyed them! The results were precisely as predicted, and this paved the way for a flurry of research that tested the exciting, often dramatic, and counterintuitive predictions that arose from cognitive dissonance theory.

Alternate Versions of Dissonance Theory.

Very soon after the publication of Festinger's theory, research revealed that the theory might need to be revised somewhat, to account for more of the data that were being published, which didn't quite fit with the theory. In one notable revision, one of Festinger's protégés, Aronson (1969) posited that the theory would be strengthened if it stated that dissonance would be most clearly aroused when the self-concept of the person is engaged. In other words, dissonance is stronger and more clearly evoked when the way we think about ourselves is at odds with our cognitions or behavior. This modification was supported by much subsequent research (Aronson 1980). Less an alternate version and more of a theoretical competitor, Bem's (1967) self-perception theory was the first major theory that offered a plausible account of the dissonance data, and pointed to different causal mechanisms. Unlike cognitive dissonance theory, Bem's approach did not invoke reference to hypothetical motivational processes, but rather tried to account for the person's behavior in terms of the stimuli present in the individual's environment and his or her related behavior. Bem's theory proposed that attitudinal change in dissonance experiments happens not due to an aversive tension (or other motivation), but due to a person's perceptions of his or her own behavior. Specifically, Bem said that people infer their attitudes from their actions, in much the same way that observers of our behavior infer the nature of our attitudes from our behavior. Attitude change occurs when their most recent behavior is different from their previous attitudes.

This behavioral approach to dissonance phenomena recasts the Festinger and Carlsmith experiment in a very different light. In a replication of the Festinger and Carlsmith study, Bem asked participants to listen to a tape describing a person named Bob, who did some boring motor tasks. Control condition participants then were asked to assess Bob's attitude toward the tasks. Other subjects then learned that Bob was given \$1 or \$20 to say to the next participant that the motor tasks were fun. Participants then listened to a recording of Bob enthusiastically telling a subsequent woman participant how enjoyable the motor tasks were. Participants were then asked to evaluate Bob's attitude toward the motor tasks. Those who were told that Bob was given \$20 to tell the lie inferred that the only reason he told the lie was because he was paid a lot of money. They assumed that he didn't really have a positive attitude toward the motor tasks. Those who were told that Bob received \$1 didn't think Bob had a good reason for lying, so his behavior (lying) told participants that Bob must really feel positively about the motor tasks. Control condition participants inferred that Bob negatively evaluated the motor tasks. As can be seen, these results are virtually identical to those obtained in the Festinger and Carlsmith experiment. Thus, according to self-perception, the Festinger and Carlsmith participants inferred their attitudes toward the boring tasks based on their recent behavior.

Subsequent research on self-perception theory was aimed at testing the self-perception theory contention that no arousal exists as a result of the dissonance situation. Zanna and Cooper (1976) found that arousal did indeed accompany counterattitudinal advocacy, so it was apparent that self-perception did not apply to all dissonance situations. Fazio, Zanna, and Cooper (1977) suggested that dissonance accounted for attitude change when behavior is truly counterattitudinal, but that self-perception can account for situations where behavior is only mildly counterattitudinal. For most researchers, this seems to have settled the debate about the situations to which each theory may be applied (Abelson 1983).

A final major revision was proposed by Cooper and Fazio (1984). They suggested that dissonance does not result from mere cognitive inconsistency, but only is evoked when the person feels personally responsible for causing an aversive event.

The theory suggests, then, that aversive consequences are necessary for dissonance to occur. In subsequent experiments, however, Aronson and his colleagues (Aronson, Fried, and Stone 1991) induced participants to make an educational video advocating the use of condoms for safe sex, to be shown in high schools. Then, the participant was subsequently reminded of situations in which he or she had not used condoms in the past. According to Cooper and Fazio, there should be no dissonance because the participant had not produced an aversive event, but rather, a positive one (advocating safe sex in an educational video). According to Aronson, however, the participant should feel dissonance because he or she was saying one thing and doing another (acting like a hypocrite). Aronson predicted that if dissonance was aroused in those hypocrites, they should be more likely to (if given the opportunity) take more free pamphlets and condoms at the end of the study, as a way of regaining consistency with their advocated position (i.e. they were making an effort to change their behavior to be consistent with their advocated message). Results showed that this is precisely what occurred. Subsequent research has demonstrated strong support for Aronson and colleagues' (1991) contention that the production of aversive consequences is not necessary to create dissonance (Harmon-Jones, Brehm, Greenberg, Simon, and Nelson 1996).

CURRENT STATUS OF COGNITIVE CONSISTENCY THEORIES

In the 1990s, cognitive consistency theories experienced a rebirth, primarily through renewed interest in cognitive dissonance theory (Aronson 1992). With the renewed interest in motivation, and the interaction of cognition and affect, researchers are once again taking up the questions (and there are many) left unanswered by earlier cognitive dissonance researchers. For example, while research has shown that dissonance evokes (as Festinger theorized) psychological discomfort (in comparison to physiological arousal), researchers know little about what occurs between the onset of the psychological discomfort and the start of the discomfort reduction process (Elliot and Devine 1994). Some have called for an effort to more fully explicate the conditions under which dissonance occurs, and when it does not occur (Aronson 1992), and researchers are beginning to

do just that (Shultz and Lepper 1996). Cognitive consistency theories have been a cornerstone of psychology for over four decades, and while they receded into the background in the 1970s, they are experiencing a strong resurgence of empirical and theoretical interest.

COHORT PERSPECTIVES

The birth cohort, or set of people born in approximately the same period of time, has a triple reference as an analytical tool in sociology: (1) to cohorts of people who are *aging* and succeeding each other in particular eras of history; (2) to the *age composition* of the population and its changes; and (3) to the interplay between cohorts of people and the age-differentiated *roles and structures* of society. Diverse sociological studies illustrate the use of these cohort perspectives (i.e., both theoretical and empirical approaches) to investigate varied aspects of aging and cohort succession, population composition, and the reciprocal relationships between cohorts and social structures.

CONCEPTUAL FRAMEWORK

Figure 1 is a rough schematization of the major conceptual elements implicated in these interrelated cohort perspectives as they have relevance for sociology (for an overview, see Riley, Johnson, and Foner 1972; Riley, Foner and Riley 1999).

Aging and Cohort Succession. The *diagonal bars* represent cohorts of people born at particular

time periods who are aging from birth to death—that is, moving across time and upward with age. As they age, the people in each cohort are changing socially and psychologically as well as biologically; they are actively participating with other people; and they are accumulating knowledge, attitudes, and experiences. The series of diagonal bars (as in the selected cohorts A, B, and C) denote how successive cohorts of people are continually being born, grow older through different eras of time, and eventually die.

Age Composition of the Population. The *perpendicular* lines direct attention to the people simultaneously alive in the society at particular dates. A single cross-sectional slice through the many coexisting cohorts (as in 1990) demonstrates how people who differ in cohort membership also differ in age—they are stratified by age from the youngest at the bottom to the oldest at the top. Over time, while society moves through historical events and changes, this vertical line should be seen as moving across the space from one period to the next. At different time periods the people in particular age strata are no longer the same people; inevitably, they have been replaced by younger entrants from more recent cohorts with more recent life experiences.

Cohorts and Social Structures. Corresponding to the age strata in the population, the perpendicular lines also denote the age-related role opportunities and normative expectations available in the various social structures (e.g., in schools for the young, in work organizations for those in the middle years, in nursing homes for the old, in families for all ages, etc.). People and structures are interdependent: changes in one influence changes in the other. Yet the two are often out of alignment, causing problems for both individuals and society.

This three-fold heuristic schematization, though highly oversimplified, aids interpretation and design of sociological work that takes cohort perspectives into account. (For simplicity, the discussion is limited here to cohorts in the larger society, with entry into the system indexed by date of birth. Parallel conceptualization refers also to studies of cohorts entering other systems, such as hospitals, with entry indexed by date of admission, or the community of scientists, with entry indexed by date of the doctoral degree—e.g., Zuckerman and

Figure 1

SOURCE: Riley, Foner, and Waring, 1998, p. 245 (adapted).

Merton 1972; here “aging” refers to duration in the particular system.)

AGING PERSPECTIVES

Research on the processes of aging within and across cohorts illuminates the interrelated aspects of people’s lives and the particular characteristics and historical backgrounds of the cohorts to which they belong.

Intracohort Perspectives. Many empirical studies and much conceptual work uses the “life-course approach” to trace over time the lives of members of a single cohort (e.g., Clausen 1986). As one familiar example, studies of “status attainment” investigate lifelong trajectories of achievement behaviors, using longitudinal and causal modeling to examine the interconnections among such variables as family background, scholastic achievement, succession of jobs, and employment and unemployment (cf. Featherman 1981). The intracohort perspective is used in many forms—micro-

and macro-level, objective and subjective—in a range of studies on how people as they develop and grow older move through diverse paths in the changing society (Dannefer 1987), how sequences of role transitions are experienced, and how aging people relate to the changing environment. Psychologists as well as sociologists study interindividual changes in performance over the life course (e.g., Schaie 1996), while Nesselroade (1991) looks at intra-individual fluctuations over shorter periods of time.

Longitudinal studies of aging in a single cohort can contribute importantly to causal analysis by establishing the time order of correlated aspects of people’s lives and environmental events. However, this perspective is vulnerable to possible misinterpretation through the *fallacy of “cohort-centrism,”* that is, erroneously assuming that members of all cohorts will age in exactly the same fashion as members of the cohort under study (Riley 1978). Yet in fact, members of different cohorts, as they respond to different periods of

history, usually age in different ways. For example, the enjoyment of “midlife” experienced at around age 50 by cohort members studied in the 1990s may not be felt by some future cohort until age 85.

Intercohort Perspectives. Broader than the intracohort focus, is a focus on the lives of members of two or more successive cohorts who are growing older under differing historical or socio-cultural conditions. Studies of intercohort differences in the late-twentieth century demonstrated for other sciences what sociologists had learned early: the central principle that the process of aging is not immutable or fixed for all time, but varies across and within cohorts as society changes (Riley 1978). Such studies have shown that members of cohorts already old differ markedly from those in cohorts not yet old in such respects as standard of living, education, work history, age of menarche, experience with acute vs. chronic diseases, and perhaps most importantly the number of years they can expect to live. These cohort differences cannot be explained by evolutionary changes in the human genome, which remains much the same from cohort to cohort; instead, they result from a relatively unchanging genetic background combined with a continually changing society (Riley and Abeles 1990, p.iii). Thus the finding of cohort differences has pointed to possible linkages of lives with particular social or cultural changes over historical time, or with particular “period” events such as epidemics, wars, or depressions (e.g., Elder and Rockwell 1979). These linkages are useful in postulating explanations for changes—or absence of changes—in the process of aging.

Studies of cohort differences focus on aging processes at either the individual or the collective level. At the individual level, cohort membership is treated as a *contextual characteristic* of the individual, and then analyzed together with education, religion, and other personal characteristics to investigate how history and other factors affect the heterogeneous ways individuals grow older (e.g., Messeri 1988; but see Riley 1998). At the collective level, the lives of members are aggregated within each cohort to examine alterations in average patterns of aging. Striking advances have recently been made in the data banks available for intercohort comparisons. Archived data from many large-scale studies now cover long periods of history, multiple societies, and multidisciplinary aspects of the life

course; and repeated longitudinal studies are being launched, such as the National Institute on Aging’s Health and Retirement Study (HRS) and Asset and Health Dynamics Among the Oldest Old (AHEAD) (cf. Campbell 1994; O’Rand and Campbell 1999).

Cohort perspectives are useful, not only in explaining past changes in aging processes, but also in improving forecasts of future changes. Unlike the more usual straight projections of cross-sectional information, forecasts based on cohorts can be informed by established facts about the past lives of people in each of the cohorts already alive (e.g., Manton 1989). Thus, if cohorts of teenagers today are on the average less healthy, less cared for, or less prepared for life than their parents were at the same age (National Association of State Boards of Education 1990), the lives of both offspring and parents will predictably also differ in the future when both have grown older.

COMPOSITIONAL PERSPECTIVES.

Complementing sociological work on cohort differences (or similarities) in the aging process are studies of how cohort succession contributes to formation and change in the age composition of the population. Thus in Figure 1, the perpendicular lines indicate how cohorts of people fit together at given historical periods to form the cross-sectional *age strata* of society; and how, as society changes, new cohorts of people are continually aging and entering these strata, replacing the previous incumbents.

Single Period of Time. In Figure 1, as indicated above, a single vertical line at a given period (as in 1990) is a cross-sectional slice through all the coexisting cohorts, each with its unique size, composition, earlier life experiences, and historical background. This familiar cross-sectional view of all the age strata is often denigrated because its misinterpretation is the source of the *life-course fallacy*—that is, the erroneous assumption that cross-sectional age differences refer directly to the process of aging, hence disregarding the cohort differences that may also be implicated (Riley 1973). That people who are differentially located in the age composition of society differ not only in age but also in cohort membership was dramatized early by Mannheim ([1928] 1952) and Ryder

(1968); yet persistent failure to comprehend this duality has perpetuated numerous false stereotypes (e.g., that intelligence or physical functioning begin inevitable declines at very early ages).

Properly interpreted, of course, a cross-sectional perspective has its special uses: for describing current differences and similarities, social relationships, and interactions among coexisting people who differ in age-cum-cohort membership. Thus, for example, issues of “intergenerational equity” require explication by both age and cohort, as a larger share of the federal budget is reportedly spent on cohorts of people now old than on cohorts of children (Duncan, Hill, and Rodgers 1986; Preston 1984).

Across Time. Comprehension of the underlying dynamics of the age strata requires going beyond the single cross-sectional snapshot to a sequence of cross-sections (the moving perpendicular line in Figure 1), as successive cohorts interact with historical trends in the society (Ryder 1965; Riley 1982). Historical change means not only that new cohorts are continually entering the system through birth or immigration, while others are leaving it through death or emigration (e.g., men tend to die earlier than women, and blacks earlier than whites). Historical change also means that the members of *all* existing cohorts are simultaneously aging and thus moving from younger to older strata. As successive cohorts move concurrently through the system, they affect the age strata in several ways. They can alter the numbers and kinds of people in particular strata, as each cohort starts the life course with a characteristic size, genetic makeup, sex ratio, racial and ethnic background, and other properties that are subsequently modified through migration, mortality, and environmental contact. The succession of cohorts can also affect the capacities, attitudes, and actions of people in particular strata as the members of each cohort bring to society their experiences with the social and environmental events spanned by their respective lifetimes.

The most significant alterations in the age composition of modern societies stem from the dramatic and unprecedented increases in the longevity of successive cohorts. Age pyramids diagramming the age composition of the United States in 2010 compared with 1955, for example, demonstrate that entirely new strata have been added at

the oldest ages (Taeuber 1992)—strata of old people who are healthier and more competent than their predecessors (Manton, Corder, and Stallard 1997). The advent of these “new” old people is already having untold consequences: Individuals now have time to spread education, work, family activities, and leisure more evenly over their long lives, and wider structural opportunities are needed in society for the age-heterogenous population.

SOCIAL STRUCTURAL PERSPECTIVES

Cohorts, as described above, are composed of people, who age and fit together in strata to form the composition of the population; but cohorts also shape, and are shaped by social structures—the surrounding families, communities, work organizations, educational institutions, and the like. Against the backdrop of history, social structures, like lives, tend to change, and two “dynamisms”—changing structures and changing lives—are in continuing interplay, as each influences the other. Thus full understanding of cohorts requires understanding their reciprocal relations with structures (as in Foner and Kertzer 1978; Mayer 1988). Toward this end, some studies examine how the processes of aging and cohort flow relate to structures, while other studies examine the congruence—or lack of congruence—between age composition and social structures.

Aging and Structures . Because cohorts differ in size and character, and because their members age in new ways (the diagonal lines in Figure 1), they exert collective pressures for adjustments—not only in people’s ideas, values, and beliefs—but also in role opportunities throughout the social institutions.

As one example, the influences of cohort differences in *size* were defined early by Joan Waring’s (1975) powerful analysis of “disordered cohort flow.” This disordered flow has been dramatically brought to attention as the Baby Boom cohorts first pressed for expansions in the school systems and the labor force, and will become the twenty-first century “senior boom” that will exacerbate the inadequacy of roles for the elderly. Later, as large cohorts were followed by smaller successors, ways were sought to reduce these expanded structures again. Meanwhile, as structures changed, the lives of people moving through these structures also changed.

In another example, the influences of cohort differences in *norms* has been analyzed as the process of “cohort norm formation” (Riley 1978). As members of a cohort respond to shared historical experiences, they gradually and subtly develop common patterns of response, common definitions, and common beliefs, that crystallize into new norms and become institutionalized in altered social structures. For instance, over the past century many individual women in successive cohorts have responded to common social changes by making many millions of separate but similar personal decisions to move in new directions: to go to college, have a career, or form their families in innovative ways. Such decisions, beginning in one cohort and transmitted from cohort to cohort, can feed back into the social structures and gradually pervade entire segments of society. Thus, many new age norms have become expectations that women should work, and have stimulated the demand for new role opportunities at work and in the family for people of all ages.

Age Composition and Structures. At any given period of history, the coexisting cohorts of people that form the age strata coincide with the existing role structures (both indicated by the perpendicular lines in Figure 1). People who differ in age and experience confront the available age-related opportunities, or lack of opportunities, in work, education, recreation, the family, and elsewhere. However, people and structures rarely fit together smoothly: there is a mismatch or “lag” of one dynamism behind the other.

Structural Lag. While people sometimes lag behind structures as technology advances, more frequent in modern society is the failure of structural changes to keep pace with the increasing numbers of long-lived and competent people (Riley, Kahn, and Foner 1994). Cohorts of those who are young today have few “real-world” opportunities; those in the middle years are stressed by the combined demands of work and family; and those who have reached old age are restive in the prolonged “roleless role” of retirement. Cohorts of people now old are more numerous, better educated, and more vigorous than their predecessors were in 1920 or 1950; but few changes in the places for them in society have been made. Capable people and empty role structures cannot long coexist. Thus, implicit in the lag are perpetual pressures toward structural change.

Age Integration. Among societal responses to structural lag are current tendencies toward “age integration” (Riley, Foner, and Riley 1999, p.338). With pressures from the expanded numbers of age strata, many age barriers dividing education, work and family, and retirement are gradually becoming more flexible. People of different ages are more often brought together, as lifelong education means that old and young study together, as new entrepreneurs hire employees of mixed ages, as in many families four generations are alive at the same time, or as the age segregation of nursing homes is replaced by home health care with wide access to others. Where such tendencies may lead in the future is not yet known. But the interdependence between cohorts and structure is clear.

RESEARCH METHODS.

When aspects of these broad cohort perspectives are translated into empirical studies, a variety of research methods are required for specific objectives: from analyses of historical documents and subjective reports, to panel analyses and mathematical modeling, to rigorous tests of specific hypotheses. This brief overview can only hint at the diverse research designs involved in analyses of the multiple factors affecting lives of people in particular cohorts; or in the shifting role opportunities for cohort members confronting economic, religious, political, and other social institutions (for one example, see Hendricks and Cutler 1990).

Cohort Analysis. The tool most widely used in large-scale studies is “cohort analysis,” which takes the intercohort aging perspective—in contrast to “period analysis” (Susser 1969), which takes the cross-sectional perspective. (The difference is illustrated in Figure 1 by comparison of the diagonal cohort lines, in contrast to comparison of a sequence of vertical compositional slices). In his 1992 formulation of the technical aspects of cohort analysis, Ryder defines the term as “the parameterization of the life cycle behavior of individuals over personal time, considered in the aggregate, and the study of change in those parameters over historical time” (p. 230). He conceptualizes the cohort as “providing a macro-analytic link between movements of individuals from one to another status, and movements of the population composition from one period to the next.”

His classic work on “demographic translation” sets out the mathematical procedure for moving between the cohort and the period “modes of temporal aggregation” (Ryder 1963, 1983).

Central to this method is the *identification problem* confounding many attempts at cohort analysis. This problem occurs from efforts to interpret the separate effects of three concepts—cohort, period, and age (C, P, and A)—when only two variables, such as date and years of age, are indexed. Apart from various procedures that assume one of the parameters is zero, the most appropriate solution to this problem is to specify and measure directly the three concepts used in the particular analysis (Cohn 1972; Rodgers 1982; Riley, Foner, and Waring 1988, pp. 260–261). After all, as Ryder puts it (1992, p. 228), the cohort (C) is a set of actors, the age (A) is their age, and the period (P) stands for the social context at the time of observation.

Wide Range of Methods. Ryder’s exegesis of this particular method illustrates, through its strengths and limitations, the utility of the tripartite conceptualization of cohort perspectives as a heuristic guide. The strengths in Ryder’s formulation focus exclusively on the significance of cohorts as a macro-analytic vehicle for social change. In the broader cohort perspectives outlined here, many other methods are useful for specific objectives where cohort analysis is inappropriate. Some employ a cross-sectional approach. Others utilize intercohort comparisons to focus on aging processes at the individual as well as the collective levels. Still others complement demographic analyses of populations with examination of the related structures of social roles and institutions.

Thus, despite its signal contributions, neither cohort analysis nor any other single method can comprehend the full power of cohorts as ingredients of aging processes, age composition, and the complex interplay with social structure.

MATILDA WHITE RILEY

COLLECTIVE BEHAVIOR

Collective behavior consists of those forms of social behavior in which the usual conventions cease to guide social action and people collectively transcend, bypass, or subvert established institutional patterns and structures. As the name indicates, the behavior is collective rather than individual. Unlike small group behavior, it is not principally coordinated by each-to-each personal relationships, though such relationships do play an important part. Unlike organizational behavior, it is not coordinated by formally established goals, authority, roles, and membership designations, though emergent leadership and an informal role structure are important components. The best known forms of collective behavior are rumor, spontaneous collective responses to crises such as natural disasters; crowds, collective panics,

crazes, fads, fashions, publics (participants in forming public opinion), cults, followings; and reform and revolutionary movements. Social movements are sometimes treated as forms of collective behavior, but are often viewed as a different order of phenomena because of the degree of organization necessary to sustain social action. This essay will include only those social movement theories that also have relevance for the more elementary forms of collective behavior.

Theories of collective behavior can be classified broadly as focusing on the behavior itself (microlevel) or on the larger social and cultural settings within which the behavior occurs (macrolevel or structural). An adequate theory at the microlevel must answer three questions, namely: How is it that people come to transcend, bypass, or subvert institutional patterns and structures in their activity; how do people come to translate their attitudes into significant overt action; and how do people come to act collectively rather than singly? Structural theories identify the processes and conditions in culture and social structure that are conducive to the development of collective behavior. Microlevel theories can be further divided into *action* or *convergence* theories and *interaction* theories.

MICROLEVEL CONVERGENCE THEORIES

Convergence theories assume that when a critical mass of individuals with the same disposition to act in a situation come together, collective action occurs almost automatically. In all convergence theories it is assumed that: "The individual in the crowd behaves just as he would behave alone, *only more so*," (Allport 1924, p. 295), meaning that individuals in collective behavior are doing what they wanted to do anyway, but could not or feared to do without the "facilitating" effect of similar behavior by others. The psychological hypothesis that frustration leads to aggression has been widely applied in this way to explain racial lynchings and riots, rebellion and revolution, and other forms of collective violence. Collective behavior has been conceived as a collective pursuit of meaning and personal identity when strains and imbalances in social institutions have made meaning and identity problematic (Klapp 1972). In order to explain the convergence of a critical mass of people experiencing similar frustrations, investigators

posit deprivation shared by members of a social class, ethnic group, gender group, age group, or other social category. Because empirical evidence has shown consistently that the most deprived are not the most likely to engage in collective protest, more sophisticated investigators assume a condition of *relative deprivation* (Gurr 1970), based on a discrepancy between expectations and actual conditions. Relative deprivation frequently follows a period of rising expectations brought on by improving conditions, interrupted by a setback, as in the J-curve hypothesis of revolution (Davies 1962). Early explanations for collective behavior, generally contradicted by empirical evidence and repudiated by serious scholars, characterized much crowd behavior and many social movements as the work of criminals, the mentally disturbed, persons suffering from personal identity problems, and other deviants.

Rational decision theories. Several recent convergence theories assume that people make rational decisions to participate or not to participate in collective behavior on the basis of selfinterest. Two important theories of this sort are those of Richard Berk and Mark Granovetter.

Berk (1974) defines collective behavior as the behavior of people in crowds, which means activity that is transitory, not well planned in advance, involving face-to-face contact among participants, and considerable cooperation, though he also includes panic as competitive collective behavior. Fundamental to his theory is the assumption that crowd activity involves rational, goal-directed action, in which possible rewards and costs are considered along with the chances of support from others in the crowd. Rational decision making means reviewing viable options, forecasting events that may occur, arranging information and choices in chronological order, evaluating the possible consequences of alternative courses of action, judging the chances that uncertain events will occur, and choosing actions that minimize costs and maximize benefits. Since the best outcome for an individual in collective behavior depends fundamentally on what other people will do, participants attempt to advance their own interests by recruiting others and through negotiation. Berk's theory does not explain the origin and nature of the proposals for action that are heard in the crowd, but describes the process by which these proposals

are sifted as the crowd moves toward collaborative action, usually involving a division of labor. To explain decision making, he offers a simple equation in which the probability of a person beginning to act (e.g., to loot) is a function of the product of the net anticipated personal payoff for acting (e.g., equipment or liquor pilfered) and the probability of group support in that action (e.g., bystanders condoning or joining in the looting.)

Granovetter's (1978) application of rational decision theory focuses on the concept of *threshold*. He assumes that each person, in a given situation, has a threshold number or percentage of other people who must already be engaging in a particular action before he or she will join in. Since it can be less risky for the individual to engage in collective behavior (riotous behavior, for example) when many others are doing so than when few are involved, the benefit-to-cost ratio improves as participation increases. Based on the personal importance of the action in question, individual estimation of risk, and a host of other conditions, individual thresholds will vary widely in any situation. Collective behavior cannot develop without low-threshold individuals to get it started, and development will stop when there is no one with the threshold necessary for the next escalation step. Collective behavior reaches an equilibrium, which can be ascertained in advance from knowing the distribution of thresholds, when this point is reached. Like Berk, Granovetter makes no effort to explain what actions people will value. Furthermore, intuitively appealing as the theory may be, operationalizing and measuring individual thresholds may be, for all practical purposes, impossible.

MICRO-LEVEL INTERACTION THEORIES

Contagion Theories. Early interaction theories, which lay more emphasis on what happens to people in the context of a crowd or other collectivity than on the dispositions people bring to the collectivity, stressed either the emergence of a group mind or processes of imitation, suggestion, or social contagion. Serge Moscovici (1985a, 1985b) is a defender of these early views, stressing that normal people suffer a lowering of intellectual faculties, an intensification of emotional reactions, and a disregard for personal profit in a crowd. The fundamental crowd process is suggestion, emanating from charismatic leaders. During the twentieth

century, the breakdown of social ties has created masses who form larger and larger crowds that are controlled by a few national and international leaders, creating an historically new politics or appeal to the masses.

Herbert Blumer (1939) developed a version of the contagion approach that has been the starting point for theories of collective behavior for most American scholars. Blumer explains that the fitting together of individual actions in most group behavior is based on shared understandings under the influence of custom, tradition, conventions, rules, or institutional regulations. In contrast, collective behavior is group behavior that arises spontaneously, and not under the guidance of preestablished understandings, traditions, or rules of any kind. If sociology in general studies the social order, collective behavior consists of the processes by which that order comes into existence. While coordination in publics and social movements and involving more complex cognitive processes called *interpretation interaction*, coordination in the crowd and other elementary forms of collective behavior is accomplished through a process of *circular reaction*. Circular reaction is a type of interstimulation in which the response by others to one individual's expression of feeling simply reproduces that feeling, thereby reinforcing the first individual's feeling, which in turn reinforces the feelings of the others, setting in motion an escalating spiral of emotion. Circular reaction begins with individual restlessness, when people have a blocked impulse to act. When many people share such restlessness, and are already sensitized to one another, circular reaction can set in and create a process of *social unrest* in which the restless state is mutually intensified into a state of *milling*. In milling, people move or shift their attention aimlessly among each other, thereby becoming preoccupied with each other and decreasingly responsive to ordinary objects and events. In the state of *rapport*, collective excitement readily takes over, leading to a final stage of *social contagion*, the "relatively rapid, unwitting, and non-rational dissemination of a mood, impulse, or form of conduct." (Blumer 1939) Social unrest is also a prelude to the formation of publics and social movements. In the case of the public, the identification of an issue rather than a mood or point of view converts the interaction into discussion rather than circular reaction. Social movements begin with circular

reaction, but with persisting concerns they acquire organization and programs, and interpretative interaction prevails.

Emergent Norm Theory. Ralph Turner and Lewis Killian [(1957) 1989] criticize convergence theories for underemphasizing the contribution of interaction processes in the development of collective behavior, and found both convergence and contagion theories at fault for assuming that participants in collective behavior become homogeneous in their moods and attitudes. Instead of emotional contagion, it is the emergence of a norm or norms in collective behavior that facilitates coordinated action and creates the illusion of unanimity. The emergent norm is characteristically based on established norms, but transforms or applies those norms in ways that would not ordinarily be acceptable. What the emergent norm permits or requires people to believe, feel, and do corresponds to a disposition that is prevalent but not universal among the participants. In contrast to convergence theories, however, it is assumed that participants are usually somewhat ambivalent, so that people could have felt and acted in quite different ways if the emergent norm had been different. For example, many rioters also have beliefs in law and order and fair play that might have been converted into action had the emergent norm been different. Striking events, symbols, and keynoting—a gesture or symbolic utterance that crystallizes sentiment in an undecided and ambivalent audience—shape the norm and supply the normative power, introducing an element of unpredictability into the development and direction of all collective behavior.

