There is abundant evidence, however, that individuals do not always disclose their emotions surrounding a major life event to those around them. Although people may have an intense desire to express or discuss negative events, social constraints may force them not to do so (Lepore, Silver, Wortman, & Wayment, 1996; Pennebaker & Harber, 1993). Some negative life events, such as rape or abuse, may have a social stigma attached to them. Some people may not have access to sympathetic or supportive listeners. Others may have access to a support network, but receive support that is perceived as inappropriate or insensitive. For instance, a support provider may not know how to respond to a traumatized individual and either minimize the event or resort to glib responses (e.g., “it could be worse”; Wortman & Silver, 1989). To avoid hearing such unhelpful and painful responses, many individuals will

choose not to disclose the trauma. Similarly, revealing struggles tends to elicit more rejection from others than acting as if you are coping well. Finally, some individuals may be abandoned by their social network during times of crisis. This is especially true in cases of “irrevocable” stressors, such as death or terminal illness, where support providers feel especially helpless (Lehman, Wortman, & Williams, 1987).

Talk therapy (including psychoanalysis, behavioral, and cognitive therapies) provides individuals a safe environment to disclose, and has been shown to reduce distress and to promote physical and mental well-being (Mumford, Schlesinger, & Glass, 1983; Smith, Glass, & Miller, 1980). A process common to most therapies is the labeling of the problem and a discussion of its causes and consequences. Further, participating in therapy presupposes that the individual acknowledges the existence of a problem and openly discusses it with another. Emotional writing also provides individuals with the chance to disclose without fear of negative social consequences. As is discussed in this chapter, the mere act of disclosure is a powerful therapeutic agent that may account for a substantial portion of the healing process.

It is important to briefly highlight the differences between emotional expression and emotional disclosure. Emotional expression refers to the natural venting of feelings, often in nonverbal ways: crying, laughter, screams of rage. Emotional disclosure, on the other hand, requires the translation of feelings into language and, thus, is a more self-reflective process.

Raw emotional expression—without self-reflection and language—may be unhealthy. A number of studies have now linked the persistent tendencies to express negative emotion

with increased stress and health problems (Pennebaker & Beall, 1986; Watson, 1988; Watson & Pennebaker, 1989), depression (Nolen-Hoeksema, 1987), and hopelessness (Keltner, Ellsworth, & Edwards, 1993). It may not be emotional expression itself that is helpful, but rather when emotional and cognitive components are facilitated into an improved understanding or worldview (Bowlby, 1980; Parkes & Weiss, 1983; Shuchter & Zisook, 1993). Emotional disclosure, then, represents the willful expression of emotional material coupled with the self-reflection and language processes necessary for improvement. Nonverbal emotional expression (or disclosure) may be less effective than verbal or written disclosure, as it lacks the organizing principles of the transduction of emotional experience into language (see Berry & Pennebaker, 1993).

Over the last decade, researchers have been exploring the value of talking or writing about emotional experiences by both inducing disclosure in the laboratory and examining disclosure in individuals' day-to-day lives. Disclosing about deeply personal issues has been found to promote physical health, subjective well-being, and certain adaptive behaviors. There is increasing empirical evidence that emotions and attitudes affect physical health (see Dienstfrey, 1991; Locke & Colligan, 1987). Severe and minor naturalistic stressors, for instance, have been associated with both symptoms and illness (Antoni, 1985; Brantley & Jones, 1993; Cohen, Tyrell, & Smith, 1991, 1993; Pennebaker & Susman, 1988; Stone, Reed, & Neale, 1987). This chapter focuses specifically on emotional disclosure about stressful events and how this process may influence health.

There are now several studies that have found comparable beneficial emotional, cognitive, and physiological effects from writing (while alone), speaking into a tape recorder, and speaking to a therapist (Donnelly & Murray, 1991; Esterling, Antoni, Fletcher, Margulies, & Schneiderman, 1994; Murray, Lamnin, & Carver, 1989). Both writing and speaking about emotional experiences produce greater improvements than writing about superficial topics. It is important to note, however, that all of these cases are dissimilar from the normal daily exchanges individuals may have with their friends. These are actual or implied interactions where no feedback is given, thus eliminating the possibility of social punishment. Hence, examining disclosure in this fashion allows a relatively "pure" view of the effects of disclosure uncontaminated by social feedback/stigma processes. This section discusses the general findings and limitations of disclosure paradigms. Whereas a few studies have asked individuals to disclose personal experiences through talking, most involve writing.

Although Pennebaker and others have investigated the effects of written disclosure (described in detail later), emotional disclosure more generally has been shown to have a variety of positive effects. Disclosure to a receptive audience may help people make sense of traumatic events (Silver, Boon, & Stones, 1983), and/or gain coping strategies or enhanced control over their emotions (Clark, 1993). Ornish and colleagues (e.g., 1990), for example, demonstrated that improvement of coronary atherosclerosis may occur as a result of comprehensive lifestyle changes, and suggest that emo-

tional disclosure and support are vital components of this improvement.

Although beyond the scope of this chapter to review, emotional expression and emotional disclosure seem to play an important role in many illnesses (see Davison & Pennebaker, 1996; Friedman & Booth-Kewley, 1987). Similarly, there is considerable historical evidence that the repression or denial of emotions is linked to the development of a variety of disorders (see Singer, 1990).

One area producing accumulating support for the important role of emotional disclosure is cancer research. Temoshok and colleagues (1985) found that the tendency to suppress negative emotions was associated with unfavorable outcomes in malignant melanoma (skin cancer) patients (part of the "Type C" personality style). Expressing emotion, however, was positively related to lymphocytes at tumor base—a response related to favorable outcomes (Temoshok, 1985). Temoshok concluded that emotional expression variables may be the more active components of the type C personality. Reviews consistently support the hypothesis that emotional disclosure is involved in the onset and progression of a variety of cancers (e.g., Gross, 1989; Meyer & Mark, 1995).

Several studies have attempted to manipulate the degree of social support and emotional disclosure in cancer patients. Spiegel, Bloom, Kraemer, and Gottheil (1989) found that women suffering from advanced breast cancer who were randomly assigned to nonspecific group therapy (a context that allowed them to talk over their day-to-day troubles in a supportive setting) lived, on average, one and a half years longer than those in an information-only control group. A subsequent study (Classen, Koopman, Angell, & Spiegel, 1996) suggested that inhibiting emotional expression was associated with poorer adjustment to advanced breast cancer. Although social support is a broad concept with many components, certainly the opportunity to disclose to others is one of them. To what degree the therapeutic effects of social support are due to disclosure is not yet clear; at least for some groups or circumstances, however, it may be substantial (e.g., Caplan, 1990).

Pennebaker and colleagues conducted several surveys in attempts to understand the link between disclosure and more general health. Pennebaker and O'Heeron (1984) found that in spouses of suicide or accidental death victims, talking about the death was associated with fewer self-report health problems and ruminations in the year following the death. Three larger surveys were conducted by Pennebaker. In the first, over 700 female undergraduates completed a questionnaire assessing current health history, trauma history, and additional related variables. Three groups of participants had experienced sexual trauma ($n = 58$), death of a parent ($n = 41$), parents' divorce ($n = 81$), and another was a group of controls ($n = 536$). Of these four groups, those having experienced sexual trauma were most likely to report all physical symptoms, and groups that had experienced parental death or divorce reported more symptoms than the control group (Pennebaker, 1985). This finding was partially replicated in a survey published in *Psychology Today* that received over 24,000 responses. A random sample of just over 2,000 of these responses revealed that responders who reported sexual

trauma prior to age 17 were more likely to report nearly every physical or emotional health problem than all other responders. Finally, in a survey of 115 medical students, those students who had experienced a trauma and had not disclosed about it had more self-reported health provider visits, diseases, symptoms, and nonprescription medication use than the other participants.

These and related studies supported a link between the experience of trauma and subsequent self-reported health, and suggested the salutary role of disclosure in this relation. Although promising, they relied on correlational designs that attempted to demonstrate the potential value of confiding in others or, the converse, the health risks of not talking. In order to isolate some of the causal mechanisms, a group of studies was conducted whereby participants were encouraged to either disclose or not disclose emotional experiences that they had experienced earlier in their lives.

Although studies involving both talking and writing have been conducted in examining the effects of disclosure, most of the stronger ones have relied on writing. The remainder of the chapter focuses on written disclosure for several reasons. First, this is a relatively recent and exciting area of experimental research that has shown promising results across a variety of outcomes. Second, as mentioned earlier, written disclosure allows the investigation of the health effects of disclosure "uncontaminated" by stigma processes. Writing may thus ultimately prove more useful than interpersonally based disclosure procedures. Third, written disclosure has received a relatively large amount of media coverage and is likely high in public awareness. *American Health*, for instance, published articles entitled "Writing your wrongs" (Pennebaker, 1991) and "Writing off the unemployment blues" (Wilenski, 1993), both lauding the benefits of emotional writing. Numerous articles on written disclosure have appeared in *USA Today* and *Psychology Today*.

The standard laboratory writing technique has involved randomly assigning participants to one of two (or more) groups: an experimental group that discloses emotional material, and a control group that does not. Both groups are asked to write about assigned topics for 3 to 5 consecutive days, for 15 to 30 minutes each day. Writing is generally done in the laboratory with no feedback given. Those assigned to the control conditions are typically asked to write about superficial topics, such as how they use their time. The standard instructions for those assigned to the experimental group are a variation on the following:

For the next (three) days, I would like for you to write about your very deepest thoughts and feeling about an extremely important emotional issue that has affected you and your life. In your writing, I'd like you to really let go and explore your very deepest emotions and thoughts. You might tie your topic to your relationships with others, including parents, lovers, friends, or relatives, to your past, your present, or your future, or to who you have been, who you would like to be, or who you are now. You may write about the same general issues or experiences on all days of writing or on

different topics each day. All of your writing will be completely confidential. Don't worry about spelling, sentence structure, or grammar. The only rule is that once you begin writing, continue to do so until your time is up.

This writing process seems exceptionally powerful at producing emotional disclosure. Participants—from children to the elderly, from honor students to maximum security prisoners—disclose a remarkable range and depth of traumatic experiences. Examples of the various writing topics include (from Greenberg & Stone, 1992): death of a loved one (15%); divorce-separation (4%); serious problems of close other (13%); family problems (9%); problems with friends or peers (7%); physical or sexual abuse-attack (actual or threatened, not including mild physical punishment; 5%); problems concerning sexuality or intimacy (26%); frightening or dangerous nonpersonal event (e.g., car accident, injury-illness of self; 7%); admitting to doing something bad, shameful, or stupid (5%); and difficulties involving school or job (5%). Lost loves, deaths, sexual and physical abuse incidents, and tragic failures are all common themes in studies. If nothing else, the writing paradigm demonstrates that when individuals are given the opportunity to disclose deeply personal aspects of their lives, they readily do so. Even though a large number of participants report crying or being deeply upset by the experience, the overwhelming majority report that the writing experience was valuable and meaningful in their lives.

EFFECTS OF DISCLOSURE ON OUTCOME MEASURES

Researchers have relied on a variety of physical and mental health measures to evaluate the effect of writing: those pertaining to health reports and visits to health professionals, emotional and well-being measures, employment/academic functioning outcomes (e.g., reemployment and academic achievement), immunological outcomes associated with the writing procedure, and assessments of short-term effects. Although more complete reviews may be found elsewhere (Pennebaker, 1993; Smyth, 1998), studies from each category are discussed later. The health reports are considered first.

Written Disclosure and Health Reports

Pennebaker and Beall (1986) showed that college students who disclosed had significantly fewer visits to health services, as compared to control subjects, for 6 months following the experiment. Greenberg and Stone (1992) found a decrease in physician visits for college students who wrote about deeply traumatic events as opposed to subjects who wrote about relatively mild traumatic events or superficial topics. Richards, Pennebaker, and Beall (1995) found that among 95 maximum security prison inmates, those assigned to write about past traumas showed a drop in illness visits after writing (compared to controls). Some studies have altered the instructions to subjects regarding what to write about in attempts to

ascertain both the mechanism and parameters of these expression effects. Pennebaker and his colleagues (Pennebaker, 1991; Pennebaker, Colder, & Sharp, 1990; Pennebaker & Francis, 1996) had college freshman write about their deepest thoughts and feelings about coming to college, while control subjects wrote about superficial topics. These studies found that experimental subjects had improved physical health (as measured by visits to health providers) relative to control subjects for the 2 to 4 months following writing. In sum, these self-report symptom studies have revealed beneficial effects from written expression on reported health.

Written Disclosure and Affective/Well-Being Measures

Distress, negative moods, and depression have each been improved in several disclosure studies (Greenberg & Stone, 1992; Greenberg, Stone, & Wortman, 1996; Murray & Segal, 1994; Rimé, 1995; Schoutrop, Lange, Brosschot, & Everaerd, 1996; Spera, Buhrfeind, & Pennebaker, 1994). Several studies have also failed to find hypothesized improvements in self-reported well-being and affect (Pennebaker & Beall, 1986; Pennebaker & Francis, 1996; Pennebaker, Kiecolt-Glaser, & Glaser, 1988; Petrie, Booth, Pennebaker, Davison, & Thomas, 1995). Although such equivocal results exist, a meta-analysis of well-being and affect measures in written disclosure studies found an overall significant positive effect (see Smyth, 1998). Inconsistent results may be due to procedural or measurement differences between studies, or to moderating variables that influence the magnitude of the effect of written disclosure on psychological well-being (Smyth, 1998).

Written Emotional Expression and Employment or Academic Functioning

Some studies have examined outcomes related to employment and academic functioning. Francis and Pennebaker (1992) found that in a group of university employees, experimental subjects writing once a week for 4 weeks showed a reduction in absentee rates relative to control subjects for the 2 months subsequent to writing about upsetting experiences. Spera et al. (1994) found that among 63 recently unemployed professionals, those assigned to write about the thoughts and emotions surrounding their job loss were reemployed more quickly than those who wrote about nontraumatic topics. Pennebaker and colleagues (Pennebaker, 1991; Pennebaker et al., 1990) found that college students assigned to the experimental group performed better than control subjects on measures of academic achievement, such as grade point average, even after controlling for academic history (SAT scores and prior GPA).

Written Disclosure and Immune Function

Other studies have examined the immunological effects of written disclosure. Pennebaker et al. (1988) showed that students assigned to the experimental condition exhibited improved immune function relative to control subjects after the

last day of writing. Francis and Pennebaker (1992) found that experimental subjects (university employees) writing once a week for 4 weeks had improved liver enzyme function relative to control subjects for the 2 months subsequent to writing about upsetting experiences. Esterling, Antoni, Kumar, and Schneiderman (1990) found that college student subjects with the highest proportion of emotion-focused words in their essays (interpreted as high disclosers) evidenced more efficient immune function than those subjects whose essays conveyed less emotion. Esterling et al. (1994) showed that college students assigned to write about traumatic topics had significantly better cellular immune control over a latent herpes virus (Epstein-Barr) than did controls. Finally, Petrie et al. (1995) assigned subjects who tested negative to Hepatitis B antibodies to write about traumatic or neutral events immediately prior to receiving their first Hepatitis B vaccine (with booster injections at 1 and 4 months). Subjects in the emotional expression group showed significantly higher antibody levels against Hepatitis B at 4 and 6 month follow-up periods. Overall, subjects assigned to write about traumatic events consistently show improvements in immunological function when compared to subjects assigned to write about neutral topics.