Emergent norm theory differs from contagion theories in at least six important and empirically testable ways. First, the appearance of unanimity in crowds, social movements, and other forms of collective behavior is an illusion, produced by the effect of the emergent norm in silencing dissent. Second, while the collectivity's mood and definition of the situation are spontaneously induced in some of the participants, many participants experience group pressure first and only later, if at all, come to share the collectivity's mood and definition of the situation. Third, unlike collective excitement and contagion, normative pressure is as applicable to quiet states such as dread and sorrow as it is to excited states. Fourth,

according to emergent norm theory, a conspicuous component in the symbolic exchange connected with the development of collective behavior should consist of seeking and supplying justifications for the collectivity's definition of the situation and action, whereas there should be no need for justifications if the feelings were spontaneously induced through contagion. Fifth, a norm not only requires or permits certain definitions and behaviors; it also sets acceptable limits, while limits are difficult to explain in terms of a circular reaction spiral. Finally, while contagion theories stress anonymity within the collectivity as facilitating the diffusion of definitions and behavior that deviate from conventional norms, emergent norm theory asserts that familiarity among participants in collective behavior enhances the controlling effect of the emergent norm.

Emergent norm theory has been broadened to make explicit the answers to all three of the key questions microlevel theories must answer: The emergent normative process as just described provides the principal answer to the question, why people adopt definitions and behavior that transcend, bypass, or contravene established social norms; participants translate their attitudes into overt action rather than remaining passive principally because they see action as feasible and timely; and action is collective rather than individual primarily because of preexisting groupings and networks and because an event or events that challenge conventional understandings impel people to turn to others for help in fashioning a convincing definition of the problematic situation. In addition, these three sets of processes interact and are mutually reinforcing in the development and maintenance of collective behavior. This elaboration of the emergent norm approach is presented as equally applicable to elementary forms of collective behavior such as crowds and to highly developed and organized forms such as social movements.

Other Interaction Theories. Although all interactional theories presume that collective behavior develops through a cumulative process, Max Heirich (1964) makes this central to his theory of collective conflict, formulated to explain the 1964–1965 year of spiraling conflict between students and the administration at the University of California, Berkeley. Common action occurs when observers perceive a situation as critical, with limited time for action, with the crisis having a simple

cause and being susceptible to influence by simple acts. Heirich specifies determinants of the process by which such common perceptions are created and the process by which successive redefinitions of the situation take place. Under organizational conditions that create unbridged cleavages between groups that must interact regularly, conflict escalates through successive encounters in which cleavages become wider, issues shift, and new participants join the fray, until the conflict becomes focused around the major points of structural strain in the organization.

Also studying collective conflict as a cumulative process, Bert Useem and Peter Kimball (1989) developed a sequence of stages for prison riots, proceeding from pre-riot conditions, to initiation, expansion, siege, and finally termination. While they identify disorganization of the governing body as the key causative factor, they stress that what happens at any one stage is important in determining what happens at the next stage.

Clark McPhail (1991), in an extensive critique of all prior work, rejects the concept of collective behavior as useless because it denotes too little and fails to recognize variation and alternation within assemblages. Instead of studying collective behavior or crowds, he proposes the study of *temporary gatherings*, defined as two or more persons in a common space and time frame. Gatherings are analyzed in three stages, namely, assembling, gathering, and dispersing. Rather than positing an overarching principle such as contagion or norm emergence, this approach uses detailed observation of individual actions and interactions within gatherings and seeks explanations at this level. Larger events such as campaigns and large gatherings are to be explained as the "repetition and/or combination of individual and collective sequences of actions." (McPhail 1991, p. 221). These elementary actions consist of simple observable actions such as clustering, booing, chanting, collective gesticulation, "locomotion," synchroclapping, and many others. The approach has been implemented by precise behavioral observation of people assembling for demonstrations and other preplanned gatherings. A promised further work will help determine how much this approach will contribute to the understanding of those fairly frequent events usually encompassed by the term collective behavior.

MACROLEVEL OR STRUCTURAL THEORIES

Microlevel theories attempt first to understand the internal dynamics of collective behavior, then use that understanding to infer the nature of conditions in the society most likely to give rise to collective behavior. In contrast, macrolevel or structural theories depend primarily on an understanding of the dynamics of society as the basis for developing propositions concerning when and where collective behavior will occur. Historically, most theories of elementary collective behavior have been microlevel theories, while most theories of social movements have been structural. Neil Smelser's 1993 *value-added* theory is primarily structural but encompasses the full range from panic and crazes to social movements.

Smelser attempted to integrate major elements from the Blumer and Turner/Killian tradition of microtheory into an action and structural theory derived from the work of Talcott Parsons. Smelser describes the normal flow of social action as proceeding from values to norms to mobilization into social roles and finally to situational facilities. Values are the more general guides to behavior; norms specify more precisely how values are to be applied. Mobilization into roles is organization for action in terms of the relevant values and norms. Situational facilities are the means and obstacles that facilitate and hinder attainment of concrete goals. The four "components of social action" are hierarchized in the sense that any redefinition of a component requires readjustment in the components below it, but not necessarily in those above. Each of the four components in turn has seven levels of specificity with the same hierarchical ordering as the components. Types of collective behavior differ in the level of the action components they aim to restructure. Social movements address either values, in the case of most revolutionary movements, or norms, in the case of most reform movements. Elementary collective behavior is focused at either the mobilization or the situational facilities level. Collective behavior is characterized formally as "an uninstitutionalized mobilization for action in order to modify one or more kinds of strain on the basis of a generalized reconstitution of a component of action." (Smelser 1963 p. 71). The distinguishing feature of this action is a shortcircuiting of the normal flow of

action from the general to the specific. There is a jump from extremely high levels of generality to specific, concrete situations, without attention to the intervening components and their levels of specificity. Thus, in Smelser's view, collective behavior is intrinsically irrational.

In order for collective behavior to occur, six conditions must be met, each of which is necessary but insufficient without the others. Smelser likens the relationship among the six determinants to the value-added process in economics, with each adding an essential component to the finished product. The first determinant is *structural conduciveness*, meaning that the social structure is organized in a way that makes the particular pattern of action feasible. The second determinant is *structural strain*, consisting of ambiguities, deprivations, conflicts, and discrepancies experienced by particular population segments. Third (and central in Smelser's theorizing), is the growth and spread of a *generalized belief* that identifies and characterizes the supposed source of strain and specifies appropriate responses. The generalized belief incorporates the short-circuiting of the components of action that is a distinctive feature of collective behavior. Fourth are *precipitating factors*, usually a dramatic event or series of events that give the generalized belief concrete and immediate substance and provide a concrete setting toward which collective action can be directed. The fifth determinant is *mobilization of participants for action*, in which leadership behavior is critical. The final determinant is the *operation of social control*. Controls may serve to minimize conduciveness and strain, thus preventing the occurrence of an episode of collective behavior, or they may come into action only after collective behavior has begun to materialize, either dampening or intensifying the action by the way controls are applied. These determinants need not occur in any particular order.

Addressing a more limited range of phenomena, David Waddington, Karen Jones, and Chas Critcher (1989) have formulated a *flashpoint* model to explain public disorders that bears some resemblance to the value-added component of Smelser's theory. Public disorders typically begin when some ostensibly trivial incident becomes a flashpoint. The flashpoint model is a theory of the conditions that give a minor incident grave significance. Explanatory conditions exist at six levels. At

the *structural* level are conflicts inherent in material and ideological differences between social groups that are not easily resolvable within the existing social structure, meaning especially the state. At the *political/ideological* level, dissenting groups are unable to express their dissent through established channels, and their declared ends and means are considered illegitimate. At the *cultural* level, the existence of groups with incompatible definitions of the situation, appropriate behavior, or legitimate rights can lead to conflict. At the *contextual* level, a history of past conflicts between a dissenting group and police or other authorities enhances the likelihood that a minor incident will become a flashpoint. At the *situational* level, immediate spatial and social conditions can make public control and effective negotiation difficult. Finally, at the *interactional* level, the dynamics of interaction between police and protesters, as influenced by meanings derived from the other five levels, ultimately determine whether there will or will not be public disorder and how severe it will be. Unlike Smelser, Waddington and associates make no assumption that all levels of determinants must be operative. Also, they make no explicit assumption that disorderly behavior is irrational, though their goal is to formulate public policy that will minimize the incidence of public disorders.

Resource mobilization theories have been advanced as alternatives to Smelser's value-added theory and to most microlevel theories. Although they have generally been formulated to explain social movements and usually disavow continuity between social movements and elementary collective behavior, they have some obvious implications for most forms of collective behavior. There are now several versions of resource mobilization theory, but certain core assumptions can be identified. Resource mobilization theorists are critical of prior collective behavior and social movement theories for placing too much emphasis on "structural strain," social unrest, or grievances; on "generalized beliefs," values, ideologies, or ideas of any kind; and on grass-roots spontaneity in accounting for the development and characteristics of collective behavior. They assume that there is always sufficient grievance and unrest in society to serve as the basis for collective protest (McCarthy and Zald 1977), and that the ideas and beliefs exploited in protest are readily available in the culture (Oberschall 1973). They see collective protest as

centrally organized, with the bulk of the participants “mobilized” much as soldiers in an army are mobilized and directed by their commanders. In explaining the rise of collective protest they emphasize the availability of essential resources, such as money, skills, disposable time, media access, and access to power centers, and prior organization as the base for effectively mobilizing the resources. Resource mobilization theorists favor the use of rational decision models to explain the formulation of strategy and tactics, and emphasize the role of social movement professionals in directing protest.

There has been some convergence between resource mobilization theorists and the theorists they criticize. The broadened formulation of emergent norm theory to incorporate resources (under “feasibility”) and prior organization as determinants of collective behavior takes account of the resource mobilization contribution without, however, giving primacy to these elements. Similarly, many resource mobilization theorists have incorporated social psychological variables in their models.

Alberto Melucci (1989) offers a *constructivist* view of collective action which combines macro- and micro-orientations. Collective action is the product of purposeful negotiations whereby a plurality of perspectives, meanings, and relationships crystallize into a pattern of action. Action is constructed to take account of the goals of action, the means to be utilized, and the environment within which action takes place, which remain in a continual state of tension. The critical process is the negotiation of collective identities for the participants. In the current post-industrial era, conflicts leading to collective action develop in those areas of communities and complex organizations in which there is greatest pressure on individuals to conform to the institutions that produce and circulate information and symbolic codes.

COMMUNITARIANISM

Communitarianism is a social philosophy that core assumption is the required shared (“social”) formulations of the good. The assumption is both empirical (social life exhibits shared values) and normative (shared values ought to be formulated). While many sociologists may consider such an assumption as subject to little controversy, communitarianism is in effect a highly contested social philosophy. It is often contrasted with liberalism (based on the works of John Locke, Adam Smith, and John Stuart Mill, not to be confused with liberalism as the term is used in contemporary American politics). Liberalism’s core assumption is that what people consider right or wrong, their values, should strictly be a matter for each individual to determine. To the extent that social arrangements and public policies are needed, these should not be driven by shared values but by voluntary arrangements and contracts among the individuals involved, thus reflecting their values and interests. Communitarians, in contrast, see social institutions and policies as affected by tradition and hence by values passed from generation to generation. These become part of the self through nonrational processes, especially internalization, and are changed by other processes such as persuasion, religious or political indoctrination, leadership, and moral dialogues.

In addition, communitarianism emphasizes particularism, the special moral obligations people have to their families, kin, communities, and societies. In contrast, liberalism stresses the universal rights of all individuals, regardless of their particular membership. Indeed, liberal philosopher Jeremy Bentham declared that the very notion of a society is a fiction.

Until 1990, sociological and social psychological researchers and theorists and communitarian

philosophers often ignored one another’s works, despite the fact that they dealt with closely related issues. It should be noted, though, that communitarians were much more inclined to be openly and systematically normative than many social scientists.

HISTORY

Like many other schools of thought, communitarianism has changed considerably throughout its history, and has various existing camps that differentiate significantly. As far as can be determined, the term “communitarian” was not used until 1841, when Goodwyn Barmby, an official of the Communist Church, founded the Universal Communitarian Association.

Communitarian issues were addressed long before that date, however, for instance in Aristotle’s comparison of the isolated lives of people in the big metropolis to close relationships in the smaller city. Both the Old and the New Testament deal with various issues one would consider communitarian today, for instance the obligations to one’s community. The social teaching of the Catholic Church (for instance, concerning subsidiarity) and of early utopian socialism (for example, regarding communal life and solidarity), all contain strong communitarian *elements*, although these works are not comprehensive communitarian statements and are not usually considered as communitarian works per se.

Among early sociologists whose work is strongly communitarian, although this fact is as a rule overlooked by social philosophers, are Ferdinand Tönnies, especially his comparison of the *Gemeinschaft* and *Gessellschaft*, (or community and society); Emile Durkheim, especially his concerns about the integrating role of social values and the relations between the individual and society; and George Herbert Mead. These works are extensively examined elsewhere in this encyclopedia and hence are not discussed here.

A communitarian who combined social philosophy and sociology Martin Buber. Especially relevant are Buber’s contrast between I-It and I-Thou relations, his interest in dialogue, and his distinction between genuine communal relationships and objectified ones.

Other sociologists whose work contains communitarian elements are Robert E. Park, William Kornhauser, and Robert Nisbet. Philip Selznick, Robert Bellah and his associates, and Amitai Etzioni wrote books that laid the foundations for new (or responsive) communitarianism, which Etzioni launched as a “school” and somewhat of a social movement in 1990.

Selznick’s *The Moral Commonwealth* is especially key in forming a strong intellectual grounding for new communitarian thinking, and presents an integration of moral and social theory in a synthesis of “communitarian liberalism.” According to Selznick, communitarianism does not reject basic liberal ideals and achievements; it seeks reconstruction of liberal perspectives to mitigate the excesses of individualism and rationalism, and to encourage an ethic of responsibility (in contrast to liberalism, where the concept of responsibility has no major role). In a community there is an irrepressible tension between exclusion and inclusion, and between civility and piety. Thus community is not a restful idea, a realm of peace and harmony. On the contrary, competing principles must be recognized and dealt with.

AUTHORITARIAN, POLITICAL THEORETICAL, AND RESPONSIVE COMMUNITARIANISM

Different communitarian camps are no closer to one another than National Socialists (Nazis) are to Scandinavian Social Democrats (also considered socialists). It is hence important to keep in mind which camp one is considering. The differences concern the normative relations between social order and liberty, and the relations between the community and the individual.

Authoritarian Communitarians. Authoritarian communitarians (some of whom are often referred to as “Asian” or “East Asian” communitarians) are those who argue that to maintain social order and harmony, individual rights and political liberties must be curtailed. Some believe in the strong arm of the state (such as former Singapore Prime Minister Lee Kuan Yew and Malaysian head of state Mahathir Bin Mohamad), and some in strong social bonds and the voice of the family and community (especially the kind of society Japan had, at

least until 1990). Among the arguments made by authoritarian communitarians is that social order is important to people, while what the West calls “liberty” actually amounts to social, political, and moral anarchy; that curbing legal and political rights is essential for rapid economic development; and that legal and political rights are a Western idea, which the West uses to harshly judge other cultures that have their own inherent values. The extent to which early sociological works, for instance, by Tönnies and *Community and Power* by Robert Nisbet, include authoritarian elements, is open to question.

Political Theoreticians . In the 1980s communitarian thinking became largely associated with three scholars: Charles Taylor, Michael Sandel, and Michael Walzer. They criticized liberalism for its failure to realize that people are socially “situated” or contextualized, and its negligence of the greater common good in favor of individualistic self-interests. In addition, as Chandran Kukathas relates in *The Communitarian Challenge to Liberalism* (Paul, Miller, Paul, eds. 1990, p.90), communitarians argue that political community is an important value which is neglected by liberal political theory. Liberalism, they contend, views political society as a supposedly neutral framework of rules within which a diversity of moral traditions coexist. . . . [Such a view] neglects the fact that people have, or can have, a strong and ‘deep’ attachment to their societies—to their nations.

While for many outside sociology, especially until 1990, these three scholars were considered the founding fathers of communitarian thinking, none of them uses the term in their work, possibly to avoid being confused with authoritarian communitarians. These scholars almost completely ignored sociological works that preceded them, and were largely ignored by sociologists.

New or Responsive Communitarians. Early in 1990, a school of communitarianism was founded in which sociologists played a key role, although it included scholars from other disciplines such as William A. Galston (political theory), Mary Ann Glendon (law), Thomas Spragens, Jr. (political science), and Alan Ehrenhalt (writer) to mention but a few. The group, founded by Amitai Etzioni, took communitarianism from a small and somewhat esoteric academic discipline and introduced

it into public life, and recast its academic content. Its tools were *The Responsive Communitarian Platform: Rights and Responsibilities*, a joint manifesto summarizing the guiding principles of the group; an intellectual quarterly, *The Responsive Community*, whose editors include several sociologists; several books; position papers on issues ranging from a communitarian view of the family to organ donation and to bicultural education; and numerous public conferences, op-eds, and a web site (www.gwu.edu/~ccps).

Key Assumptions and Concepts. Responsive communitarianism methodologically is based on the macro-sociological assumption that societies have multiple and not wholly compatible needs and values, in contrast to philosophies that derive their core assumptions from one overarching principle, for instance liberty for libertarianism. Responsive communitarianism assumes that a “good society” is based on a carefully crafted balance between liberty and social order, between individual rights and social responsibilities, between particularistic (ethnic, racial, communal) and society-wide values and bonds. In that sense, far from representing a Western model, the communitarian good society combines ‘Asian’ values (also reflecting tenets of Islam and Judaism that stress social responsibilities) with a Western concern with political liberty and individual rights.

While the model of the good society is applicable to all societies, communitarianism stresses that different societies, during various historical periods, may be off balance in rather contrasting ways and hence may need to move in *different* directions in order to approximate the *same* balance. Thus, contemporary East Asian societies require much greater tolerance for individual and communal differences, while in the American society—especially at the end of the 1980s—excessive individualism needs to be reigned in. To put it differently, communitarianism suggests that the specific normative directives that flow from the good society model are historically and culturally contingent.

Responsive communitarians stress that the relationship between liberty and social order is not a zero-sum situation; up to a point they are mutually supportive. Thus, in situations such as those prevailing in late-1990s Moscow, where liberty and social order are neglected, increasing order might well also enhance people’s autonomy and life

choices. The same might be said about reducing crime in American cities when it reached the point where people did not venture into parks, and were reluctant to ride the subway or walk the streets after dark. Moreover, totalitarian regimes, the ultimate loss of freedom, are said to arise when order is minimized.

While up to a point social order and liberty enhance one another, if the level of social order is increased further and further, responsive communitarians expect it to reach a level where it will erode people’s liberty. And, if the scope of liberty is extended ever more, it will reach a point where it will undermine the social order. This idea is expressed in the term *inverting symbiosis*, which indicates that up to a point liberty and order nourish one another, and beyond it they turn antagonistic.

The same point applies to the relationship between the self and the community. Political theorists have tended to depict the self as “encumbered,” “situated,” or “contextualized,” all of which imply that it is constrained by social order. Responsive communitarians stress that individuals within communities are able to be more reasonable and productive than isolated individuals, but if social pressure to conform reaches a high level, such pressures undermine the development and expression of the self.

The next question is: Under what conditions can the zone of symbiosis be expanded, and that of antagonism between liberty and order be minimized? To answer that question the communitarian view of human nature must be introduced. While sociologists tend to avoid this term, on the grounds that it is not testable and can lead to racism (as evident in the notion that some groups of people are more intelligent by nature), communitarians use the term with less reluctance.

The view of human nature most compatible with responsive communitarian thinking is a *dynamic* (developmental) view, which holds that people at birth are akin to animals. But unlike social conservatives, who tend to embrace a dour view of human nature, and tend to view even adults after socialization as impulsive, irrational, dangerous, or sinful—communitarians maintain that people can become increasingly virtuous if the proper processes of value-internalization and reinforcement of undergirding social institutions, the “moral

infrastructure,” are in place. At the same time, communitarians do not presume that people can be made as virtuous as liberals assume them to be from the onset. (Liberals tend to assume that crime and forms of deviant behavior reflect social conditions, especially government interventions that pervert good people, rather than criminals’ innate nature.)

The moral infrastructure, an essential foundation of a good society, draws on four social formations: families, schools, communities, and the community of communities. The four core elements of the moral infrastructure are arranged like Chinese nesting boxes, one within the other, and in a sociological progression. Infants are born into *families*, which communitarians stress have been entrusted throughout human history with beginning the process of instilling values and launching the moral self. *Schools* join the process as children grow older, further developing the moral self (“character”), or trying to remedy character neglect suffered under family care. Schools are hence viewed not merely or even primarily as places of teaching, where the passing of knowledge and skills occur, but as educational institutions in the broadest sense of the term.

Human nature, communitarians note, is such that even if children are reared in families dedicated to child raising and moral education, and children graduate from strong and dedicated schools, these youngsters are still not sufficiently equipped for a good, communitarian society. This is a point ignored by social philosophers who often assume that once people have acquired virtue and are habituated, they will be guided by their inner moral compass. The very concept of “conscience” assumes the formation of a perpetual inner gyroscope.

In contrast, communitarians—following standard sociological positions—assume that the good character of those who have acquired it tends to degrade. If left to their own devices, individuals gradually lose much of their commitments to their values, unless these are continuously reinforced. A major function of the *community*, as a building block of the moral infrastructure, is to reinforce the character of its members. This is achieved by the community’s “moral voice,” the informal sanction of others, built into a web of informal affect-laden relationships, which communities provide.

In general, the weaker the community—because of high population turnover, few shared core values, high heterogeneity, etc.—the thinner the social web and the slacker the moral voice. The strength of the moral voice and the values it speaks for have been studied using a series of questions such as, Should one speak up if child abuse is witnessed? Or if children are seen painting swastikas? What about less dire situations, such as insisting that friends wear their seatbelts, or admonishing a nondisabled person one witnesses parking in a handicap space?

Informal surveys show that Americans in the 1980s were very reluctant to raise their moral voice; many accepted the liberal ideology that what is morally sound is to be determined by each individual, and one should not pass judgments over others. Alan Wolfe’s study, *One Nation After All*, found that Americans, even in conservative parts of the country, have grown very tolerant of a great variety of social behavior. Increase in tolerance is of course by itself virtuous; communitarians, though, raise the question: At which point does such increased tolerance engendering an amoral culture where spousal abuse, discrimination, child neglect, drunk drivers, obsessive materialism, and other forms of antisocial behavior become matters the community should ignore, leaving them to individual discretion or the law.

More specifically, communitarians inquire various elements of the moral infrastructure whether they reinforce, neglect, or undermine it. In this context, the special communitarian perspective of voluntary associations is especially important. Previously, the significance of these associations has been highlighted as protecting individuals from the state (a protection they would not have if they faced the state as isolated or “atomized” individuals), and as intermediating bodies that aggregate, transmit, and underwrite individual signals to the state.

Communitarians argue that, in addition, the very same voluntary associations often fulfill a rather different role: They serve as social spaces in which members of communities reinforce their social webs and articulate their moral voice. That is, voluntary associations often constitute a basis of communal relationships. Thus, the members of a local chapter of the Masons, Elks, or Lions care

about one another and reinforce each other's particular brand of conservative views. Similarly, the members of the New York City Reform Clubs, Americans for Democratic Action, and local chapters of the ACLU reinforce one another's particular brand of liberal views.

Communitarians pay special attention to the condition of public spaces as places communities happen (as distinct from private places like homes and cars). Even though one may carpool with friends or have them over for a visit, these are mainly activities of small friendship groups (what Robert Putnam calls "bowling alone"). Communities need more encompassing webs, and those are formed and reinforced in public gathering places—from school assembly halls to parks, from plazas to promenades. To the extent that these spaces become unsafe, communities lose one of their major sources of reinforcement; recapturing them for community use is hence a major element of community regeneration.

Most important, drawing again on sociology, and particularly on what has been called the "consensus" rather than the "conflict" model, communitarians tend to maintain that if in addition to strong families and schools that build character, a society has communities, where social webs are intact and that moral voice is clearly articulate, that society will be able to base its social order largely on moral commitments rather than the forces of the state. This is the case, communitarians argue, drawing on sociological assumptions and studies, because once moral commitments are internalized and reinforced they help shape people's preferences in favor of prosocial behavior—thus reducing the need for coercion by the state and diminishing the tension between liberty and social order.

Many discussions of community and of the moral infrastructure stop at this point, having explored the moral agency of family, school, and community. However, social and moral communities are not freestanding; they are often parts of more encompassing social entities. Moreover, communitarians note that unless communities are bound socially and morally into more encompassing entities, they may war with one another. Hence, the importance of *communities of communities*, the society.

Communitarians argue that one should not view society as composed of millions of individuals, but as pluralism within unity. They further maintain that subcultures and loyalties are not a threat to the integrity of society as long as a core of shared values and institutions (such as the Constitution and its Bill of Rights, the democratic way of life, and mutual tolerance) are respected.

Communitarians draw on the four elements of the moral infrastructure—families, schools, communities, and communities of communities—as a sort of a checklist to help determine the state of the moral infrastructure in a given society. They argue that the decline of the two-parent family (due to high divorce rates, growing legitimation of single-parent families, and psychological disinvestment of parents in children), the deterioration of schools (due to automatic promotions and deterioration of social order in schools), the decline of communities (due to modernization), and the decline of the community of communities (as a result of excessive emphasis on diversity without parallel concern over shared bonds) resulted in the decline of moral and social order in the American society during the 1970s and 1980s. This was evidenced by the sharp rise in violent crime, drug abuse, teen pregnancy, and in the decline of voluntarism, among other factors. The fact that some of these trends slowed down and reversed in the 1990s is viewed in part by communitarians as a reflection of changes in social thinking and practices they helped champion.

Here lies a great difference between the communitarian position and that of various religious social conservatives. Both groups recognize the need to regenerate the moral infrastructure, but conservatives favor returning to traditional social formations while communitarians point to new ways of shoring up society's ethical framework. For instance, many social conservatives favor women "graciously submitting to their husbands" and returning to homemaking, while communitarians argue for peer marriage, a concept introduced by Pepper Schwartz. Peer marriage suggests equal rights and responsibilities for mothers and fathers, but favors marriages that last, as compared to the liberal argument that single-parent families or child care centers can socialize children as well if not better than two-parent families. (Among the sociologists who have struck a

communitarian position in this matter are Linda Waite, Glen Elder, Alice Rossi, and David Popenoe).

The communitarian argument over the role of communities in maintaining social order is strongly supported by sociological research of the kind conducted by Robert Sampson on the role of communities in fighting crime and drug abuse. David Karp and Todd Clear have also studied community involvement in criminal justice, focusing on ideas of restorative justice and policies that are concerned more with reintegrating offenders into their communities than merely punishing them.

Other communitarian themes examined by sociologists include topics explored by Edward W. Lehman, especially his writing on macro-sociology; Martin Whyte's work on the family; and Richard Coughlin's comparison of communitarian thinking to socioeconomics.

CIVIL SOCIETY, THE THIRD WAY, AND THE GOOD SOCIETY

Much of the normative debate in the West, at least since the middle of the nineteenth century, has focused on the merit of the free market (or capitalism) versus the role of the state in securing the citizens' well-being. Communitarians have basically leapfrogged this debate, focusing instead on the importance of the third element of social life, that of the civic society, which is neither state nor market. Communitarians have played a key role in the debate over the condition of civic society in the West, such as examining whether participation in voluntary associations, voting, and trust in institutions have declined, and to what effect. The work of Robert Bellah and his associates has been particularly influential here, demonstrating the rise of first expressive and then instrumental individualism, and their ill effects.

Communitarians have argued that rather than dumping people (often the most vulnerable members of society) into the marketplace as the welfare state is curtailed, civic society's various institutions can empower these individuals to help one another in attending to some of their social needs. Communal institutions (including places of worship) can shoulder important parts of care previously provided by state agencies, although the state will have to continue to shoulder an important part of the burden.

Communitarians stress that mutuality, rather than charity, is the basis for community-wide action that is not solely limited to helping one particular vulnerable group or another. The CPR training of some 400,000 Seattle citizens, who are thus able to help one another without public costs or private charges, is held up as a key case in point. Other examples include voluntary recycling programs, crime watch patrols, and above all the massive assistance given to immigrants by members of their own ethnic group. Communitarians have also pointed to the importance of a culture of civility in maintaining a society's ability to work out differences without excessive conflict.

Communitarians have argued that a civic society is good, but not good enough. Civic society tends to be morally neutral on many matters other than values concerning its own inherent virtue and the attributes citizens need to make them into effective members of a civic society, for instance, to be able to think critically. Thus, all voluntary associations, from the KKK to the Urban League, from militias to Hadassah, are considered to have the same basic standing. In contrast, a good society seeks to promote a core of substantive values, and thus views some social associations and activities as more virtuous than others. In the same vein, communitarians have stressed that while everyone's legal right to free speech should be respected, there is no denying that some speech—seen from the community's viewpoint—is morally sound while other speech is abhorrent. For instance, the (legal) right to speak does not make hate speech (morally) right. Communitarians would not seek to suppress hate speech by legal means, however, but they urge communities to draw on their moral voice to chastise those who speak in ways that are offensive.

CRITICS AND RESPONSES

Critics of responsive communitarianism argue that the concept of community is vague; indeed that the term "community" itself cannot be well defined. In response, *community* has been defined as a combination of two elements: a) A web of affect-laden relationships among a group of individuals, relationships that often crisscross and reinforce one another (rather than merely one-on-one or chainlike individual relationships) and b) A measure of commitment to a set of shared values,

norms, and meanings, and a shared history and identity to a particular culture.

Some critics also contend that the quest for community is anachronistic, that contemporary societies are urban and populations geographically highly mobile, and thus bereft of community. Communitarians respond that communities exist in contemporary societies in small towns, suburbs, campuses and within city neighborhoods, often based on ethnic ties in places such as Korea Town in Los Angeles, Little Italy in New York City, the Irish section of South Boston, and so on. Moreover, communitarians point out that communities need not be geographic, members can be spread among nonmembers. For instance, homosexual groups often constitute communities even if they are not all neighbors.

Critics maintain that communities are authoritarian and oppressive, and have charged communitarians with seeking "Salem without witches." Communitarians respond that communities vary regarding this assessment. Contemporary communities tend to be relatively freer, given the relative ease of intercommunity mobility as well as shifting loyalties and psychic investments among various groups of which the same person is a member.

Critics also maintain that communities are exclusionary, and hence bigoted. Communitarians respond that communities must respect the laws of the society in which they are situated, but do tend to thrive on a measure of homogeneity and on people's desire to be with others of their own kind. Moreover, given the human benefit of community membership, a measure of self-segregation should be tolerated.

Critics of responsive communitarianism claim that communitarians ignore matters of power and injustice as well as economic considerations, and are generally inclined to adopt a consensus rather than a conflict model. Communitarians agree that they ought to pay more attention to the effects of these factors on communities. However, they do envision the possibilities of conflict within communities, and responsive communitarians do propose that one should not treat conflict and community as mutually exclusive. Extending this idea to the treatment of diversity and multiculturalism, communitarians argue in favor of a society in which many differences can be celebrated as long

as a set of commitments to the overarching society is upheld.

VALUES AND VIRTUES

While sociologists greatly altered and enriched communitarian thinking, communitarian thinking's main contribution to sociology is the challenge of facing issues raised by the moral standing of various values, and the related question of cross-cultural moral judgments. Sociologists tend to treat all values as conceptually equal; a sociologist may refer to racist Afrikaners' beliefs and to humanitarian beliefs using the same "neutral" term, calling both "values." Communitarians use the term virtue to denote that some values (or belief systems) have a higher standing than others because they are compatible with the good society, while other values are not (and hence aberrant).

In the same vein, communitarians do not shy away from passing cross-cultural moral judgments, rejecting cultural relativism's claim that all cultures have basically equal moral standing. Thus, they view female circumcision, sex slaves, and *hudud* (chopping off the right hand of thieves) as violations of liberty and individual rights, and abandoning children, violating implicit contracts built into communal mutuality, or neglecting the environment, as evidence of a lack of commitment to social order and neglect of social responsibilities.

IMPACT

So far this examination has focused on the place of communitarian thinking in academic, conceptual, theoretical, and imperial works. Responsive communitarians have also been playing a considerable public role, presenting themselves as the founders of a new kind of environmental movement, one dedicated to shoring up society (not the state) rather than nature. Like environmentalism, communitarianism appeals to audiences across the political spectrum, although it has found greater acceptance with some groups rather than others. British Prime Minister Tony Blair is reported to have adopted the communitarian platform, and German Social Democrat Rudolf Scharping has suggested that his party should meet the communitarians "half way." President Bill Clinton and his wife Hillary Rodham Clinton (author of *It*

Takes a Village) have combined communitarian with welfare-liberal themes. Among conservatives, Jack Kemp, a group of Tory members of the British parliament (especially David Willet), and German governor Kurt Biedenkopf are often listed as influenced by communitarianism. While this is only a partial list, it serves to illustrate the scope of communitarianism's influence and its cross over traditional ideological lines.

Communitarian terms have become part of the public vocabulary in the 1990s, especially references to "assuming responsibilities to match rights," while "communitarianism" itself is used much less often. The number of articles about communitarian thinking in the popular press increased twelvefold during the last decade of the twentieth century. The increase in the number of books, articles, and Ph.D. dissertations in academia for the same period, has been about eightfold. Interestingly, taking communitarianism from academia to the "streets" in the early 1990s resulted in the middle and late 1990s into a significant increase in academic interest. In the process, bridges have been built between social philosophers, sociologists, and community members and leaders, although they still sometimes travel on parallel rather than convergent pathways.

An extensive bibliography of communitarian works is also listed on The Communitarian Network's website, <http://www.gwu.edu/~ccps>.

COMMUNITY

The sociology of community has been a dominant source of sociological inquiry since the earliest days of the discipline. Each of the three most influential nineteenth century sociologists (Marx, Durkheim, and Weber) regarded the social transformation of community in its various forms to be a fundamental problem of sociology and sociological theory. Thomas Bender (1978) suggests that as early social thinkers observed the disruption of the traditional social order and traditional patterns of social life associated with industrialization, urbanization, and the rise of capitalism, significant attention was focused on the social transformation of community and communal life. It should be emphasized that contemporary sociology remains, at its core, a discipline largely concerned with the definition and persistence of community as a form of social organization, social existence, and social experience.

The definition of community in sociology has been problematic for several reasons, not the least of which has been nostalgic attachment to the idealized notion that community is embodied in the village or small town where human associations are characterized as *Gemeinschaft*: that is, associations that are intimate, familiar, sympathetic, mutually interdependent, and reflective of a shared social consciousness (in contrast to relationships that are *Gesellschaft*—casual, transitory, without emotional investment, and based on self-interest). According to this traditional concept of community, the requirements of community or communal existence can be met only in the context of a certain quality of human association occurring within the confines of limited, shared physical territory.

The classic perspective on community offered by Carle Zimmerman (1938) is consistent with this theme, in that the basic four characteristics argued by Zimmerman to define community (social fact,

specification, association, and limited area) require a territorial context. George Hillary (1955), in a content analysis of ninety-four definitions of community advanced in sociological literature, discovered basic consensus on only three definitional elements: social interaction between people, one or more shared ties, and an area context. However, Hillary noted that area context was the least required of these three definitional elements. Others (e.g., Lindeman 1930; Bender 1978; McMillan and Chavis 1986) argue that community can be achieved independently of territorial context where social networks exist sufficiently to sustain a *Gemeinschaft* quality of interaction and association. According to this point of view, territory is neither a necessary nor a sufficient condition to define the existence of community. In this vein, David McMillan and David Chavis suggest a state of community exists when four elements co-exist: membership, influence, integration and fulfillment of needs, and shared emotional connections. They argue that communities can be defined either in relational terms or territorial terms as long as these four elements are present together.

MAJOR QUESTIONS IN THE SOCIOLOGY OF COMMUNITY

The major questions that concern the sociology of community include the distinguishing characteristics and definition of community, the bases of communal experience and integration, the unique functions and tasks of community, the units of social structure within the community and the relationships and interactions between structural units, the economic and social bases of the community social structure, the relationship and distinction between internal community social structure and macrosocial structures external to the community, the relationship between individual experience and behavior and communal experience and behavior, the causes and processes of transformation from *Gemeinschaft* to *Gesellschaft* states of social existence, and processes of community persistence and adaptation in the face of social change.

COMMUNITY STUDIES

Community studies undertaken by sociologists over the past sixty years have to a large extent

sought to address some if not all of these issues. The most famous and controversial include Robert and Helen Lynd's Middletown studies (1929, 1937) and the Yankee City series by W. Lloyd Warner and his associates (1963). The more well-known studies that have focused on the problem of community within large cities have included William Whyte's *Street Corner Society* and Gerald Suttles's *The Social Order of the Slum*, which themselves are aligned with earlier Robert Park and Ernest Burgess conceptions of the "natural community" arising within the confines of a seemingly faceless, anonymous, large city (Suttles 1972, pp. 7-9). Descriptive studies that emphasize field work and examine social structure as a spatial phenomenon are the hallmark of the highly influential Chicago School that arose and flourished under Robert Park and Ernest Burgess of the University of Chicago Department of Sociology during the 1920s and 1930s.

Robert and Helen Lynd carried out two studies (1929, 1937) involving extensive personal field work on the town of Muncie, Indiana: *Middletown* (1929) and *Middletown in Transition* (1937). In the first Middletown study, the Lynds spent the years 1924-1925 participating in and observing the community life of Middletown (population 36,500), and performing extensive survey work. Their objective was to address all aspects of social life and social structure of the community. A fundamental focus of the Lynds' earlier analysis concerned the consequences of technological change (industrialization) on the social structure of Middletown, in particular the emergence of social class conflicts subsequent to turn-of-the-century industrialization.

Although the Lynds found distinctions between the living conditions and opportunity structures of business and working-class families that were consistent with their Marxist expectations (i.e., children of the working class were more likely to drop out of school to help support the family, working-class families labored longer hours for less pay and less financial security, and living conditions in general were more harsh for working-class families), they failed to discover a disparate value structure or alienation among the working class. At all levels of social class, the Middletown of 1925 shared a common conservative value structure that entailed self-reliance, faith in the future, and a belief in hard work. The subsequent study, undertaken in 1935 by Robert Lynd and a staff of

five assistants, addressed the effects on Muncie of certain events during the period between 1925 and 1935, some of which were economic boom times, a thirty-seven percent population increase, and the emergence of the Great Depression. The Lynds' fundamental questions in the later study addressed the persistence of the social fabric and culture of the community in the face of the "hard times" and other aspects of social change, the stability of community values concerning self-reliance and faith in the future when confronted by structurally-induced poverty and dependence, whether the Depression promoted a sense of community or undermined community solidarity by introducing new social cleavages, and the outcomes of latent conflicts observed in the mid-1920s (Lynd and Lynd 1937, p. 4).

The conclusion reached by the Lynds was that the years of depression did little to diminish or otherwise change the essentially bourgeois value structure and way of life in Middletown, and that in almost all fundamental respects the community culture of Middletown remained much as it did a tumultuous decade earlier: "In the main, a Rip Van Winkle, fallen asleep in 1925 while addressing Rotary or the Central Labor Union, could have awakened in 1935 and gone right on with his interrupted address to the same people with much the same ideas" (Lynd and Lynd 1937, p. 490). Although this remark seems to reflect some amount of disappointment on the Lynds' part that Middletown's bourgeois value system and class structure remained so unchanged in the face of widespread and unprecedented destitution, the Lynds still remained convinced that the Middletown family was in jeopardy, as evidenced by (among other things) an ever-widening generation gap. The Lynds' apprehensions concerning the survival of the American family were (and are) in keeping with the popular belief concerning the decline of the American family as its socialization functions are assumed by other formal social institutions external to the family.

The Middletown III study undertaken from 1976 to 1978 by Theodore Caplow, Howard M. Bahr, and Bruce A. Chadwick, attempted to closely replicate the methodology of the Lynds. However, their findings were at odds with the more pessimistic predictions of the Lynds. In contrast to the Lynds' foreboding in 1935 and popular sociology since that time, Caplow and his associates

contend that Middletown's families of the 1970s have "increased family solidarity, a smaller generation gap, closer marital communication, more religion, and less mobility" (Caplow et al. 1982, p. 323). The conclusions derived from the third Middletown studies also reject similar assumptions concerning consistent linear trends in equalization, secularization, bureaucratization, and depersonalization consistent with the relentless *Gemeinschaft* to *Gesellschaft* theme (Bahr, Caplow, and Chadwick 1983).

Although many of the Lynds' predictions concerning the social transformation of Middletown failed to pan out as history unfolded, their work and remarkable powers of observation remain unparalleled in many respects. Of equal importance, the early Middletown studies helped to inspire such other works as *Street Corner Society* and the Yankee City studies, and they remain the standard by which all other community studies are judged.

The largest scale community study undertaken remains W. Lloyd Warner's Yankee City, published in a five volume series from 1941 through 1959 (W. Lloyd Warner and Paul S. Lund, *The Social Life of a Modern Community* 1941; W. Lloyd Warner and Paul S. Lund, *The Status System of a Modern Community* 1942; W. Lloyd Warner and Leo Srole, *The Social Systems of American Ethnic Groups* 1945; W. Lloyd Warner and J. O. Low, *The Social System of the Modern Factory* 1947; and W. Lloyd Warner *The Living and the Dead* 1959). The Yankee City project was undertaken by Warner and his associates in Newburyport, Massachusetts during the late 1930s. Warner, an anthropologist, attempted to obtain a complete ethnographic account of a "representative" American small community with a population range from 10,000 to 20,000. To accomplish this task, Warner's staff (numbering in the thirties) conducted aerial surveys of Newburyport and its surrounding communities, gathered some 17,000 "social personality" cards on every member of the community, gathered data on the professed and de facto reading preferences of its citizens, and even subjected plots of local plays to content analysis (Thernstrom 1964).

Warner's conception of Yankee City was that of a stable, rather closed community with a social structure being transformed in very negative ways

by the latter stages of industrialization. According to Warner's vision of Yankee City, the loss of local economic control over its industries through a factory system controlled by "outsiders" disrupted traditional management-labor relations and communal identification with local leadership. Moreover, the factory system was seen by Warner as promoting an increasingly rigid class structure and decreased opportunities for social mobility. In particular, Warner's discussion of the loss of local economic control through horizontal and vertical affiliation, orientation, and delegation of authority seems to have offered a prophetic glimpse into the future for many American communities.

Although the Yankee City study produced a voluminous ethnographic record of an American city that has remained untouched in scale, Warner found little support for his contention that the ethnographic portrait of Newburyport produced by the Yankee City series could be generalized to other small American communities. Moreover, Warner's contention that social mobility is reduced by industrial change was not supported by the quality of his data and was less true in Warner's time than it probably is today. Other critiques of Warner's Yankee City study primarily concern his nearly exclusive reliance on ethnographic information as the basis for all measures of social structure and his disdain for historical data (Thernstrom 1964).

Both Gerald Suttles's *The Social Order of the Slum* (1968) and William Whyte's *Street Corner Society* (1943) provide sociology with unparalleled ethnographic accounts of neighborhood social structure and communal life in urban environs. Suttles's work focuses on the territorial relationships, neighborhood social structure, and communal life among Italian, Latino, and African American inhabitants of the slums of Chicago's Near West Side in the 1960s. Whyte's *Street Corner Society*, based on Whyte's residence in a Chicago Italian slum district a generation earlier, provides sociology with an understanding of the complex and stable social organization that existed within slum neighborhoods conventionally believed to have epitomized social disorganization. Whyte's observations and keen insights concerning small group behavior are pioneering contributions to that area of sociology. Both studies, in method, theory, and substance are classic examples of Chicago School

sociology. More contemporary community studies, while they draw heavily on Chicago School sociological traditions in theory and method, have as their primary concern aspects of community that relate to poverty, juvenile delinquency, and violence. For example, Robert Sampson and his colleagues conducted a large-scale study of Chicago neighborhoods that linked subjective definitions of neighborhood with social cohesion and violence inhibiting actions on the part of neighbors (Sampson 1997a, 1997b). Theoretically, Sampson's work draws heavily on Robert Park's conception of the social cohesion that exists within the "natural areas" of the city that are defined by both physical and sentimental boundaries (Park 1925), while methodologically Sampson and his colleagues employed the classic Chicago School preference for field observation—albeit with the modern advantages of a video camera located within a slowly moving van in place of the shoe leather sociology of their predecessors.

COMMUNITY IN THE CONTEXT OF SOCIAL REFORM

Efforts to enhance the social context of human existence continuously take place at all levels of social organization, from the microcontext of the nuclear family to the macrocontext of relationships between nation-states. No unit of social organization has received more attention in theories and activities linked to social reform than the human community, however it is defined and measured. Community in the context of social reform is typically viewed or employed in one of the following four ways: as a unit of analysis for the purpose of broad generalization, as a critical mediating influence between the organization of mass society and individual outcomes, as a specific target of social reform efforts, or as a symbolic conception of whatever is "right" or "wrong" with society at large.

The use of rural and urban communities as the basis for reform-motivated generalization emerged in the United States during the Progressive era, when social activists affiliated with Chicago's famous settlement house, Hull House, and the newly formed Department of Sociology at the University of Chicago shared a common geographically-rooted conception of social science and concern for the living conditions of Chicago's urban

poor (Sklar 1998). *Hull House Maps and Papers*, published in 1895, provides a remarkably detailed description of the lives and living conditions within Chicago's ethnic neighborhoods based on the field research of university students and full-time residents of Hull House. In fact, the beginnings of Chicago School sociology were clearly rooted in the methods if not the concerns of Hull House social reformers, despite the fact that as women they were excluded from holding academic appointments until the creation of the Chicago School of Civics and Philanthropy in 1907 (Muncy 1991).

In later years, small towns and neighborhoods within larger towns became a common unit of analysis as community studies conducted by the federal Children's Bureau tried to assess the incidence and causes of infant mortality. The first of these studies, conducted in Johnstown, Pennsylvania in 1913, was the earliest scientific study of the incidence of infant mortality by social class, education, occupation, and specific living conditions conducted in the United States (Duke 1915). Reform-driven community studies since then have addressed such social issues as child labor, juvenile delinquency, education, industrial working conditions, and adequate housing. Although single communities are still used by social reformers as a basis for broad generalization, such studies are enormously expensive to conduct, often of limited use for generalization, and altogether less frequent with the availability of national survey data.

Despite the conceptual ambiguities involved, the geographically-bounded community (e.g., census tract, city ward, resident defined neighborhood) is generally viewed by liberal and conservative social reformers alike as the critical mediating social context between the well-being of individuals, the effective functioning and stability of families, and society at large. Robert Hauser and his associates identify such factors as the physical infrastructure, the quality and quantity of neighborhood institutions, the demographic composition, and the degree of "social capital" present as measurable aspects of neighborhoods that are critical to the well-being of children and families (Hauser, Brown, and Prosser 1997). The concept of social capital, introduced by James Coleman, refers to the beneficial normative context that arises in some neighborhoods based on the social ties among neighboring households and local institutions (Coleman 1988). In this vein, Robert

Sampson demonstrates that neighborhoods with evidence of more social capital are more effective in inhibiting adolescent delinquency (Sampson, 1997b). Speaking from the opposite perspective of social disorganization, William Julius Wilson (1987, 1996), and Douglas Massey and Nancy Denton (1993) emphasize the deleterious effects on the normative context within communities created by such macrolevel exogenous factors as economic restructuring, concentrated poverty, and racial segregation. A related concern is the extent to which increased spatial stratification by social class may be promoting neighborhoods and larger communities, which function as distinct social worlds with ever more divergent values and opportunity structures (Massey 1996).

Efforts to effect social reform at the community level have a long tradition of sentiment, failure, and mixed success. There are a variety of reasons for failure, not the least of which is that communities, like individuals, both mirror and are shaped by complex exogenous social processes. Contemporary issues include conceptual differences in the measures used for community, the fact that community effects on individual outcomes are difficult to isolate and often weaker than popular theory would suggest (Plotnick and Hoffman 1999; Brooks-Gunn, Duncan, and Aber 1997), and the limiting effect of macrolevel processes on community-level reform efforts (Wallace and Wallace 1990; Halpern 1991). Recent efforts at community-level social reform have placed more emphasis on understanding the unique social context within a target community before applying social prescriptions that appear logically appealing or may have worked elsewhere. For example, David Hawkins and Richard Catalano, in their work on juvenile drug and alcohol abuse, focus on a community assessment process that considers the risk and protective factors that are unique to each community before deciding upon specific community-level interventions (Hawkins and Catalano 1992).

SOCIAL THEORY AND THE TRANSFORMATION OF COMMUNITY

Every generation of sociologists since the time of Durkheim have concerned themselves with the social transformation and meaning of community in the face of industrial change and urbanization.

Roland Warren (1978) describes the modern social transformation of community as a change of orientation by the local community units toward the extracommunity systems of which they are a part, with a corresponding decrease in community cohesion and autonomy (Warren 1978, pp. 52–53). Warren identifies seven areas through which social transformation can be analyzed: division of labor, differentiation of interests and association, increasing systemic relationships to the larger society, bureaucratization and impersonalization, transfer of functions to profit enterprise and government, urbanization and suburbanization, and changing value.

Bender (1978) proposes that the observations by various community scholars at different points in historical time, each suggesting that theirs is the historical tipping point from community to mass society, contradict linear decline or an interpretation of history that stresses the collapse of community. He suggests that a “bifurcation of social experience” or sharpening of the distinction between *Gemeinschaft* and *Gesellschaft* realms of social interaction is a more accurate interpretation of the historical transformation of community than that provided by the linear *Gemeinschaft-to-gesellschaft* framework.

Barry Wellman and Barry Leighton (1979) suggest that there are three essential arguments concerning the fate of community in mass society: community “lost,” community “saved,” and community “liberated.” The community “lost” argument emerged during the Industrial Revolution, as traditional communal modes of production and interaction gave way to centralized, industrialized sources of production and dependence. According to this hypothesis and its variations, the intimate, sustained, and mutually interdependent human associations based on shared fate and shared consciousness observed in traditional communal society are relentlessly giving way to the casual, impersonal, transitory, and instrumental relationships based on self-interest that are characteristic of social existence in modern industrial society.

The classic essay in the community “lost” tradition is Louis Wirth’s “Urbanism as a Way of Life” (1938). Wirth’s eloquent essay presents a perspective of urban existence that continues to capture sociological thinking about the emergence

of a heterogeneous urban mass society characterized by a breakdown of informal, communal ways of meeting human need and the rise of human relationships that are best characterized as “largely anonymous, superficial, and transitory” (Wirth 1938, p. 1). Another important contribution in the decline of community tradition is the “community of limited liability” thesis (Janowitz 1952; Greer 1962). According to this thesis, networks of human association and interdependence exist at various levels of social organization, and there are social status characteristics associated with differentiated levels of participation in community life (e.g., family life-cycle phase). The idea of “limited liability” poses the argument that, in a highly mobile society, the attachments to community tend to be based on rationalism rather than on sentiment and that even those “invested” in the community are limited in their sense of personal commitment.

In direct contrast to the community “lost” perspective, the community “saved” argument suggests that communities and communal relationships continue to exist within industrialized bureaucratic urban societies as people are increasingly motivated to seek “safe communal havens” (William and Lieghton 1979, p. 373). For example, Bahr, Caplow, and Chadwick (1983), forty years after the Lynds’ *Middletown in Transition* study, failed to find the singular trends in bureaucratization, secularization, mobility, and depersonalization that would be predicted from a linear decline of community hypothesis. Their observation of Middletown in the 1970s was more consistent with the perspective proposed by Robert Redfield (1955); that both urban ways and folkways coexist within contemporary small towns and cities: “In every isolated little community there is civilization; in every city there is the folk society” (Redfield 1955, p. 146).

The community “liberated” argument concedes and to some extent qualifies key aspects of both the community “lost” and community “saved” perspectives. While it acknowledges that neighborhood-level communal ties have been weakened in the face of urbanization, it argues that communal ties and folkways still flourish, albeit in alternative non-spatial forms. The community “liberated” argument suggests that the spatial dependence of communal ties have been replaced by ease of mobility and communication across boundaries of

both geographic and social distance. Although the community “liberated” argument preceeded the development of the Internet and cyberspace “chatrooms” by decades, it emphasizes the role of communication technology in the creation of such future manifestations of community and in that sense was strikingly prophetic.

Despite the fact that the decline of community or the community “lost” perspective continues to hold broad appeal (e.g., Robert Putnam’s “The Strange Disappearance of Civic America,” *The American Prospect*, Winter, 1996), the empirical evidence for a real decline in community is far from conclusive. A time trend analysis of national surveys concerning the persistence of community in American society by Avery Guest and Susan Wierzbicki (1999) suggests that while traditional intra-neighborhood forms of socializing have slowly declined over the past two decades, they have been largely replaced by communal ties outside the local neighborhood. Moreover, Guest and Wierzbicki’s findings also suggest that spatial “with-in neighborhood” communal ties continue to be important to a large segment of the population. Their findings imply that the major questions about the place of community in mass society should not be about whether communal forms of relationships will continue to exist, but rather under what conditions and in what form.

COMPARABLE WORTH

"Comparable worth" is one approach to increasing pay equity between jobs done primarily by women and minorities and those done primarily by majority men. It refers to equalizing compensation for jobs requiring comparable levels of effort, skill, and responsibility. The concept of comparable worth defines "equal work" as "work of equivalent value," a broader concept than limiting "equal work" to meaning the "same work." Comparable worth uses job-evaluation methods to establish equivalencies of different jobs in order to identify and correct disparities in pay between jobs held primarily by women and minority men and jobs held primarily by nonminority men. It is worth noting that the term *pay equity* is often used in conjunction with discussions of comparable worth; it usually refers not only to comparable worth but also to other approaches to achieving equity and justice in wages. Pay equity is the best subject heading or "key word" to use when doing further research on the topic of comparable worth.

Proponents of using comparable worth to establish pay equity argue that 1) at least some part of the lower wages in female-dominated jobs and occupations is due to pay discrimination against women, and 2) job evaluation systems can determine the equivalency of different jobs and thus identify the jobs and occupations where this form of discrimination exists.

The issue of comparable worth arose in response to obvious differences in the rewards for jobs held primarily by women and those held primarily by men—even when those jobs required the same or similar levels of education, skill, and responsibility. Advocates of comparable worth and pay equity argue that these wage differences are based on historical and current discrimination in the setting of wages for jobs held primarily by women and minorities. That is, jobs in which workers are primarily women and minorities have been, and remain, systematically undervalued relative to equivalent jobs held by majority men. This undervaluation depresses the wages in jobs done by women and minorities relative to the wages for jobs historically performed by white men. Thus, discrimination is embedded in the current wage structure of jobs (Remick 1984; Marini 1989). Continued job and occupational segregation by sex, combined with the continued systematic undervaluation of jobs held by women and minorities, is thereby a cause of continued inequality and a form of labor market discrimination.

The argument that discrimination is the basis for the inequality of wages between men's and women's jobs is not new. In the 1922 presidential address to the British Association of Economists, F.Y. Edgeworth spoke on "Equal Pay to Men and Women for Equal Work." Edgeworth outlined three major conclusions regarding wage inequality between men and women. First, that men and women work in different jobs, albeit jobs that often require similar levels of effort and skill. Second, that jobs held by women are paid far less than those held by men. Third, that removing overt discrimination would be unlikely to equalize wages for men and women fully (Edgeworth 1922). The findings of recent empirical studies have generally supported these three conclusions.

There is considerable evidence demonstrating that men and women work in different occupations. Comparisons of occupational segregation

by sex in the United States since 1900 show that levels of segregation have been persistent through the 1960s and 1980s (Gross 1968; Jacobs 1989). During the 1980s more than half of the workers of one sex would have had to change occupations in order to equalize the distribution of men and women across all occupations (Jacobs 1989). Researchers using more specific job titles within firms have found that almost no men and women work together in the same job in the same firm (Bielby and Baron 1986).

On average, women continue to earn substantially less than men. Women earned 62 percent of what men earned in 1975 and just over 75 percent of what men earned in 1995 (Figart and Kahn 1997). The concentration of women in low-paying, female-dominated occupations has been found to account for a substantial portion of this income difference. The amount of the income gap between men and women explained by the sex segregation of occupations varies from 25 percent to over 33 percent across many studies of this issue (Sorensen 1986; Figart and Kahn 1997). The remainder of the difference between men's and women's average earnings is due to other factors, such as differences in the overall skills and experience individual men and women bring with them to the labor market.

Empirical studies have examined whether the gap in wages between female-dominated and male-dominated occupations is based on differences in the occupations with regard to the skills required or the work environments. Treiman and colleagues (1984), in an evaluation of the effects of differences in characteristics of male and female occupations on wages, found that "about 40 percent of the earnings gap between male- and female-dominated occupations can be attributed to differences in job characteristics and 60 percent to differences in the rate of return on these characteristics." That is, he found that the premium paid for skills in male-dominated occupations was higher than that paid for the same skills in female-dominated occupations. Other research has confirmed the findings that specific skills (such as dealing with the public) or requirements (such as having a high school diploma) increase wages more in a male-dominated occupation than in a female-dominated occupation (McLaughlin 1978; Beck and Kemp 1986). Other possible explanations for differences

in wages between male-dominated and female-dominated occupations—such as that female-dominated occupations have greater nonmonetary compensations (such as vacation, sick leave, flexibility in working hours) (Jencks, Perman and Rainwater 1988) or that they are more accommodating to intermittent careers (England 1982)—have not been supported by empirical studies.

The conclusion of J.S. Mill in 1865, as quoted by Edgeworth in 1922—“The remuneration of the peculiar employments of women is always, I believe, greatly below that of employments of equal skill and equal disagreeableness carried on by men.”—is similar to the conclusion reached by the National Research Council/National Academy of Sciences committee report in 1981:

“[Such] differential earnings patterns have existed for many decades. They may arise in part because women and minority men are paid less than white men for doing the same (or very similar) jobs within the same firm, or in part because the job structure is substantially segregated by sex, race, and ethnicity and the jobs held mainly by women and minority men pay less than the jobs held mainly by non-minority men” (Treiman and Hartmann 1981, p.92).

The evidence is fairly conclusive that occupational-level wage discrimination exists—that is, that skills and requirements are less well rewarded in jobs held primarily by women than they are in jobs held primarily by men. Comparable worth advocates argue that applying job-evaluation methods is a viable method for reducing this form of wage discrimination. This is clarified in Helen Remick’s proposed working definition of comparable worth as “the application of a single, bias-free point factor job evaluation system within a given establishment, across job families, both to rank-order jobs and to set salaries” (1984, p.99).

Job-evaluation methods are well established and have been used for decades to establish equivalencies across jobs. Actual methods of job evaluation differ, but the usual approach is to start by describing all jobs within a given organization. Next, a list of important job requirements is developed and jobs are rated on each requirement. For example, one requirement could be the use of mathematics. In this case each job would be rated from “low” (e.g. addition and subtraction of whole

numbers) to “high” (e.g., the use of differential equations). Most job-evaluation methods include job requirements such as level of education, skills, level of responsibility, and the environment in which the work is performed. Some job-evaluation methods also include such characteristics of job incumbents as average education, training, and experience. More complex job-evaluation systems also consider how jobs rank with regard to fringe benefits (e.g. sick leave), hours (e.g. shift work), training and promotion opportunities, hazards, autonomy (e.g. can leave work without permission), authority (e.g. supervises others), and organizational setting (e.g. organizational size) (see Jencks et al. 1988). After each job is rated and given a certain number of “points” for each requirement, the points are then added into an overall “score” for each job. These scores are then weighted based on the importance assigned to a particular job attribute. Each job then receives a total number of points based on all of the appropriate factors in order to compare the value to the firm of different jobs. These composite scores are then used to rank jobs in order to help determine appropriate wages (Blau and Ferber 1986). This makes it possible to compare wages paid for jobs with very different—but comparable—content. In addition to considering the training and work requirements for jobs within the firm, systems of job evaluation often also take into account whatever information is available on prevailing wages for different types of labor. The use of job evaluation is neither new nor unusual, and currently job evaluation is often used to determine pay scales by governments and by many businesses. Job evaluations are primarily used when employers cannot rely on the market to establish wages. (See Spilerman 1986, for a discussion of the types of organizations that determine wages based on nonmarket mechanisms.) Employers must determine wages, for example, when positions are filled entirely from within an organizational unit (e.g. through promotion of an existing workforce) or when they fill jobs that are unique to a particular firm. In these cases, “going rates” for all jobs are not always available in local labor markets.