Short-Term Effects of Written Emotional Disclosure

Subjects' mood is also influenced by the writing procedure. During the procedure, subjects writing about traumas have a distinct shift to more negative moods; no changes in affect are observed for subjects writing about innocuous topics. Similarly, experimental subjects show marked increases on measures on autonomic arousal, such as blood pressure and skin conductance. This is interesting because the effect of the writing task several weeks later is the opposite: Subjects who wrote about traumas typically have more positive affect and less negative affect than control subjects. In the absence of intervening coping strategies, this is contrary to the prediction of stress and coping theory, which would suggest that the short-term stress produced by writing about past trauma would result in negative long-term outcomes (both in terms of mood and health). This implies that the negative state initially engendered by writing must reverse or be alleviated at some point following writing, yet prior to measurement of (improved) health outcomes. Clearly, additional information on factors contributing to this shift is important to understanding the manner in which disclosure is producing health benefits.

Are Outcomes Related?

Although presented in isolation, it is also recognized that these various outcome types are likely related. For example, the impact of writing on academic/employment functioning outcomes may be mediated by changes in well-being, reported health, and physiological function. Reemployment, for example, may be more likely for individuals with improved well-being (who may be more pleasant), whereas grade point average will be higher for those who are healthier (who do not miss classes). This is partially supported by

Pennebaker, Mayne, and Francis (1997), who found that outcomes included in the academic/employment functioning category (grade point average and reemployment) were consistently associated with physical health outcomes. It should also be noted that the relation among these outcome types is likely quite dynamic. Changes in mood (possibly resulting from changes in well-being), for example, are known to impact the immune system (Knapp, 1990). Improved health is likely to result in improved well-being, and so forth.

PROCEDURAL DIFFERENCES THAT AFFECT THE DISCLOSURE EFFECTS

Writing about emotional experiences clearly influences measures of physical and mental health. In recent years, several investigators have attempted to define the boundary conditions of the disclosure effect. Some of the most important findings are as follows:

1. **Writing versus talking about traumas.** Most studies comparing writing alone versus talking either into a tape recorder (Esterling et al., 1994) or to a therapist (Murray et al., 1989; Donnelly & Murray, 1991) find comparable biological, mood, and cognitive effects. Talking and writing about emotional experiences are both superior to writing about superficial topics.
2. **Topic of disclosure.** Whereas two studies have found that health effects only occur among individuals who write about particularly traumatic experiences (Greenberg & Stone, 1992; Lutgendorf, Antoni, Kumar, & Scheiderman, 1994), most studies have found that disclosure is more broadly beneficial. Choice of topic, however, may selectively influence the outcome. For beginning college students, for example, writing about emotional issues about coming to college influences grades more than writing about traumatic experiences (Pennebaker & Beall, 1986; Pennebaker, Colder, & Sharp, 1990).
3. **Length or days of writing.** Different experiments have variously asked participants to write from 1 to 5 days, ranging from consecutive days to sessions separated by a week, ranging from 15 to 30 minutes for each writing session. In Smyth's (1998) meta-analysis, a promising trend was found, suggesting that the more days over which the experiment lapses, the stronger the effects. This suggests that writing once each week over a month may be more effective than writing four times within a single week. Self-reports of the value of writing do not distinguish shorter writing from longer writing sessions.
4. **Actual or implied social factors.** Unlike psychotherapy, the writing paradigm does not employ feedback to the participant. Rather, after individuals write about their own experiences, they are asked to place their essays into an anonymous-looking box with the promise that their writing will not be linked to their name. In one study comparing the effects of having students either write on paper that would be handed in to the experimenter versus write on a "magic pad" (wherein the writing disappears when the per-

son lifts the plastic writing cover), no autonomic or self-report differences were found (Czajka, 1987).

5. **Individual differences.** No consistent personality or individual difference measures have distinguished who does versus does not benefit from writing. Most commonly examined variables unrelated to outcomes include age, anxiety (or negative affectivity), and inhibition or constraint. The one study that preselected participants on hostility found that those high in hostility benefited more from writing than those low in hostility (Christensen et al., 1996). Additionally, the recent meta-analysis by Smyth (1998) suggests that males may benefit from written disclosure more than females (although both benefit overall).

6. **Educational, linguistic, or cultural effects.** Within the United States, the disclosure paradigm has benefited senior professionals with advanced degrees at rates comparable to maximum security prisoners with 6th-grade educations (Richards et al., 1995; Spera et al., 1994). Among college students, no differences have been found as a function of the students' ethnicity or native language. The disclosure paradigm has produced consistently positive results among French-speaking Belgians (Rimé, 1995), Spanish-speaking residents of Mexico City (Dominguez et al., 1995), multiple samples of adults and students in The Netherlands (Schoutrop et al., 1996), and even English-speaking New Zealand medical students (Petrie et al., 1995).

7. **Writing in clinical samples.** There is some evidence that writing may not work by itself in samples that may have disordered cognitive processing or relatively severe depression. For instance, a recent large-scale study by M. Stroebe and W. Stroebe (1996) on recently bereaved older adults failed to find benefits of writing. Similarly, Gidron and colleagues (1996) found that in a group of 14 posttraumatic stress syndrome (PTSD) patients, the half assigned to write and orally expand about their traumas seemed to get worse (compared to controls). The authors suggest that writing may not benefit PTSD patients in the absence of cognitive and/or coping skills training. Although this study has several limitations (small sample size, confounding of oral elaboration with written disclosure), it nonetheless sounds a cautionary note for the use of written disclosure in clinically at-risk populations. Additionally, Richards and colleagues (1995) found that men imprisoned for sexual crimes benefited from writing, whereas men imprisoned for other reasons did not benefit. These studies collectively suggest that care must be taken to evaluate the effect of written disclosure in varying populations prior to its potential therapeutic application.

Overall, the effects of written disclosure appear generalizable across age, gender, race/ethnicity, social class, and a variety of other demographic variables. Although several moderating variables were found in the recent meta-analysis (Smyth, 1998), these were the exception, not the rule. One clear caveat must be repeated: Beneficial effects have only been clearly demonstrated in subjects that are both psychologically and physically healthy.

WHAT IS THE CLINICAL BENEFIT OF EMOTIONAL WRITING ABOUT TRAUMATIC OR STRESSFUL EVENTS?

The results of a recent meta-analysis demonstrate that emotional writing about traumatic or stressful events produces significant health benefits in healthy subjects (Smyth, 1998). Thirteen experimental studies, comprising over 800 individuals, were included in this analysis. It is important to note that all of the participants in these studies were psychologically and physically healthy. The binomial effect size display (BESD) is a method of showing the practical importance of an effect size, and is presented as the difference in outcome rates between experimental and control groups (Rosenthal & Rubin, 1982). The overall effect size of writing about trauma ($d = .47$), in terms of a BESD, is a 23% improvement in the experimental group over the control group. For example, illness rates decreasing from 75% in the control group to 52% in the experimental group, or experimental subjects being 23% more likely to find reemployment after layoffs.

When evaluating clinical relevance, it may be more illustrative to compare this writing task to other psychological, behavioral, or educational treatments. (For ease in comparison, all effect size estimates have been translated into BESD.) In a landmark meta-analysis of psychotherapy outcomes, Smith and Glass (1977) reported an average 32% improvement for those receiving psychotherapy over those who do not. Although their analyses of subgroups (i.e., particular psychotherapeutic orientations) has been challenged, the overall effect size is comparable, albeit somewhat larger, to that achieved by writing (a 23% improvement). More recent analyses of psychological, behavioral, or educational interventions have reported similar or smaller effect sizes than the writing task. Wells-Parker, Bangert-Drowns, McMillen, and Williams (1995), in an examination of the effects of remediation with drinking/driving offenders, found an average reduction of from 8% to 9% over controls (no remediation), as compared to the 23% difference between experimental and control conditions in the emotional writing task. A research synthesis of the effects of psychosocial interventions with adult cancer patients found improvement ranging from 9% to 14% across various outcome measures, again somewhat lower than the improvement produced by writing (Meyer & Mark, 1995). Lipsey and Wilson (1993) examined effect sizes from 302 meta-analyses of behavioral and educational interventions, and reported very similar average improvements for randomized experiments (23%). It is not possible to strictly compare effect sizes between studies when the outcome measures are dissimilar. But these findings support the view that the effect produced by the writing task is clinically significant and similar to that found in other quantitative analyses of psychological interventions.

Summary

When healthy individuals write or talk about personally upsetting experiences in the laboratory, consistent and signifi-

cant health improvements are found. The effects include both subjective and objective markers of health and well-being, and are of clinically relevant magnitude. The effects produced by disclosure appear to generalize across settings, most individual differences, many Western cultures, and are independent of social feedback.

WHY DOES DISCLOSURE WORK?

Most of the research on disclosure has been devoted to demonstrating its effectiveness rather than on identifying the underlying mechanisms. The following are general models that attempt to explain the value of disclosure.

Inhibition and Disclosure

The original theory that motivated the first studies on disclosure was based on the assumption that not talking about important psychological phenomena was a form of inhibition. Disclosure (via writing or otherwise) was conceptualized as allowing individuals to confront upsetting topics, reducing the constraints or inhibitions associated with not talking about the event. Drawing on existing animal and psychophysiological literatures, it was asserted that active inhibition was a form of physiological work. This inhibitory work, reflected in autonomic and central nervous system arousal, was viewed as a chronic low level stressor. This prolonged stress response could then cause or exacerbate psychosomatic processes, increasing the risk of illness and other stress-related problems. Just as constraining thoughts, feelings, or behaviors linked to a stressful or traumatic event was stressful, disclosing thoughts and feelings about these experiences should, in theory, reduce the stress of inhibition.

Findings to support the inhibition model of psychosomatics are growing. Individuals who conceal their gay status (Cole, Kemeny, Taylor, & Visscher, in press), traumatic experiences in their past (Pennebaker, 1993), or who are considered inhibited or shy by others (Kagan, Reznick, & Snidman, 1988), exhibit more health problems than those less inhibited. Although inhibition seems to contribute to long-term health problems, the idea that disclosure reduces inhibition and should therefore improve health is not as well supported. Greenberg and Stone (1992) found that individuals benefited equally from writing about traumas about which they had told others as about traumas that they had kept secret. Self-reports of inhibition before and after disclosure have not consistently related to health benefits. At this point, the role of inhibition in promoting health within the paradigm of emotional disclosure is not fully understood.

It should also be noted that it is not clear how inhibition and disclosure are related: Are they distinct constructs or opposite ends of a continuum? Several factor analyses have suggested that, in fact, inhibition and disclosure are distinct constructs (Larson & Chastain, 1990; Malatesta & Culver, 1993). In both cases, self-concealment (viz. inhibition) was correlated with physical symptoms, whereas self-disclosure was unrelated to symptoms. Finally, self-concealment predicted physical and

psychological symptomatology even after statistically controlling for trauma level, trauma distress, trauma disclosure, social support variables, and general disclosure tendencies.

Cognitive and Linguistic Changes Associated With Writing

In recent years, researchers have begun analyzing the language that individuals use in writing about emotional topics. A first strategy was to have independent raters evaluate the essays' overall contents to see if it was possible to predict who would benefit most from writing. Interestingly, judges noted that essays of people who benefit from writing appeared to be "smarter," "more thoughtful," and "more emotional" (Pennebaker, 1993). However, the relatively poor interjudge reliability led to the development of a computerized text analysis system.

In 1991, a computer program called Linguistic Inquiry and Word Count (LIWC) was created that analyzed essays in text format. LIWC had been developed by having groups of judges evaluate the degree to which about 2,000 words or word stems were related to each of several dozen categories (for a full description, see Pennebaker & Francis, 1996). The categories included negative emotion words (sad, angry), positive emotion words (happy, laugh), causal words (because, reason), and insight words (understand, realize). For each essay that a person wrote, it was possible to quickly compute the percentage of total words that these and other linguistic categories represented.

Analyzing the experimental subjects' data from six writing studies, three linguistic factors reliably predict improved physical health. First, the more that individuals use positive emotion words, the better their subsequent health. Second, a moderate number of negative emotion words predicts health. Both very high and very low levels of negative emotion word use correlate with poorer health. Third, and most important, an increase in both causal and insight words over the course of writing is strongly associated with improved health (Pennebaker, Mayne, & Francis, 1997). Indeed, this increase in cognitive words covaries with judges' evaluations of the construction of a story or narrative. That is, people who benefit from writing begin with a poorly organized description and progress to a coherent story by the last day of writing.

The language analyses are particularly promising in that they suggest that certain features of essays predict long-term physical health. Further, these features are congruent with current views on narratives in psychology. The next issue that is currently being addressed is the degree to which cohesive stories or narratives predict changes in real-world cognitive processes. That is, does a coherent story about a trauma produce improvements in health by reducing ruminations or flashbacks? Does a story ultimately result in the assimilation of an unexplained experience that allows the person to get on with life? To what degree does the use and integration of emotion language affect the narrative and, ultimately, health (see also, Lee & Beattie, 1996)? These are the theoretical questions that psychologists must address.

Traumatic Memory Research

Additional information can be drawn from traumatic stress and memory research. Traumatic stress research has often noted the distinction between memories for ordinary events and memories for traumatic events; memories for traumatic events seem immutable, and are more emotional and perceptual than declarative in nature (Terr, 1994). Memories for traumatic events are often initially experienced as sensory fragments of the original event. Visual, olfactory, auditory, or even kinesthetic sensations, as well as intense feelings thought to represent those sensations at the time of the traumatic event, are typically reported (van der Kolk & van der Hart, 1991). Memories for traumatic events are also encoded differently, perhaps due to restricted attentional focus or altered hippocampal memory function due to extreme arousal (van der Kolk, 1994).

When an individual is upset about a traumatic event, memories cannot be integrated into a personal narrative, resulting in the memory being stored as sensory perceptions, obsessional ruminations, or behavioral reenactments (Janet, 1909; van der Kolk & van der Hart, 1991). McFarlane and others have noted that it is the persistence of intrusive and distressing symptoms, avoidance, and hyperarousal, not the traumatic memory itself, that result in observed psychological and biological dysfunction (e.g., McFarlane, 1992). Traumatized individuals often, for example, narrow their attentional focus to be "on guard" for sources of potential threat. This creates a state of chronic physiological overarousal. Such hyperarousal promotes state-dependent recall of traumatic memories and involuntary intrusions of the trauma, leading in turn to further increased arousal.

One goal in treating traumatic memories is thus to facilitate the processing of traumatic memory (Foa, Rothbaum, & Molnar, 1995). Foa and Riggs (1994) noted that traumatic memories are more disorganized than other memories, and treatments aimed at organizing memory should thus be particularly effective (as more organized memories should be easier to integrate into existing memory). This is supported by work in both clinical and healthy populations. DiSavino and colleagues (1993) analyzed victims' trauma-related narratives during exposure and found that evidence of decreasing disorganization over time was associated with improvement. Similarly, increases in linguistic indicators of coherence and evidence of a narrative becoming more focused over writing sessions is associated with increased improvement (Pennebaker et al., 1997). Van der Kolk and Fisler (1995) found traumatized individuals initially had no narrative memories of traumatic events, and developed a narrative over time only as they became aware of more elements of the traumatic experience.

The primary problem with processing, organizing, and integrating traumatic memories may be that they lack any verbal component, and therefore cannot be effectively communicated or organized. Rauch and colleagues (1996) found that during the provocation of traumatic memories there was a decrease in activation of Broca's area (the area

most involved in the transduction of subjective experience into speech), and a simultaneous increase of activation in areas of the right hemisphere that are thought to process intense emotions and visual images. It seems the lack of a linguistic representation interferes with the development of a personal narrative and the assimilation of traumatic memories. Disclosing about the traumatic event (through writing or speech) may force the transduction of the memories from sensory/affective components into an organized, linguistic format (Pennebaker et al., 1997). Disclosure about traumatic events may thus facilitate several processes considered central in the treatment of traumatic memory, specifically: the deconditioning of memories related to the traumatic event from affective/physiological responses, and restructuring of dissociated traumatic memories from intrusive reexperiencing of feelings and sensations into a personal, integrated narrative (Foa & Kozak, 1986). Written or verbal disclosure may be necessary as deconditioning of traumatic memories and responses will not occur merely through reexperiencing fragments of the trauma (e.g., intrusions, ruminations), as affective and sensory elements of the trauma remain separate from the rest of memory. This prevents the creation of an integrated memory that is no longer a trigger for conditioned (fear) responses.

The process of disclosure about traumatic or stressful events may produce positive effects by initially forcing the encoding of the traumatic memory into narrative language. Although initially increasing distress, it should allow a modification of the fear structure associated with the trauma, in turn facilitating the integration of the traumatic memory. A more integrated memory should lead to a reduction in intrusive reexperiencing and the attenuation of conditioned fear responses. Reductions in intrusive remembering and fear responses should ameliorate chronic hyperarousal and ultimately lead to the reduction of both psychological and physiological symptomatology.

CONCLUSIONS

Both subjective and quantitative evaluations of the evidence support the conclusion that written disclosure about traumatic or stressful events produces health benefits in both somatic and psychological domains. Several theoretical explanations of how these changes may occur were presented, focusing primarily on how disclosure may promote the formation of a structured narrative out of previously unstructured sensory fragments. This new structure should lead to the cognitive assimilation of traumatic memories and subsequent biological alterations. Developments in relating linguistic parameters to health outcomes offer exciting insight into this process. It should be noted that, although plausible, these models are speculative and must be tested in future research. The degree to which individuals improve after writing was related to several factors, suggesting that existing research cannot be easily generalized to subgroups of individuals not well-represented in existing research. As the health benefits of written disclosure in healthy people seems clear, future research needs to explore the theoretical basis

of disclosure and evaluate emotional writing as a supplemental treatment for individuals who have experienced traumatic events.

Preventive Management of Work Stress: Current Themes and Future Challenges

Debra L. Nelson
Oklahoma State University

James Campbell Quick
The University of Texas at Arlington

Bret L. Simmons
Oklahoma State University

Work stress may be defined, in broader though parallel fashion to job stress (J. C. Quick & Nelson, 1997), as the mind–body arousal resulting from physical and/or psychological demands associated with work. Work stress may lead to enhanced work performance up to an optimum level of stress. Conversely, it may place an employee at risk of distress if the work stress is too intense, frequent, chronic, unremitting, or employees do not possess necessary skills to meet the work demands and manage their stress response. Work stress underload may also lead to potential problems associated with boredom, lack of attention, and other less than desirable psychological outcomes due to unused capacity within the employee. Understanding work stress is important so as to reduce strain, distress, and dysfunction for employees in working environments. Health psychology and occupational health psychology become important in the context of work stress research and practice to the extent that they are central to: assessing risk factors for strain, distress, and dysfunction and designing preventive management programs to enhance healthy work stress. The aims of the latter may be either to reduce, to increase, and/or to modify the amount, focus, and direction of stress in the work environment.

A BRIEF HISTORICAL OVERVIEW

The concern of psychology with work stress may be arguably traced to Hugo Münsterberg's efforts to study industrial accidents and human safety in the early 20th century (Offermann & Gowing, 1990), as indicated in Fig. 19.1. The figure includes key historical events during the 20th century related to work stress. In the extreme, industrial accidents can become full-blown crises in which the human, organizational, and technological elements of the system are overwhelmed, such as occurred in Union Carbide's plant in Bhopal (J. C. Quick, 1997; Shrivastava, 1987). This chapter focuses on the less extreme yet more frequently occurring forms of work stress, strain, and distress that occur in organizations.

Kahn, Wolfe, Quinn, Snoek, and Rosenthal's (1964) studies in role conflict and ambiguity drew attention to the organizational stress problem of role taking in large industrial organizations. Kahn et al. (1964) used social psychology as their conceptual and theoretical point of departure. Prior to this seminal program of research, the primary focus in stress research has been its physiological origins and medical consequences, neither with particular attention to the work or or-

ganizational context. Kahn et al.'s (1964) research drew attention to the sources of role stress as a subset of work stress, to the adverse interpersonal and psychological consequences of role stress, and to some of the strategies for achieving a better fit between the person and the work environment. This line of investigation emphasized the psychosocial work environment and attributed the source of the stress to various aspects of individual's interpersonal environment at work in contrast to Münsterberg's attention to the physical environment and safety.

Levinson (1963, 1975) took a different approach to understanding the psychological dimensions of work stress. Whereas his focus was on executives, his basic psychological model does not differ across organizational levels or between functions. His psychoanalytic model draws attention to the role of psychodynamics and the individual's responsibility in the stress process. Although Kahn focused on the interpersonal environment, Levinson emphasized the intrapersonal psychological processes related to stress and strain for executives at work. The two key intrapersonal concepts in Levinson's psychoanalytic model for executive stress are the ego-ideal and the self-image. The conflict between these two is the root of stress for the individual within the psychoanalytic model. Intense conflict between the ego-ideal and self-image may lead to extreme stress and self-destructive behavior, as in executive suicide (Levinson, 1963).

Shortly after Kahn et al. (1964) and Levinson (1963, 1975) were formulating their approaches to work and executive stress, as noted in Fig. 19.1, Gardell (1971) was in the midst of

evolving his framework for understanding work environment psychology. Developed within the Swedish cultural and intellectual tradition, Gardell's (1987) approach emphasized *workload* and *self-determination* as the two independent constructs necessary to understand work stress and strain. Karasek (1979), an American who brought these concepts concerning work environment psychology to the United States, relabeled the dimensions *job demands* and *job decision latitude*.

Work stress and occupational health psychology became matters of serious public concern in the United States with the passage of public law 91-596 (Occupational Safety and Health Act, 1970; J. C. Quick, Camara, et al., 1997). By the early 1980s, work-related psychological disorders and distress were among the top 10 occupational health risks identified by the National Institute for Occupational Safety and Health (Ordin, 1992; see Fig. 19.1). At about the same time, J. C. Quick and J. D. Quick (1984) were translating the public health notions of prevention and preventive medicine into an organizational stress context (also noted in Fig. 19.1).

MAJOR THEORETICAL FRAMEWORKS

There is a major theoretical framework in the domain of work stress and health psychology associated with each of the unfolding events in the brief historical time line included in Fig. 19.1. Each theoretical framework has associated with it a conceptual model as the basis for the theory. In addition, Cooper (1998) collected the theories of organizational stress in one

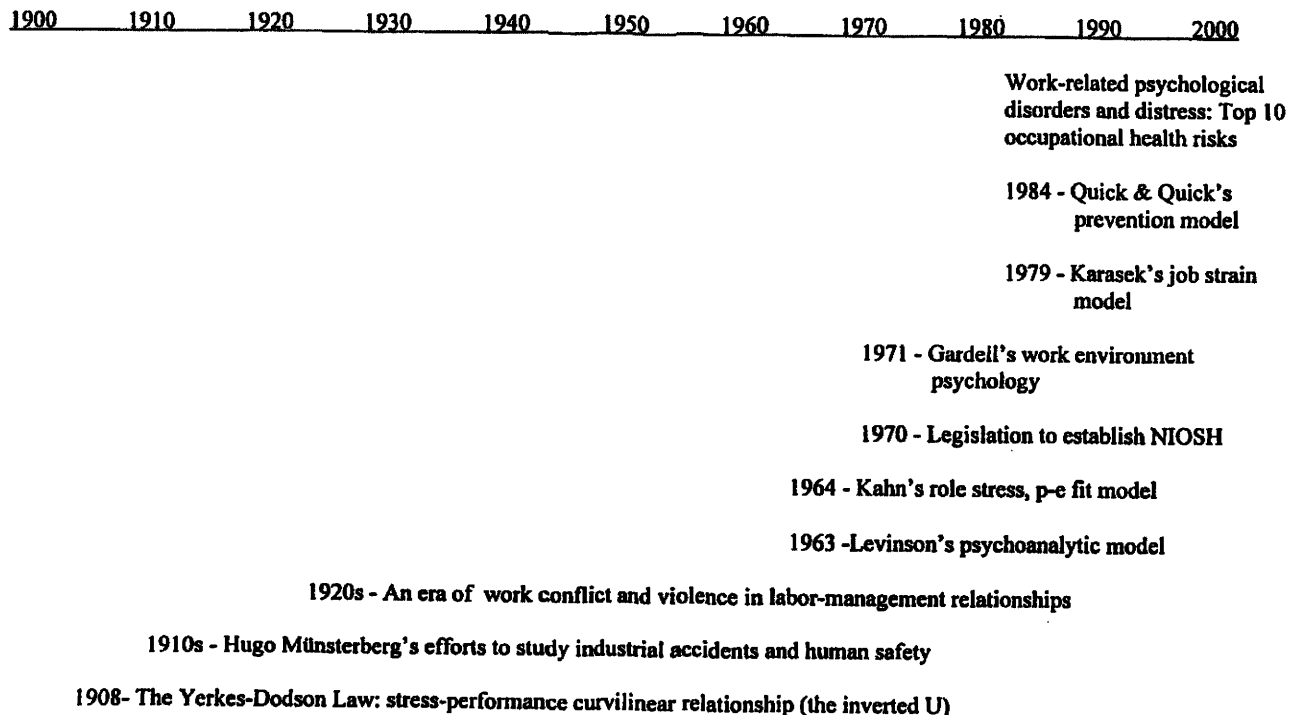

FIG. 19.1. A brief historical overview of work stress and health psychology.

volume, which goes beyond the relatively brief treatment of theoretical frameworks and conceptual models in this section. There is some overlap of theories in the domain of work stress and there is a differential impact of these theories in the field.

The Role Stress/Person–Environment Fit Model

Kahn et al. (1964) used a role set framework as the basis for examining role stress in organizations. The role set may refer either to the variety of social roles a person engages at different times (e.g., researcher, father, and coach) or to the aggregation of role senders (e.g., supervisors, peers, and customers) who communicate expectations to an employee in a focal role (Merton, 1957). When these expectations are ambiguous, conflicting, and/or excessive, they create role stress for the focal person. Sutton and Kahn (1987) subsequently focused attention on uncertainty and lack of control as major sources of stress in the psychosocial organization, suggesting that prediction, understanding, and control are antidotes for organizational stress.

The evolution of this theoretical framework led to an examination of the person's fit within the psychosocial environment; that is, the individual's expectational fit within the role set. The person–environment fit approach to organizational stress took Kahn's original role stress approach one step further (Edwards & Cooper, 1990). The person–environment fit approach was later expanded to consider competing versions of the approach (Edwards, 1996). Specifically, the Supplies–Values (S–V) fit approach considers environmental supplies and employee values and the Demands–Abilities (D–A) fit approach considers environmental demands and employee abilities. This framework continues within a social psychological context.

The Psychoanalytic Framework

Levinson's (1963, 1975) stress framework was developed in the context of psychoanalytic theory. The two key personality elements or concepts within the theory were defined in a psychoanalytic context. The first concept is the ego-ideal, defined as the internalized image of an individual's idealized self or perfected self. The ego-ideal is the standard toward which an individual strives over time. The second concept is the self-image, defined as the set of one's positive and negative attributes. The self-image is that which the individual strives to remake in the image of the ego-ideal. The degree of discrepancy between these two elements of the personality is a measure of the amount of stress a person experiences at a given point in time.

Schwartz (1990) extended this psychoanalytic model to examine the processes of corporate decay within the National Aeronautics and Space Administration (NASA) and within General Motors Corporation (GMC). His research indicated that although narcissism and fantasy may reduce momentary stress associated with external reality, these psychological processes may have serious adverse consequences for individual and organizational well-being.

The Demand–Control Model

The core of the demand–control, or job strain, model suggested that increasing work demands lead to a linear increase in job stress and the combination of increasing work demands and restricted work environment control leads to a linear increase in unresolved strain. Hence, this framework makes a rather clear distinction between job stress and job strain: The former does not carry a pejorative or negative denotation, whereas the latter does. This is consistent with the Yerkes–Dodson law's positive performance implications of increasing stress up to some optimum point on the inverted-U.

The negative effects of job strain, or job distress, are manifested in a variety of behavioral, psychological, and medical consequences (J. C. Quick, J. D. Quick, Nelson, & Hurrell, 1997). Common forms of psychological distress include depression, job burnout, anger, and job dissatisfaction (Karasek, 1979). Common forms of medical distress are backaches and headaches, ulcer disease and cardiovascular problems (Theorell & Karasek, 1996). Common forms of behavioral distress are workplace violence, accident proneness, and substance abuse (Mack, Shannon, J. D. Quick, & J. C. Quick, 1998). High strain jobs, characterized by high job demands and low employee control, have significantly higher incidence rates of distress in the forms of exhaustion, dissatisfaction, illness days, pill (i.e., tranquilizers and sleeping pills) consumption, and even myocardial infarctions (Karasek et al., 1988).

The Effort–Reward Imbalance Model

Siegrist (1996) proposed a third theoretical framework and conceptual model to assess adverse health effects of stressful experience at work that is an addition to the person–environment fit model and the demand–control model. The effort–reward imbalance model uses a sociological backdrop, as opposed to a psychological one, and focuses on reciprocity of exchange in occupational life where high cost/low gain conditions are considered particularly stressful. This model considers both extrinsic (work pressures and obligations) and intrinsic (personal coping patterns) effort variables, as well as extrinsic (money and social status) and intrinsic (self-esteem) reward variables. A prospective study and a cross-sectional study of blue collar men ($n_1 = 416$; $n_2 = 179$) provided support for the effort–reward imbalance model when new cardiovascular events is used as the strain indicator.

The Preventive Stress Management Model

The preventive stress management model evolved from the translation of the public health notions of prevention and preventive medicine into an organizational stress context (J. C. Quick & J. D. Quick, 1984). The core of the model is a stress process framework that proposes that organizational demands and stressors (i.e., physical, task specific, role, and interpersonal demands) trigger the stress response within individuals. This stress response may lead to enhanced health

and performance on the job (eustress) or may lead to reduced health and performance on the job (distress). Organizations are concerned with work stress because of the organizational costs that may accrue from employees' psychological, medical, and behavioral distress (J. C. Quick, J. D. Quick, et al., 1997). The direct organizational costs of job strain take the form of turnover and absenteeism, performance problems on the job, and compensation awards. In addition, there are indirect organizational costs of job strain that may be reflected in low morale, low job satisfaction, faulty decision making, and distrust in working relationships.

The preventive intervention and treatment components of the preventive stress management model center on the public health and preventive medicine stages of primary, secondary, and tertiary prevention. Primary prevention aims to change the environment and manage organizational demands and stressors. Secondary prevention aims to change the employees and alter their responses to necessary and inevitable demands in the work environment. Tertiary prevention aims to heal individuals and/or organizations in distress. These three stages of prevention afford organizations a platform for leadership and managerial action and intervention for the purpose of creating healthy, high performance organizations. In addition to the stages of prevention as a basis for translation, public health and preventive medicine also offer the notions of surveillance, monitoring, and screening for use in an organizational stress context (Ordin, 1992).

INTERNATIONAL NATURE OF RESEARCH

These theoretical frameworks and conceptual models are crafted by a range of international scholars and researchers. The international nature of research related to work stress and occupational health psychology is reflected in diversity of 50 scholars from Europe, North America, and Israel who wrote the section on psychosocial and organizational factors of health hazards on the job for the *Encyclopaedia of Occupational Health and Safety* (Sauter, Murphy, Hurrell, & Levi, 1997). What emerges from these and similar efforts is an appreciation for the cultural diversity associated with what is defined as stressful at work and value differences regarding healthy interventions.

The preceding historical overview described the early foundations of work stress research. The next section discusses the contemporary research, identifying major themes and important issues that have evolved.