There are at least two critical limitations to using job-evaluation methods in establishing comparable worth. First, it is difficult to eliminate the effects of past practices on the identification and the weighting of important job characteristics.

Existing job-evaluation schemes have been criticized for undervaluing, or not even considering, the skills and abilities that are emphasized in some female jobs (Beatty and Beatty 1984; Stienberg 1992). For example, at one time the coding in the job-evaluation system used in the Dictionary of Occupational Titles rated the primarily male occupation "Dog Pound Attendant" as requiring a higher level of complexity with regard to working with data, people, and things than the primarily female occupations of "Nursery School Teacher" and "Practical Nurse"—which were rated as having minimal or no relationship with data, people, or things (Miller et al. 1980). Second, because job-evaluation methods are used within a particular firm or organization, they do not address wage inequalities *across* firms or organizations. This particularly limits the scope of comparable worth because, with the exception of governments (which often employ individuals across a wide range of occupational categories), most organizations are staffed by individuals in a relatively narrow span of occupations. For example, jobs in the textile and poultry-processing industries, usually held by women, and jobs in the lumber industry, usually held by men, could have the same overall scores in terms of job characteristics. However, because these jobs are usually not in the same organization, it is unlikely that job-evaluation methods could be used to equalize wages for these jobs.

Comparable-worth methods have been used in a number of legal actions in attempts to increase the equivalencies of wages for jobs held primarily by women and those held primarily by men. The outcomes of these cases have been mixed (see Remick 1984; Heen 1984; Steinberg 1987; and Figart and Kahn 1997 for reviews and discussions of cases). In the United States, the right of "equal pay for equal work" is provided by Title VII of the Civil Rights Act of 1964. An important legal action based on the premise of comparable worth was the Supreme Court ruling in the *County of Washington v Gunther*, 452 U.S. 161 (1981). This ruling removed a major legal obstacle to comparable worth as the basis of equalizing wages. Although it did not endorse the comparable worth approach, it did rule that a man and woman need not do "equal work" in order to establish pay discrimination under Title VII (Heen 1984). Subsequent lower court rulings have not resulted in clear-cut decisions regarding comparable worth, and at present

it seems unlikely that, in the United States, court decisions will mandate the comparable-worth approach. Legal and legislative actions based on comparable worth and pay equity also have emerged in countries other than the United States. Canada included a provision for equal pay for work of equal value in the Canadian Human Rights Act of 1977 (see Cadieux 1984; and Ontario Pay Equity Commission 1998). The implementation of this legislation has resulted in significant decisions regarding the need to increase wages in female-dominated occupations—both in private industry and in the government. However, the implementation of these decisions has not been without difficulty. For example, the government and the government-workers union of the Northwest Territories were, in early 1998, in disagreement with regard to whether the evaluation system used by the government to establish comparable worth was biased (Government of the Northwest Territories 1998).

Despite its limitations and difficulties in implementation, the concept of comparable worth as a basis for pay equity remains important in public policy initiatives. The National Committee on Pay Equity (1999), the American Federation of State, County, and Municipal Employees (1999), and other organizations provide information and support for advocates of comparable worth. As one approach to increasing pay equity, comparable-worth applications have the potential for identifying and correcting one of the most persistent bases for the disparity between earnings for majority men and earnings for women and minorities.

NANCY E. DURBIN
BARBARA MELBER

COMPARATIVE HEALTH-CARE SYSTEMS

At the dawn of the twenty-first century, access to health-care services, their cost and quality constitute key social, political, and economic issues for virtually every country in the world. Identifying the conditions under which health-care systems function most effectively has become a vital, albeit elusive, goal. One point is certain: It is impossible to fully understand the dynamics of health-care systems without comparative health-care research. Knowledge of systems other than one's own provides the observer with multiple vantage points from which to gain a fresh perspective on strengths and weaknesses at home. Studying other systems, including their successful as well as failed health-reform efforts, provides a global laboratory for health-systems development. While some countries have been quick to draw upon the health-care innovations of their neighbors, the United States has been relatively slow to look internationally for health-reform ideas. Fortunately, the proliferation of comparative health-care studies promises that such insularity will be much less likely in the future.

The comparative study of health-care systems focuses on two broad types of issues. The first

involves *describing* the range of health-care services in populations or societies, particularly their organization and functioning. By far the most common type of research, descriptive studies, brings together statistical indicators and factual explanations about how various national systems operate (van Atteveld et al. 1987). Some of this work incorporates an analytical dimension by categorizing systems in terms of conceptual schemes or typologies. Less attention has been paid to the second type of research, which looks more closely at the dynamics of how health-care systems behave. The intent in this type of research is to *analyze* the patterns among system characteristics, especially with the idea of anticipating the outcomes that are likely with specific types of system arrangements. Still in its infancy, this work promises an in-depth yet practical understanding of how health-care can be organized and financed to achieve desirable levels of both quality and access.

Interest in cross-national studies of health-care systems increased dramatically in the early 1990s as a result of national debates over reorganizing American health-care. Rapidly aging populations in many advanced, capitalistic countries, in combination with the expanding scope of high technology medicine, resulted in increased public demand for health-care. At the same time, poverty and other forms of social inequality as well as ineffective societal institutions created major public health problems in many developing countries, such as hazardous water, inadequate or harmful food supplies, poor air quality, unsafe homes and workplaces, and the swift spread of infectious diseases. In both cases, health-care systems have been severely challenged and often cannot meet the needs of citizens. Because of these problems and also due to enhanced global cooperation, social scientists and policy makers are increasingly turning their attention to the experience of other countries.

KEY CHARACTERISTICS FOR THE COMPARISON OF HEALTH-CARE SYSTEMS

Drawing on the work of Anderson (1989) and Frenk (1994), a health-care system can be defined as the combination of health-care institutions, supporting human resources, financing mechanisms, information systems, organizational structures that link institutions and resources, and management

structures that collectively culminate in the delivery of health services to patients. Within this broad framework, the methodology for comparing health-care systems can vary widely. A standard approach would include some or all of the dimensions outlined below.

The most fundamental comparative dimension is the *organization, financing, and control* of a health-care system. This involves comparing which health services are provided; how they are paid for; how they are configured, planned, and regulated; and how citizens gain access to them. Among countries with advanced economies, health-care services today look much the same to the casual observer; however, the financing arrangements and policy-making mechanisms that underlie them vary widely. The role of government is perhaps the most significant organizational variable in international health-care. All governments, with the notable exception of the U.S. government, accept responsibility for the health-care of citizens (Evans 1997). Some governments take it upon themselves to actually provide health services and, therefore, own their own clinics and hospitals and hire their own physicians and staff—examples are Sweden and Denmark. Within the U.S., the Veteran's Administration operates its own health-care system this way. In a variation of this model, the government acts as the purchaser (but not the owner) of health-care services, obtaining services from private providers on behalf of patients, such as in Canada or the reformed health-care system in Britain. In Finland, local governments can purchase from either public or private providers. In another model, illustrated by Germany and Japan, the government avoids acting as the major payer, and instead takes the role of an overseer, setting mandates for health coverage, including the type and level of coverage, and regulating the terms of what is largely a private system. Due to economic pressures, national governments in both Germany and Japan provided increasing subsidies to support their systems in the 1990s.

It is important also to compare health-care systems in terms of *physician characteristics and provider arrangements for primary care and prevention*. The supply of medical personnel (e.g., the number of physicians per unit of population) is a key comparative indicator. Interestingly, there is significant variation in the number of physicians in advanced economy nations, ranging per 10,000

population from fifty-five in Italy to thirty-four in Germany to twenty-six in the United States, which is more typical, to seventeen in the United Kingdom (Anderson and Poullier 1999). Equally interesting is that there is no apparent corresponding variation in the health status of these populations. A more complex issue is how different systems organize and divide medical work between various professions and occupations. In some countries, such as Sweden, Finland, and the Netherlands, midwives or nurse midwives have primary responsibility for normal prenatal care and childbirth; in others, such as the United States, physicians have responsibility for these tasks and midwives are relatively rare. Practice arrangements between generalist and specialist physicians are another point of comparison. The United States is unique among its peers because primary care physicians working in ambulatory settings also have hospital privileges, and, therefore, have the right to admit patients and to treat hospitalized patients. In Britain, Sweden, Germany, and many other countries, on the other hand, only specialists comprise the hospital medical staff and only they can treat patients there.

Hospitals and long-term care arrangements constitute another dimension in comparing health-care systems. Countries vary widely in how they use hospitals, as well as in how and where citizens with chronic illnesses and other debilitating conditions receive ongoing, nonacute care. Many Western countries today are in the process of shifting from institutional to community-based care. There are many factors affecting this transition, including whether alternatives to institutional care, such as home health and support programs, are readily available. In countries such as Japan and Germany, that through the 1990s have relied on informal family caregiving arrangements rather than institutions or community-based services, sociodemographic changes (elders living longer as well as changes in the work force participation of caregivers) are producing a long-term care crisis.

Health-systems also can be compared according to the degree to which care is *integrated and coordinated* between various sectors and levels of services. Systems that have rigid boundaries between ambulatory and hospital services, or between general medical and mental health services and that are so highly specialized that patients are required to transfer among multiple providers, illustrate arrangements where communication

across “borders” is vital for optimal patient care. The Nordic countries, in particular, have been highly conscious of gaps in the coordination and continuity of care, and have developed reforms to bridge them. Finland has adopted a model that integrates the basic education of both health-care and social care personnel, a strategy intended to link the biomedical and social aspects of health and health-care at the very beginning of professional education.

Perhaps the most common basis for comparing countries’ health-care systems is various outcome statistics such as *economic characteristics, personnel resources, utilization rates, and population health status measures*. The proportion of the population covered by government-assured health insurance stands as the indicator with the least international variation. Of the twenty-nine countries analyzed by the Organization for Economic Cooperation and Development in 1998, governments in twenty-four countries assured coverage to 99 percent to 100 percent of their population. The five exceptions were Germany with 92 percent coverage, Mexico and the Netherlands with 72 percent, Turkey with 66 percent, and the U.S. with 33 percent (Anderson and Poullier 1999). Other indicators in the same report vary widely. In per capita health-care spending, the United States spends just less than \$4,000, an amount that is substantially more than for the other nations, which range from Switzerland’s \$2547 to Turkey’s \$260. Contrary to what one might think, the amount a country spends on health-care is not reflected in the longevity of its population. Men in twenty-one countries live longer than do men in the United States (up to an average of 77 years in Japan compared to 72.7 in the United States). Similarly, women in nineteen countries live longer than American women (up to an average of 83.6 years in Japan versus 79.4 in the United States). In fact, relatively few of the high-spending countries appear among those with the greatest longevity.

Detailed comparisons of statistical characteristics have limited value when neither issues of measurement nor the contextual meanings associated with each measure are immediately clear. Each country has its own distinctive set of *sociohistorical and cultural characteristics*; these should be considered in comparative research, since they often play an important role in explaining the origin and

development of health-care systems (Payer 1996). For example, Starr (1982) has posed and explored the question of why the United States ignored national health insurance at the same time most European countries were adopting such programs. National insurance, he argues, was a form of social protectionism and was, therefore, most likely to be enacted by paternalistic regimes such as Germany and only later by more liberal states such as France and the United Kingdom. In addition, the United States' long history of rejecting national health insurance reflects its decentralized government, the relative lack of domestic unrest, and the failure of major interest groups (labor, business, and medicine) to provide support. Regarding the same issue, Steinmo and Watts (1995) contend that the structure of American political institutions creates conditions that work against the adoption of national health insurance.

A final means of comparing health-care systems is on the basis of *specific problems*, including assessments of citizen satisfaction (Donelan et al. 1999). Closely related comparisons focus on the various *strategies for reform* that countries have implemented in an attempt to address their problems (Graig 1993). Much can be learned by studying and comparing which solutions seem to work best for certain types of problems, as well as observing patterns of failure across multiple systems.

FRAMEWORKS FOR COMPARING HEALTH-CARE SYSTEMS

While it is useful to compare health-care systems on the basis of a series of characteristics, in-depth understanding of the variation in systems requires a more analytical approach. Most frameworks proposed by comparative health-system researchers can be characterized as typologies that, though they add a conceptual basis for distinguishing among systems, offer limited analytical complexity or depth. These typologies typically emphasize political or economic criteria, and several of the more complex schemes attempt to integrate the two. Graig (1993) organized the six countries she analyzed on a continuum with public systems (e.g., the United Kingdom) at one end, private systems (the United States) at the other, and mixed or "convergence" systems, such as Japan, Germany, and the Netherlands, in the middle. Roemer

(1991) developed a sixteen-cell typology that combines political and economic elements, describing systems in relation to government policies (entrepreneurial/permissive, welfare oriented, universal/comprehensive, and socialist/centrally planned) as they intersect with economic conditions (affluent, developing, poor and resource rich). These and similar approaches offered by Anderson (1989) and Light (1990) offer descriptive distinctions, but do not emphasize the theoretical basis for the particular category schemes.

Mechanic (1996) hypothesizes that health-systems internationally are converging, based on the idea that medicine forms a world culture in which knowledge and health-care ideas are quickly disseminated. He proposes six areas of convergence: nations' concerns with controlling cost and improving the efficiency and effectiveness of health-care, nations' realization that population health outcomes are largely a product of circumstances outside the medical care system, nations' concern and attempts to address inequalities in health outcomes and access to care, nations' growing interest in patient satisfaction and consumer choice, and the increasing attention nations are placing on the linkage between medical and social factors in health-care, and the struggle all nations are having between technology, specialization, and the need to develop primary care. Field (1980) also theorizes a progression of health-system development with a scheme placing systems along a continuum according to the extent to which health-care is seen as a social good. He identifies five system types in order of their progression toward a socialized system: anomic, pluralistic, insurance/social security, national health service, and socialized health-care.

Elling (1994) takes issue with the notion of "automatic convergence" and with typologies that posit unidirectional evolution or change, pointing out that countries are involved in ongoing, dynamic class struggles in the development of health-systems. His neo-Marxist framework, influenced by Wallerstein's world-systems theory, allows for countries to move back and forth among five types: core capitalist (e.g., the United States and Germany), core capitalist/social welfare (e.g., Canada, Japan, Sweden, United Kingdom), industrialized socialist-oriented (e.g., pre-1990s Soviet and

eastern European systems), capitalist dependencies in the periphery and semi-periphery (e.g., Brazil and India), and socialist-oriented, quasi-independent of the world system (e.g., China and Cuba).

In 1990, Esping-Andersen (1990) contributed an important theoretical framework to the field of comparative welfare states research, that can also be useful in distinguishing among health-care systems in advanced capitalist nations. Esping-Andersen conceptualizes all welfare activities, including health-care, as a product of a state-market-family nexus. His typology organizes “welfare regimes” around this nexus, specifically as it results in the decommodification of workers in a country; that is, the degree to which a citizen can obtain basic health and social welfare services outside of the market. In terms of health-care, this would mean a citizen’s ability to access health-care services without having to purchase them “out-of-pocket.” Esping-Andersen identifies three types of systems: conservative or corporatist, liberal, and socialist or social democratic. In *The Three Worlds of Welfare Capitalism*, he constructs measures of decommodification that he applies to data from eighteen nations in order to assess where each nation’s welfare regime ranks according to the three types. Under Esping-Andersen’s scheme, social democratic systems include the Nordic countries and the Netherlands; liberal systems include Canada, Japan, and the United States; and the conservative or corporatist welfare states include France, Germany, and Italy. These placements appear similar to what Graig proposed using a much simpler public-private dimension; however, Esping-Andersen’s methodology is unique in its theoretical approach and because it can be operationalized quantitatively to allow precise distinctions among a large number of nations.

Reviewing various health-care system frameworks shows a wide variety of approaches and scholarly emphases. Comparative research is in the process of moving beyond simple typologies to focus on the conditions under which different types of systems emerge and under which they change. This work demonstrates the value of a broad approach, integrating the key aspects that affect the development of health-care systems, including historical, cultural, political, and economic factors.

REVIEW OF SELECTED HEALTH-CARE SYSTEMS

Comparative international research on health-care systems requires information that is both detailed and current. Obtaining data is complicated by the fact that health-systems throughout the world operate in a state of constant flux. These summaries present the most recent information available for the health-care systems of selected countries. Among countries with advanced economies, Sweden and the United States often occupy opposite extremes when it comes to health-care organization and financing. For this reason, Sweden is the first country discussed along with three countries that have similar systems—Finland, the United Kingdom, and Canada—followed next by Germany, Japan, Russia, and China, with additional discussions of France, Mexico, Argentina, Chile, Colombia, and Ghana.

Swedish health-care reflects three basic principles: *equality* among citizens in access to health-care; *universality* in the nature of services (the idea that everyone should receive the same quality of services); and *solidarity*, the concept of one social group sacrificing for another group in the interest of the whole society (Zimmerman and Halpert 1997). Solidarity in this context refers to taxing those who use fewer services at the same rate as those who use more—for example, similar health-care taxation for younger persons or affluent persons versus the elderly or the poor). The Swedish health-care system is predominantly a publicly owned and funded system; thus, approximately 85 percent of Swedish health-care is publicly funded, whereas in the United States the public portion is just under 50 percent (Lassey, Lassey, and Jinks 1997). The differences between the two systems are more startling in terms of the growth of overall spending. In the early 1980s, both countries were spending approximately 9.5 percent of their Gross Domestic Product on health-care. By the end of the century, the situation had changed dramatically; in 1999, Sweden was spending 8.6 percent (\$1728 per capita) compared to 13.5 percent (\$3924 per capita) in the United States (Anderson and Poullier 1999). Populations in the two nations also differ markedly on several basic health status indicators. Infant mortality Sweden is four deaths per thousand live births compared to 7.8 in the United States. Swedish men live nearly four years longer

on average than American men, and Swedish women live two years longer than their American counterparts. These favorable statistical indicators compel a closer look into how the Swedish health-care system is organized.

The Swedish welfare state, including health-care and social services, is one of the most comprehensive and universal in the world. Health-care in Sweden is the responsibility of the state, which delegates it, in turn, to each of Sweden's twenty-one county councils (Swedish Institute 1999). Elected officials in each county are charged with providing comprehensive health services for residents, and with levying the taxes to finance them. The system is decentralized; each county by law must provide the same generous common core of services to all residents, although just how they decide to do it can vary. In the 1990s, Sweden embarked on a series of reforms in order to increase health-care quality and efficiency. As a result, Swedish citizens now have greater freedom in choosing their own primary care physicians. The vast majority of these doctors are employed by the county councils to practice in small group clinics and health centers distributed geographically throughout the country. Specialist physicians practice in hospitals where they also see outpatients on both a referral and self-referral basis. The medical division of labor also includes district nurses, physical therapists, and midwives, all of whom are used extensively to deliver care through local health centers (maternity clinics in the case of midwives). Midwives also work in hospitals where they have responsibility for normal cases of labor and delivery. Sweden's elderly constitute an increasing proportion of the population, creating significant challenges for both current and future health and social services. Sweden's social policy emphasizes that citizens should be able to live in their own homes for as long as possible, meaning that nursing home placement occurs only when absolutely necessary. Services for the elderly may involve as many as five or six home nursing visits per day in order for the disabled and elderly to remain at home in the community.

Swedish citizens are taxed heavily to maintain the quality and level of services they expect; at the same time, they have shown high levels of political support for maintaining their expensive system. In the 1980s, many services were entirely free; however, today there typically is a modest copayment.

The copayment for a primary care physician visit, for example, currently ranges from \$12 to \$17 depending on the county council. For specialist physician visits the copayment ranges from \$15 to \$31, and for hospital stays it is fixed at \$10/day. The Swedish system includes a high-cost ceiling so that, after a person spends approximately \$113 out-of-pocket each year, health-care services are free. Medications must be purchased by the individual until they have reached a threshold of a little more than \$100. Prescriptions are then discounted until the patient has spent \$225, at which point medications become free (Swedish Institute 1999). These amounts have increased somewhat during the 1990s, but due to Sweden's already high taxation rate, county councils were hesitant to ask patients to pay more. Reforms during the same period included establishing internal performance incentives or "public competition" (Saltman and Von Otter 1992), a structural arrangement that arguably enabled Sweden to maintain the basic features of its health-care system without large tax or out-of-pocket increases. Some have expressed concern that the system is stretched to its limits. Regardless of which view is correct, the Swedish system requires a healthy economy in order to continue, given continuing cost pressures and an increasingly aged population.

The Swedish model of a publicly owned and financed health-care system shares common features with systems in several other countries, including the United Kingdom, Finland, and Canada. The British National Health Service (NHS), like its Swedish counterpart, provides publicly funded, comprehensive health-care to the population, and enjoys a solid base of citizen support, albeit under ongoing criticism. What distinguishes the NHS from health-care systems in other Western countries is its frugality. Characterized by long waiting lists and what Klein (1998) refers to as "rationing by professionally defined need," Britain runs the cheapest health-care system in Europe, outside of Spain and Portugal. In the early 1990s, the NHS went through a series of dramatic changes, creating "internal markets," a system of inside competition intended to increase productivity and further decentralize its historically large and unwieldy bureaucracy. These reforms—several of which were adopted by Sweden—reorganized primary care practices and shifted physician payment from fixed salary to capitation. NHS

hospitals also entered into new arrangements where they have greater structural independence and compete among themselves. In 1997, the British government introduced new proposals that changed course yet again. The direction of the NHS in the twenty-first century is unclear (Klein 1998).

Finland's health-care system also is publicly owned, financed through general taxation, and decentralized. In fact, Finland operates with more health-care decentralization than Sweden. Since 1993, Finnish funding for health-care has been incorporated into block grants from the national government that are given annually to each of the country's 455 municipalities, some of which form partnerships for purposes of delivering health-care (Hermanson, Aro, and Bennett 1994). Within the parameters of national guidelines, elected officials in each of these jurisdictions (similar to the county councils in Sweden) have the responsibility to obtain and deliver health-care services to the population. High standards, a comprehensive array of services, as well as modest out-of-pocket payments, make the Finnish system comparable to the Swedish system. Canada also provides health-care to its entire population. The Canadian system is administered by the provinces and is financed largely by public taxation, roughly three-quarters of which is from the provincial government. While basic services remain constant, some specific provisions of health-care in Canada vary considerably from province to province. Unlike in Sweden, Finland, and the United Kingdom, Canadian physicians are paid on a fee-for-service basis. Furthermore, Canadian primary care physicians act as gatekeepers to specialists and hospitals (much as they do in Finland and the United Kingdom, but not in Sweden). As is the case with all the countries in this group of four, Canadians have extreme pride in their health-care system. They appear resolute in maintaining it, although a number of controversial cost-cutting measures and as yet unsolved problems raise considerable concern about the future (Lassey, Lassey, and Jinks 1997).

Germany and Japan, as well as France, have achieved comprehensive and universal coverage (92 percent in the case of Germany) with a model that is closer to that of the United States than the social democratic model of Sweden discussed above (U.S. General Accounting Office 1991). In all three of these countries, medical care is provided by

private physicians, by both private and public hospitals, and patients can choose their physicians. Benefits are comprehensive and mandated by the national government, which also regulates enrollment, premiums, and reimbursement of providers. In contrast to the four countries discussed earlier, financing in Germany, Japan, and France is predominantly private with multiple payers. Workplace-based insurance (financed typically through payroll deductions) covers most employees and their dependents while other payers cover the remainder of the population. Patients make copayments for physician visits and hospital stays, ranging from a nominal amount in Germany to as much as 20 percent or 30 percent of the fee in France and Japan. There is national regulation to ensure consistency. Coverage and care conditions vary from fund to fund, resulting in greater inequalities of benefits compared to the public systems of Sweden, Finland, Canada, and the United Kingdom. Arguing that such systems actually help maintain social divisions and inequality, Esping-Andersen (1990) refers to them as conservative or corporatist.

Although Germany privately finances much of its health-care system, the national government plays a strong role. All but the most wealthy of German citizens are required by law to join one of Germany's 750 insuring organizations, called "sickness funds." In practice, all but about 10 percent of the population opt to join the system, encouraged to participate by the great difficulty of getting back in later on. Sickness funds are private, non-profit organizations that collect premiums or "contributions" for each member—half paid by the individual and half by the employer—and, in turn, contract for health services with physician organizations and hospitals. One of the biggest problems for the German system is continuing cost pressures, exacerbated by the reunification of East and West Germany in 1991. The system uses fixed budgets for hospitals and strict fee schedules for physicians, with punitive measures for inordinate increases in volume, to combat the problem. These were tightened in a major 1993 reform that imposed strict three-year budgets on all major sectors of the system as well as longer-term structural reforms. Early results have been positive (U.S. General Accounting Office 1994).

Japanese health-care follows much the same private, multi-payer model as in Germany, with health-care provided to all citizens through 5,000

independent insurance plans. The plans fall into three major groups, each enrolling about a third of the population: large-firm employees, small-firm employees, and self-employed persons and pensioners. In the case of the first two plans, as is the case with the German sickness funds, the employer pays approximately half of the premium and the employee pays the remaining portion. The similarity to the German system is no accident; Japan has consciously patterned its health-care system after Germany's, dating back to its modernization in the late nineteenth and early twentieth centuries (Lassey, Lassey, and Jinks 1997). Despite these similarities, Japan's health-care system presents some unique and somewhat startling features compared to the other systems discussed here.

Compared to other systems with a significant private component, the Japanese system costs considerably less (Andersen and Poullier 1999). In 1997, for example, per capita health-care spending in Japan was \$1741, less than in the United States, Canada, France, Germany, and many other European countries. Of the nations discussed here, only the austere British system (\$1347 per capita) and efficiency-conscious Finnish system (\$1492 per capita) spent less. Japan's economical approach to delivering health-care raises two paradoxes. First, the low levels of spending would seem to contradict the fact that Japan currently has the longest life expectancy and the lowest infant mortality in the world. In addition, utilization rates in Japan are high, which some would argue indicates a sicker rather than a healthier population. Specifically, the Japanese visit physicians two to three times more frequently, stay in the hospital three to four times longer, and devote considerably more health spending to pharmaceuticals than the other nations discussed here. How can these contradictions be explained? Ikegami and Campbell (1999) argue that, in part, the paradox can be explained by the country's much lower incidence of social problems related to health, such as crime, drug use, high-speed motor vehicle accidents, teen-age births, and HIV infections. Less aggressive medicine and lower hospital staffing and amenities also are thought to keep down costs in Japan.

Health-care arrangements in nations where the political economy is neither "advanced" nor a stronghold of capitalistic democracy can also be instructive. During the latter part of the twentieth

century and until today, both China and Russia have been faced with the monumental challenge of providing health-care with very limited financial resources to huge, diverse populations, many of which live under poor social conditions. Their health-care systems, however, are quite different and their current problems reflect the distinctive political and economic trajectories of the two countries. Russian health-care at the dawn of the twenty-first century is a system in crisis. Based on socialist principles of universal and free access, the old Soviet system included a primary care network of local clinics ("polyclinics") typically connected to a general hospital, as well as more specialized hospitals. This means that a regional city might have separate hospitals for emergencies, maternity, children, and various infectious diseases (Albrecht and Salmon 1992). Funding came directly from the central government until 1993 when a new health insurance law was approved, shifting the source of financing to employer payroll deductions. There are major questions, however, as to whether such a system can be effective during the current period of resource scarcity and instability in major social institutions (Lassey, Lassey, and Jinks 1997).

Chinese health-care, for most Westerners, evokes images of acupuncture and other forms of Eastern medicine, as well as the idealized "barefoot doctors" of the 1960s and 1970s, practitioners with basic medical training who provided primary care in rural areas. In reality, traditional Chinese medicine exists alongside an increasingly dominant Western medical establishment, and the barefoot doctors have all but disappeared. Since new leadership took over the Communist Party in the late 1970s, China has encouraged privatization and decentralization in health-care. By the 1990s, nearly half of all village health-care was provided by private practitioners (Lassey, Lassey, and Jinks 1997). These changes reportedly have been accompanied by a decline in preventive care and public health efforts in rural areas. At the same time, the situation in urban areas seems to have improved. China's revolutionary-era network of local and regional clinics and hospitals has been modernized, although resource shortages continue to limit the level of technological advancement. The most significant change in China is the growing impact of privatization, which appears to be bringing China many of the same problems that

have plagued privatized systems elsewhere: lack of insurance coverage, increasing costs, maldistribution of providers, and inequalities in the overall quality of care (Liu, Liu, and Meng 1994). As in the United States, the gap between the health-care received by the rich and that received by the poor is growing (Shi 1993).

Huge disparities between the rich and poor are characteristic of Latin America where they constitute a significant barrier to universal health coverage. Latin-American health-systems vary considerably, reflecting socioeconomic differences between countries as well as historical and political contingencies. The Mexican system illustrates many of the obstacles faced by developing nations, whether in Latin America or elsewhere. The Mexican constitution established federal responsibility for health-care in 1917, along with a centralized administrative tradition that still exists; yet, to date, the two major government insurance schemes cover only about 47 percent of the population, with another 7 percent insured privately. Ostensibly, there are programs for the remaining 46 percent of the population, most of whom are low income, but in reality, many low income areas and impoverished communities are poorly served. Some have argued that a basic health-care infrastructure is in place and that there are sufficient numbers of well-trained health-care professionals available (Lassey, Lassey, and Jinks 1997). They contend that, had it not been for several national crises in the 1980s and 1990s, coupled with a lack of political will, more of the Mexican population would now be covered by the health-care system.