CURRENT THEMES AND RESEARCH ISSUES

Research on work stress has burgeoned in the recent past, and the literature reflects the interdisciplinary nature of this line of inquiry. The early studies were conducted in the tradition of the major theoretical approaches described in the preceding section. Role stress, the job control model, and the identification of stress-related outcomes were dominant themes. The contemporary literature has continued somewhat in these traditions; however, there are emerging themes that have

evolved and flourished. Three of these themes are the changing nature of work and organizations, individual differences in the stress experience, and the role of social support.

The Changing Nature of Work

Change is the order of the day in organizations. Although the world of work has always been a dynamic one, today's changes come at a frantic pace. Globalization, new technologies, increased workforce diversity, and the accompanying changes in organizational environments have placed increased pressure on individuals. The reengineering of business processes, smaller companies that employ fewer people, the shift from making a product to providing a service, and the increasing disappearance of the job as a fixed collection of tasks have changed the nature of work and the workplace (Cascio, 1995). Although the common stressors of role conflict and role ambiguity, time pressures, and interpersonal demands abound, there are some stressors that are of particular concern in organizations facing massive change in such short time frames.

The work of Staw, Sandelands, and Dutton (1981) identified the tendency for change to be perceived as a threat by individuals, groups, and organizations. The response to this threat is rigidity, including a restriction of information flow and a constriction of control. These actions may well be counterproductive, because they are not responsive to the types of change characteristic of today's work environment. Some of the stressors emanating from the environment are working with computers, electronic performance monitoring, violence, job insecurity, interactive demands, work/home conflicts, teamwork, and workforce diversity.

The physical and psychological stressors that emanate from working with computers are realities for many workers. Many companies are paying the price: U.S. West directory assistance operators were diagnosed as suffering from cumulative trauma disorder, costing the company \$5 million (Fernberg, 1990). The social isolation that sometimes stems from jobs high in computer use may prove stressful as well. Particularly vulnerable to lack of social contact are those individuals who work in virtual offices or who telecommute. Whereas telecommuting was once an option initiated by employees who wanted to balance work and family concerns, companies are now trying to reduce real estate costs through offering telecommuting.

Electronic performance monitoring (EPM) has grown along with the increase in computerization of work. Although EPM facilitates managerial knowledge of detailed performance of employees, it may feel to workers like omnipresent and camouflaged surveillance. Mounting evidence indicates that electronically monitored workers experience more stress than their nonmonitored coworkers (Aiello & Kolb, 1995). EPM can also lead to deteriorated quality of working relationships with supervisors and peers.

There has been a dramatic increase in violence in the workplace. Assaults and violent actions are the second leading cause of death in the U.S. workplace, following transportation accidents (Bureau of Labor Statistics, 1995). Almost

7,600 workers were murdered on the job in the United States during the 1980s (Harvey & Cosier, 1995).

As a result of the massive restructuring of the 1990s, job insecurity abounds. More than 7 million permanent layoffs have been announced since 1987 in the United States (Cascio, 1995). As organizational retrenchment and restructuring continue, global job loss is expected to persist throughout the 1990s (Haugen & Meisenheimer, 1991). These changes create fears of job loss and worries about whether people will be able to fit into the "new" organizational arrangement. Survivors of restructuring may have feelings of guilt, and resent the loss of valued relationships at work. At the least, survivors suffer from work overload, as the organization attempts to accomplish more work with a smaller workforce.

The very notion of the career has evolved from one in which the model was one of working for one, or a very few, organizations and advancing up the organizational hierarchy. The premium is now on employability rather than employment, on taking charge of one's own career by developing portable skills, and on adding value to the organization.

The expansion of the service sector has resulted in an increase in jobs characterized by interactive demands; that is, jobs that require interaction with a wide variety of constituencies. Service jobs are inherently stressful, due to the requirement to give quality service to sometimes demanding and often irate customers (Singh, Goolsby, & Rhoads, 1994). Service jobs are often characterized by emotional labor, defined by Hochschild (1983) as "the management of feeling to create a publicly observable facial and bodily display" (p. 7). Emotional labor has been linked to substance abuse, headaches, absenteeism, and other forms of psychological distress. Often, what must be displayed to others is at odds with what is really felt, which creates dissonance and alienation from one's own emotions. Preliminary evidence indicates that this dissonance between feelings and expression may be the prime source of distress (Adelmann, 1995).

Work-home demands are a source of chronic stress. Over 75% of all families are characterized by dual careers (Guinn, 1989). Some companies are attempting to accommodate employees with flexible work arrangements and child-care assistance, but many workers are not privy to these amenities. The potential for overload from balancing multiple expectations is high. Parenting has an additive effect on work-home conflict.

Teamwork is the order of the day in most organizations. Teams, although sometimes the source of satisfaction, can also place a premium on the individual's interpersonal skills. Members that violate behavioral norms are often harshly sanctioned. As self-directed teams take on the work that was once reserved for managers, role ambiguity and role conflict may result.

The workforce is much more diverse than ever. Although this has obvious advantages, many employees find that working with those who are different from themselves can be stressful. Members of minority groups may experience distress from conflict, confusion, and denigration. A major contributing factor to this distress is the prevalence of ethnocentric attitudes among employees (Marsella, 1994).

Individual Differences

Another theme in the current research literature is that of the role of individual differences in the stress process. Past studies have focused on Type A behavior and locus of control as personality influences, among others, accumulating substantial knowledge. The contemporary literature has seen an emphasis on identifying other personologic variables that affect the stress-strain relation. The focus is on three emerging individual differences: hardiness, self-reliance, and negative affect. These dispositional factors hold potential for strongly affecting the stress-strain connection, with implications for designing interventions in organizations.

Hardiness. Hardiness is a personality disposition that influences how people interact with others and with the environment (Maddi, 1998). It is defined as the individuals' view of their place in the world that simultaneously expresses commitment, control, and challenge (Kobasa, 1979; Kobasa, Maddi, & Kahn, 1982). Commitment, as a dimension of hardiness, is a tendency to be involved in whatever one encounters. Individuals who are committed find the persons, events, and things in their environments to be meaningful. Control reflects a tendency to feel, think, and act as if one is influential, rather than helpless, in affecting life (Ouellette, 1997). Challenge is the belief that change is normal, and that changes are opportunities for growth rather than threats.

Hardiness is learned rather than inherited, and is presumed to decrease the likelihood of stress-related illnesses and performance problems. It achieves these effects through transformational coping, the search for social support to supplement this coping, and beneficial health practices (Maddi, 1998). Early evidence on hardiness was accumulated from retrospective and longitudinal studies at a large Midwestern telephone company. Executives were tracked for a 5-year period using questionnaires. Results indicated that executives who were hardy were less likely to report physical illness than those who were low on hardiness. In addition, hardiness was independent of education, age, managerial level, and marital status (Maddi, 1998; Ouellette, 1997).

Subsequent research has examined the effects of hardiness in a variety of samples and settings. Strategies have ranged from qualitative investigations to controlled experiments (for reviews, see Maddi, 1990; Ouellette, 1993). The majority of the studies have confirmed the relation between hardiness and health. Some studies have examined the relation between hardiness and performance. A study of military officer training candidates in Israel indicated that hardiness was related to successful completion of training (Westman, 1990). Hardiness was also found to be related to basketball performance throughout the season in a study of male high school athletes (Maddi & Hess, 1992).

The measurement of hardiness was originally achieved with an instrument containing a combination of true-false, forced-choice, and rating scale items. The original measure was criticized for the finding that the challenge dimension was unrelated to the other two dimensions in several samples

(Funk & Houston, 1987; Hull, Van Treuren, & Virnelli, 1987). The PVS-II, a second generation hardiness measure, was developed to avoid these difficulties. The 50-item measure has been shown to possess commitment, control, and challenge scores that are internally consistent, moderately intercorrelated, and strongly correlated with overall hardiness score (Maddi, 1997). Some problems, however, seem to persist, including a low internal reliability for the challenge dimension (Ouellette, 1997). This raises questions as to whether hardiness is unidimensional, or should be conceived of as multidimensional, with the dimensions showing separate relations with health.

Most of the research on hardiness has utilized data gathered by self-report measures. Cohen and Edwards (1988) viewed the evidence linking hardiness and improved well-being as equivocal. Because hardiness is proposed to be a disposition, coping efforts related to hardiness should be stable over time and across situations. Cohen and Edwards (1988) considered this evidence to be contradictory.

Despite its criticisms, hardiness remains an intriguing dispositional factor with potential to influence the stress-strain relation. Preliminary evidence in small groups indicates the efficacy of using focusing, situational reconstruction, and compensatory self-improvement techniques for enhancing hardiness among individuals (Maddi, 1994).

Self-reliance. Self-reliance is an individual difference reflected by the development of healthy, secure, interdependent relationships with others. Its roots are in Ainsworth and Bowlby's (1991) early studies of personality that resulted in attachment theory. Bowlby suggested that attachment is a biological imperative, controlled by the central nervous system, thus contributing to the survival of the human species. Ainsworth, Blehar, Waters, and Wall's (1978) studies identified three dominant patterns of attachment in infants: secure (called self-reliant by Bowlby, 1982, 1988), avoidant, and anxious-ambivalent. These early experiences become internal working models of self and other, and influence the individual's beliefs about the availability and responsiveness of attachment figures (Lopez, 1995).

Recent research suggests that attachment orientations extend into adult years and across the life span (Hazan & Shaver, 1987). Hazan and Shaver (1990) proposed that adulthood attachments are essential for effectiveness and satisfaction at work. Ainsworth's three patterns of attachment are labeled in the management literature as self-reliant (secure), counterdependent (avoidant), and overdependent (anxious-ambivalent; Nelson, J. C. Quick, & Joplin, 1991; J. C. Quick, Nelson, & J. D. Quick, 1990).

Self-reliance is an orientation characterized by a reciprocity and flexibility in relationships, and a pattern of interdependence. It is based on the belief that others will be available in stressful and anxious times of need. Adults who are self-reliant form secure, supportive relationships at work and at home. At work, interdependence is evidenced by close relationships with a variety of colleagues both inside and outside the organization. Self-reliance may be a critical factor in newcomer adjustment to organizations (Nelson & J. C. Quick,

1991). An attrition analysis of military officer candidates and basic trainees indicated that candidates who were self-reliant were better able to develop the social support necessary for successful completion of training (J. C. Quick, Joplin, Nelson, Manglesdorff, & Fiedler, 1996).

Counterdependence is an orientation rooted in the belief that no one will be available in situations of distress. Counterdependent individuals frequently overinvest in work activities, preferring to complete tasks themselves rather than ask for assistance. They may resist offers of support from others, and isolate themselves in the workplace.

Overdependence is an orientation based on a belief that others may not be available when needed. The overdependent individual seeks out and relies on more supports than are necessary or appropriate for the situation. Overdependence frequently leads to an individual relinquishing responsibility for personal well-being. Individuals who use an overdependent orientation may "drain" their social support relationships by their clingy nature and their failure to reciprocate.

Self-reliant individuals possess a sense of felt security, derived from internal working models that view others as available and responsive. They report fewer symptoms of distress (J. C. Quick, Joplin, Nelson, & J. D. Quick, 1992). Counterdependent and overdependent individuals report more physical symptoms (Hazan & Shaver, 1990) and higher levels of distress (Mikulincer, Florian, & Weller, 1993). Self-reliance may moderate the stress-distress relation. Future research should examine the relations between quality and quantity of social support relationships and the three attachment orientations.

Negative Affect. Negative affect is a stable disposition that contributes to dysphoric mood that permeates an individual's attitudes and behavior (Watson & Clark, 1984). Individuals high on negative affect (NA) possess more negative perceptions and appraisals than individuals low on NA. It is possible that individuals high on NA report more distress because they are more sensitive to stressors, or because they create the stressors they experience due to their negative world views (McCrae & Costa, 1994).

Because individuals high on negative affect (NA) possess negative views of themselves and the world around them, NA is likely to strengthen the relation between self-reported job stressors and psychological outcomes (Watson, Pennebaker, & Folger, 1987). Evidence provided by Brief, Burke, George, Robinson, and Webster (1988) indicated that NA was confounded with measures of self-reported work and nonwork stressors and distress in the form of job dissatisfaction, somatic complaints, life dissatisfaction, and depressive symptoms; thus, correlations between self-reports of stressors and distress may be inflated by NA. Other researchers have found that controlling for NA diminished the relation between stressors and somatic complaints, but not between stressors and other forms of distress (Chen & Spector, 1991).

Many of the studies of NA are cross-sectional in nature. In an attempt to improve on existing designs and measures, Schonfeld (1996) conducted a longitudinal study of teachers that included measures taken during preemployment and from 4 to 5 months on the new job. Three "neutrally worded"

stressor measures were constructed in an attempt to minimize reference to distress. The stressors were moderately related to postemployment depressive symptoms and job satisfaction, and to motivation among Whites (but not among Blacks and Hispanics). Correlation and regression coefficients were largely unchanged when NA and psychophysiological symptoms, measured at preemployment, were controlled.

Complicating the comparison of studies is the fact that various measures of NA have been utilized. These include measures of anxiety, psychasthenia, repression-sensitization, neuroticism, and others (Watson & Clark, 1984). Brief et al. (1988) used the Taylor Manifest Anxiety Scale (Taylor, 1953) and Schonfeld (1996) utilized the Center for Epidemiologic Studies Depression Scale (Radloff, 1977) and a psychophysiological symptoms measure; both state measures with time frames of 1 week.

Despite these complications, NA appears to be an important dispositional variable in work stress research. It may be a methodological "nuisance" variable, or it may be a cause of work stressors. Future studies that are longitudinal, utilizing objective measures of stressors and strains, and are conducted using a variety of samples and settings will enhance knowledge in this regard.

Social Support

The past decade has witnessed a dramatic increase in the literature on social support and work stress. House's (1981) framework identified four dimensions of support related to work stress, including emotional (empathy and caring), informational (suggestions for problem solving), appraisal (feedback on behavior), and instrumental (direct aid) forms of support. He noted the importance of support from the supervisor and co-workers, and argued that organizations can be barriers to social support or facilitators of it. According to House, social supports allow individuals to extend their repertoires of skills and knowledge by drawing on the resources of support providers.

House, Landis, and Umberson (1988) conducted a meta-analysis that indicated that individuals with lower social support levels possessed significantly higher morbidity and mortality. Although lower levels of support are associated with higher distress, the mechanisms whereby this association occurs have not been adequately identified. A long-standing debate surrounding this issue centers on the question of whether social support has a main effect or buffering effect on health. Social support can have a main effect on health by promoting better health (Corneil, 1997) or lack of social support can cause ill health (Cohen & Syme, 1985). The buffering hypothesis suggests that social support intervenes between the stressor and distress to reduce its deleterious effects. There seems to be evidence in support of both hypotheses. Cohen and Wills (1985) found evidence for both main effects and buffering effects. Workplace social support was added to the job strain model, and a buffering of the effects of job strain by social support was found in three of four studies on cardiovascular disease (Landsbergis, Schnall, Schwartz, Warren, & Pickering, 1995). Ganster (1995) concluded that the evidence regarding the buffering hypothesis is mixed at best.

Uchino, Cacioppo, and Kiecolt-Glaser (1996) examined the research on social support and physiological processes using meta-analysis and qualitative procedures. Their review indicated that social support was related to positive effects on the cardiovascular, immune, and endocrine systems. Health-related behaviors did not appear to be responsible for the associations between social support and health. Further, they found evidence for the buffering effect in some studies.

A study of 92 newcomers in organizations indicated that the availability of social support was associated with positive newcomer adjustment (Nelson & J. C. Quick, 1991). Recent evidence also indicates that it is the perception of social support that is most closely related to adjustment and health (J. G. Sarason, B. R. Sarason, Brock, & Pierce, 1996). If this is the case, then it is possible that another variable, potentially an individual difference/personality factor, is affecting both stress and social support. Self-reliance, or attachment orientation, is one such variable.

In summary, the changing nature of work, individual differences, and social support are three themes common to the current work stress literature. The next section turns to potential challenges and opportunities for those researchers who study work stress.

FUTURE CHALLENGES FOR RESEARCH

The challenge for future researchers in occupational health psychology is to advance the creation of "healthy" organizations. A healthy organization is one in which all people have the opportunity to achieve high performance, high satisfaction, and well-being (Quick, Quick, Nelson, & Hurrell, 1997). Through enhanced emphasis on the root causes of both health and distress in the workplace, healthy organizations should experience diminishing reliance on secondary and tertiary preventive interventions (Cooper & Cartwright, 1994). The challenge for researchers and practitioners alike is that the discovery of some of these root causes may require a fundamentally new, or at least an expanded, frame of reference. Three particularly challenging areas of future opportunity are research into eustress and positive affect (PA), diversity issues, and nonrecursive relations.

Eustress and Positive Affect

Eustress has been defined as "a positive discrepancy between and individual's perceived state and desired state, provided that the presence of this discrepancy is considered important by the individual" (Edwards & Cooper, 1988, p. 1448). Eustress is analogous with an overall, general state of happiness or subjective well-being (Brebner & Martin, 1995). Characterizing eustress as the stress of fulfillment, Kahn and Byosiere (1992) advocated that because the stress of life cannot be avoided, people should seek to maximize the eustress component. Engaging work and the generation of frequent positive events are two possible paths to eustress.

Eustress was identified earlier in this chapter as the type of stress that may lead to enhanced health and performance on the job. Edwards and Cooper (1988) posited that eustress may

improve health not only by decreasing the rate of development of degenerative diseases but also by actually reversing the development of disease. They described the ways eustress may improve health directly through hormonal and biochemical changes or indirectly by facilitating attempts to cope with existing stress.

A longitudinal study of air traffic controllers (ATCs) provides an exceptional example of healthy stress (Rose, 1987). Over a 3-year period, the cortisol values of 201 men were measured every 20 minutes for 5 hours on 3 or more days and compared to both objective and subjective assessments of workload. Whereas the increases in cortisol for all levels of workload were slight, the men who showed the highest increase in cortisol to increased work reported themselves as more satisfied and were regarded by peers as more competent. These high cortisol responders also showed less frequent illness than those with lower cortisol levels, who for any given level of work tended to have more minor health problems. Rose described the men whose cortisol increased in response to challenging work as *engaged* rather than stressed. Elsewhere, the happiness derived from engagement in mindful challenge has been termed "flow" (Csikszentmihalyi, 1990). In their review of Rose's study, Ganster and Schaubroeck (1991) described the healthy state of physiological arousal experienced by the engaged workers as eustress.

Although there is a paucity of research on eustress in the workplace, recent reviews on health psychology concur that evidence supports the suggestion that positive daily events and positive cognitions may directly contribute to physical health outcomes (Adler & Matthews, 1994; Cohen & Herbert, 1996). Indirectly, both trait positive affect (PA) and eustress-induced state PA may facilitate coping through social support by improving social interactions (Edwards & Cooper, 1988). Studies have shown that PA is positively related to both frequency (Watson, Clark, McIntyre, & Hamaker, 1992) and quality (Berry & Hansen, 1996) of social interaction.

The personality trait PA reflects an individual's predisposition to experience positive emotional states (Burke, Brief, & George, 1993). It is well established that NA and PA are independent constructs (Burke et al., 1993; George & Brief, 1992). Similar to eustress, PA has received relatively little attention from occupational stress researchers. Although negative affect (NA) influences self-reports of stressors and strains, it is not expected to exert a strong influence on self-reports of positive experiences at work; however, PA is expected to be very influential in this regard (Burke et al., 1993). Positive affect may exert more general and longer lasting effects than negative affect, and even modest and temporary shifts in affect can improve patterns of social interaction in the workplace (Baron, 1993).

In a recent study of both state PA and state NA in Canadian workers, Brown and Moskowitz (1997) determined that individuals who reported state PA reported less subjective experiences of physical illness. Using daily event-sampling methodology to minimize problems with retrospection, they found that unpleasant affective state (NA) alone influenced occurrence of minor illness with no contribution from trait

neuroticism. Interestingly, participants in their study reported more than twice as many occurrences of pleasant as unpleasant affect.

A similar bias for the positive was found in a study of stress reactions on and off the job for employees of Volvo in Sweden (Frankenhaeuser et al., 1989). Both managers and clerical workers experienced more positive stress (effort involvement) than negative stress (work overload). Female clerical workers self-reported positive stress twice as often as negative stress.

In fact, recent studies suggest that most people are reasonably happy most of the time (E. Diener & C. Diener, 1996; Lykken & Tellegen, 1996). E. Diener and C. Diener (1996) posited that this may indicate a positive baseline for affect in humans. Individual differences in this happiness baseline may be determined by traits (e.g., optimism, extroversion, and self-esteem), supportive personal relationships, religious faith, a culture that offers positive interpretations for most daily events, and engaging work and leisure (Myers & E. Diener, 1995).

Individuals with a positive orientation to life seem to be more engaged in their lives and make the best of both work and nonwork situations. These optimistic individuals manage challenging and stressful events with less subjective distress and less adverse impact on their physical well-being (Scheier & Carver, 1992).

A growing body of research suggests that the way people habitually explain to themselves why events happen influences their expectations for controlling future events, which may in turn affect their well-being (Seligman, 1991). Compared to pessimists, people with an optimistic style of explaining bad events tend to experience better health (Peterson, 1995). Similar to the underdeveloped knowledge of eustress and PA, less is known about the significance of explanatory style for good events (Peterson, Buchanan, & Seligman, 1995). Because an optimistic explanatory style can be learned (Seligman, 1991), this knowledge could help organizations that discern the value of generating eustress and PA through purposeful attention to positive events to maximize their effort and investment.

The growing evidence that happiness is healthy, and that most people are happy, suggests that a shift in focus to the positive from the negative in occupational stress research merits strong consideration. In as much as the subjective well-being purposed by the study of occupational health psychology results from the complex interaction of both frequent positive and infrequent negative stress outcomes, the optimal research agenda implores balance. The creation of healthy workplaces implies that processes designed to generate eustress are at least as important as processes designed to prevent distress.

Five principles guide the preventive stress management philosophy (J. C. Quick & J. D. Quick, 1984):

1. Individual and organizational health are interdependent.
2. Management has a responsibility for individual and organizational health.
3. Individual and organizational distress are not inevitable.
4. Each individual and organization reacts uniquely to stress.

5. Organizations are dynamic, ever-changing entities.

The lack of knowledge about eustress suggests that researchers have equated individual and organizational health with the absence of distress. Because eustress and distress are independent constructs, a better understanding of the sources and healthy consequences of engaging work experiences is in order. Practitioners, then, could have enhanced confidence in the value of providing engaging work and consistently generating small positive events in the workplace.

Diversity Issues in Occupational Stress Research

The experience of eustress and distress in the workplace will vary according to an individual's culture, gender, age, and the interaction between these variables. For example, an extensive review of social support reveals that it is a multidimensional construct across the spectrum of diversity variables (Uchino et al., 1996). Although social support predicts better cardiovascular regulation in both men and women, sex differences appear to determine the importance of type of social support. Because the association between social support and cardiovascular function may vary across cultures, Uchino et al. (1996) emphasized the importance of proper operationalization of social relationships within a specific cultural context. Their review also suggested that whereas social support has beneficial effects on physiological processes across all age groups, it may be more important to the health of older adults. They even suggested that individuals with high social support may biologically age at a slower rate.

Understanding the particular stresses experienced by females, ethnic minorities, and aging workers is improving but still insufficient. Keita and Hurrell (1994) offered a collection of studies on diversity and family issues that represents important progress in this area. There is considerable opportunity to increase the understanding of cross-national as well as cross-cultural objective stressors, coping processes, and approaches to research (Cooper & Payne, 1992).

H. F. Myers (1996) stated that despite the heterogeneity of American society, the theorizing and research of health psychology reflects the mainstream bias of psychology and medicine, focused primarily on White, heterosexual, middle-class American men. This is problematic because if research samples are not adequately diverse, then false conclusions about particular groups could subsequently lead to providing them with ineffective health care interventions (Mann & Kato, 1996). If there are to be genuinely healthy organizations, then the challenge in occupational health psychology must be to generate opportunities for engagement and prevent sources of distress for all people in these organizations.

To do so requires recognizing the heterogeneity that exists within groups and incorporating it into the design of studies. For example, although it is important to understand the differences in stress and health that exist between Whites and Hispanics (Gutierrez, Saenz, & Green, 1994), researchers should appreciate that Mexicans, Cubans, and Puerto Ricans may themselves differ with regard to perception of and response to stress (Krause & Goldenhar, 1992). An exploratory study of

stressors for professional women found that Mexican American women reported experiencing less racism at work than Puerto Rican and African American women and less sexism than Anglo-American women (Walcott-McQuigg, 1994). These within-group differences should also exist for Asian Americans, and within all groups should be most apparent among more recent immigrants.

Sex and gender issues present especially important challenges. Most researchers confuse the terms *sex* and *gender* by using the two interchangeably. Unfortunately, Jick and Mitz's (1985) observation that "virtually all of the research dealing with sex differences in the stress process makes the implicit assumption that sex and sex-role identity are equivalent" (p. 415) is still true today. Enhanced understanding of *sex differences* in occupational stress is very important, but this term should be reserved for reference to biological distinctions between males and females.

Conversely, the term *gender differences* should be reserved for differential role behaviors that are learned as appropriate for either males or females (Mann, 1996). Gays, lesbians, and single fathers are all invisible in the study of occupational stress and health. Accordingly, a fundamental rethinking of the value of capturing the within-group variance of gender differences is in order (Matuszek, Nelson, & J. C. Quick, 1995). Although the few studies that attempt to address gender differences and such things as work-family conflict are encouraging (Frone, Russell, & Barnes, 1996), the challenge remains to explore ways to operationalize gender beyond "0 = male and 1 = female."

It is important to remember that the purpose for studying the aforementioned cultural and gender differences is in order to better target interventions and promote health for all people (Mann & Kato, 1996). Women's work roles, family composition, the allocation of family responsibilities, and the cultural diversity of the workplace will all continue to evolve. A balanced preventive and generative approach to occupational stress and health suggests that researchers become increasingly anticipatory of these changes.

Nonrecursive Relationships Among Variables

A methodological challenge for future occupational stress researchers is the examination of nonrecursive relations among variables. A nonrecursive relation is one in which two (or more) variables are involved in two-way causation (Bentler & Chou, 1987). Although few current structural models in occupational stress research incorporate nonrecursive models, reciprocal causation among variables may be especially important to consider when studying chronic stress and chronic ill health.

When individuals consistently experience both role-related stress and health problems, it may be difficult to determine which came first. In order to obtain an unbiased estimate of the effect of stress on health requires the researcher to partial out the reciprocal effect of health on stress (Kessler, Magee, & Nelson, 1996). Nonrecursive models may also be required in other situations where the temporal order between cause and effect is ambiguous.

Nonrecursive relations require that instrumental variables be incorporated into the model. Instrumental variables are theoretically related to only one of the antecedent variables in the reciprocal relation (Bentler & Chou, 1987). Frone, Russell, and Cooper's (1992) specification of a nonrecursive model in their study of stress and work-family conflict (WFC) provides a very good example of proper methodology. In their cross-sectional study, job distress and family distress functioned as the instrumental variables in the nonrecursive model of work-family conflict. Their results support the concept that the conflict relations between work and family are reciprocal.

Nonrecursive models require careful a priori theorization and research design to allow estimation of the structural equation model (SEM). The use of SEM is advantageous because it allows simultaneous examination of reciprocal relations between several variables (Williams & Podsakoff, 1989). The use of nonrecursive models should contribute additional support for causal inference as stress researchers increase their use of longitudinal designs.

THE RESEARCH-PRACTICE DIALOGUE

Perhaps the greatest challenge for the future of preventive stress management lies in establishing and maintaining an effective dialogue between researchers and practitioners. Communication between the two groups has increased in recent years, but there still remains a perceptible division between them. Undoubtedly there are successful workplace interventions that go unpublished, and there is knowledge gleaned by researchers that fails to be translated into application by practitioners. For several decades, scholars have called for more rigorous evaluation studies of workplace interventions. A review of recent literature suggests that there may be reasons for cautious optimism.

Workplace Interventions

One of the guiding principles of preventive stress management is that individuals and organizations are responsible for health and well-being. Accordingly, workplace interventions can be classified as focusing on the individual or on the organization. Most interventions at the individual level, typically referred to as "stress management interventions," consist of secondary prevention efforts that help individuals alter the ways they respond to job stressors. In contrast, most organizational interventions are primary prevention programs aimed at changing the nature of job and/or organizational stressors. A review of the literature on interventions indicates substantial progress in the knowledge of individual level interventions, with comparably less progress in the knowledge of organizational interventions.

The increase in published studies of stress management interventions is evidenced by two reviews by Murphy (1984, 1996). Murphy (1984) contained only one third as many studies as Murphy (1996). Stress management interventions are typically offered as a single session focusing on techniques for helping individuals identify and manage symptoms of

stress (Hurrell & Murphy, 1996). Common techniques for such programs include muscle relaxation, meditation, cognitive-behavioral skills, biofeedback, or a combination of these. Most interventions use a combination of techniques.

Murphy (1996) reviewed 64 studies that were published in peer-reviewed literature and evaluated a health outcome. Almost 90% of the studies used reliable and valid outcome measures, including physiologic/biochemical markers or validated self-report measures. Most of the studies were preventive, and were offered to all employees on a voluntary basis. The effectiveness of the techniques varied. Cognitive-behavioral methods were more effective for psychological outcomes, whereas muscle relaxation was more effective for physiologic outcomes. Biofeedback was the least frequently used technique and the least effective. Meditation was the sole technique that showed significant effects on all outcome measures, although it was used in only three studies. Interventions that used a combination of techniques produced more consistent results across all outcomes.

This review indicated considerable progress in evaluating the efficacy of individual-level interventions. Along with the progress in terms of the number of published studies came a wider range of outcome measures. Three studies evaluated biochemical changes after training (e.g., catecholamines, angiotensin, renin, and aldosterone) with positive results. In addition, three studies assessed health care costs following stress management interventions and reported impressive results.

Kahn and Byosiere (1992) noted a surge in practitioner interventions that focus on the effects of stress and target individuals, and indicated that most of these efforts have not been evaluated in terms of serious research. Although cautioning that research evidence is meager and methodological problems abound, they concluded that evaluation studies show that stress management interventions produced significant reductions in subjective distress and psychophysiological indicators.

Turning to those programs that focus on the organizational level and seek to alter, reduce, or eliminate stressors, the evidence is sparse. Several case studies have been documented. Terra (1995), for example, recounted a case study of a participatory approach to job redesign and implementation of self-managing teams in the Dutch metal can industry. Murphy (1996) reported that a few empirical studies have demonstrated the reductions in strain associated with flexible work schedules (Pierce & Newstrom, 1983), increased employee participation in decision making (Jackson, 1983), and increased worker autonomy (Wall & Clegg, 1981). Each of these methods has the net effect of increasing employee control over work.

Karasek and Theorell (1990) posited the thesis that the design of workplaces may be more important than individual coping responses in creating ill health. Their research at the Karolinska Institute of Sweden suggested that redesign efforts should focus on increasing worker control and social support in order to enhance individual health.