Bertranou (1999) has compared Argentina, Chile, and Columbia, all of which have employed various ways to reform health insurance arrangements in recent years. Chile's reforms date back to its military dictatorship in the early 1980s. At that time, private health insurers were allowed to compete for worker payroll contributions. There was little regulation of the system which encouraged adverse selection, resulting in significant inequities within the system. Even so, approximately 70 percent of the Chilean population today is covered by insurance, compared to 64 percent in Argentina and only 43 percent in Colombia. Argentina faces numerous obstacles in reforming its complex and confusing system of three types of health-care arrangements (social insurance organizations,

private health insurers and providers, and the public health-system). Its goals include universal coverage and a standard benefits package. In the case of Columbia, reform goals are more related to the relative poverty in the country and the fact that large segments of the population cannot afford health insurance. Per capita expenditures for health-care in Columbia are 42 percent of what they are in Chile and 20 percent of the expenditure level in Argentina. Instead of giving free access to public facilities, Columbia's reforms involve providing vouchers that allow low-income families to join the health organization of their choice. To be successful, all these reform efforts require social equilibrium where governments are able to maintain political and economic stability.

The political instability and socioeconomic inequality that have characterized Latin America are also a hindrance to health-care systems in Africa. An even more fundamental problem in Africa, however, is the formidable lack of resources to address overwhelming health-care needs (Schieber and Maeda 1999). Even where clinics, hospitals, and medical personnel exist, there is likely to be a lack of the required equipment and medicines. In Africa as a whole, 80 percent of the physicians live and practice in the cities where less than 20 percent of the population lives. According to Sanneh (1999), this continuing situation supports the prominent role of traditional healers, 85 percent of whom live in rural areas. The difficulties encountered by Ghana in implementing a system of primary care illustrate the situation affecting many African nations. In 1983, soon after the primary care system was adopted, the government attempted cost containment by introducing "user fees" in all public health facilities, clinics as well as hospitals. Two years later the fees were increased and, subsequently, a health insurance program was instituted. One must question the practical significance of these developments in a country where over half of rural residents and nearly half of those in urban areas live below poverty (Anyinam 1989). These circumstances are a reminder that developing countries contain 84 percent of the world's population, yet account for only 11 percent of global health-care spending (Schieber and Maeda 1999), making the task of designing strategies for effective health-care delivery in the developing world the true challenge for comparative health-care system researchers.

Comparing health-care systems entails a vast array of information, including historical background, cultural patterns and beliefs, geographic considerations, as well as social, economic, and political factors. It involves detailed descriptions of policies and procedures, complex statistical profiles, as well as an understanding of conceptual frameworks, theory, and comparative methods. The potential rewards of comparative work, however, balance the challenges. Whether there is convergence in the structure and functioning of health-care systems or not, many of the problems faced by nations in delivering health-care to citizens are similar. There are lessons to be learned from comparing health-care systems internationally that can only aid in addressing these problems.

MARY KO ZIMMERMAN

COMPARATIVE-HISTORICAL SOCIOLOGY

Explicit analytic attention to time and space as the context, cause, or outcome of fundamental social processes distinguishes comparative-historical analysis from other forms of social research. Historical processes occurring in or across geographic, political, or economic units (e.g., regions, nation-states, multi-state alliances, or entire world systems) are systematically compared for the purposes of more generally understanding patterns of social stability and social change (Abrams 1982; Skocpol 1984a; Tilly 1984; Mahoney 1999). Three very different and influential studies illustrate both

the kinds of questions comparative-historical sociologists address and the approaches they use.

First is the classic study by Reinhard Bendix ([1956] 1974) on work and authority in industry. Bendix initially observed that all industrial societies must authoritatively coordinate productive activities. Yet by systematically comparing how this was done in four countries during particular historical periods—pre-1917 Russia, post-World War II East Germany, and England and United States during epochs of intense industrialization—he showed that national variation in ideologies of workplace dominance were related to differences in the social structures of the countries studied.

Second is the analysis of the historical origins and development of the modern world system by Immanuel Wallerstein (1974). Wallerstein took as his unit of analysis the entire sixteenth-century capitalist world economy. Through comparing instances of the geographic division of labor, and especially the increasing bifurcation of global economic activity into "core" and "peripheral" areas, Wallerstein suggested that the economic interdependence of nation-states likely conditions their developmental trajectories.

Third is the analysis of social revolutions by Theda Skocpol (1979). Skocpol compared the histories of revolution in three ancient regime states: pre-1789 France, czarist Russia, and imperial China, and found that revolutionary situations emerged in these states because international crises exacerbated problems induced by their agrarian class structures and political institutions. She then buttressed her causal generalizations by comparing similar agrarian societies—Meiji Japan, Germany in 1806 and 1848, and seventeenth century England—that witnessed failed revolutions.

Each of these influential studies combined theoretical concepts and nonexperimental research methods to compare and contrast historical processes occurring within and across a number of geographic cases or instances. By using such research methods, Bendix, Wallerstein, Skocpol, and many others are following in the footsteps of the founders of sociology. In their attempts to understand and explain the sweeping transformations of nineteenth-century Europe, Alexis de Tocqueville, Karl Marx, Emile Durkheim, and Max Weber all employed and contributed to the formulation of this broad analytic frame (Smelser 1976; Abrams

1982). Comparative-historical analysis in sociology—and, as we shall see, debate over how it should be conducted—thus is as old as sociology itself.

PURPOSES, PROMISE, ACHIEVEMENTS

The analytic power of comparative-historical strategies stems from the uniquely paradoxical quality of the perspectives, data, and procedures in comparative-historical research. On the one hand, historical comparisons have the potential to harness and exploit the huge variation in social processes and institutions. Some scholars believe this essential to the development of truly general theory and to transcultural/transhistorical explanation (Przeworski and Tuene 1970; Kiser and Hechter 1991). On the other hand, historical comparisons have the potential to exploit the “time-space boundedness” of social life and its historical antecedents and specificity. Others view this as equally essential to theoretical development and to concrete, “real world” explanation (Moore 1966; Skocpol 1984b; Tilly 1984; Stryker 1996). Most comparative-historical sociologists capitalize in some fashion on this paradox, finding diversity in the midst of uniformity and producing regularities from differences.

One of the great advantages of historical comparisons is that they reduce bias induced by culturally and historically limited analyses and interpretations of the social world. Social structures and processes in the past were generally quite different from those observed today, and contemporary institutional arrangements and social relations differ substantially across cultures, regions, and states. Patterns of historical change and continuity, moreover, have varied from one country or culture to another. Some scholars, such as Bendix (1963, [1956] 1974), relish this diversity and use historical comparisons to emphasize and interpret the peculiarities of each case. Even seeming uniformities across cases may mask important differences, and comparative-historical inquiry may be used to detect these “false similarities” (Bloch [1928] 1969).

Examination of historical or national differences also can lead to the detection of previously unknown facts that may suggest a research problem or pose a hypothesis amenable to empirical exploration. Marc Bloch ([1928] 1969), for example, tells of how his knowledge of the English land

enclosures led him to discover similar events in France. Comparing histories also aids in the formation of concepts and the construction of “ideal types” (Weber 1949; Bendix 1963; Smelser 1976). For example, Weber’s ([1904] 1958) concepts of “the Protestant ethic” and “the spirit of capitalism” and Wallerstein’s (1974) notion of the “world system” derive from comparative-historical inquiry. Linking apparently disparate historical and geographical phenomena, as Karl Polanyi ([1944] 1957) does when he relates the gold standard to the relative geopolitical tranquility throughout much of the nineteenth century, also is one of the fruits of comparative-historical analysis. New information, conceptual development and the discovery of unlikely commonalities, linkages, and previously unappreciated differences are necessary for the generation, elaboration, and historical grounding of social theory.

The analysis of comparative-historical patterns can allow for more adequate testing of established theory than does study of a single nation, culture, or time period. Plausible theories of large-scale social change, for example, are intrinsically processual and so require historical analysis for a genuine elaboration or examination of their hypotheses (Tilly 1984). Historical comparisons also can be used to assess the generality of putative “universal” explanations for social structure and social action (e.g., functionalism, Marxism). Abstract propositions thought operative across time and space, for example, can be directly confronted through the analysis of parallel cases that should display the same theoretical process (Skocpol and Summers 1980), thereby specifying a theory’s generality and empirical scope.

Comparative-historical analysis sometimes is directed toward developing explanations that explicitly are “relative” to space and time (Beer 1963) or that represent historically or culturally “limited generalizations” (Joynt and Rescher 1960). Skocpol’s (1979) analysis of social revolutions in France, Russia, and China, for example, resulted in limited causal generalizations deemed valid for these three cases only. Exceptions to theoretical and empirical generality, moreover, can be conceptualized as deviant cases—anomalies or puzzles. For example, Werner Sombart ([1906] 1976) posed the question “Why is there no socialism in the United States?” precisely because the United

States, when contrasted to the European experience and stacked up against available explanations for the development of class-conscious labor politics, appeared both historically and theoretically anomalous. To explain such puzzles, the original theory is modified and new concepts and theories with greater explanatory power are formulated. The improved theory then serves as the new starting point for subsequent inquiry, so that cumulation of knowledge is facilitated (Stryker 1996). Thus historical patterns are comparatively situated, the “inexplicable” residue of time and place therefore is potentially “explicable” (Sewell 1967), and sociological theory is further developed.

ANALYTIC TYPES OF HISTORICAL COMPARISONS

Contemporary comparative-historical research practice rests upon diverse, even contradictory, epistemologies and research strategies (Bonnell 1980, Skocpol 1984b, Tilly 1984; Ragin 1987; McMichael 1990; Kiser and Hechter 1991; Griffin 1992; Sewell 1996; Stryker 1996; Mahoney 1999). These can be initially grouped into two basic approaches, labeled here “analytical formalism” and “interpretivism.” Each displays considerable internal diversity, and the two can overlap and be combined in practice. Moreover, they can be synthesized in creative ways, thereby capitalizing on the strengths of each approach and reducing their respective weaknesses. The synthesis, “causal interpretivism,” is sufficiently distinct as to constitute a third approach to the analysis of comparative history.

Analytically formal comparison. *Formal comparison* conforms generally to conventional scientific practice in that causal explanation is the goal. It is therefore generally characterized by the development and empirical examination or testing of falsifiable theory of wide historical scope, by the assumption of the preexistence of discrete and identifiable cases, and by the use of formal logical or statistical tools and replicable analytic procedures. Historical narration and the “unities of time and place” (Skocpol 1984b, p. 383) are deliberately replaced by the language of causal analysis. Analytic formal comparison can be used to generalize across time and space, to uncover or produce limited causal regularities among a set of carefully

chosen cases, and to establish a theory’s scope conditions. There are two major procedural subtypes in this genre, statistical comparisons and formal qualitative comparisons.

Statistical analyses of comparative-historical phenomena are logically and inferentially identical to statistical analyses of any other social phenomena. Thus, they rely on numerical counts, theoretical models, and techniques of statistical inference to assess the effects of theoretically salient variables, to test the validity of causal arguments, and to develop parsimonious, mathematically precise generalizations and explanations. One important way in which the statistical method appears in comparative-historical inquiry is in the form of “comparative time-series” analysis, in which statistical series charting historical change are systematically compared across countries. Charles, Louise, and Richard Tilly (1978) and Bruce Western (1994), for example, first use statistical time-series procedures to map and explain historical variation in working-class activity within European nations. They then compare, either qualitatively (the Tillys) or quantitatively (Western), these national statistical patterns to detect and explain historical differences and similarities across these countries. The second major use of statistical procedures relies on quantitative data from many social units for only one or a few time points. Emphasis in this “cross-national” tradition (e.g., Chase-Dunn 1979; Jackman 1984; Korpi 1989) is on detecting causal generalizations that are valid for a large sample or even an entire population of countries. Though the results of such studies typically resemble a static, cross sectional snapshot of historical process, this analytic strategy sometimes is necessitated because complete time-series data do not exist for very many nations, especially those now undergoing economic and social development (e.g., Pempel and Williamson 1989). Due both to their data limitations and to their focus on statistical regularities and theory testing, cross-national studies typically slight historical processes and homogenize cultural differences across cases. The understanding of cases as real social units deserving of explanation in their own right consequently is sometimes lost (Tilly 1984; Skocpol 1984b; Ragin 1987; Stryker 1996). In the 1990s, however, some cross-national statistical analysts, though continuing their search for general patterns, began to

incorporate a more thorough appreciation of history and cultural difference into their analyses (e.g., Western 1994).

Formal qualitative comparison, by way of contrast, views cases “holistically,” as qualitatively distinct and independent units that cannot (or should not) be decomposed into scores on quantitative variables as in statistical analysis. This strategy adopts a “case-oriented” approach that pervades the entire research process (Ragin 1987). The explanation of a few carefully chosen cases, for example, generally is the rationale for and product of the analysis, and explicit strategies have been designed to select proper instances to be compared and analyzed (Przeworski and Teune 1970; Frensdreis 1983; Lijphart 1971; Stryker 1996). Detection of causal regularities is often inferred through the application of John Stuart Mill’s ([1843] 1967) inductive canons or “method of agreement” and “method of difference” to comparative data (Skocpol 1984b; Ragin 1987). Using the method of agreement, analysts select cases that have positive outcomes on the phenomenon under study but that differ on putative explanatory conditions. These cases are then compared to see what causal factor they share. Alternative explanations are eliminated if antecedent conditions representing those claims do not occur in all cases with positive outcomes. The “method of difference” is used to guard against false inferences adduced from the method of agreement. Here analysis is conducted with cases instancing both positive and negative outcomes but that are as similar as possible on the putative causal factors. The objective of Mill’s methods is to find the one condition that is present in all positive cases and absent in all negative cases (Skocpol 1984b; Ragin 1987).

Mill’s methods are marred because they presuppose that one causal factor or configuration holds for all cases with positive instances. Historical patterns displaying “causal heterogeneity” or “multiple causal conjunctures”—two or more distinct combinations of causal forces generating the same outcome (Ragin 1987)—are therefore logically ruled out. This shortcoming results from the excessive weight Mill’s canons give negative cases: Because exceptions exist to almost any general process, the inability to find causal universals that are doubly confirmed by the twin logics of agreement and difference can rule out virtually any nontrivial explanation (Lijphart 1971; Ragin 1987;

Mahoney 1999). However, Charles Ragin’s (1987) alternative comparative algorithm—“qualitative comparative analysis” (QCA)—allows for the detection of causal heterogeneity in a large number of cases. QCA uses a data reduction strategy rooted in Boolean algebra to search for similarities among positive instances and to exploit the inferential utility of negative cases. Negative or “deviant” cases may be explained by, or give rise to, an alternative causal process, but they are not allowed to invalidate all causal generalizations. Ragin argues that QCA’s Boolean logic most closely approximates the mode of reasoning—including the use of logically possible “historical hypotheticals” and “historical counterfactuals”—employed by Weber (1949) and Barrington Moore (1966) in their powerful but less formalized comparative-historical studies.

Formal qualitative comparison can provide both historically grounded explanation and theoretical generalization. QCA is especially useful because it permits multiple causal configurations to emerge from comparative historical data and largely removes the inferential problems induced by the analysis of a small number of cases of unknown representativeness. Nonetheless, detractors—who otherwise disagree about preferred research strategies—believe that formal comparison via either Mill’s methods or QCA often is fraught with hidden substantive assumptions, unable to exert sufficient analytical control over the multitude of competing explanations, and compromised by its roots in inductive logic (Burawoy 1989; Kiser and Hechter 1991). Moreover, formal comparisons rest on a key assumption that is seriously challenged by proponents of holistic interpretive comparison—that the historical cases themselves are not systematically interrelated (Wallerstein 1974; McMichael 1990).

Interpretive comparisons. Interpretive comparisons are most concerned with developing a meaningful understanding of broad cultural or historical patterns (Skocpol 1984b). Two very different comparative logics, “holistic” and “individualizing,” are used to construct historical interpretations. Although neither logic relies extensively on formal analytic procedures, nor is geared toward testing theory, interpretive comparisons are not necessarily atheoretical or lacking in rigor. Indeed, concepts and theories, often of sweeping scope and grandeur, are extensively developed

and deployed, but for the most part as interpretive and organizing frames, or as lenses through which history is understood and represented. Interpretive comparisons often are thought impressive, but sometimes of questionable validity due either to their self-validating logic or to their lack of explicit scientific criteria for evaluating the truth content of the interpretation (Bonnell 1980; Skocpol 1984b; Tilly 1984; Stryker 1996; Mahoney 1999).

Holistic comparisons usually are tied to particular theories and are used when a “social whole” such as a world system (Wallerstein 1974) is methodologically posited. Conceptualizing the entire world system in this manner suggests that there is but one theoretical unit of analysis, and that unit is the world system. What are considered to be separate “units of analysis” or “cases” in most comparative-historical strategies are, in the holistic methodological frame, really only interrelated and interdependent historical realizations of a singular emergent process or social system. Whether nation-states, regions, or cultures, these “moments” therefore are not the discrete and independent units demanded by analytic formalism. Analysts using holistic historical comparisons in this manner often depend on an “encompassing” functional logic that explains similarities or differences among parts of a whole by the relationship the parts have to the whole (Tilly 1984). Thus, Wallerstein’s (1974) comparisons explain the differential development of temporally and spatially specific (though interdependent) economic units in the world system—the core, periphery, and semi-periphery—by their differential positions and roles in the world economy. Such explanations are often circular in their reasoning and always difficult to test, but they may serve as useful illustrations of the workings of a social whole or of the inner logic of a theory (Bonnell 1980; Skocpol 1984b).

Philip McMichael (1990) suggests “incorporated comparison” as an alternative to purge holistic comparison of its mechanistic and self-validating logic. Here a kind of social whole is posited, but it does not preexist and regulate its parts, as does the world system. Instead, it is analytically “reconstituted” by conceptualizing different historical instances as interdependent moments, which, when cumulated and connected through time and space, “form” the whole as a general but empirically diverse historical process. Thus the very definition and selection of “cases” becomes

the object of theorizing and research and not its point of departure or merely the vehicle conveying data for analysis. Karl Polanyi’s ([1944] 1957) analysis of the emergence and decline of laissez-faire capitalism is a compelling example of this form of holistic comparison.

Individualizing interpretive analysts use historical comparison to demonstrate the historical and cultural particularity of individual cases. Analysts in this tradition often choose research questions and cases on the basis of their recurrent moral and historical significance rather than scientific representativeness or comprehensiveness. They also tend self-consciously to eschew general theory, quantification, and the methodology of causal analysis. Rather, interpretation is grounded in rich historical narration, in anthropological sensitivity to the import of cultural practice, in the culturally embedded meanings in social action, and in the use of persuasive concepts that crystallize or resonate with significant social values and themes (Bendix 1963; Geertz 1973; Bonnell 1980; Tilly 1984; Skocpol 1984b). Bendix’s ([1956] 1974) research on work and authority in industry is an exemplar of this strategy, and Daniel Goldhagen’s (1996) recent study, *Hitler’s Willing Executioners*, is another much more controversial example.

Causal Interpretivism. Historical comparisons rooted in *causal interpretivism* synthesize aspects of both analytical-formal and interpretive-historical comparisons. Inspired in part by Weber’s (1949) formulation of “causal interpretation” (and anthropologist Clifford Geertz’s [1980] similar idea of “interpretive explanation”), this strategy is stamped by explicit causal reasoning, the potential for explanatory generality across comparable instances, and the use of methodological procedures allowing for strict replication, on the one hand, and attention to historical narrative, cultural particularity, and subjective meaning, on the other.

Causal interpretivism has been most fruitfully developed and applied in the analysis of historical narratives (Sewell 1996; Griffin 1992, 1993; Quadagno and Knapp 1992; Somers 1998). Narratives are “sequential accounts” organizing information into “chronological order to tell stories about what happened. . .” and why it happened as it did, and, as such, are “tools for joining sequentiality, contingency, and generalizability” (Stryker 1996, p.305, 307). Narrativists conceptualize historical time so

that it is “eventful.” Any given moment in a historical chain of unfolding sequences is both a repository of past actions and a harbinger of future possibilities (Thompson 1978). Temporal order and the causal relationships among actions that make up events therefore become the major object of inquiry in comparative narrative analysis.

Narrative focuses squarely on the import of human agency in reproducing or changing societal arrangements, thereby complementing the attentiveness comparative-historical sociologists have traditionally given social structural constraints and opportunities (Stryker 1996). Channeling analytical attention in this fashion directs narrativists both to transformative historical happenings (the French Revolution, for instance [Sewell 1996]) and to the development and deployment of decidedly temporal concepts, such as path dependence, sequential unfolding, temporally cumulative causation, and the pace of social action (Abrams 1982; Aminzade 1992). The structure of action underpinning particular historical narratives, moreover, can also be strictly compared with an eye toward both showing general patterns across events and individual exceptions to those generalizations (Abbott 1992; Griffin 1993). Dietrich Rueschemeyer and John Stephens (1997), for example, demonstrate how “eventful time, including the order and sequence of key actions, can both be incorporated into causal generalizations for such large scale processes as democratization and capitalist economic development and [be] exploited to ascertain where those generalizations break down.

Comparative narrativists have developed a variety of procedures to enhance the theoretical payoff and replicability of their research: (1) event-structure analysis (Griffin 1993), which allows explicit codification of reasons for inferences and for cross-level generalization; (2) semantic grammar analysis, which uses linguistic rules to convert text, such as newspaper accounts of strikes in Italy, into numbers for subsequent statistical analysis (Franzosi 1995, 1998); and (3) systematizing electronic means to collect, store, code, and analyze diverse types of historical texts, from newspaper articles to court opinions and legislative hearings (Stryker 1996; Pedriana and Stryker 1997). Robin Stryker (1996) has also developed the useful notion of “strategic narrative” as a guide to case selection in comparative-historical analysis: Strategic narrative suggests

that some historical events and ways of constructing stories will promote theory-building more than will others, thus facilitating cumulation of knowledge.

Regardless of precisely how analytical formalism is incorporated, unpacking a narrative and reconstituting it as an explicit causal account—that is, comprehending and explaining the logical within the chronological, and the general within the particular—often requires that analysts imaginatively reconstruct participants’ cultural understandings (interpretation), as well as systematically harness theoretical abstractions, comparative generalizations, and replicable research methods. In effect, then, analysts explain because they are compelled to interpret, and they interpret because causal explanation is demanded (Beer 1963; Griffin 1993; Mahoney 1999).

METHODOLOGICAL ISSUES AND DIFFICULTIES

Though comparative-historical analysis is neither necessarily cross-national or cross-cultural, nor always confronting the same obstacles as narrative history, it does share many of the methodological problems (and solutions) and dilemmas traditionally associated with both types of research. These include, among others: (1) defining and selecting comparable analytical units; (2) case interdependence; (3) the nonrepresentativeness of cases; (4) determining conceptual equivalence and measurement reliability and validity across time and space; (5) the paucity of data, especially that which is quantitative, over long periods of time, and for newly emerging nations; (6) the selectivity and general unsoundness of the historical record; (7) the use of spatially and temporally aggregated data, and, more generally, the distance between what can be collected and systematically measured and what the theory or research question actually calls for; and (8) fruitful ways to wed historical narration and cultural specificity, on the one hand, to the development of general sociological theory and cumulative, replicable results, on the other. Some of these difficulties especially plague analytically formal comparisons (e.g., the artificiality and interdependence of cases; the paucity of systematic, quantifiable data at the proper theoretical level of analysis; and the excessive generality at the cost of important historical and cultural specificity);

others haunt with more force interpretive comparisons (e.g., nonrepresentative cases; analytical looseness and non replicability; and excessive particularity at the expense of generalization and theoretical development).

Granting their very real import, these difficulties are not normally intractable. As we have shown, methodologically self-conscious comparative-historical scholars, both qualitative and quantitative, have devised strategies to: construct and select the most relevant cases for analysis; exploit cross-level data (e.g., within and between nation-states) and make causal inferences across levels of analysis; guard against logically false or self-validating inferences; infuse the analysis of historical narrative with greater theoretical and analytical rigor; and increase the number and representativeness of their cases. They have also devised or imported useful ways to ensure maximum measurement equivalence across cultures; sample historical records; estimate data missing from statistical series and to correct for truncated data; capitalize on case interdependence with new statistical methods; historically ground time-series analysis; etc. (see Bloch [1928] 1969; Carr 1961; Przeworski and Teune 1970; Zelditch 1971; Tuma and Hannan 1984; Skocpol 1984b; Ragin 1987; Kohn 1989; Isaac and Griffin 1989; McMichael 1990; Kiser and Hechter 1991; Griffin 1993; Western 1994; Deane, Beck, and Tolnay 1998).

Some problems, admittedly, have no satisfactory solution, and nothing can compensate for the utter dearth of valid information on particular happenings or variables. This, though, is hardly different from any other form of social research. The litany of methodological difficulties discussed above, in fact, afflict all social research. Survey analysts, for example, deal with questionnaire responses of dubious accuracy and unknown meaning taken from geographically and temporally limited samples, and scholars working with institutional records of any sort must deal with information collected by institutionally self-interested actors.

It is important to recognize that although comparative-historical inquiry is no more "error-prone" or unreliable than are other forms of social research, it often adopts a very different underlying "working philosophy" from most theory-driven quantitative analysis. Usually in highly deductive and statistical analysis (including comparative

strategies), theory construction and theory testing are two clearly defined and quite separate phases of a research program (Kiser and Hechter 1991; Stryker 1996). Segmenting research practice in this way is thought necessary to ensure that hypothesis testing produces a fair empirical test, unbiased by prior analysis, or even intimate foreknowledge of the data. Given these rules and objectives, then, concepts, indicators, hypotheses, and theory are not usually changed in the middle of analysis; that would invalidate the statistical or logical test.

In contrast, comparative-historical inquiry that is qualitative and inductive, though often also analytically formal, establishes a continual dialogue between social theory and empirical evidence, so that conceptual abstraction and comparative history are mutually defined and constructed in reference to each other. In *The Protestant Ethic and the Spirit of Capitalism*, for example, Weber ([1904] 1958) used historical evidence on economic and religious practices and beliefs to refine his ideal types and his hypotheses and, simultaneously, conceptually frame that empirical data to render it intelligible and explicable. Many comparative-historical sociologists follow Weber's general strategy, that is, they start their inquiry with one set of concepts, indicators, or hypotheses, or all three, and end with another, modified set because they mutually adjust data and theory, ensuring a good "fit" between the two as analysis progresses. In their study of capitalist economic development and democratic political practice in many nations, for example, Rueschemeyer, John Stephens, and Evelyne Huber Stephens (1992) amended their theoretical definition of democracy, both broadening its historical scope and specifying more precisely its meaning, as they moved in their analysis from Europe to Latin America. Thus what may look like scientific "cheating" to a deductive or quantitative scholar is an appropriate, fruitful strategy for comparative-historical sociologists whose goals are concept formulation and reformulation, theory construction, and empirical understanding, rather than strict hypothesis testing.

Analytic rigor does not rest with the mechanistic application of technique per se, but, instead, with a systematic and methodologically self-disciplined stance toward both data collection and analysis and the use of evidence to advance inferences. Most comparative-historical scholars adhere

to explicit decision rules, permitting others to replicate, critically judge, and constructively critique the research. To help ensure the validity and reliability of measures in this sort of inquiry, and while also maintaining the needed flexibility to improve key concepts and measures during the analysis, for instance, Stryker (1996) has shown how researchers can adapt traditional content-analytic coding techniques to capture time and space as explanatory context. Context can be conceptualized and measured as a conjunction of “values” on general theoretical constructs, and, at the same time, researchers can develop what she terms “action coding” to construct more systematically the who, what, when, where, how, and why of action and event sequences. With enhanced systematization—that is, the use of precise concepts, measures, and coding techniques, and the clear communication of these—comes enhanced reliability and replicability (Stryker 1996).

THE FUTURE OF COMPARATIVE-HISTORICAL ANALYSIS

Jack Goldstone (1997, p. 119) has stated that comparative-historical inquiry has produced “many of the greatest achievements of macro-sociological scholarship.” At the end of the twentieth century, these achievements were severely tested by a series of interdependent, large-scale social transformations of every bit the historical magnitude and moral significance of those motivating sociology’s founders: economic and cultural globalization; the growth of transnational “super states” brought about by strategic military and economic alliances among sovereign nation-states; post-communist marketization and democratization in former Soviet-bloc nations; and armed nationalist struggles and resurgent ethnic conflicts. Broad interest in, and need for, illuminating comparative-historical analysis therefore is only likely to increase.

The utility of research in this tradition rests more on the creative use of good theory than it does on its methodology. But “creative use” of theory is itself largely a matter of how theory is combined with research strategy. On this score, the future of comparative-historical sociology would seem bright.

One encouraging trend is the increasing use of statistical techniques developed explicitly to

analyze temporal (Tuma and Hanna 1984; Isaac and Griffin 1989; Abbott 1992; McCammon 1998) and spatial processes (Deane et al. 1998). Time-series and spatial analyses are not always subject to the same limitations as are cross-national statistical analyses, and quantitative spatial techniques are particularly apt given heightened global interdependence. Spatial analysis, for instance, can uncover how historical processes move from place to place (country, region, etc.), and it can ascertain whether structures or practices in one country are diffused into other countries or deterred from entering them (Deane et al. 1998).

Another very positive trend that probably will become more widespread is combining and synthesizing different kinds of comparative logics. Both Jeffrey Paige (1975) and John Stephens (1980) combined cross-national quantitative analysis of a large number of nation-states with qualitative, case-oriented work on a small, but theoretically strategic subset of their cases. Paige combined his statistical generalizations with three parallel case studies, finding differences in the nature of agrarian revolts. Stephens, on the other hand, systematically compared a subset of four countries to show how the historical processes of welfare-state development differed from one nation to another. He therefore used both generalizing and individualizing comparative logics. Goldstone (1991) followed a similar strategy, combining “within-case” quantitative analyses with case-oriented comparisons to show how long-term population growth contributed to state breakdown in the early modern world. Combining diverse comparative-historical approaches in this way, and synthesizing analytical formalism and interpretation in causal interpretivism, yield insights that simply are not possible with any single methodological strategy.

Even if the differences among diverse approaches prove too great to overcome completely—a possibility suggested by the debate over the utility of highly deductive explanatory schemas such as rational choice theory in comparative-historical research (Quadagno and Knapp 1992; Kiser and Hechter 1991, 1998; Somers 1998)—diversity in goals, strategies, and procedures has spurred methodological innovation and the cross-fertilization of scholarship from divergent methodological strategies (Beer 1963; Rueschemeyer and Stephens 1997; Goldstone 1997). It thereby provides the continued promise of enhanced knowledge and richly

textured, multi-voiced portrayals and understandings of perennial questions of fundamental human significance.

COMPLEX ORGANIZATIONS

Organizations, as a class, are socially constructed innovations, deliberately designed as solutions to problems. Although some forms of organization, such as churches and armies, have been around for centuries, only since the Industrial Revolution have complex organizations assumed the form people take for granted today. Because they are

shaped by the contexts or environments in which they are established, contemporary organizations reflect the impact of their historical origins in societies characterized by growing affluence and conflicts over the control and distribution of wealth. Organizations come in a bewildering variety of forms because they have been explicitly designed to deal with a wide range of problems and because they have emerged under widely varying environmental conditions.

THE IMPORTANCE OF ORGANIZATIONS

Why are complex organizations important? Organizations, which produce goods, deliver services, maintain order, and challenge the established order are the fundamental building blocks of modern societies, and the basic vehicles through which collective action is undertaken. The prominence of organizations in contemporary society is apparent when we consider some consequences of their actions.

Organizations coordinate the actions of people in pursuit of activities too broad in scope to be accomplished by individuals alone. Railroads were the first large corporations in the United States, arising because small autonomous merchants and traders could not effectively coordinate the passage of long-distance shipments. In the twentieth century, the production of mass-market consumption goods, such as automobiles and electric appliances, was made possible by the rise of large, vertically integrated manufacturing firms. Similarly, in the public sector, the implementation of government social policies has necessitated the development of large government agencies that process thousands of cases on a universalistic, impersonal basis.

The concentration of power in organizations contributes not only to the attainment of large-scale goals in modern societies, but also to some major social problems. When organizations focus on attaining specific goals, such as making profits for shareholders, they may neglect the side effects or externalities of their actions. Examples include air and water pollution and the careless disposal of unwanted hazardous materials by large manufacturers. The manufacture of unsafe consumer products and instances of large-scale fraud and collusion also illustrate the capacity of organizations to do harm as well as good.

Increasingly, major tasks in society are addressed not by single organizations but instead by networks of interdependent organizations. Interorganizational arrangements pool the efforts of numerous specialized organizations in pursuit of a common end. For example, automobiles are produced in *vertical* production networks centered on assemblers that maintain ongoing relationships with multiple tiers of suppliers responsible for the manufacture and delivery of components. However, in the industrial districts of northern Italy, textile production occurs within *horizontal* production networks consisting of small and specialized firms that employ flexible machinery and temporarily cooperate with one another for particular projects. Cooperation enables them to adapt to changing market demands and to learn from one another. Likewise, services for the severely mentally ill are delivered by independent but interrelated agencies providing specific medical and social services. Many large-scale motion pictures are produced not by self-contained studios, but rather by combinations of producers, directors, cinematographers, and other personnel assembled only for the duration of a particular project. Ongoing arrangements involving hospitals, doctors, and university laboratories have been created by the National Cancer Institute to coordinate cancer research and treatment. As these examples demonstrate, interorganizational arrangements give organizations the flexibility to address the unique features of specific cases, while avoiding the rigidities sometimes found in very large organizations.

DEFINITIONS OF ORGANIZATIONS

What are complex organizations? A simple definition is that organizations are goal-directed, boundary-maintaining, socially-constructed systems of human activity. Some definitions add other criteria, such as deliberateness of design, the existence of status structures, patterned understandings between participants, orientation to an environment, possession of a technical system for accomplishing tasks, and substitutability of personnel (Scott 1998).

Goal orientation and deliberate design of activity systems are distinctive features discriminating between organizations and other collectivities, such as families and small groups. Organizations are purposive systems in which members behave as if they are committed to the organization's

goals, although individual participants might personally feel indifferent toward those goals or even alienated from their organizations. Concerted collective action toward an apparent common purpose also distinguishes organizations from social units such as friendship circles, audiences, and mass publics. Because many organizational forms are now institutionalized in modern societies, people readily turn to them or construct them when a task or objective exceeds their own personal abilities and resources (Meyer and Rowan 1977; Zucker 1988).

Organizations have activity systems—or technologies—for accomplishing work, which can include processing raw materials, information, or people. Activity systems consist of bounded sets of interdependent role behaviors; the nature of the interdependencies is often contingent upon the techniques used.

Other key elements of organizations, such as socially constructed boundaries, are shared with other types of collectivities. The establishment of an “organization” implies a distinction between members and nonmembers, thus marking off organizations from their environments. Maintaining this distinction requires boundary-maintenance activity, because boundaries may be permeable, and thus some organizations establish an authoritative process to enforce membership distinctions. For example, businesses have human resource management departments that select, socialize, and monitor employees, and voluntary associations have membership committees that perform similar functions. Distinctive symbols of membership may include unique modes of dress and special vocabularies.

Within organizations, goal attainment and boundary maintenance manifest themselves as issues of coordination and control, as authorities construct arrangements for allocating resources or integrating workflows. These internal structures affect the perceived meaning and satisfaction of individual participants by, for example, differentially allocating power and affecting the characteristics of jobs. Control structures, which shape the way participants are directed, evaluated, and rewarded are constrained by participants’ multiple external social roles, some complementing, but others conflicting with organizational roles.

ENVIRONMENTS

Organizations, with few exceptions, are incomplete social systems that are not self-sufficient and thus depend on interchanges with their environments. Therefore, goal setting by owners or leaders must take into account the sometimes contrary preferences of organizations and other actors, because activity systems are fueled by resources obtained from outsiders. For example, participants must be enticed or coerced into contributing to the organization’s activities: businesses pay people to work for them, while voluntary nonprofit organizations may offer more intangible benefits, such as sociable occasions.

Over the past few decades, organizational sociology has gradually expanded its scope to include more of the external elements associated with organizational life. Initially, theorists emphasized relatively tangible features: environments were seen as stocks of resources (such as raw materials, capital, or personnel) and information. To the degree that resources are scarce or concentrated in a few hands, organizations are more dependent on their environments and may be vulnerable to exploitation or external control by outsiders (Pfeffer and Salancik 1978). To the degree that information is dispersed, heterogeneous, or subject to change, organizations confront problems of uncertainty.

Much research has been devoted to understanding how organizations deal with the problems of dependence and uncertainty that environments pose. Some organizations respond internally, by developing specialized structures and processes. For example, boundary-spanning personnel are charged with dealing with actors outside the organization, acquiring resources, and disposing of products; they thereby enable others in the technical core to work under more certain conditions. Some organizations respond externally, by building bridges that stabilize their ties to environments. They use interorganizational devices such as long-term contracts and working agreements, joint programs or alliances, and interlocking directorates (Mizruchi and Galaskiewicz 1993).

More recent scholarship has stressed the socially constructed, *institutional* aspects of environments. Organizations must be attentive to these external aspects to acquire and maintain legitimacy and social standing. Scott (1995) distinguished

between regulative, normative, and cognitive-cultural understandings of institutions. Regulative institutions are external systems of rules, often established by states, to which organizations must conform. External rules may be prescriptive, such as when a law requires that publicly traded corporations have boards of directors with at least three members. Rules may also be proscriptive, such as when regulatory bodies or courts prohibit particular trade practices and ownership patterns.

Normative institutions are sets of beliefs and values shared by organizations and their participants about the morally appropriate way in which to organize activities. Professional associations are common sources of normative prescriptions, enforced through processes such as certification. Cognitive institutions are cultural frames or scripts that constitute the social forms seen as natural and taken for granted in a given society. In contemporary society, the idea of organizations itself is institutionalized; legitimate pursuit of an activity often requires the formation of an organization because of the widespread belief that this is an efficient, effective, and fair manner in which to proceed (Meyer and Rowan 1977).

ORGANIZATIONAL DEMOGRAPHICS

The number of organizations in industrial societies is very large. Over five million businesses with at least one employee existed in the United States in 1998, and there were thousands of governmental agencies, nonprofit organizations, and voluntary associations (Aldrich 1999). Social scientists have developed various schemes to describe the diversity of organizations. For example, the North American Industry Classification System (Office of Management and the Budget 1997) classifies establishments by their products and the processes used to make them. Organizations can also be classified according to their goals or the social functions they serve (Parsons 1960), or on the basis of the prime beneficiaries of organizational actions: owners, members, clients, or the general public (Blau and Scott 1962). Another classification contrasts generalist and specialist organizations and hypothesizes that each type thrives in a different kind of environment (Hannan and Freeman 1989).

Industrial societies contain a large number of organizations, with three characteristics of special

note. First, the size distribution of businesses and nonprofit organizations is highly skewed, with a large number of very small organizations. In 1990, approximately 90 percent of the five million firms in the United States with employees employed fewer than twenty people. Over 98 percent employed fewer than one hundred workers (Small Business Administration 1994). Employment statistics were very similar in the European Union (ENSR 1993), with about 93 percent of firms employing fewer than ten workers, although the figure varied by nation. In 1994, most of the 4.3 million corporations in the United States had fewer than \$one hundred,000 in assets, and they accounted for less than 0.3 percent of all corporate assets. Thus, most organizations are fairly vulnerable to environmental forces and must adapt to them or disband.

Second, although the number of large organizations is small, they have achieved a dominant share of revenues and assets. Business organizations are highly stratified by size, and large firms have more resources with which to resist and counter environmental pressures. In 1994, the top 0.002 percent of corporations, each with a quarter-billion or more in assets, held about 83 percent of all corporate assets. In 1992, the fifty largest manufacturing firms in the United States accounted for about 24 percent of value added and about 13 percent of employment, and the two hundred largest firms accounted for 42 percent of value added and around 25 percent of employment (U.S. Bureau of the Census 1996).

Third, smaller organizations still employ a relatively large share of all workers. In the United States, about 39 percent of all employees work in firms that employ fewer than one hundred workers. In particular industries, such as agriculture and construction, substantially more than half the work force is employed in organizations with fewer than one hundred workers. In the European Union, firms with fewer than one hundred workers employ about 55 percent of the labor force, although variation across nations is substantial. For example, in Germany and the United Kingdom, firms larger than one hundred employ more than half the labor force, whereas in Greece and Italy, such firms employ only about 20 percent of the labor force (ESNR 1993).

Populations of organizations in modern societies are constantly undergoing processes of expansion, contraction, and change. Some organizations are founded in a flash of creative energy and then disband almost immediately, whereas others emerge slowly and then last for decades. Some organizations adapt readily to every environmental challenge, whereas others succumb to the first traumatic event they face. Sociologists have turned their attention to these vital events surrounding the reproduction and renewal of organizational populations, focusing on three processes: foundings, transformations, and disbandings (Aldrich 1999; Hannan and Freeman 1989).

New organizations are established fairly frequently, although systematic data on founding rates are available only for businesses. Studies in the United States and other Western industrialized nations show that about ten businesses are founded per year for every one hundred businesses active at the start of the year. In the United States, approximately 4 to 6 percent of the adult population in the mid-1990s has engaged in some activities with an intent to start a business, and about half of them actually succeeded in their initial efforts (Reynolds and White 1997). Explanations for variations in rates of organizational foundings have stressed the characteristics of opportunity structures, the organizing capacities of groups, and strategies adopted by entrepreneurs as they take account of opportunities and resources available to them (Aldrich and Wiedenmayer 1991).

Societal demands for special-purpose organizations increased with urbanization and with economic, political, and social differentiation, while the resources required to construct organizations grew more abundant with the development of a money economy and the spread of literacy (Stinchcombe 1965). The spread of facilitative legal, political, and other institutions also played a major role, by creating a stable, predictable context within which entrepreneurs could look forward to appropriating the gains from organizational foundings. Occasional periods of political upheaval and revolution stimulate foundings by freeing resources from previous uses, and thus massive changes occurred in the organizational populations of Eastern Europe in the 1990s. For example, centralized health care systems were disbanded with the demise of state socialist regimes,

and there is a good deal of flux in the organizations within this sector (Mechanic and Rochefort 1996).

Transformations occur when existing organizations adapt their structures to changing conditions. The issue of how frequently and under what conditions organizations change has provoked some of the most spirited debates in organizational sociology. Strategic choice-theorists have argued for managerial autonomy and adaptability, whereas ecological and institutional theorists have tended to stress organizational inertia and dependence. Research has moved away from polarizing debates and reframed the question of transformation, asking about the conditions under which organizations change and whether changes occur more frequently in core or peripheral features (Singh and Lumsden 1990).

In the 1980s and 1990s, growing awareness of techniques for performing dynamic analyses have produced some useful studies of transformation, such as those on diversification, top executive changes, and changes in corporate form (Fligstein 1991). These studies tell us that changes *do* occur, although they do not report whether rates of change go up or down over an organization's life cycle. Most of these studies are of the very largest business firms, for which data are publicly available, and not for representative samples.

If all newly founded organizations lived forever, the study of organizational change would be confined to issues of founding, adaptation, and inertia. Research has shown that organizations disband at a fairly high rate, however, and a sizable literature has grown up on organizational mortality (Baum 1996; Singh 1990). Organizations can cease to exist as separate entities in two ways: by completely dissolving—the process by which the vast majority of organizations disband—or by becoming part of a different entity through merger or acquisition. Throughout the 1990s, between two and six thousand mergers and acquisitions a year took place, amounting to less than 1 percent of the incorporated firm population in any given year (Aldrich 1999). For example, in 1994, mergers and acquisitions involved about one-tenth of one percent of all corporate assets. By contrast, between 1976 and 1984, the annual rate of dissolution in the business population of the United States was about 10 percent (Small Business Administration 1994).

Age and size are the strongest predictors of how long an organization will survive. Young organizations disband at a substantially higher rate than older ones; a conservative estimate is that only half of new organizations survive more than five years. Internally, new organizations depend upon the cooperation of strangers who must be taught new routines, some of which are unique to particular organizations (Stinchcombe 1965). Externally, new organizations must penetrate niches in potentially hostile environments, overcoming competitors and establishing their legitimacy with potential members, customers, suppliers, and others. Survival beyond infancy is easier when an organization adopts a form that has already been institutionalized and is widely regarded as legitimate and proper (Zucker 1988). Population ecologists have given special attention to the density of an organizational form—the number of organizations of a given kind—in their analyses of vital rates. Density is thought to be an indicator both of the acceptance or legitimacy of a form (which raises foundings and decreases disbandings) and of the number of competitors attempting to survive within a given environmental niche (which reduces foundings and increases disbandings). The life chances of an organization initially increase—though not smoothly—as density rises, and then decrease as competition intensifies.

SOURCES OF INTERNAL DIVERSITY AMONG ORGANIZATIONS

All models of organizations as coherent entities can be reduced to two basic views. The systemic view sees organizations as social systems, sustained by the roles allocated to their participants, whereas an associative perspective treats organizations as associations of self-interested parties, sustained by the rewards the participants derive from their association with the organization (Swanson 1971). These two views each have a venerable heritage in the social sciences. Despite subtle variations, all perspectives on organizations ultimately use one or both of these models.

Institutional, functionalist, and ecological perspectives rely on a systemic model, viewing organizations as relatively coherent, stable entities. Such models emphasize the activity systems in organizations that are deliberately designed to accomplish specific goals. Formal structures of organizations,

including a division of labor, authority relationships, and prescribed communication channels, are treated as fulfilling a purposeful design. For example, an institutional approach emphasizes member socialization and other processes that make the transmission of shared meanings easier. Ecological models usually treat organizations as units that are being selected for or against by their environments, and thus assume that organizations cohere as units.

Interpretive and more micro analytic views rely more on an associative model, leading to the expectation that organizations are constantly at risk of dissolution (March and Olsen 1976). For example, in the interpretive view, the reproduction of organizational structure depends on participants resubscribing to, or continually negotiating, a shared understanding of what they jointly are doing. Some cultural theories of organization emphasize the different, conflicting views that coexist within one organization (Martin 1992).

Views of organizations as marketplaces of incentives (Dow 1988), bundles of transactions (Williamson 1981), or arenas of class conflict (Clegg 1989), are in harmony with the associative view, insofar as they focus on actors' contributions to sustaining interaction. Indeed, organizational economics views organizations primarily as mechanisms for mediating exchanges among individuals, arguing that they arise only when market coordination has proven inadequate (Williamson 1981). One variant on this approach, agency theory, focuses on the relationships between self-interested principals (such as owners or stockholders) and the self-interested agents (such as workers or managers) engaged on behalf of principals. The self-interests of these actors may be divergent, and hence agency theory examines how systems of incentives, monitoring, and coordination can be designed to align the activities of agents with the objectives of principals, at minimal cost.

These complementary views of organizations—the associative and the systemic—highlight the sources of two fundamental problems of social organization, those of differentiation and integration. Some differentiation occurs through the division of labor among different roles and subunits; for example, employees may be divided into departments such as sales, finance, and manufacturing. Differentiation pressures also arise because

participants sometimes bring widely varying expectations to the same organization. Differentiation is thus a centrifugal force threatening the coherence of social units. Integration, by contrast, refers to procedures for maintaining coherence, as diverse roles are linked and activities coordinated to sustain an organization as a coherent entity. Examples of integrative processes include the holding of weekly departmental meetings or the circulation of inter office memos.

Differentiation increases organizational complexity because it increases the extent and nature of specialization (Blau 1972). Complexity increases with the number of different components, and may be horizontal (tasks spread over many roles or units), vertical (many levels in a hierarchy of authority), or spatial (many operating sites). Complexity also increases when tasks are grouped by product/market (soap, paper products, or foods) or by function (finance, production, or marketing).

Problems of coordination are present for any activity system, but especially for a complex one. Many concepts used to describe organization structure involve alternative processes used in attempts to achieve integration. One scheme, for example, identified five coordinating mechanisms: direct supervision, three forms of standardization, and mutual adjustment (Mintzberg 1983). With direct supervision, or simple control, decision making is highly centralized: persons at the top of a hierarchy make decisions that lower level personnel simply carry out. This coordination pattern was prevalent in preindustrial organizations, and today is especially likely within small organizations (Edwards 1979).

Coordination also can be attained through standardizing work processes, skills, or outputs. Work processes may be standardized through formalization, that is, the development of rules and procedures. Examples include rules for processing orders, for assembling and packaging products, or for conducting screening interviews for clients. A formalized organization may appear decentralized, since few explicit commands are given, and lower-level participants have freedom in making decisions within the rules. The rules may, however, be so restrictive as to leave little room for discretion. A variant on process standardization is technical control; here, rules and

procedures—and thereby coordination and control—are built into the design of machinery, as in an assembly line. Most worker discretion is eliminated by the structure of the technical system, and what remains is centralized in the upper echelons of the organization.

Standardization of skills involves considerable training and indoctrination of personnel, so that participants will carry out organizational policies with minimal oversight. Organizations employing large numbers of professionals are likely to rely on this coordination strategy (Von Glinow 1988). Professional participants enjoy considerable autonomy in making decisions, but their prior socialization sets most decision premises for them.

By producing products with standard properties, subunits of an organization are able to work independently of one another; if they use each other's outputs, the standards tell them what to anticipate. For example, large clothing firms produce massive runs of identical garments, and thus the various departments within firms know precisely what to expect from one another as they follow daily routines. Similar purposes are served by precise tolerances for parts used in manufacturing machinery and information systems designed to permit easy sharing of data within offices.

In small, young organizations, coordination is achieved by the simple mutual adjustment of personnel to one another. This form of coordination is also found in larger organizations working on complex, novel tasks, for which innovation is at a premium, such as consulting firms or research and development units. In such organizations, the activities of participants are reciprocally contingent, rather than sequentially ordered as in an assembly line. Formal structural devices have been advocated as ways of facilitating mutual adjustment under complex circumstances, such as integrating managers and project teams into matrix-management structures.

Standardization, bureaucratization, and formalization have done much to enable organizations to perform repetitive work efficiently. The same phenomena contribute to some well-known organizational pathologies; in particular, these coordination devices tend to reduce flexibility. In the 1990s, organizations struggled to develop less rigid structures for accomplishing work. Efforts to

achieve flexibility included reductions in size, expansion of the scope of employee responsibilities through cross-training and broadened job descriptions, reductions in layers of management, and maintenance of long-term relationships with suppliers as an alternative to vertical integration. Many of these devices rely on strengthening the internal social networks that link an organization's personnel as well as the external ones linking it to the environment. Such linkages enable organizations to remain adaptable, cope with market uncertainties, and take advantage of opportunities for learning.

CONCLUSION

Complex organizations are the building blocks of industrial and post industrial societies, enabling people to accomplish tasks otherwise beyond their individual competencies. Organizations also help create and sustain structures of opportunities and constraints that affect nearly every aspect of societies. Sociologists and other social scientists are grappling with a variety of complementary and conflicting perspectives on organizations, ranging from microanalytic interpretive views to macroevolutionary institutional and ecological views. Regardless of perspective, research on organizations has shown its capacity to interest, inform, and provoke us, as sociologists investigate these social constructions that figure so prominently in our lives.

COMPLIANCE AND CONFORMITY

Conformity is a change in behavior or belief toward a group standard as a result of the group's influence on an individual. As this definition indicates, conformity is a type of social influence through which group members come to share similar beliefs and standards of behavior. It includes the processes by which group members converge on a given standard of belief or behavior as well as the pressures they exert on one another to uphold such standards. *Compliance* is behavioral conformity in order to achieve rewards or avoid punishments (Kelman 1958). Since one can behaviorally adhere to a group standard without personally believing in it, the term is often used to indicate conformity that is merely public rather than private as well. Compliance can also refer to behavioral conformity to the request or demand of another, especially an authority.

In an individualistic society such as the United States, conformity has a negative connotation (Markus and Kitayama 1994). Yet conformity is a fundamental social process without which people would be unable to organize into groups and take effective action as a collectivity. For people to coordinate their behavior so that they can organize and work together as a group, they must develop and adhere to standards of behavior that make each other's actions mutually predictable. Simply driving down a street would be nearly impossible if most people did not conform to group norms that organize driving.

Conformity is also the process that establishes boundaries between groups. Through the conformity process, the members of one group become similar to one another and different from those of another group. This, in turn, creates a shared social identity for people as the members of a distinctive group. Given the pressure of ever-changing circumstances, social groups such as families, peer groups, business firms, and nations, only maintain their distinctive cultural beliefs and moderately stable social structures through the constant operation of conformity processes.

Perhaps because it is essential for social organization, conformity appears to be a universal human phenomenon. The level of conformity varies by culture, however. Collectivist cultures (e.g., Japan) that emphasize the interdependence of individuals show higher levels of conformity than individualistic cultures (e.g., the United States) that focus on the independence of individuals (Bond and Smith 1996).

Although essential, conformity always entails a conflict between a group standard and an alternative belief or behavior (Asch 1951; Moscovici 1985). For their physical and psychological survival, people need and want to belong to social groups. Yet to do so, they must curb the diversity and independence of their beliefs and behavior. Without even being aware of it, people usually willingly adopt the group position. Occasionally, however, individuals believe an alternative to be superior to the group standard and suffer painful conflict when pressured to conform.

Sometimes a nonconforming, deviate alternative is indeed superior to the group standard in that it offers a better response to the group circumstances. Innovation and change is as important to

a group's ability to adjust and survive as is conformity. In fact, a nonconforming member can influence the majority opinion even as the majority pressures the deviate to conform. As Irving Janis (1972) points out in his analysis of "groupthink," however, conformity pressures can grow so strong that they silence alternative opinions and strangle a group's ability to critically analyze and respond to the problems it faces. Thus, conformity is a double-edged sword. It enables people to unify for collective endeavors but it exacts a cost in potential innovation.

CLASSIC EXPERIMENTS

The social scientific investigation of conformity began with the pioneering experiments of Muzafer Sherif (1936). They beautifully illustrate the easy, almost unconscious way people in groups influence one another to become similar. Sherif made use of the autokinetic effect, which is a visual illusion that makes a stationary pinpoint of light in a dark room appear to move. Sherif asked subjects in his experiments to estimate how far the light moved.

When individuals estimated the light alone, their estimates were often quite divergent. In one condition of the experiment, however, subjects viewed the light with two or three others, giving their estimates out loud, allowing them to hear each other's judgments. In this group setting, individuals gave initial estimates that were similar to one another and rapidly converged on a single group estimate. Different groups settled on very different estimates but all groups developed a consensus judgment that remained stable over time.

After three sessions together, group members were split up. When tested alone they continued to use their group standard to guide their personal estimates. This indicates that the group members had not merely induced one another to conform in outward behavior. They had influenced one another's very perception of the light so that they believed the group estimate to be the most accurate judgment of reality.

In another condition, Sherif first tested subjects alone so that they developed personal standards for their estimates. He then put together two or three people with widely divergent personal standards and tested them in a group setting. Over three group sessions, individual estimates merged

into a group standard. Thus, even when participants had well-established personal standards for judging, mere exposure to the differing judgments of others influenced them to gradually abandon their divergent points of view for a uniform group standard. This occurred despite a setting where the subjects, all strangers, had no power over one another and were only minimally organized as a group.

The Sherif experiment suggests that conformity pressures in groups are subtle and extremely powerful. But critics quickly noted that the extreme ambiguity of the autokinetic situation might be responsible for Sherif's results. In such an ambiguous situation, participants have little to base their personal judgments on, so perhaps it is not surprising that they turn to others to help them decide what to think. Do people conform when the task is clear and unambiguous? Will they yield to a group consensus if it is obvious that the consensus is wrong? These are the questions Solomon Asch (1951, 1956) addressed in his classic experiments.

To eliminate ambiguity, Asch employed clear-cut judgment tasks where subjects chose which of three comparison lines was the same length as a standard line. The correct answers were so obvious that individuals working alone reached 98 percent accuracy. Similar to the Sherif experiment, Asch's subjects gave their judgments in the presence of seven to nine of their peers (all participants were male college students). Unknown to the single naive subject in each group, all other group members were confederates of the experimenter. On seven of twelve trials, as the confederates announced their judgments one by one, they unanimously gave the wrong answer. It was arranged so that the naive subject always gave his judgment after the confederates.

The subject here was placed in a position of absolute conflict. Should he abide by what he knows to be true or go along with the unanimous opinion of others? A third of the time subjects violated the evidence of their own senses to agree with the group.

The Asch experiments clearly demonstrated that people feel pressure to conform to group standards even when they know the standards are wrong. It is striking that Asch, like Sherif, obtained these results with a minimal group situation. The

group members were strangers who meant little to one another. Yet they exerted substantial influence over one another simply by being in the same situation together. Because of the dramatic way it highlights the conflict inherent in conformity between individuals and groups, Asch's experimental design has become the paradigm for studying conformity.

NORMATIVE AND INFORMATIONAL INFLUENCE

Sherif's and Asch's striking results stimulated an explosion of research to explain how conformity occurs (see Kiesler and Kiesler 1976, Cialdini and Trost 1998 for reviews). It is now clear that two analytically distinct influence processes are involved. Either or both can produce conformity in a given situation. Morton Deutsch and Harold Gerard (1955) labelled these *informational influence* and *normative influence*.

In informational influence, the group defines perceptual reality for the individual. Sherif's experiment is a good illustration of this. The best explanation derives from Leon Festinger's (1954) social comparison theory. According to the theory, people form judgments about ambiguous events by comparing their perceptions with those of similar others and constructing shared, socially validated definitions of the "reality" of the event. These consensual definitions constitute the social reality of the situation (Festinger 1950). Because people want the support of others to assure them of the validity of their beliefs, disagreeing with the majority is uncomfortable. People in such situations doubt their own judgment. They change to agree with the majority because they assume that the majority view is more likely to be accurate.

As this indicates, conformity as a result of informational influence is not unwilling compliance with the demands of others. Rather, the individual adopts the group standard as a matter of private belief as well as public behavior. Informational influence is especially powerful in regard to social beliefs, opinions, and situations since these are inherently ambiguous and socially constructed.

Normative influence occurs when people go along with the group majority in order to gain

rewards or avoid unpleasant costs. Thus it is normative influence that is behind compliance. People depend on others for many valued outcomes, such as inclusion in social relationships, a sense of shared identity, and social approval. Because of this dependency, even strangers have some power to reward and punish one another. Asch's results are a good example. Although a few of Asch's participants actually doubted their judgment (informational influence), most conformed in order to avoid the implicit rejection of being the odd person out. Studies show that fears of rejection for nonconformity are not unfounded (see Levine 1980 for a review). While nonconformists are sometimes admired, they are rarely liked. Furthermore, they are subject to intense persuasive pressure and criticism from the majority.

FACTORS THAT INCREASE CONFORMITY

Anything that increases vulnerability to informational and normative influence increases conformity. Although there may be personality traits that incline people to conform, the evidence for this is conflicting (Crowne and Marlowe 1969; Moscovici 1985). Situational factors seem to be the most important determinants of conformity. Research indicates that conformity is increased by a) the ambiguity or difficulty of the task, b) the relative unimportance of the issue to the person, c) the necessity of making a public rather than private response, d) the similarity of group members, e) high interdependence among the group members, f) the attractiveness and cohesiveness of the group, and g) the unanimity of the majority (see Kiesler and Kiesler 1976; Cialdini and Trost 1998 for reviews).