Kompiers (1996) reviewed five theoretical approaches to job design to isolate the factors that affect stress, psychologi-

cal well-being, and job satisfaction. The approaches examined included the job characteristics model (JCM), the Michigan organizational stress model (MOS), the job demands/job control model (JD-JC), the sociotechnical approach, and the action-theoretical approach with its roots in German work psychology. Kompier concluded that there is remarkable similarity in the approaches. The factors that appear to affect motivation and enjoyment of work are control, meaningfulness and feedback, and cooperation at the workplace. Kompier concluded that the answer is "no" to the question of whether stress prevention programs utilize this knowledge and emphasize job redesign.

Ganster (1995) examined three theoretical bases for interventions. The job demands–job control model, he argued, has sufficient empirical evidence to warrant job redesign interventions to improve employee well-being. He cautioned that Type A and other personality factors need to be considered when implementing these interventions. Evidence suggests that social support can play a key role in enhancing employee well-being, yet there is little research on how or if social support can be augmented in organizations. Role clarification is another intervention that warrants evaluation. Ganster lamented the lack of controlled evaluations of interventions, and argued that the absence of published studies does not mean that too little is known to recommend such interventions.

Given that such knowledge exists, why is it not implemented in organizational interventions? Part of the reason may be due to a lack of communication between researchers and practitioners. Another contributing factor may be the differing perspectives of managers and employees. Managers may view stress as primarily caused by individual factors, and thus the responsibility of the employee. They may view stress management programs as "quick fixes" requiring less effort than interventions directed at changing the job or the organization. On the other hand, employees view stress as caused mainly by organizational and job conditions. Such differing views do not lend themselves to effective approaches to prevention.

Ultimately, comprehensive interventions that encompass both the individual worker and the organization will be needed to address the prevention and amelioration of distress. Current themes in the stress literature point to interventions focusing on contemporary sources of distress, increasing individual hardiness and self-reliance, and improving social support at work as promising avenues. Individual adaptation and organizational change need to be integrated. Individual interventions must not be used as temporary measures to pacify employees while distressful organizational conditions go untreated. The effective implementation of work stress interventions requires organizational stress diagnosis, planning for prevention, organizational and individual intervention, and careful evaluation of the outcomes of the intervention (J. C. Quick, J. D. Quick, et al., 1997). Given the dynamic nature of the stress experience, this is of necessity an iterative, ongoing process.

Participatory action research has been cited by a number of authors (cf. Hurrell & Murphy, 1996; Landsbergis et al., 1995) as a preferred approach for evaluating comprehensive interventions. This approach involves researchers and orga-

nization members joining in all aspects of the intervention, from needs assessment to evaluation. Worker involvement in all phases of the change process is critical for sustained change. In addition, both qualitative and quantitative methods are needed, along with assessments of both the process and the outcomes of the intervention.

Bridging the Research–Practice Gap

The notion of the "healthy company" has received increased attention in the literature (Cooper & Williams, 1994). This notion suggests an expanded definition of organizational effectiveness that goes beyond profitability. Healthy organizations create health and well-being for employees and other constituents (Jaffe, 1995).

To accomplish the aim of creating and maintaining healthy organizations, the gap between research and practice must be bridged. There are two avenues for accomplishing this goal. First, an exchange program can be set up for researchers and practitioners, similar to those programs in place in organizations and universities. Such an exchange would allow both parties to experience the world of the other party. Researchers would see the reality of organizational constraints like budgets and politics, and practitioners, removed from their element, might be able to explore a wider range of alternatives for intervention. Another advantage of such exchanges would be to establish a common medium for dialogue between the two groups. This would work to eliminate the common feeling that researchers and practitioners each have their own languages, and that there is often little common ground.

Second, venues should be created to facilitate increased interaction between researchers and practitioners. Such venues allow individuals to meet on neutral ground, away from their workplaces, to work on the overarching goal of increasing individual and organizational health. Some laudable efforts are already underway. The National Institute for Occupational Safety and Health (NIOSH) and the American Psychological Association (APA) formed a partnership to refine and implement strategies for the prevention of work-related psychological disorders. The partnership has resulted in three conferences: "Work and Well-Being: An Agenda for the 1990s" (1990), "Stress in the '90s: A Changing Workforce in a Changing Workplace" (1992), and "Work Stress and Health '95: Creating Healthier Workplaces." The three conferences drew a wealth of international researchers and practitioners and produced a series of books, with several contributions devoted to work stress interventions.

Another venture of note is that of the International Stress Management Association, which held its Sixth International Congress on Stress and Health in Australia in 1996. The Congress attendees were an impressive mix of researchers and practitioners, with many sessions focusing on organizational and individual interventions.

Exchange programs and venues for establishing dialogues are ways of promoting joint ventures between researchers and practitioners. The evaluation of workplace interventions requires such partnerships, particularly given the calls for action research as a preferred approach. Effective interventions

demand attention to both individuals and organizations, and they demand the best efforts of researchers and practitioners in collaboration.

Environmental Stress and Health

Gary W. Evans
Cornell University

Although environmental conditions play a prominent role in health and psychological processes, antecedent factors in these processes have largely been neglected within health psychology. Instead, the focus has been on various markers of health, with considerable attention to stress-related mechanisms, interceding between the environment and health. Another focus within health psychology that has directed attention away from environmental factors has been coping resources, with the examination of either social support, personality, or coping strategies that potentially alter the impact of environmental demands on health. But what characteristics of the environment itself are likely to impinge on health and psychological processes? When this question has been addressed within health psychology, environment has been operationalized primarily in social terms. Family and work social climates, as well as sociocultural and economic conditions, predominate in the few environmental studies in health psychology. This chapter intends to draw greater attention to the potential role of the physical environment in health and psychological processes.

Why might the physical environment be important to health psychology? For one reason, the physical environment clearly impacts health. Adverse physical conditions can cause toxicological reactions, challenge homeostatic balance, produce physical trauma, or function as vectors bearing pathogens. Physical factors can also be a source of environmental demands that pressure coping resources.

A second reason the physical environment is worthy of scrutiny within health psychology is because the environment can be modified and thus becomes a potential intervention target to improve health and well-being. Third, environmental conditions are objective and thus can be measured more readily

in reliable and valid ways. For example, researchers can systematically monitor density or noise levels in precise, accurate ways that can then be examined as possible causal factors in health. Fourth, physical environmental conditions tend to be stable. Increasingly, research suggests that chronic environmental demands are most likely to have negative impacts on health (Lepore, 1995). Finally, the concept of psychological stress that is central to several formulations of health, behavior, and disease (see chap. 17, this volume) has been utilized to broaden understanding of how physical features of the environment can influence human health and well-being.

There are at least three major ways in which the physical environment might operate as a psychological stressor, straining human adaptive capacities. First, this can occur when a stressor directly loads, or pressures, the system. Both crowding and noise, for example, create a surfeit of stimulation that can directly overload the system, causing discomfort, negative affect, and under some circumstances, the marshaling of adaptive resources. Both negative affect and adaptive responses to challenge or threat in turn directly affect neuroendocrine and cardiovascular functioning. Physical stressors can also interact with psychosocial conditions to exacerbate negative affect and/or psychophysiological mobilization. For example, noise plus high workload demands leads to more serious health outcomes than workload levels alone. Noise and crowding frequently covary with other psychosocial risk factors (e.g., poverty, inadequate working conditions), and thus have the potential to contribute to multiple risk situations.

A second manner in which the physical environment can contribute to stress is by damaging or ameliorating coping resources themselves. People rarely respond to suboptimal physical or psychosocial conditions passively; instead, they

invoke various coping strategies to reestablish some modicum of balance between environmental demands and personal resources. Evidence is presented herein, for example, that crowding interferes with the development and maintenance of socially supportive relationships in the residential environment. Both chronic noise and chronic crowding appear to contribute to learned helplessness, adversely affecting self-efficacy and related motivational processes.

The third way in which physical conditions can operate as stressors is to elicit coping strategies that in turn lead to poor health. Studies of noise, for example, reveal that increases in substance abuse occur under noisy working conditions.

Another aspect of research on psychological stress and health relevant to this chapter on environmental stressors are the concepts of vulnerability and resilience (Cohen, Kessler, & Gordon, 1995; Rutter, 1983). Just as certain personal or situational characteristics can render individuals more or less vulnerable to social stressors, there is evidence of vulnerable subgroups among the population who appear more adversely affected by noise and by crowding, respectively. Thus throughout both direct, main effects and associations between environmental stressors and health, as well as occasions with vulnerable subgroups, are noted.

The field of environmental stress (Cohen, Evans, Stokols, & Krantz, 1986; Evans, 1982; Evans & Cohen, 1987) is sufficiently developed such that exhaustive coverage is impossible. A small amount of environmental stress research has examined climatic conditions as potential psychological stressors influencing human stress responses (Bell & Greene, 1982; Evans, 1994). Research on housing conditions as a possible stressor have also been undertaken (Freeman, 1984). The focus of this chapter is on the two most studied environmental stressors, crowding and noise. Health outcomes include physical health and psychological health. Moreover, the chapter examines underlying psychosocial and psychophysiological processes that may help explain the linkages between noise and crowding and major physical and psychological health outcomes. Psychophysiological mechanisms, immune function, social resources, coping strategies, and motivational processes are examined.

CROWDING

The element of crowding that relates most strongly to physical and psychological health is people per room. Traffic congestion may also prove to be a potent stressor. Area measures of crowding, such as people per acre, generally have little or no relation to health. Although some studies of crowding separate group size effects from density effects, the vast majority of studies have confounded these two factors, manipulating or measuring density as it covaries with group size. Therefore, some of the effects attributed to crowding may be due to group size rather than the amount of space per person. At the same time, when attempts have been made to distinguish between these related concepts, density and group size, the impacts of density typically persist.

Physical Health

Early interest in crowding in the public health field emanated from concerns about the spread of disease among crowded populations (Cox, Paulus, McCain, & Karlovac, 1982). There is a large literature on this topic. Physical health has been operationalized in this literature as rates of illness based on archival data, visits to infirmary, physical development among children, and self-reports of somatic symptoms. Archival evidence for positive associations between crowding and ill health come from studies in prisons (McCain, Cox, & Paulus, 1976; Paulus, 1988), refugee camps (Arnow, Hierholzer, Higbee, & Harris, 1977), and schools (Essen, Fogelman, & Head, 1978; Koopman, 1978). The Arnow et al. (1977) study is noteworthy because they demonstrated good correlation over time between Vietnamese refugee camp population fluctuations with changes in a highly contagious disease (acute conjunctivitis). There is also evidence that crowded residential conditions are linked to disease both among children (Booth & Johnson, 1975; Jacobson, Chester, & Fraser, 1977) and among adults (Levy & Herzog, 1978; McGlashen, 1977; Menton & Meyers, 1977; Sims, Downham, McQuillin, & Gardner, 1976; Wyndham, Gonin, & Reid, 1978; Yarnell, 1979). Yodfat, Fidel, Cohen, and Eliakim (1979) found that linkages among residential crowding and asthma were due to number of children rather than density per se. Booth (1976) found that male adults, but not women, had greater levels of disease in crowded homes. Traffic congestion levels among commuters is also associated with illness-related absenteeism from work (Novaco, Stokols, & Milanese, 1990).

Several studies of residential crowding find little or no correlates with disease (Brett & Benjamin, 1957; Collette & Webb, 1974; Mackintosh, 1934; McKinlay & Truelove, 1947; Quinn, Lowry, & Zwaag, 1978), and Winsborough (1965) uncovered an inverse relation between areal density and tuberculosis. Schmitt and colleagues also found no relation between residential density and disease rates, but found small, positive correlations with areal density (people per acre) measures (Schmitt, 1966; Schmitt, Zane, & Nishi, 1978). Similar trends have been uncovered by Levy and Herzog (1974). Kellett (1984) made the important point that certain diseases should be expected a priori to correlate with crowding more so than others. Kellett examined mortality patterns for specific diseases in London for a 5-year period. As in prior work, persons per room rather than people per acre appeared more useful in predicting mortality. Second, diseases wherein a major stress component is believed to be operative (e.g., hypertension, myocardial infarction, vascular disorders, asthma) were related to household crowding whereas many other diseases (e.g., various forms of cancer) were not.

Freedman and colleagues challenged many of these studies of crowding and disease, noting that poor or nonexistent controls for other variables such as socioeconomic status are common in the crowding and epidemiological literature. They found in a well-controlled epidemiological analysis that residential crowding was not a significant predictor of disease (Freedman, Heshka, & Levy, 1975). However, the prison

studies and a few of the residential studies (e.g., Menton & Meyers, 1977) do have good controls for SES. Furthermore, there are trends in the data indicating that when individual levels of exposure to density and individual indices of health are compared rather than aggregated population statistics, such as used by Freedman and colleagues, stronger results occur. Nonetheless, Freedman and colleagues' cautious perspective on crowding and disease is well taken. Overall findings are suggestive but not rigorously or consistently supportive of a crowding-disease link. It would be useful to include, in the same individual-based study, disease rates for disorders that ought to vary with stress exposure plus inclusion of immunological measures.

A handful of studies in institutional contexts have examined crowding and infirmary visits. These studies converge on positive associations between levels of crowding and infirmary visits among shipboard military personnel (Dean, Pugh, & Gunderson, 1975, 1978), college campus residents (Baron, Mandel, Adams, & Griffen, 1976; Stokols, Ohlig, & Resnik, 1978), and prisoners (Paulus, 1988). The prison effects were most noticeable among inmates forced to live under dormitory-like conditions rather than in single cells. Trends also indicated that the associations in prisons were somewhat stronger for men than women and for African American in comparison to Anglo prisoners (Paulus, 1988). Wener and Keys (1988) found that increases in density (doubling up cell mates) markedly elevated (nearly 50%) sick call rates among prison inmates.

A few studies have examined physical development among crowded children, uncovering evidence of negative associations between household density and physical stature (Booth, 1976; Essen et al., 1978; Goduka, Poole, & Aotaki-Phenice, 1992). Crowded children, particularly boys, are shorter. Shapiro (1974) also found that boys, but not girls, motoric development appeared to be inhibited in crowded homes. Moreover, this effect was amplified among children of less educated mothers. More recently, Widmayer and colleagues (1990) found delayed psychomotor development among infants as a function of household density, controlling for socioeconomic status (SES).

Self-reported levels of physical illness are positively associated with crowding in prisons (Cox, Paulus, & McCain, 1984; McCain et al., 1976), among college dormitory women but not men (Karlín, Epstein, & Aiello, 1978), and among crowded home settings (Gove & Hughes, 1983)—although Booth (1976) found this association among men, but not women, in crowded homes. Giel and Ormel (1977) and Baldassare (1979) failed to replicate the association between home crowding levels and self-reported illness. The validity of all the self-report data on illness and crowding is suspect given retrospective self-report indices. On the other hand, Cox et al. (1984) found a dose-response function between number of inmates per cell and self-reported illness levels among male prisoners. Of additional interest, Gove and Hughes (1983) provided some evidence that heightened illness levels associated with crowded residences are related to lack of sleep and lower resistance when exposed to other sick family members (all self-reported).

There is evidence that some of the association between crowded living conditions and self-reported health symptoms is mediated by loss of perceived control over the living environment. Ruback and associates found that both female and male prisoners' reports of ill health in association with crowding were also negatively related to perceived control (Ruback & Carr, 1984; Ruback, Carr, & Hopper, 1986). Another way in which environmental stressors like crowding can impinge on health is through injuries. Rhesus monkeys when crowded, for example, show a 5-fold increase in incidents of injuries (Boyce, O'Neill-Wagner, Price, Haines, & Suomi, 1998).