When a task or situation is ambiguous or difficult, it is not easy to tell what the best response to it would be. As a result, much as in Sherif's experiments, group members rely heavily on each other's opinions to decide what is best, increasing their susceptibility to informational influence. When decision-making groups in government or business face complex, difficult decisions where the right choice is uncertain, informational influence increases the members' tendency to agree and can affect their critical analysis of the situation (Janis 1972). Tastes and beliefs about matters, such as clothing style or music, about which there are no objectively right choices are subject to

sudden fads or fashions for similar reasons. Powerful conformity processes take over as group standards define for the individual what the “right” clothes or music are.

The less people care about an issue, the more open they are to both informational and normative influence. Without the motivation to examine an issue personally, people usually accept the group standard about it, both because the agreement of others makes the standard seem right and because there are more rewards and fewer costs in going along with the group. Because of such rewards and costs, people are especially likely to go along when their response must be public rather than private.

Since people compare their perceptions and views most closely to those of people who are socially similar to them, similarity increases group members’ informational influence on one another. Similarity also increases liking and, when people like one another, they have more power to reward or punish each other, so normative influence increases as well. Because of the increased power of both informational and normative influence, conformity pressures are often especially strong in peer groups.

When members are highly dependent on one another for something they value, conformity pressure increases because the members have more power to reward or frustrate one another (normative influence). Similarly, when a group is very attractive to an individual, its members have more power to normatively influence the individual. Gangs, fraternities, and professional societies all use this principle to induce new members to adopt their groups’ distinctive standards. Also, when a group is very tight knit and cohesive, members’ commitment to the group gives it more power over their behavior, increasing the forces of conformity.

The unanimity of the majority in a group is an especially important factor in the conformity process. In his studies, Asch (1951) found that as long as it was unanimous, a majority of three was as effective in inducing conformity as one of sixteen. Subsequent research generally confirms that the size of a majority past three is not a crucial factor in conformity. It is unanimity that counts (see Allen 1975 for a review). When Asch (1951) had one confederate give the correct answer to the line

task, the naive subjects’ conformity to the majority dropped from a third to only 5 percent. One fellow dissenter shows an individual that nonconformity is possible and provides much needed social support for an alternate construction of social reality. Interestingly, a dissenter need not agree with an individual to encourage nonconformity. It is only necessary that the dissenter also break with the majority.

Another factor that affects conformity is the sex composition of the group. Although the results of studies are inconsistent, statistical summaries of them, called meta-analyses, indicate that there is an overall tendency for women to conform slightly more than men (Becker 1986; Eagly and Wood 1985). Sex differences in conformity are most likely when behavior is under the surveillance of others. The evidence suggests two explanations (see Eagly 1987 for a review). First, sex carries status value in interaction, which creates social expectations for women to be less competent and influential in the situation than men (Ridgeway 1993). Second, sex stereotypes pressure men to display independence when they are being observed.

THE INFLUENCE OF THE MINORITY ON THE MAJORITY

Conformity arises out of a social influence process between an individual and the group majority. The influence process is not always one way, however. As Serge Moscovici (1976) points out, a dissenting group member is not just a recipient of pressure from the majority, but also someone who, by breaking consensus, challenges the validity of the majority view, creating conflict, doubt, and the possibility of opinion change in the group. Dissenters sometimes modify the opinion of the majority in a process called *minority influence*. Research shows that for a minority opinion to affect the majority it must be presented consistently and clearly without wavering and it helps if there are two such dissenters in the group rather than one (see Moscovici 1985; Moscovici, Mucchi-Faina, and Maass 1994; Wood et al. 1994, for reviews). A dissenting minority increases divergent thinking among group members that can enhance the likelihood that they will arrive at creative solutions to the problems the group faces (Nemeth 1986).

CONFORMITY AND STATUS

Research in the Asch and Sherif paradigms focuses on conformity pressures among peers. However, when group members differ in status, it affects the group's tolerance of their nonconformity. Higher status members receive fewer sanctions for nonconformity than lower status members (Gerson 1975). As long as they adhere to central group norms, high status members' nonconformity can actually increase their influence in the group (Berkowitz and Macauley 1961). Edwin Hollander (1958) argues that, because high status members are valued by the group, they are accorded "idiosyncrasy credits" that allow them to nonconform and innovate without penalty as long as they stay within certain bounds. It is middle status members who actually conform the most (Harvey and Consalvi 1960). They have fewer idiosyncrasy credits than high status members and more investment in the group than low status members.

Nonconformity can also affect the position of status and influence a person achieves in the group. Hollander (1958, 1960) proposed that individuals earn status and idiosyncrasy credits by initially conforming to group norms, but replications of his study do not support this conclusion (see Ridgeway 1981 for a review). Conformity tends to make a person "invisible" in a group and so does little to gain status. Nonconformity attracts attention and gives the appearance of confidence and competence which can enhance status. But it also appears self-interested, which detracts from status (Ridgeway 1981). Consequently, moderate levels of nonconformity are most likely to facilitate status attainment.

COMPLIANCE WITH AUTHORITY

Reacting to the Nazi phenomenon of World War II, studies of compliance to authority have focused on explaining people's obedience even when ordered to engage in extreme or immoral behavior. Compliance in this situation is comparable to conformity in the Asch paradigm in that individuals must go against their own standards of conduct to obey. The power of a legitimate authority to compel obedience was dramatically demonstrated in the Milgram (1963, 1974) experiments. As part of an apparent learning study, a scientist-experimenter ordered subjects to give increasingly strong

electric shocks to another person. The shock generator used by the subject labelled increasing levels as "danger-severe shock" and "XXX" (at 450 volts). The victim (a confederate who received no actual shocks) protested, cried out, and complained of heart trouble. Despite this, 65 percent of the subjects complied with the scientist-experimenter and shocked the victim all the way to the 450 volt maximum. It is clear that most of the time, people do as they are told by legitimate authorities.

Uncertainty over their responsibilities in the situation (a definition of social reality issue) and concern for the authority's ability to punish or reward them seem to be the principle causes for people's compliance in such circumstances. Note the comparability of these factors to informational and normative influence. Situational factors that socially define the responsibility question as a duty to obey rather than to disobey increase compliance (Kelman and Hamilton 1989), as do factors that increase the authority's ability to sanction.

Research has demonstrated several such factors. Compliance is increased by the legitimacy of the authority figure and his or her surveillance of the individual's behavior (Milgram 1974; Zelditch and Walker 1984). When others in the situation obey or when the individual's position in the chain of command removes direct contact with the victim, compliance increases (Milgram 1974). On the other hand, when others present resist the authority, compliance drops dramatically. Stanley Milgram (1974) found that when two confederates working with the subject refused to obey the experimenter, only 10 percent of subjects complied fully themselves. As with a fellow dissenter from a unanimous majority, other resisters define disobedience as appropriate and provide support for resisting. In an analysis of "crimes of obedience" in many government and military settings, Herbert Kelman and Lee Hamilton (1989) show how such factors lead to compliance to illegal or immoral commands from authority.

Conformity and compliance are fundamental to the development of norms, social organization, group culture, and people's shared social identities. As a result, research on conformity and compliance continues to develop in several directions. Efforts are underway to develop broader models of the social influence process that can incorporate both conformity and compliance (see Cialdini

and Trost 1998). These efforts give added emphasis to people's dependence on social relationships and groups and address questions such as whether minority and majority influence work through different or similar processes. Also, new, more systematic cross-cultural research attempts to understand both what is universal and what is culturally variable about conformity and compliance (Markus and Kitayama 1994; Smith and Bond 1996).

COMPUTER APPLICATIONS IN SOCIOLOGY

Most sociologists, both professionals and students, now have their own computer with direct access to a printer for writing and to the Internet for electronic mail (e-mail). Beyond the basic tasks of writing and e-mailing are a variety of other computer-supported research applications, both quantitative and qualitative. This article describes how sociologists and other social scientists use these applications and what resources are available.

The data and modeling requirements of social research have united sociologists with computers for over a hundred years. It was the 1890 U. S. census that inspired Herman Hollerith, a census researcher, to construct the first automated data processing machinery. Hollerith's punchcard system, while not a true computer by today's definitions, provided the foundation for contemporary computer-based data management.

In 1948 the U. S. Bureau of the Census, anticipating the voluminous tabulating requirements of the 1950 census, contracted for the building of Univac I, the first commercially produced electronic computer. The need to count, sort, and analyze the 1950 census data on this milestone computer led to the development of the first high-speed magnetic tape storage system, the first sort-merge software package, and the first statistical package, a set of matrix algebra programs.

Only a decade later many social scientists were exploring ways to use computers in their research. In the early 1960s, the first book devoted entirely to computer applications in social science research (Borko 1962) was published. Not only were social scientists writing about how to apply computers, they were designing and developing new software. Some of the most popular statistical software packages, e.g., SPSS (Nie, Bent, and Hull 1975), were developed by social scientists.

During the 1980s, universities and colleges began to acquire microcomputers, accepting the premise that all researchers needed their own desktop computing equipment. The American Council of Learned Societies (ACLS) survey in 1985 (Morton and Price 1986) reported that 50 percent of sociologists had a computer for exclusive use. A survey of academic departments supported by the American Sociological Association (Koppel, Dowdall, and Shostak 1985) found that slightly less than half of the sociology faculty reported to have immediate access to microcomputers. To put these findings into a more complete perspective, of the approximately 9,000 sociologists in 1985, about 4,500 had their own computers and about 5,200 reported routine computer use. Now, it is hard to find a sociologist's office without at least one computer. And in many countries most students in sociology have a computer for writing papers and accessing online resources.

Sociology and the Web. The Internet may be one of the largest and probably the most rapidly growing peaceful social movements in history. It is not just a technology, or a family of technologies, but a rapidly evolving socio-cultural phenomena often called "cyberspace" or "cyberculture." No matter how this phenomena is defined, it is changing the way sociologists conduct their work.

By the mid-1990s sociology, like most other academic disciplines, had come to depend upon e-mail. In addition, a rapidly growing number had begun to use the World Wide Web (WWW), commonly called the Web (Babbie 1996). Bainbridge (1995) claimed that the Web is "a significant medium of communication for sociologists, and extrapolation of present trends suggests it may swiftly become the essential fabric of sociology's existence." In January 1999, the author searched Web sites with the Alta Vista search engine for the word

“sociology” and found 750,000 instances. Two years earlier a search yielded only 250,000. Sociology is indeed rapidly building its presence on the Web.

The Internet and the Web are often described as a medium of communication because e-mail, electronic conferencing, online chats (synchronous discussion), groupware, and data exchange imply social interaction. Another major metaphor of the Web is that of a database for information search and retrieval. However, new roles are emerging for the Web. For the individual, the Web has become an important “presentation of self,” an opportunity for publishing personal and professional resumes and other such information. For the organization, the Web has become an opportunity for advertising, recruiting, communicating with the public, and conducting commerce itself. The rapid proliferation of personal Web sites in the form of various home pages suggests that many now see the Web primarily as a medium for personal and organizational impression management.

An appendix to this article provides a number of sources of sociological activity and information on the Internet, especially the Web. Not only does the appendix serve as a resource for information about sociology, but it also portrays the diverse, complex state of the institutionalization of sociology on the Web.

In the next few years the Web and its technologies will offer many new opportunities for conducting research. Already there are software packages developed for Web-assisted surveys and other types of data collection. The amount of data accumulating on the Web is enormous. And the graphical content of the Web is indeed a challenge to sociologists conducting computerized content analyses. The pace of these new developments will continue to challenge sociologists to not only to stay current with the new tools for research but to conduct research on the rapidly growing cultures of the Internet.

Publications on Sociological Computing. The primary source for articles on social science computer applications is the *Social Science Computer Review*, a quarterly publication of Sage Publications, Inc., which also regularly offers book and software reviews. Other relevant software reviews periodically appear in such journals as *Educational*

and Psychological Measurement, the *Journal of Marketing Research*, *The American Statistician*, and *Simulation and Games*. In addition, JAI Press publishes an occasional series volume on “Computers and the Social Sciences.”

In the late 1980s, the American Sociological Association (ASA) formed a “Section on Microcomputing.” Over 350 sociologists joined this new section in 1990, making it the fastest-growing new section in the history of the ASA. The section publishes a quarterly newsletter and organizes sessions at annual meetings. In 1993, the section name was officially changed to “Sociology and Computers.” A regular newsletter called *SCAN (Sociology and Computers: A Newsletter)* is published by members.

Another indicator of growing involvement in computing was the first annual conference, “Computing in the Social Sciences,” held in 1990 at Williamsburg, Virginia. From this conference emerged a professional association, the Social Science Computing Association. The official journal of this association is the *Social Science Computer Review*, and they still hold an annual conference.

Computer Applications in Sociology. The practice of computing in sociology has evolved rapidly. Computers have been applied to practically every research task, including such unlikely ones as field note-taking, interviewing, and hundreds of other tasks (Brent and Anderson 1990). The many diverse uses of computing technology in social research are difficult to categorize because applications overlap and evolve unpredictably. Nonetheless, it is necessary to discuss different categories of applications in order to describe the state of the art of computing in sociology. Since 1987, the Winter issue of the *Social Science Computer Review* has been devoted to an annual symposium on the “State of the Art of Social Science Computing.” The categorization of computer applications in this article reflects these discussions. First, some major types of applications are summarized in order of descending popularity. Then some of the challenges of computing for sociological research are noted.

Writing and Publishing. Once equated with the secretarial pool, word processing now is an

activity of nearly every graduate student and professional in sociology. It consists not only of writing but preparing tables, "typesetting" mathematical equations, and resizing objects, such as three-dimensional graphs embedded within text. Social researchers are using such capabilities and moving rapidly toward workstation environments that obscure the transition between data analysis and manuscript preparation (Steiger and Fouladi 1990). Not only do researchers use their computers for writing papers, but word processing software plays a central role in the refinement of data collection instruments, especially questionnaires and codebooks, which allows for rapid production of alternative forms and multiple drafts.

Trends in text production that blur traditional distinctions between writing and publishing (Lyman 1989) may in the long term have the most impact on what sociologists do. The growing body of articles and books in electronic-text form propel scholarship toward *hypertext*, which is a document system that provides for nonsequential reading of text using links that automatically access other documents. Contemporary word processors contain the capacity to easily produce documents in HTML (Hypertext Markup Language) that are ready for installation as sites on the Web. HTML can contain hypertext links, which with a single click of the mouse can bring up a totally different document from anywhere in the world, making it a truly new form of publishing.

There are several major forms of text entry that may also change the nature of writing and publishing. These forms include scanning for optical character recognition (OCR), voice recognition, and automated language translation. The technology for scanning text documents and producing computer text files has been in use for some years and requires only a scanning device and OCR software. This technology will continue to improve and its use will yield fewer errors and require considerably less effort in the future.

Likewise it is now possible to use voice recognition software to automatically transcribe dictation, interviews, and field notes into computer text files. One of the remaining problems in this approach is that all voice recognition software now requires considerable "training" time where the errors made in recognizing a speaker's word-sound pattern are corrected. The software is thus "taught"

to make refined guesses in translating vocalized sounds into electronic text. Even the best voice recognition software now makes a moderate number of errors, so it is not yet a panacea for manual transcription of either the spoken word or audio recordings.

It is possible now to find software that will translate text into many different languages. However, like voice recognition software, translation software still requires considerable time to manually check, decipher, and make judgments about the text produced by such programs. Future software may yield significantly improved results, automating nearly all of the voice recognition and translation process.

Communicating Electronically (E-mail, etc.)

Networks for computer-mediated communication (CMC) continue to expand internationally following the traditional logistic diffusion curve (Gurbaxani 1990). Electronic networks now supplement most other forms of social communication. E-mail, which is asynchronous or nonsimultaneous, is still the most common form of electronic interaction, but Internet-based, synchronous (simultaneous) "mailing lists" and "newsgroups" are also popular, as are "chat rooms" or "discussion groups." With improvements in transmitting digital audio and video files on the Internet, it is expected that some new forms of video conferencing will become commonplace. At the turn of the millennium, desktop video conferencing is available "off the shelf," but suffers from extraneous noise and rough motion. While individual sociologists vary greatly in how they utilize e-mail, nearly all sociologists in economically developed countries depend upon it for certain types of communication.

While e-mail messages are generally written in plain text, "attachments" to e-mail now make it possible for formatted documents, even those including graphics and multimedia, to be shared with others around the world in a matter of minutes. This remarkable technology makes co-authoring, and other forms of collaboration, far more feasible due to reduced time and cost.

As e-mail systems continue to expand, they offer social researchers new opportunities for conducting studies using electronic networks. For instance, Gaiser (1997) explored issues of running online focus groups. Online surveys have become

quite common in various forms: e-mail texts, e-mail attachments, entry forms on the Web, and as programs in external storage devices like diskettes and CD-ROMs. Sampling problems and low completion rates pose the greatest challenges. Ongoing methodological investigations will be necessary to determine the implications of this new mode of research.

Statistics. Hundreds of computer programs and articles have been written to address the needs of statistical computing in social research. Prior to the 1980s, all statistical work was performed on large or medium-size, mainframe computers. But advances in both hardware and software for microcomputers now make it possible to conduct the statistical data analysis of most small or moderate-size research studies on microcomputers. A large share of ongoing social data analysis, like analysis of massive census files, would never get done without computer technology. For example, one use of LISREL, a computer procedure which analyzes linear structural relationships by the method of maximum likelihood, would consume weeks or months without a computer.

Not only does statistical computing save time but it offers unique views of the patterns in one's data. Without the ability to quickly reorganize data and display it in a variety of forms, social researchers neglect important patterns and subtle relationships within complex data. Some patterns cannot be observed without special software tools. For example, Heise's (1988) computer program called Ethno gives the researcher a framework for conceptualizing, examining, and analyzing data containing event sequences. In addition, several general-purpose statistical packages offer powerful exploratory data analysis capabilities with bidirectionality through dynamic data links (Steiger and Fouladi 1990). One type of bidirectionality puts a graph in one window and frequency distributions in another, and when the user adjusts the data in one window, it automatically changes in the other.

Finding a statistical program tailored to a particular problem or technique is often challenging as the potential "user community" may be quite small. The best sources for such software are the notices and reviews in journals such as the *Social Science Computer Review*, *Educational and Psychological Measurement*, *Journal of Marketing Research*,

and *The American Statistician*. Another important source is the annual *Sociological Methodology* and its software list on the Web (<http://weber.u.washington.edu/~socmeth2/software.html>). Some of the software noted in these sources can be obtained at no cost or very low cost. No matter what the cost, one cannot assume that any complex program is free of errors. Thus is it important to run test data and to apply data to multiple programs in order to check for inaccuracies.

Accessing, Retrieving and Managing Data.

While years ago students and researchers had to use a library or similar institution to gain access to bibliographic data files, now such services are available from one's desktop using the Web or external storage units such as CD-ROM or DVD-ROM. Large bibliographic databases including Sociological Abstracts and Psychological Abstracts are available in these forms, as is a vast amount of data in the form of statistical tables and maps. Now that devices for "writing" onto CD-ROMs have become inexpensive, it is expected that data from even small research projects will be disseminated in this medium.

One major development is interactive access to data by means of the Web. A variety of models are used for interactive access to both preformatted text files and precoded data files. Among the systems are GSSDIRS from ICPSR at the University of Michigan (<http://www.ICPSR.umich.edu/gss>), IPUMS at the University of Minnesota (<http://www.hist.umn.edu/~ipums>), QSERVE from Queens College-CUNY (<http://www.soc.qc.edu/qserve>), and SDA Archive from the University of California at Berkeley (<http://csa.berkeley.edu:7502/archive.htm>).

The software technology for archiving and analyzing social data is less than a half-century old. But it is very plausible to expect many advancements in the next fifty years. Interactive data analysis sites of the Web hint about what these advancements might be. For instance, using the SDA Archive Web site (see [http](http://csa.berkeley.edu:7502/archive.htm) address above), one can get a large crosstabulation table for any three variables in the full General Social Survey of over 35,000 respondents in less time than it takes to type in the variable names.

The refinement of such systems faces issues such as how to balance functionality with ease of use, the plausibility of standardizing interfaces for

many numeric data files, and the use of gateways between the Web and third-party software such as statistical packages. It will take considerable research and development to sort out the feasibility of providing many different analytical facilities in the Web environment. A major challenge is determining the amount and type of data documentation necessary for typical users to get meaningful results in a reasonable amount of time. A considerable challenge is created when a variety of types of materials are necessary for retrieving useful data-related information. The main types are text, graphics, meta databases (data about databases), fielded text/data (such as bibliographic databases), and multimedia (audio and video) clips.

Qualitative Computing. Computer-based content analysis began with Stone (1966) and associates, and now plays an important role in the social sciences (Weber 1984; Kelle 1995). A survey of 110 qualitative-oriented researchers found three-fourths regularly used computers (Brent, Scott, and Spencer 1987). Ragin and Becker (1989, p. 54) persuasively claimed that qualitative research using these computing tools yields more systematic attention to diversity, for example, by encouraging a "more thorough examination of comparative contrasts among cases."

This type of computing became much more common as researchers combined content analysis with other tasks associated with qualitative analysis. Several general-purpose programs for qualitative analysis have been widely distributed (Tesch 1989; Fielding and Lee 1991). These tools make the analysis of large amounts of text more accurate and efficient, and potentially direct the focus of attention to analytic procedures. The general tasks of text entry, code assignment, counting, and data organization have been extended to include special routines for improving the quality of coding and code management (Carley 1988). Hesse-Biber, Dupuis, and Kinder (1997) technically extended this methodology to include the management and analysis of audio and video segments as well as text.

Simulating and Modeling. Early in the history of sociological computing, Coleman (1962) and McPhee and Glaser (1962) designed computer simulation models and showed how they could be used to identify elusive implications of different theoretical assumptions. Other social scientists

followed in their footsteps but the excitement of the pioneers was lost and few simulations and formal computer models were developed in the 1970s. With the emergence of artificial intelligence and other modeling methodologies, social researchers demonstrated renewed interest in formal computer-supported models of social processes (cf. Feinberg and Johnson 1995; Hanneman 1988; Markovsky, Lovaglia, and Thye 1997). New computer simulations for social policy analysis as well as pedagogy or instruction have emerged as well (Brent and Anderson 1990, pp. 188–210).

Neural networks combined with other techniques of artificial intelligence and expert systems have excited a number of social scientists (Garson 1990). Neural nets organize computer memory in ways that model human brain cells and their ability to process many things in parallel. Systems that use neural nets are especially good when pattern matching is required, however, the computations require high-performance computers.

Computer-Assisted Data Collection. CATI (Computer-Assisted Telephone Interviewing) is a computing system with online questionnaires or entry screens for telephone interviewers. It has become very common in sociological research, although its impact is not fully understood (Groves et al. 1988). It is used on free-standing PCs, networked PCs, or larger computers. These systems generally, but not always, have the following characteristics: centralized facilities for monitoring individual interviewer stations, instantaneous edit-checks with feedback for invalid responses, and automatic branching to different questions depending upon the respondents' answers. Other major forms of computer-supported data collection include (1) CAPI (Computer-Assisted Personal Interviewing), the acronym used in survey research to refer to face-to-face interviewing assisted with a laptop or hand-held computing device; (2) Computerized Self-Administered Questionnaires (CSAQ), online programs designed for direct input from respondents; and (3) data-entry programs to facilitate the entry of data collected manually at a prior time.

A related innovation is software built for designing online questionnaires. For example, the Questionnaire Programming Language (QPL), developed by Dooley (1989), allows the researcher to

draft a questionnaire with any word processor. From embedded branching commands within the questionnaire document, the QPL software package simultaneously produces two versions of the questionnaire: one for computer administration and the other for interviewer- or self-administration. An additional bonus of the program is that it automatically produces data definition commands for SPSS or SAS to use for data analysis.

Visualization and Graphics. Many social researchers have come to rely on computer graphic systems to produce maps, charts summarizing statistical data, network diagrams, and to retrieve data from GIS (Geographic Information Systems) databases. GIS data contain coordinates to associate a specific spatial point or area with any attribute, e.g., social density, associated with that point or collection of points. Because of the complexities of these data structures, the integration of these techniques onto sociologists' desktops has been slow. Another constraint is the paucity of techniques for analyzing such data. Work such as that of Cleveland (1993) for analyzing and visualizing data graphically may increase the utilization of such data by sociologists. In addition, techniques for storing and delivering interactive audio and video by means of the Web may stimulate sociologists to investigate multimedia data containing sounds and moving images.

Teaching and Learning. During the 1970s long before the microcomputer, a small group of social science instructors began to explore how to utilize computer technology in teaching (Bailey 1978). Now it has become quite common, and several sociologically-oriented instructional packages are widely used. The most popular have been Chipendale, designed by James Davis (1990), and MicroCase, developed by Roberts and Stark (cf. Roberts and Corbett 1996). These two packages have served as the basis for the exercises contained in at least a dozen published textbooks and workbooks. A variety of instructional approaches and software tools are described regularly in *Teaching Sociology* and the *Social Science Computer Review*.

ISSUES AND CHALLENGES

The practice of computing in social research has evolved rapidly. Computers have been applied to

practically every research task, including such unlikely ones as interviewing, and hundreds of other tasks (Brent and Anderson 1990). This variety of computer applications will continue to evolve with the newer Internet-based technologies.

The application of computing to sociology is not without problems. Errors in data and software abound yet rarely do social scientists check their results by running more than one program on the same data. Data and software tend to be very costly, but there are many impediments to the sharing of these critical resources. Better software is needed but graduate students often are discouraged from programming new software. Nonetheless, new breakthroughs in computer technology will continue, and major new opportunities will emerge. Many of the advances in sociological computing during the next few years undoubtedly will follow the lines of progress already described: hypertext networks; integrated, high performance, graphic data analysis stations; software for computer-supported cooperative work; and neural networks for complex models of social systems.

Perhaps the most exciting challenge for the future involves a concert of these innovations directed at the problem of modeling and analyzing vast amounts of social data. One solution would incorporate three-dimensional, multicolored, dynamic graphical representations of complex social data structures. But new techniques for analyzing these data will require new models of dynamic social structures as well as parallel social processes. Computer representations of these models tend to require extremely fast processing. Access to such models on the Web, supplemented with audio and video displays, may evolve into an important part of the sociologist's tool kit of the future.

**APPENDIX: SOCIOLOGY WEB/
INTERNET SITES**

These lists of Web and other Internet sites include electronic addresses for some of sociology's professional associations and some special interest groups, several resource referral sites giving many additional links, several sites giving access to sociological data, and lists of Internet Mailing Lists on "listservs." The addresses given were all current as of January 1, 1999. While many of the addresses have been stable for several years, there is no guarantee that they will remain accessible. Nonetheless, these addresses profile sociology's presence or representation on the Internet, especially the Web, and serve as entry points to sociology-related information in "cyberspace."

SOCIOLOGY USENET NEWSGROUPS

In contrast to Internet Mailing Lists, UseNet Newsgroups do not broadcast a message to all those included on the list. Internet users must specifically access the postings (messages) for any such newsgroup. While on any given day, “sociology” will be mentioned in a variety of newsgroup discussions, the only newsgroup where academic sociological topics are regularly discussed is: alt.sci.sociology. Generally a few messages are added to this discussion area every day.

CONFIDENCE INTERVALS

See Statistical Inference.

CONFLICT THEORY

NOTE: Although the following article has not been revised for this edition of the Encyclopedia, the substantive coverage is currently appropriate. The editors have provided a list of recent works at the end of the article to facilitate research and exploration of the topic.

Conflict theory explains social structure and changes in it by arguing that actors pursue their interests in conflict with others and according to their resources for social organization. Conflict theory builds upon Marxist analysis of class conflicts, but it is detached from any ideological commitment to socialism. Max Weber generalized conflict to the arenas of power and status as well as economic class, and this multidimensional approach has become widespread since the 1950s.

WHAT CONSTITUTES A CONFLICT GROUP?

For Marx and Engels, a society's conflicting interests derive from the division between owners and nonowners of property. Dahrendorf (1959) proposed that conflicts are based on power, dividing order-givers, who have an interest in maintaining the status quo, from order-takers, who have an interest in changing it. Property is only one of the bases of power conflict, and conflicts can be expected inside any type of organization, including socialist ones. In the Weberian model there are even more types of conflict, since every cultural group (such as ethnic, religious, or intellectual groups) can also struggle for advantage. In addition, economic conflict takes place in three different types of market relations, pitting employers against workers, producers against consumers, and lenders against borrowers (Wiley 1967). Gender stratification produces yet another dimension of conflict.

THE PROCESS OF CONFLICT

Conflicting interests remain latent until a group becomes mobilized for active struggle. This occurs when its members are physically concentrated, have material resources for communicating among themselves, and share a similar culture. The higher social classes are typically more mobilized than lower classes, and most struggles over power take place among different factions of the higher classes. Lower classes tend to be fragmented into localized groups and are most easily mobilized when they are a homogeneous ethnic or religious group concentrated in a particular place. The better organized a conflict group is, the longer and more intensely it can struggle; such struggles become routinized, as in the case of entrenched labor unions or political parties. Less organized conflict groups that become temporarily mobilized are more likely to be violent but unable to sustain the conflict.

Overt conflict increases the solidarity of groups on both sides. Coser (1956), elaborating the theory of Georg Simmel, points out that conflict leads to a centralization of power within each group and motivates groups to seek allies. A conflict thus tends to polarize a society into two factions, or a world of warring states into two alliances. This

process is limited when there are cross-cutting memberships among groups, for instance, if class, ethnic, and religious categories overlap. In these cases, mobilization of one line of conflict (e.g., class conflict) puts a strain on other dimensions of conflict (e.g., ethnic identity). Thus, cross-cutting conflicts tend to neutralize each other. Conversely, when multiple lines of group membership are superimposed, conflicts are more extreme.

Conflicts escalate as each group retaliates against offenses received from the other. How long this process of escalation continues depends on how much resources a group can draw upon: its numbers of supporters, its weapons, and its economic goods. If one group has many more resources than the other, the conflict ends when the mobilizing capacity of the weaker side is exhausted. When both sides have further resources they have not yet mobilized, escalation continues. This is especially likely when one or both sides have sustained enough damage to outrage and mobilize their supporters but not great enough damage to destroy their organizational resources for struggle.

Deescalation of conflict occurs in two very different ways. If one side has overwhelming superiority over the other, it can destroy opposition by breaking the other group's organizational capacity to fight. The result is not harmony but an uneasy peace, in which the defeated party has been turned back into an unmobilized latent interest. If neither side is able to break up the other's organization, conflict eventually deescalates when resources are eaten up and the prospects of winning become dimmer. Although wars usually arouse popular solidarity at first, costs and casualties reduce enthusiasm and bring most wars to an end within a few years. Civilian uprisings, strikes, and other small-scale conflicts typically have fewer resources to sustain them; these conflicts deescalate more quickly. During a deescalation, the points of contention among the opponents modulate from extreme demands toward compromises and piecemeal negotiation of smaller issues (Kriesberg 1982). Very destructive levels of conflict tend to end more rapidly than moderate conflicts in which resources are continuously replenished.

COERCIVE POWER AND REVOLUTION

In a highly coercive state, such as a traditional aristocracy or a military dictatorship, power is

organized as an enforcement coalition (Collins 1988; Schelling 1962). Members of the ruling organization monitor each other to ensure loyalty. A change in power is possible only when a majority of the enforcers disobey orders simultaneously. Revolts occur in a rapid “bandwagon effect,” during which most members scramble to become part of the winning coalition. The more coercive the state, the more extreme the swings between long periods of tyrannical stability and brief moments of political upheaval.

Since the state claims a monopoly on the instruments of violence, revolutionary changes in power occur through the reorganization of coercive coalitions. Revolts from below are almost always unsuccessful as long as the state’s military organization stays intact. For this reason, revolutions typically are preceded by a disintegration of the military, due to defeat in war, depletion of economic resources in previous conflicts, and splits within the ruling group (Skocpol 1979). These breakdowns of military power in turn are determined by geopolitical processes affecting the expansion or contraction of states in the surrounding world (Stinchcombe 1968; Collins 1986).

WHO WINS WHAT?

Conflict shapes the distribution of power, wealth, and prestige in a society. The victorious side is generally the group that is better mobilized to act in its collective interest. In many cases, the dominant group is well organized, while the opposing interest group remains latent. The result is a stable structure of stratification, in which overt conflict rarely occurs.

Lenski (1966) showed that concentration of wealth throughout world history is determined by the interaction of two factors. The higher the production of economic surplus (beyond what is necessary to keep people alive), the greater the potential for stratification. This surplus in turn is appropriated according to the distribution of power.

Turner (1984) theorizes that the concentration of power is unequal to the extent that there is external military threat to the society or there is a high level of internal conflict among social groups. Both external and internal conflict tend to centralize power, providing that the government wins

these conflicts; hence, another condition must also be present, that the society is relatively productive and organizationally well integrated. If the state has high resources relative to its enemies, conflict is the route by which it concentrates power in its own hands.

Prestige is determined by the concentration of power and wealth. Groups that have these resources can invest them in material possessions that make them impressive in social encounters. In addition, they can invest their resources in culture-producing organizations such as education, entertainment, and art, which give them cultural domination. According to Pierre Bourdieu’s research (1984), the realm of culture is stratified along the same lines as the stratification of the surrounding society.

EFFECTS OF CONFLICT GROUPS UPON INDIVIDUALS

The latent lines of conflict in a society divide people into distinctive styles of belief and emotion. Collins (1975) proposed that the differences among stratified groups are due to the microinteractions of daily experience, which can occur along the two dimensions of vertical power and horizontal solidarity. Persons who give orders take the initiative in the interaction rituals described by Goffman (1959). These persons who enact the rituals of power identify with their front-stage selves and with the official symbols of the organizations they control; whereas persons who take orders are alienated from official rituals and identify with their private, backstage selves. Individuals who belong to tightly enclosed, localized groups emphasize conformity to the group’s traditions; persons in such positions are suspicious of outsiders and react violently and emotionally against insiders who are disrespectful of the group’s symbols. Loosely organized networks have less solidarity and exert less pressure for conformity. Individuals build up emotional energy by microexperiences that give them power or solidarity, and they lose emotional energy when they are subordinated to power or lack experiences of solidarity (Collins 1988). Both emotions and beliefs reproduce the stratification of society in everyday life.

CONTENT ANALYSIS

"Content analysis" has evolved into an umbrella label that includes various procedures for making reliable, valid inferences from qualitative data, including text, speech, and images. These procedures have improved and expanded due to numerous developments in recent years since this encyclopedia's first edition.

Traditionally, "content analysis" has referred to systematic procedures for assigning prespecified codes to text, such as interviews, newspaper editorials, open-ended survey answers, or focus-group transcripts, and then analyzing patterns in the codings. Some projects will count each specific occurrence within a text, while others will have coders tally the number of column inches assigned a code. Either way, the procedure usually employs

a “top down” strategy, beginning with a theory and hypotheses to be tested, developing reliable coding categories, applying these to coding-specified bodies of text, and finally testing the hypotheses by statistically comparing code indexes across documents.

With the increasing popularity of qualitative sociology, content analysis has also come to refer to “grounded” inductive procedures for identifying patterns in various kinds of qualitative data including text, illustrations, and videos. For example, the data might include observers’ detailed notes of children’s behaviors under different forms of supervision, possibly supplemented with videotapes of those same behaviors. While traditional content analysis usually enlisted statistical analyses to test hypotheses, many of these researchers do not start with hypotheses, but carefully search for patterns in their data.

However, rather than just produce statistical analyses or search for patterns, investigators should also situate the results of a content analysis in terms of the contexts in which the documents were produced. A content-analysis comparison of letters to stockholders, for example, should take into consideration the particular business sectors covered and the prevailing economic climates in which they were written. An analysis of American presidential nomination acceptance speeches should consider that they changed dramatically in form once they started to be broadcast live on national radio. A content analysis may have reliable coding, but the inferences drawn from that coding may have little validity unless the researcher factors in such shaping forces.

Like any expanding domain, there has been a tendency for content analysis to segment into specialized topics. For example, Roberts (1997) focuses on drawing statistical inferences from text, including Carley’s networking strategies and Gottschalk’s clinical diagnostic tools. There also has been a stream of instructional books, including several series published by Sage, that focus on particular kinds of qualitative data such as focus-group transcripts. A technical literature also has developed addressing specialized computer software and video-analysis techniques. Nevertheless the common agenda is analyzing the content of qualitative data. Inasmuch as our lives are shaped

by different forms of media, and inasmuch as different analytic procedures can complement one another in uncovering important insights, it makes sense to strive toward an integration, rather than fragmentation.

Many advances in content-analysis procedures have been made possible by the convenience and power of desktop and laptop computers. In addition, an overwhelming proportion of text documents are now generated on computers, making their text files computer accessible for content analysis. And a revolution in hand-held analogue and digital video cameras, together with computer-based technology for editing and analyzing videotapes, makes new research procedures feasible.

Consider, for example, new possibilities for analyzing responses to open-ended questions in survey research. For years, survey researchers have been well aware that closed-ended questions require respondents to frame how they think about an issue in terms of a question’s multiple choices, even when the choice options had little to do with how a respondent views an issue. But the costs and time involved in analyzing open-ended responses resulted in such questions rarely being used. Even when they were included in a survey, the interviewers usually just recorded capsule summaries of the responses that omitted most nuances of what was said.

Contrast this then with survey research using today’s audio information-capturing technologies. Telephone survey interviewers are guided by instructions appearing on a computer screen. Whenever an open-ended question appears, the interviewer no longer needs to type short summaries of the responses. Instead, a computer digitally captures an audio recording of each open-ended response, labels it, and files it as a computer record. Any audio response can later be easily fetched and replayed, allowing a researcher, for example, to identify a “leaky voice,” that is, one indicative of the respondent’s underlying emotion or attitude. And the full audio responses are then available to be transcribed to text, including, if desired, notations indicating hesitations and voice inflections. Until computer voice recognition is completely reliable, transcribing usually remains a manual task. But with spreadsheet software (such as *Excel*) no longer restrictively limiting the amount of text

in any one cell, the text of each individual's entire response to a question can be placed in a spreadsheet cell, thus capturing both the closed-ended and open-ended data for a survey into a convenient, single spreadsheet for researchers to analyze.

With the survey data in this convenient form, researchers can then code open-ended responses manually, putting their assigned codes in additional spreadsheet columns. As a teaching exercise, it is instructive to assign students a task such as identifying gender differences among a thousand responses to a broad open-ended question, such as a question asking respondents' views about peace or family values. Students first might sort the spreadsheet by gender in order to read separately samples of male responses and female responses and obtain a sense of what possible gender differences exist. They then develop coding instructions that capture these differences and apply the codes to the entire set of responses. This coding, of course, is better done without knowledge of the respondents' genders, with responses in a random order, and on different respondents than those used to develop the codes. After coding several hundred responses, however, students usually begin to glaze over and soon the most ardent humanist student is asking whether the computer could possibly be of help in assigning codes.

For some kinds of coding, computer help is indeed available in the form of computer programs that assign codes. Such codings can be treated as advisory and then manually confirmed, augmented perhaps by also assigning a weight. Or they may be used as is after being spot-checked for accuracy. Not only can a computer complete huge amounts of tedious coding in minutes, possibly assigning many different types of codings to each text, but these codings may uncover statistically significant frequency differences that human coders would not uncover, if only because computer analysis is so even-handed and untiring. The static created by occasional miscodings may be more than offset by gains from a reliable consistency in making many codings.

Computer coding assignments are usually based on the occurrence of words, particular senses of words, or multiword idioms appearing in the text. For example, the word "father" in a text might be coded as "male," "family member," etc. as well as

possibly "authority-role." Computer content-analysis software may search the contexts of words in the text to ferret out and correctly code common word senses. For example, for a national study of people's perceptions of African-American young males on several open-ended questions, it was particularly important for the computer to identify correctly each respondent's usages of such multi-meaning words as "race," "white," "black," and "color."

In addition to developing their own coding categories, researchers may enlist existing computer-scored categories that are relevant to the task at hand. For example, it might be hypothesized that one group being studied is more optimistic and its responses will reflect more "positive thinking" while another is more negative or pessimistic. To code "positive thinking" a researcher may want the computer to apply an existing content-analysis category that includes over 1200 words, word roots, word senses, phrasal verbs, and idioms, thus essentially covering most expressions of "positive-thinking" that occur as infrequently as three times per million words of ordinary English text. A similar category exists for negative-thinking, allowing the investigator to check whether the groups being studied differ in their coded positive thinking, negative thinking, or both. And by enlisting such standard categories, the results obtained in one study can be readily compared with results found in other studies.

Once data has been captured in a convenient format for computer use, they can be repeatedly analyzed. For example, should our now glazed-over students have any energy left after analyzing the responses by gender, they could be given an additional assignment of identifying and coding rural-urban differences in these same open-ended responses. Given so many analyses that can be made, it makes sense to let the computer do what it can, saving manual labor for those types of codings that would be hard to have a computer assign. Even multimedia qualitative-analysis software such as *HyperResearch* includes some rudimentary tools for automatic assignments.

Moreover, desktop computer software has also become available that identifies patterns in text without having to develop coding categories. For example, SPSS's *TextSmart* uses an algorithm that

groups respondents into clusters based on word-use co-occurrences within responses and then maps these clusters into a two-dimensional grid that uses colors to represent each cluster group. If such an automated inductive procedure can produce additional valid insights that other techniques are likely to overlook, then why not use it too?

Pioneering work in inductive automatic categorizing, such as Iker's (1969), usually enlisted procedures based upon correlation matrixes, such as factor analysis. These procedures tended not to be particularly suited to analyzing text both because of the shape of word-usage frequency distributions as well as the limited number of words that a correlation matrix could feasibly handle. *TextSmart*, based upon a word-distance measure, provides much more suitable solutions. Further automatic categorizing procedures may be expected from artificial intelligence, as well as from categorizing techniques being developed for Internet search engines.

Content-analysis research strategies can thus now easily be multipronged, spanning from completely automatic inductive procedures to manual coding. But even manual coding these days is likely to utilize computer software to help coders manage information. Consider these changes in costs and convenience: Unlike mainframe computing of the 1960s and 1970s, when the cost of an hour of computer time was about the same as a coder's wage for several weeks, the marginal cost of using a desktop computer is essentially the electricity it uses. Today's desktop computer is likely to be more than fivefold faster at content-analysis coding than those mainframe computers ever were. They also can access much larger dictionaries and other information in their RAM than was ever feasible on a user partition of a mainframe computer, thus making their coding more accurate and comprehensive. Moreover, a single CD-ROM full of text to be analyzed is easily popped into a desktop computer, whereas in the days of mainframe computing, a comparable amount of text would have to be keypunched on over 3,000 boxes of IBM cards.

Given today's convenience and low cost of computer-based procedures, there is no reason to limit an analysis to one approach, especially if insights gained from one approach will differ and

often complement those gained from another. Instead of being limited by technology, the limits now may lie in the skills, proclivities, and comfort zones of the researchers. Research teams, rather than individual researchers, may prove the best solution, for only in a team made up of people with complementary strengths is one likely to find the full range of statistical, conceptual, intuitive, experiential, and perhaps clinical strengths needed to carry out penetrating, comprehensive content-analysis projects. Moreover, some researchers will prefer to learn from the main trends while others will learn more from studying outlying cases. Some will learn from bottom-line numbers while others will learn more from innovative graphics that highlight information patterns. Some will focus on current data while others will contextualize data historically by comparing them with data in archives. Data that has been gathered and assembled at considerable cost, especially data-gathering that imposed on many respondents, merit as thorough and comprehensive analyses as these various procedures collectively offer.

Unfortunately, however, an "either-or" assumption about how to do content analysis has continued to be supported both by books and computer software. Authors who do an excellent job of describing one approach to content analysis, such as Boyatzis (1998), give an impression that an either-or decision has to be made about which approach to use. Some software—especially that ported from mainframe computers or developed for early desktop computers—still may steer or even limit researchers who use it to just one approach. For example, some software packages create specialized data formats such as "classification trees" that then in effect constrain the user to analyses that can be readily derived from that format. Software reviews such as Lewis's (1998) excellent comparison of *ATLAS/ti* and *NUD-IST* software have been explicit about what assumptions a researcher buys into when utilizing each package.

Additional leverage in analyzing qualitative information has stemmed from computer-based tools, such as newer versions of *HyperResearch* and *ATLAS/ti*, that integrate the handling of multiple media (text, illustrations, and video). Especially as more software comes from countries where there are expert programming skills and programming

labor is relatively inexpensive, we can expect ambitious content-analysis software, of which *TextAnalyst* from Russia (www.megaputer.com) may be a forerunner.

Given continuing content-analysis software developments, those who would like to learn what is currently available are advised search Internet sites rather than rely upon even recently published materials. One recommended starting point is the Georgia State University content-analysis site (www.gsu.edu/~wwwcom/content.html), which gives links to software web sites (including software mentioned in this article), indexes recent content-analysis publications, and has a mailing list of more than 700 members. Technical reviews of relevant language-analysis tools, such as Berleant's (1995), occasionally appear in computational linguistics journals and web sites. For training, the University of Essex Summer School in Social Science Data Analysis and Collection (www.essex.ac.uk), as part of a program of a European consortium, has been offering a content-analysis module for years as part of its program.

Given the developments described here, some of the contributions that content analysis should be able to make to sociological research include:

1. A major shift from reliance upon closed-ended questions to an appropriate use of open-ended questions that lets people be heard in the ways they frame issues, as well as the way they think and feel about them, as discussed in detail by Stone (1997)
2. A better understanding of both print and television media and its impact on public opinion, both in setting agendas and in influencing opinion intensity, as laid out in Neuman (1989). This will involve research that compares the content of media with the content of opinions. Not only will survey research data be archived and accessible from Internet servers, but full-display media will be accessible from Lexis-Nexis and on-line editions supplied by media providers, as well as television news archives such as those at Vanderbilt University
3. Better use of historical qualitative data, including both text and graphic materials,

to address such issues as how economic cycles impact ideology, as examined by Namenwirth and Weber (1987), or to uncover cycles of creativity, as demonstrated by Martindale (1990)

4. Investigations, several of which are already underway, of both intranet communication patterns within organizations as well as Internet communications, including analyses of the content of communications over those networks.

There is also, however, good reason for caution. Never before in history has so much qualitative information been available electronically. High-volume image scanning will also further increase the amount of information that can be electronically accessed and content-analyzed. Quite understandably, those agencies responsible for limiting terrorist activities may look on content-analysis procedures as possibly providing early warnings that could save lives. But these procedures can also become tools for a "big-brother" monitoring society. Sociologists have an important role in anticipating these problems and helping resolve them.

CONVERGENCE THEORIES

The idea that societies move toward a condition of similarity—that they converge in one or more respects—is a common feature of various theories of social change. The notion that differences among societies will decrease over time can be found in many works of eighteenth and nineteenth century social thinkers, from the prerevolutionary French *philosophes* and the Scottish moral philosophers through de Tocqueville, Toennies, Maine, Marx, Spencer, Weber, and Durkheim (Weinberg 1969; Baum 1974). More recently, the study of "postindustrial" society and the debate over "postmodernist" aspects of contemporary society also reflect to some degree the idea that there is a tendency for broadly similar conditions or attributes to emerge among otherwise distinct and dissimilar societies.

In sociological discourse since the 1960s, the term *convergence theory* has carried a more specific connotation, referring to the hypothesized link between economic development and concomitant changes in social organization, particularly work and industrial organization, class structure, demographic patterns, characteristics of the family, education, and the role of government in assuring basic social and economic security. The core notion of convergence theory is that as nations achieve similar levels of economic development they will become more alike in terms of these (and other) aspects of social life. In the 1950s and 1960s, predictions of societal convergence were most

closely associated with modernization theories, which generally held that developing societies will follow a path of economic development similar to that followed by developed societies of the West. Structural-functionalist theorists, such as Parsons (1951) and Davis (1948), while not actually employing the terminology of convergence theory, paved the way for its development and use in modernization studies through their efforts to develop a systematic statement of the functional prerequisites and structural imperatives of modern industrial society; these include an occupational structure based on achievement rather than ascription, and the common application of universalistic rather than particularistic evaluative criteria. Also, beginning in the 1960s, convergence theory was invoked to account for apparent similarities in industrial organization and patterns of stratification found in both capitalist and communist nations (Sorokin 1960; Goldthorpe 1964; Galbraith 1967).

CONVERGENCE THEORY AND MODERNIZATION

The conventional and most controversial application of convergence theory has been in the study of modernization, where it is associated with the idea that the experience of developing nations will follow the path charted by Western industrialized nations. Related to this idea is the notion of a relatively fixed pattern of development through which developing nations must pass as they modernize (Rostow 1960). Inkeles (1966), Inkeles and Smith (1974), and Kahl (1968) pursued the idea of convergence at the level of individual attitudes, values, and beliefs, arguing that the emergence of a "modern" psychosocial orientation accompanies national modernization (see Armer and Schnaiberg 1972 for a critique).

Kerr and colleagues' *Industrialism and Industrial Man* (1960) offers the classic statement of the "logic of industrialism" thesis, which the authors proposed as a response to Marxian theory's equation of industrial society with capitalism. More specifically, Kerr et al. sought to identify the "inherent tendencies and implications of industrialization for the work place," hoping to construct from this a portrait of the "principal features of the new society" (p. 33). The features common to

industrial society, they argued, include rapid changes in science, technology, and methods of production; a high degree of occupational mobility, with continual training and retraining of the work force; increasing emphasis on formal education, particularly in the natural sciences, engineering, medicine, managerial training, and administrative law; a workforce highly differentiated in terms of occupational titles and job classifications; the increasing importance of urban areas as centers of economic activity; and the increasing role of government in providing expanded public services, orchestrating the varied activities of a large and complex economy, and administering the “web of rules” of industrial society. Importantly, Kerr et al. envisioned these developments as cutting across categories of political ideology and political systems.

Although the “logic of industrialism” argument is often cited as a prime example of convergence theory (see Form 1979; Moore 1979; Goldthorpe 1971), Kerr et al. never explicitly made this claim for their study. While mentioning convergence at various points in their study, the authors pay equal attention to important countercurrents leading toward diverse outcomes among industrial societies. The concluding chapter of *Industrialism and Industrial Man* is, in fact, entitled “Pluralistic Industrialism,” and addresses the sources of diversity as well as uniformity among industrial societies. Among sources of diversity identified are the persistence of existing national institutions, enduring cultural differences, variations in the timing of industrialization (late versus early), the nature of a nation’s dominant industry, and the size and density of population. Counterposed against these factors are various sources of uniformity, such as technological change, exposure to the industrial world, and a worldwide trend toward increased access to education leading to an attenuation of social and economic inequality.

The critique of convergence theory in the study of modernization recalls critiques of earlier theories of societal evolution advanced under the rubric of social Darwinism in the nineteenth century and structural functionalism in the mid-twentieth century. The use of convergence theory to analyze modernization has been attacked for its alleged assumptions of unilinearity and determinism (i.e., a single path of development that all societies must follow), its teleological or historicist

character (Goldthorpe 1971), its Western ideological bias (Portes 1973), and for ignoring the structurally dependent position of less-developed countries in the world economy (Wallerstein 1974). Yet a careful review of the literature suggests that many criticisms have often tended to caricature convergence theory rather than addressing its application in actual research studies. Since the 1960s few if any researchers have explicitly claimed convergence theory, at least in its unreconstructed form, as their own. For example, Moore (1979), an exponent of the “conventional” view of modernization, subtitled his book, *World Modernization, “the limits of convergence,”* and went to great pains to distance himself from the “model modernized society” position associated with early versions of convergence theory (see Moore 1979, pp. 26–28, 150–153). And Parsons (1966), whose name is virtually synonymous with structural functionalism, concluded one of his later writings on comparative sociology with the statement that “any linear theory of societal evolution” is “untenable” (p. 114). As Form (1979) observes, convergence theory passed through a cycle typical of social science theories: a burst of initial interest and enthusiasm, followed by intense criticism and controversy, finally giving way to neglect. The major challenge to those wishing to revive convergence theory and rescue it from its critics is to specify its theoretical underpinnings more precisely, to develop appropriate empirical studies, and finally account for variation as well as similarity among observed cases.

FORMS OF CONVERGENCE AND DIVERGENCE

In recent years Inkeles (1980, 1981; also Inkeles and Sirowy 1983) has made the most systematic attempt to reformulate convergence theory and respecify its core hypotheses and propositions. Inkeles (1981) argues that earlier versions of convergence theory failed to distinguish adequately between different elements of the social system, which is problematic because these elements not only change at different speeds, but may move in opposite directions. He proposes dividing the social system into a minimum of five elements for purposes of assessing convergence: modes of production and patterns of resource utilization; institutional arrays and institutional forms; structures

or patterns of social relationships; systems of popular attitudes, values, and behavior; and systems of political and economic control. Finally, he specifies the different forms convergence and divergence may take: (1) simple convergence involving the movement from diversity to uniformity; (2) convergence from different directions involving movement toward a common point by an increase for some cases and a decrease for others; (3) convergence via the crossing of thresholds rather than changes in absolute differences; (4) divergent paths toward convergence, where short-term fluctuations eventually fall into line or a “deviant” case that eventually defines the norm for other cases (for example, France’s move toward small family size in the late eighteenth century); and (5) convergence in the form of parallel change, where nations all moving in the same direction along some dimension of change continue to remain separated by a gap. Although parallel change of this sort does not represent true convergence, it is consistent with the key assumption of convergence theory, namely, that “insofar as they face comparable situations of action . . . nations and individuals will respond in broadly comparable ways” (p. 21).

Inkeles (1981) also describes various forms that divergence may take: (1) simple divergence, the mirror image of simple convergence, in which movement occurs away from a common point toward new points further apart than the original condition; (2) convergence with crossover, where lines intersect and then proceed to spread apart; and (3) convergent trends masking underlying diversity (for example, although the United States, Great Britain, and Sweden all experienced large increases in public assistance programs from 1950 to the early 1970s, the social groups receiving benefits were quite different among the three nations, as were the political dynamics associated with the spending increases within each nation). Finally, Inkeles (1981) notes the importance of selecting appropriate units of analysis, levels of analysis, and the time span for which convergence, divergence, or parallel change can be assessed. These comments echo earlier sentiments expressed by Weinberg (1969) and Baum (1974) about how to salvage the useful elements of standard convergence theory while avoiding the pitfalls of a simplistic functionalist-evolutionary approach. Common to these attempts to revive convergence theory is the exhortation to develop more and better

empirical research on specific institutional spheres and social processes. As the following sections demonstrate, a good deal of work along these lines is already being done across a wide range of substantive questions and topical concerns that can aptly be described in the plural as *convergence theories*, indicating their revisionist and more pluralistic approach.

INDUSTRIAL SOCIOLOGY

Despite criticisms of Kerr and colleagues’ (1960) concept of the logic of industrialism, the question of convergent trends in industrial organization has remained the focus of active debate and much research. The large research literature related on this question, reviewed by Form (1979), has produced mixed evidence with respect to convergence. Studies by Shiba (1973, cited in Form 1979), Form (1976), and Form and Kyu Han (1988), covering a range of industrializing and advanced industrial societies found empirical support for convergence in workers’ adaptation to industrial and related social systems, while Gallie’s (1977, cited in Form 1979) study of oil refineries in Great Britain and France found consistent differences in workers’ attitudes toward systems of authority. On the question of sectoral and occupational shifts, Gibbs and Browning’s (1966) twelve-nation study of industrial and occupational division of labor found both similarities—consistent with the convergence hypothesis—as well as differences. Studies across nations varying in levels of industrial development revealed only “small and unsystematic differences” in worker commitment (Form 1979, p. 9), thus providing some support for the convergence hypothesis. Japan has been regarded as an exceptional case among industrialized nations because of its strong cultural traditions based on mutual obligation between employers and employees. These characteristics led Dore (1973), for example, to argue vigorously against the convergence hypothesis for Japan. A more recent study by Lincoln and Kalleberg (1990) “stands convergence on its head,” arguing that patterns of work organization in the United States are being impelled in the direction of the Japanese model. Finally, with respect to women in the labor force, the evidence of convergence is mixed. Some studies found no relationship between female labor-force participation and level of industrialization

(Ferber and Lowry 1977; Safilios-Rothchild 1971), though there is strong evidence of a trend toward increasing female participation in nonagricultural employment among advanced industrial societies (Paydarfar 1967; Wilensky 1968) along with the existence of dual labor markets stratified by sex, a pattern found in both communist and capitalist nations in the 1970s (Cooney 1975; Bibb and Form 1977; Lapidus 1976).

STRATIFICATION

Closely related to the study of industrial organization is the question of converging patterns of stratification and mobility. The attempt to discover common features of the class structure across advanced industrial societies is a central concern for social theorists of many stripes. The question has inspired intense debate among both neo-Weberian and Marxist sociologists, although the latter, for obvious ideological reasons, tend to eschew the language of convergence theory. An early statement of the class convergence thesis was made by Lipset and Zetterberg (1959), to the effect that observed rates of mobility between social classes tend to be similar from one industrial society to another. Erikson et al. (1983) conducted a detailed test of the class mobility convergence hypothesis in England, France, and Sweden, and found little support for it. They conclude that the “process of industrialization is associated with very variable patterns . . . of the social division of labour” (p. 339).

A subcategory of comparative stratification research concerns the evidence of convergence in occupational prestige. A study published in 1956 by Inkeles and Rossi, based on data from six industrialized societies, concluded that the prestige hierarchy of occupations was “relatively invariable” and tended to support the hypothesis that modern industrial systems are “highly coherent. . . relatively impervious to the influence of traditional culture patterns” (p. 329). Although the authors did not specifically mention convergence, their conclusions were fully consistent with the idea of emergent similarities. A subsequent study by Treiman (1977) extended the comparison of occupational prestige to some sixty nations, ranging from the least developed to the most developed. The study found that occupational-prestige rankings were markedly similar across all

societies, raising the question of whether convergence theory or an explanation based on the functional imperatives of social structure of all complex societies, past or present, was most consistent with the empirical findings. The conclusion was that both explanations had some merit, since although all complex societies—whether developed, undeveloped, or developing—showed similar occupational-prestige rankings, there was also evidence that the more similar societies were in levels of industrialization, the more similar their patterns of occupational-prestige evaluation appeared to be.

DEMOGRAPHIC PATTERNS

The theory of demographic transition provides one of the most straightforward examples of convergence. The essence of the theory is that fertility and mortality rates covary over time in a predictable and highly uniform manner. Moreover, these changes are directly linked to broad developmental patterns, such as the move from a rural, agriculturally based economy to an urban-industrial one, increases in per capita income, and adult literacy (Berelson 1978). In the first stage of the demographic transition, both fertility rates and death rates are high, with population remaining fairly constant. In the second stage, death rates drop (as a result of improvements in living conditions and medical care) while fertility rates remain high, and population levels increase rapidly. In the third stage, fertility rates begin to decline, with total size of the population leveling off or even decreasing. This simple model works remarkably well in accounting for demographic patterns observed among all industrialized (and many industrializing) societies during the post-World War II period. A large spread in fertility rates among nations at the beginning of the 1950s gave way to declining rates of fertility ending with a nearly uniform pattern of zero population growth in the 1970s.

The convergent tendencies predicted by the theory of demographic transition have not gone unchallenged, however. Freedman (1979), for example, suggests that cultural factors mediate the effects of social structural factors central to transition theory. Coale (1973) and Teitelbaum (1975) note that demographic transition theory has not provided much explanatory or predictive power