Psychophysiological

Several studies have examined the relation between crowding and blood pressure in people. Laboratory studies with random assignment to density levels have found small but significant elevations among crowded versus uncrowded participants (Epstein, Lehrer, & Woolfolk, 1978; Evans, 1979). Field studies of prisoners (D'Atri, 1975; Paulus, McCain, & Cox, 1978) and automobile commuters (Novaco, D. Stokols, Campbell, & J. Stokols, 1979; Schaeffer, Street, Singer, & Baum, 1988; Stokols et al., 1978) have also revealed correlational evidence for elevated blood pressure under more crowded or congested living or commuting conditions. The commuting studies have found that the effects are stronger for car poolers rather than solo drivers, for Type B rather than Type A drivers, among external versus internal locus of control drivers, and among drivers with less residential choice. One field study found no relations between chronic residential crowding and blood pressure or neuroendocrine indices among adults (Booth, 1976), although small, statistically significant elevations in serum cholesterol were noted among crowded men. No such correlation was noted among women. Booth's sample did not vary much in density, which may have weakened his findings. Evans, Lepore, Shejwal, and Palsane (1998) found elevated blood pressure among crowded boys, but not girls, among working-class families in India.

Another cardiovascular function, blood pressure reactivity, has been related to chronic crowding in adults. Residents of more crowded neighborhoods had higher reactivity (increase from baseline in blood pressure levels) and took longer to return to resting baseline levels (Fleming, Baum, Davidson, Rectanus, & McArdle, 1987). Both heightened reactivity and protracted recovery to baseline are potentially important precursors to the development of coronary heart disease.

Neuroendocrine markers of stress, typically urinary catecholamines and cortisol, have been noted in several studies of crowded commuters (Lundberg, 1976; Singer, Lundberg & Frankenhaeuser, 1978) and among bus drivers operating under more congested driving conditions (Evans & Carrere, 1991).

Pedestrian exposure to more crowded urban areas elevates neuroendocrine activity, at least for males (Heshka & Pylypuk, 1975), and residence in neighborhoods perceived as more crowded because of commercial establishments and more people on the street is associated with increased urinary catecholamine levels (Fleming, Baum, & Weiss, 1987). Dor-

mitory crowding, however, had no apparent effects on neuroendocrine activity among college students (Karlin et al., 1978). A small sample size may have rendered low power. These authors did find, however, that uncrowded residents' neuroendocrine indices dropped over the course of the semester, whereas crowded residents' neuroendocrine levels increased over the same time period. Schaeffer, Baum, Paulus, and Gaes (1988) found that prisoners housed in more open, unpartitioned dormitories felt more crowded and experienced elevated chronic catecholamine levels in comparison to prisoners living in smaller groups.

The critical role of control has been implicated in some of these psychophysiological crowding studies. Lundberg (1976) and his colleagues found that passengers with greater choice over seating were less negatively impacted by congested commuting. Evans and Carrere (1991) found that the neuroendocrine effects of traffic congestion on bus drivers were largely mediated by perceived control on the job. On the other hand, perceived control did not mediate the positive relation between prison crowding and neuroendocrine elevations (Schaeffer, Baum, Paulus, & Gaes, 1988).

A few laboratory studies have also utilized skin conductance as an index of psychophysiological stress, generally finding elevations among more crowded participants (Aiello, Epstein, & Kalin, 1975; Aiello, Nicosia, & Thompson, 1979; Bergman, 1971; Nicosia, Hyman, Karlin, Epstein, & Aiello, 1979). Studies of crowding and skin conductance are evenly split on gender differences, with some studies finding more pronounced effects among males than females and other studies finding no sex differences. There is also evidence that skin conductance may be more strongly affected by crowding when physical touching occurs. McCallum, Rusbult, Hong, Walden, and Schopler (1979) found that acute crowding elevated palmar sweat but only when experimental subjects were motivated to maintain high levels of group performance. When performance was permitted to deteriorate under crowding, no physiological elevations were noted. Finally, in a field study, Cox, Paulus, McCain, and Schkade (1979) found a significant positive correlation between the palmar sweat index and crowding among prison inmates.

Although indirect, some findings by Hutt and Vaizey (1966) may shed some light on psychophysiological mechanisms associated with crowding and psychophysiological responses. Chronically overaroused children responded to high density laboratory conditions by extreme social and physical withdrawal; whereas chronically underaroused children and children without arousal disturbance reacted in the opposite direction, becoming more engaged and aggressive with other children.

Many animal studies have examined endocrine activity among crowded species both under laboratory and field conditions (see Evans, 1978, for a review). Generally, this research indicates support for a population regulation feedback mechanism whereby crowded animals' fertility declines. This occurs more markedly among subordinate rather than dominant animals and appears to be mediated by adrenal cortical activity. Attempts to link crowding with population regulation among human beings have proven futile.

Immune Function

Animal but not human work has examined immunological processes as a function of crowding, generally finding evidence of compromised immune functioning among more crowded animals (Christian, 1963; E. A. Edwards & Dean, 1977; Thiessen & Rodgers, 1961). These effects appear to be stronger among subordinate rather than dominant animals and among animals without a history of crowded living conditions (Cassel, 1971). Cassel (1974) pointed out, however, that compromised immune function alone cannot account for changes in morbidity among crowded animals because both infectious and noninfectious diseases are elevated among crowded animals.

Psychological Health

Ever since 1962 when Calhoun published his famous *Scientific American* study of pathology among overpopulated rats, researchers and policymakers alike have wondered about the potential role of crowded living conditions on mental health. The chapter first reviews research on linkages between density and psychological distress and then turns its attention to recent work examining possible underlying mechanisms for this linkage.

Many studies have uncovered positive relations between residential density and self-reported psychological distress (Edwards, Fuller, Sermsri, & Vorakitphokatorn, 1990; Evans, Palsane, Lepore, & Martin, 1989; Gabe & Williams, 1987; Gove & Hughes, 1983; Hassen, 1977; Jain, 1987; Lakey, 1989; Marsella, Escudero, & Gordon, 1970). Mitchell (1971) found greater worrying among crowded families but only if they were also poor. Crowding in Mitchell's study was unrelated, however, to more serious indices of psychiatric illness. Lepore, Evans, and Schneider (1991) found evidence that residential crowding causes psychological distress in a prospective, longitudinal study of crowding and mental health. Controlling for educational levels and income, they found that crowded residents did not differ from uncrowded residents in psychological distress symptoms during initial occupancy ($r = .12$), but after 2 months and 8 months the associations became significant ($r = .21$; $r = .27$). This is the only prospective study of crowding and health. Webb and Collette (1975) found an association between residential density and use of prescription hypnotics.

Booth (1976), Baldassare (1979), and Giel and Ormel (1977) failed to find a positive association between residential crowding and psychological distress. These studies had little variance in density. Moreover, Baldassare relied on mental health indices of questionable sensitivity (one dichotomous item in one case, and three dichotomous items in a second case). Two studies of neighborhood crowding levels have also found linkages to psychological distress (Collette & Webb, 1974; Fleming, Baum, & Weiss, 1987).

Studies utilizing archival indices such as psychiatric admissions or suicide rates generally find very weak or insignificant associations between crowding and pathology when measured in the aggregate (Freedman et al., 1975; Gove &

Hughes, 1980; Schmitt, 1966; Schmitt et al., 1978). In some studies negative associations between density and psychiatric admissions have been uncovered, probably created by the association of living alone and mental disorder (Galle, Gove, & McPherson, 1972; Levy & Herzog, 1974, 1978). One exception to these generally negative trends in archival indices of mental health and crowding is notable. Several prison studies have found clear, strong associations between the total population size of prison populations and indices of psychiatric illness (Paulus, 1988).

Quite a number of studies have examined psychological symptoms among children living in crowded homes. Plant (1937) described several case studies noting a pattern of low self-sufficiency and little idealism among children from crowded homes. He attributed these patterns to mental strain associated from always having to get along with others and to exposure to adults under close quarters that made it difficult to look up to or idealize grownups. Crowded children have increased levels of various symptoms of psychological distress (Booth, 1976; Gasparini, 1973; Murray, 1974; Saegert, 1982; Wachs, 1987). Parents in more crowded homes report relief when their children are outside (Gove & Hughes, 1983), have more difficulty supervising their children (Mitchell, 1971), and are generally less responsive and involved with their children (Bradley & Caldwell, 1984; Evans, Maxwell, & Hart, 1999; Wachs & Camli, 1991) in comparison to uncrowded parents of comparable social class. These trends appear to be exacerbated in the presence of other risk factors, particularly poverty (Baldassare, 1981; Bradley et al., 1994).

Psychosocial Resources

Some of the relation between high residential density and psychological distress in children may be linked to family interactions, which have been found to be more contentious under crowded living conditions (Booth, 1976; Gasparini, 1973; Saegert, 1982). There may also be greater incidence of physical punishment and open expression of anger between parents and children in crowded homes (Booth & Edwards, 1976; Light, 1973), although Gove and Hughes' (1983) study did not support this finding.

Another factor that may help explain the link between high residential crowding and symptoms of psychological distress in children is withdrawal. Aiello, Thompson, and Baum (1985) reviewed several field and laboratory studies documenting increased social withdrawal under crowded conditions among young children. Similar trends exist in the adult literature, indicating that crowded adults interact with housemates less (Baum & Valins, 1977, 1979; Proshansky, Ittelson, & Rivlin, 1970); are less friendly with their neighbors (McCarthy & Saegert, 1978), and have impaired social support with those they live with (Evans et al., 1989; Lakey, 1989; Lepore et al., 1991). Baldassare (1979) did not replicate linkages between residential crowding and neighboring. People under crowded conditions also tend to be less affiliative in their behaviors toward others (R. L. Munroe & R. H. Munroe, 1972) and view others in more negative or suspicious terms (Bickman et al., 1973; Griffit & Veitch, 1971; McCarthy &

Saegert, 1978). There is also evidence that crowded working conditions lead to greater social withdrawal from coworkers (Oldham & Fried, 1987). Finally, as already noted, parents in crowded homes are less responsive to their children (Bradley & Caldwell, 1984; Wachs & Camli, 1991). Furthermore, this relative unresponsiveness partially accounts for less complex parent to child verbalizations to infants and toddlers (Evans, et al., 1999).

Evidence that social withdrawal and impaired social relationships are a primary mechanism accounting for the relation between crowding and psychological distress has been documented in some detail by two research programs. Baum and colleagues found that more crowded dorm residents report more unwanted social interaction in their dorms. These same crowded residents also evidence greater behavioral indices of withdrawal outside of the dorm. They sit farther away from other research participants and withdraw more in group interaction games (Baum & Valins, 1977, 1979). Residential exposure to high levels of street traffic is also associated with less neighboring (Appleyard & Lintell, 1972; Halpern, 1995). Evans and Lepore showed direct evidence for a similar pattern. They found both cross-sectionally (Evans et al., 1989) and in a prospective, longitudinal design (Lepore et al., 1991) that the negative effects of residential crowding on psychological distress (with controls for social class) are mediated by social support. Similar patterns also appear to occur among children in crowded residences (Evans, et al., 1998).

Evans and Lepore (1993a) also found that crowded relative to uncrowded residents were less likely to offer support to a confederate under stress in an uncrowded laboratory setting. Of additional interest, crowded residents in comparison to uncrowded residents were also less responsive to offers of social support during a stressful situation (see Fig. 20.1). *Ignored* meant that the subject did not look at or made no verbal acknowledgment of the confederate; *acknowledgment* meant some brief comment or a head nod was given in response to offers of support; and *accepted* meant the subject was very re-

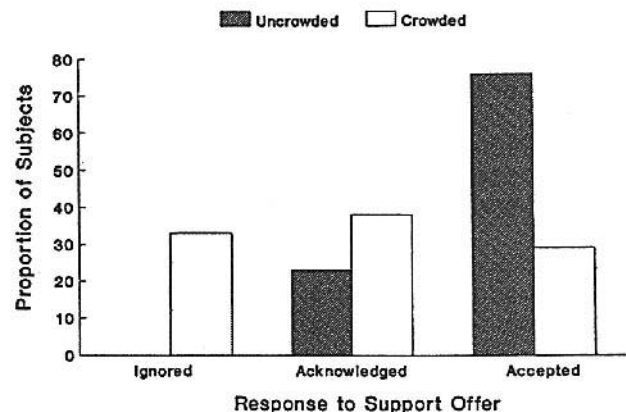

FIG. 20.1

sponsive to the confederate's offers of support, elaborating or embellishing on their offers of support.

Motivation

Many theorists have postulated that a prime reason why crowding can have negative impacts on psychological health is because of reduced behavioral options and greater difficulty in regulating social interaction (Altman, 1975; Baron & Rodin, 1978; Schmidt & Keating, 1979). An important psychological consequence of prolonged exposure to an aversive, uncontrollable stressor, such as crowding, may be learned helplessness. Persons chronically exposed to crowding report feeling a greater sense of powerlessness over their living environments than their less crowded counterparts (Baum & Valins, 1977, 1979; Baron et al., 1976; Carr, Hopper & Ruback, 1986; Saegert, 1978). Sherrod (1976), Aiello, DeRisi, Epstein, and Karlin (1977), Evans (1979), Nicosia et al. (1979), and Dooley (1978) all found negative aftereffects immediately following laboratory exposure to crowded conditions. Sherrod, Evans, and Nicosia and colleagues each utilized the Glass and Singer (1972) aftereffects paradigm that measures persistence on challenging puzzles. Giving up sooner in the face of challenge in an achievement context may be indicative of greater helplessness (Cohen, 1980; Glass & Singer, 1972). Dooley (1978) incorporated proofreading performance as her aftereffects measure. Saegert, Mackintosh, and West (1975) reported that crowded train stations produced negative aftereffects in women only. Nicosia's data also indicated more severe aftereffects of crowding among women.

Parallel trends to the laboratory work have been noted in studies of more chronic, crowded living conditions, finding less persistence on difficult puzzles among persons living in more crowded neighborhoods (Fleming, Baum, & Weiss, 1987). Moreover, perception of control over social interactions largely accounted for the main effect of neighborhood crowding on the helplessness indicator. Residents of crowded dorms feel less control over social interaction than their uncrowded counterparts (Baum & Valins, 1977, 1979) and exhibit behavioral strategies in a group prisoners' dilemma game consistent with helplessness (Baum, Aiello, & Calesnick, 1978; Baum, Gatchel, Aiello, & Thompson, 1981). Interestingly, the development of helplessness strategies in the game over the course of the initial semester under crowded conditions was mirrored by residents growing external attributions for problems in the dormitory over this same time period (Baum et al., 1981). Uncrowded residents generally felt self-efficacy over problems in their dormitory over the course of the semester and these internal attributions remained stable over time. Crowded dormitory residents are also less likely to seek clarification when given ambiguous instructions about an impending laboratory procedure than were uncrowded dormitory residents.

Traffic congestion also is related to motivational deficits. Greater traffic congestion levels have been related to decreased task motivation on challenging puzzles and proofreading (Novaco et al., 1979; Schaeffer et al., 1988; D. Stokols, et al., 1978).

The most direct evidence for helplessness induced by crowding comes from a pair of studies on residential crowding and children by Rodin (1976). Matched on socioeconomic indicators, elementary-aged schoolchildren living in more crowded public housing were less likely to control the administration of outcomes in an operant conditioning paradigm in comparison to their less crowded counterparts. In a second study, helplessness was induced in adolescents by a classic helplessness paradigm, pretreatment with an insoluble versus a soluble puzzle. Helplessness was monitored on a second challenging but solvable puzzle. The main effect of pretreatment solvability (the helplessness induction) was significantly moderated by residential crowding with heightened vulnerability to the induction of helplessness among the more crowded children. In their study of children in India, Evans, et al., (1998) replicated Rodin's effects (but for girls only). Saegert (1982), however, did not replicate these findings examining a sample of children from public housing projects in New York City.

Summary

Residential crowding has little impact on physical morbidity among the general population. Residential crowding may be linked, however, to ill health among vulnerable subgroups of the populations, particularly young children and extremely crowded, captive populations (e.g., prisons, refugee camps). Evidence linking high density exposure either under controlled conditions or in the field to elevated cardiovascular functioning is quite strong. Neuroendocrine functioning also appears elevated, although less data are available. The potential clinical implications of these two data patterns has not been explored in the crowding literature.

Psychological distress is increased by residential crowding. Individual but not aggregate level analyses continue to uncover a positive association between crowded living conditions and poorer psychological health. Several studies have excellent controls for sociodemographic factors and one is a prospective, longitudinal analysis. Psychological distress associated with residential crowding may be caused by a typical coping strategy for dealing with chronic high density living conditions—social withdrawal. An unintended consequence of this social withdrawal may be a breakdown in socially supportive relationships. There is not strong evidence, however, that human crowding is associated with more extreme forms of psychopathology characterized in some animal studies as a behavioral sink.

There is also evidence that crowding may lead to the development of motivational deficits, particularly among children in achievement-related contexts. There is indirect evidence suggesting that these motivational deficits are related to learned helplessness from diminished perceived control over the environment.

NOISE

Noise, which is defined as unwanted sound, is typically measured in decibels. Decibels is a logarithmic scale with a

change in 10 decibels perceived as approximately twice as loud. There is considerably more research on noise and health in comparison to research on crowding and health. The bulk of the noise and health research has occurred in industrial settings. More recently, studies of noise and health have also focused on people living in airport impact zones or near to road traffic noise. Prolonged exposure to high levels of noise is clearly linked to hearing damage (Kryter, 1994). Because the thrust of this chapter is on environmental stress, the noise-related hearing damage literature is not discussed.

Physical Health

Studies have examined exposure to either occupational noise or community noise and disease. Outside of cardiovascular problems, there appears to be little relation between noise exposure and physical disease. In industrial settings, noise has been associated with increased risk for myocardial infarction (Ising, Babisch, & Günther, 1999), reductions in cardiorespiratory efficiency (Semczuk & Gorny, 1971), difficulties in peripheral circulation and cardiac problems generally (Jansen, 1961), electrocardiogram abnormalities suggestive of coronary heart disease (Cuesdan et al., 1977), general sickness-related absenteeism (Cohen, 1973), and self-reported fatigue (Carlestam, Karlsson & Levi, 1973; Melamed & Bruhis, 1996). Several industrial studies have found no associations between occupational noise exposure and rates of coronary heart disease (Lees, Romeril, & Wetherall, 1980) or rates of total illness (Lees et al., 1980).

Community airport noise studies have shown that higher levels of noise exposure are associated with greater contact with physicians for coronary-related problems (Knipschild, 1977a) and, for women only, use of drugs to treat hypertension (Knipschild & Oudshoorn, 1977; Koszarny, Maziarka, & Szata, 1981). These studies also show an association with greater physician contact in general (Knipschild, 1977b), rates of colds (Ising et al., 1990), as well as total health symptoms (Pulles & Stewart, 1990), and higher levels of coronary heart disease symptoms among women but not men (Koszarny et al., 1981). Graeven (1974) and Hiramatsu, Tamamoto, Taira, Ito, and Nakasone (1993), however, found no differences in self-reported health symptoms between persons living in airport impact zones versus citizens in quiet neighborhoods.

Turning to road traffic noise, Cameron, Robertson, and Zaks (1972) found little relation between community noise levels (self-reported) and illness rates. Babisch, Elwood, Ising, and Kruppa (1993) found slight elevated risk (1.2 odds ratio) in noisier traffic areas in three different sites for men residing in areas above 65 dBA Leq. However, when comparing across different noise levels varying from > 50 dBA Leq to 70, they uncovered no linear relation.

Another area of physical health worthy of note in the noise literature is birth defects and other abnormalities during pregnancy. Not surprisingly, findings in this area are highly controversial and not at all definitive. Jones and Tauscher (1978) found higher rates of birth defects in high airport noise impact zones relative to quieter areas, but Edmonds, Layde, and

Erickson (1979) could not replicate the findings. Several rodent studies have found abnormal fetal development following noise exposure (Welch, 1973). There is evidence that women working under very noisy conditions, particularly if subjected to additional stressors like shiftwork, have more pregnancy complications such as vaginal bleeding and pregnancy-induced hypertension (Nurminen & Kurppa, 1989). Babies born in areas with high noise impact have lower birth weights (Ando & Hattori, 1977; Knipschild et al. (1981) with controls for socioeconomic status. Ando (1987) also found an increase in low birth weight babies following the opening of a new airport. Schell (1981) also noted that female infants, but not males, had significantly shorter gestation periods in high airport noise impact zones. Moreover, Ando and Hattori (1977) showed diminished levels of human placental lactogen levels in mothers living in high noise airport impact zones. Finally, Schell and Ando (1991) found a dose-response function relating airport noise levels and 3-year-olds' physical stature (but not weight) in a large epidemiological study. The data on possible linkages between noise and early development are sobering to consider in light of environmental surveys of neonatal, intensive care units that are often populated by premature babies. Levels of noise match or exceed recommended standards for ambient traffic exposure and health (Lawson, Daum, & Turkewitz, 1977).

Psychophysiological

Although previous reviews of noise indicate that cardiovascular responses (typically blood pressure or pulse) to noise under acute exposures rapidly habituate (Glass & Singer, 1972; Kryter, 1994), more careful scrutiny of this literature indicates important exceptions. Persons who are noise sensitive do not easily habituate (Conrad, 1973; Stansfeld & Shine, 1993), nor do individuals who are hypertensive (von Eiff, Friedrich, & Neus, 1982). Short-term habituation is blocked when people perform demanding cognitive tasks under noise (Carter & Beh, 1989; Conrad, 1973; Mosskov & Ettema, 1977). Evans et al. (1996) also showed that noise significantly increases blood pressure over a 20-minute period without habituation, if it follows exposure to a psychological stressor (i.e., giving a speech, taking a final examination).

Other psychophysiological indices examined under acute noise have included electrodermal activity, ECG, EEG, and neuroendocrine activity. Results parallel the cardiovascular data, indicating rapid habituation (Finkle & Poppen, 1948; Fruhstorfer & Hensel, 1980). Recent findings suggest, however, that when short-term exposure to loud noise is accompanied by demanding tasks, habituation may be blocked (Frankenhaeuser & Lundberg, 1977; Ising, Rebentisch, Poustka, & Curio, 1990; Lundberg & Frankenhaeuser, 1978). Work by Tafalla and Evans (1997) indicated a central role of effort in the performance/physiological activation tradeoff. Performance can be maintained, at least under many circumstances (e.g., short-term tasks that do not demand large amounts of attention or memory), by additional cognitive effort. Such maintenance of performance, however, appears to exact a cost of greater psychophysiological

activation. It is noteworthy that McCallum et al. (1979) found a very similar pattern for performance under crowded laboratory conditions.

There is also evidence indicating that habituation is interfered with by calling attention to the potential negative impacts of noise on the person (Vera, Vila, & Godoy, 1992). This latter finding might explain why noise sensitive persons apparently do not readily habituate to repeated exposures of acute noise in the laboratory. Perhaps they are more threatened or concerned about potential harmful effects of the noise.

Field research on noise and psychophysiologic outcomes has occurred primarily in industrial settings. The occupational noise and psychophysiologic literature is too large to review exhaustively herein. Several reviews of this literature (Kryter, 1994; Thompson, 1981, 1993; Welch, 1979) have characterized the findings similarly. Unfortunately, nonexperimental designs have frequently been employed in the occupational noise and health literature with poor or nonexistent controls, and many studies have relied on poor estimates of noise exposure. Furthermore, blood pressure is often poorly measured. Many of the industrial studies have relied on one or two measures of blood pressure taken during a physical at work by medical personnel. Moreover, annual medical examinations or other medical screenings may seriously bias estimates since some workers become excluded.

Thompson concluded from her two reviews that workers with adequate hearing protection are unlikely to show much effect of noise on the cardiovascular system. Kryter (1994) reflected greater concern but also remained skeptical, noting the paucity of well-designed research studies; Welch (1979) sounded a considerably greater sense of alarm about cardiovascular health risks from chronic, occupational exposure to noise. Interestingly, Welch's review is based primarily on Eastern European literature that includes worksites with generally very high levels of occupational noise exposure, often coupled with a paucity of hearing protection programs. The bulk of the literature in the other major reviews is based on North American and Western European studies where occupational noise levels tend to be lower and hearing protection programs more common.

Difficulties in exposure estimation in industrial studies of noise and cardiovascular functioning are illustrated by one of the most thorough investigations (Talbot et al., 1985). Although these investigators found no significant differences in blood pressure readings that were carefully administered to men from noisy and from quiet manufacturing plants, they also uncovered a clear, consistent positive link between elevated diastolic blood pressure and severe hearing loss in the noisy plant. Moreover, looking at the subset of men who had worked for at least 15 years in the two respective manufacturing plants, occupational noise exposure did significantly relate to both systolic and diastolic blood pressure (Talbot et al., 1990). See Lercher (1996) for an in-depth discussion of noise exposure estimation and health outcomes.

It is also conceivable that subsets of workers may be particularly vulnerable to the chronic effects of noise exposure on their cardiovascular systems. For example, Tarter and Robins (1990) found that male, African American automobile plant

workers suffered increased blood pressure, whereas their Anglo counterparts, who were exposed to comparable levels of high noise at work, did not show this relation. Tarter and Robins speculated that perhaps racial differences in propensity for hypertension might explain these findings. Given the fact that individual differences in noise sensitivity interfere with habituation to acute noise exposure as reviewed earlier, it might be hypothesized that noise sensitivity creates vulnerable subgroups within occupationally noise-exposed groups. This idea has not been tested, although mixed support of such a pattern has been uncovered in community studies of aircraft noise (Neus, Ruddle, & Schulte, 1983; Stansfeld, 1993).

A few longitudinal studies of noise and cardiovascular functioning in industrial settings have been conducted. By comparing the same worker in quiet and noisy periods, some of the weaknesses most endemic to cross-sectional studies (e.g., selection bias) are reduced. The U.S. Raytheon (1975) study, for example, found a significant reduction in medical problems after the implementation of a hearing conservation program in the plant. No changes in similar health indices occurred over the same time period among workers in quiet plant areas. Moreover, the greater the level of compliance observed (e.g., wearing hearing protection), the greater the apparent health benefit. Hypertension and cardiovascular disease were included in the overall health records monitored but could not be singled out because of insufficient sample size. Antonova (1971) compared miners before and after their workshifts in either noisy or quiet areas of the mine. Noise significantly elevated mean arterial pressure with no changes in the quiet group pre and post work. Systolic blood pressure was significantly elevated among brewery workers when they did not wear ear plugs in comparison to days in which they did (Ising & Melchert, 1980). Cortisol fluctuations were also shown to be dependent on the use of earplugs in a similar design (Melamed & Bruhis, 1996).

Another more rigorous approach to studying industrial noise exposure and psychophysiological responses is to simulate occupational noise exposure under experimental conditions with random assignment to noise conditions. Three-hour exposure to jet turbines significantly elevated blood pressure over resting levels among workers in a jet assembly plant (Ortiz, Arguelles, Crespín, Sposari, & Villafane, 1974). Mosskov and Ettema (1977) and Rovekamp (1983) found elevations in blood pressure in 2- to 3-hour noise exposures but at much lower intensities of noise than employed by Ortiz and colleagues. Cartwright and Thompson (1975) found no effects, however, of a 1-hour exposure to loud noise, but Carter and Beh (1989) were able to significantly elevate cardiovascular parameters from 1 hour of exposure, as long as participants simultaneously worked at a difficult task.

This latter finding, along with other experimental findings reviewed earlier on the multiplicative effects of noise and task demands on cardiovascular and neuroendocrine functioning, is interesting to consider in light of a small number of occupational noise studies that have also incorporated additional measures of working conditions. A Russian industrial study reviewed by Welch (1979) found elevated cardiovascular functioning in a noisy manufacturing plant among workers

with higher levels of workload demands. Workers with low workloads did not reveal any cardiovascular correlates of occupational noise exposure. Parallel results were recently uncovered in a longitudinal study (Melamed, Boneh-Kristal, & Froom, 1999). Cottington, Matthews, Talbott, and Kuller (1983) also reported a significant interaction of job stress and noise on diastolic blood pressure. Job stress was associated with higher blood pressure in a noisy manufacturing plant but not a quiet one with good controls for SES and cardiovascular risk. Similarly, Lercher, Hortnagl, and Kofler (1993) found that annoyance with noise at work had a small positive association with diastolic blood pressure. This relation was significantly amplified, however, among workers who also reported job dissatisfaction and low levels of social support on the job. Occupational exposure to noise levels may also interact with shift work. Ottmann, Rutenfranz, Neidhart, and Boucsein (1987) and Cesana et al. (1982) both found elevated catecholamine levels related to noise levels at work but only among workers on rotating shifts. Nonshift workers in noisy work areas did not reveal these associations. Lercher et al. (1993) also found higher levels of blood pressure among workers annoyed by noise who also engaged in shiftwork relative to nonshiftwork employees.

There has been a small number of industrial studies or simulation studies with prolonged noise exposure that have examined neuroendocrine and other biochemical markers of stress rather than cardiovascular functioning. Mixed results have been uncovered with no relation between noise exposure and cholesterol (Brown, Thompson, & Folk, 1975), cortisol (Brandenberger, Follenius, & Tremolieres, 1977; Cavatorta et al., 1987; Slob, Wink, & Radder, 1973), and with one or more catecholamines (Carlestam et al., 1973; J. Osguthorpe, Mills, & N. Osguthorpe, 1983; Paulocci, 1975; Slob et al., 1973). Other studies have uncovered significant, although typically small, associations between noise levels on the job or from simulated exposures and various psychophysiological indicators, such as reduced urine volume and 17-ketosteroid levels (Gibbons, Lewis, & Lord, 1975), elevated fatty acids (Ortiz et al., 1974; Proniewska et al., 1972), higher levels of cholesterol (Cantrell, 1974; Ortiz et al., 1974; Rai, Singh, Upadkay, Patil, & Nayer, 1981), increased epinephrine levels (Cavatorta et al., 1987; Ortiz et al., 1974; Slob et al., 1973), elevated cortisol (Cantrell, 1974; J. Osguthorpe et al., 1983; Rai et al., 1981), and increased levels of ACTH and oxytocin (Fruhstorfer & Hensel, 1980). Although there are more published positive findings, it is important to keep in mind that most of these noise and biochemical studies find small changes, and null results are more difficult to get published. On the other hand, there is also a large animal literature generally consistent with significant biochemical outcomes from acute noise exposure under controlled conditions (B. Welch & A. Welch, 1970).

Increasingly, researchers have turned their attention to community studies of noise and psychophysiological parameters, particularly blood pressure. Traffic noise levels appear to have no relation to blood pressure in community samples (Elwood, Ising, & Babisch, 1993; Lercher & Kofler, 1993; Knipschild & Salle, 1979) or show a small positive associa-

tion (von Eiff, Friedrich, & Neus, 1982; Neus, Ruedel, Schulte, & von Eiff, 1983; Wu, Chiang, Huang, & Chang, 1993). Regecova and Kellcova (1995) found that traffic noise both at home and at school was associated with elevated blood pressure among 3- to 7-year-olds. Interestingly, there were multiplicative effects as well of school and home noise. The Neus study is noteworthy because it is longitudinal. The Wu study bears mention as well since they found that traffic noise elevated young children's blood pressure as a function of hearing status. Congenitally deaf children were unaffected by road noise, whereas their able-hearing counterparts suffered small elevations. Herbold, Hense, and Keil (1974) noted a small positive relation between traffic noise levels and hypertension prevalence among adults and Babisch, Fromme, Beyer, and Ising (1996) found elevated overnight neuroendocrine stress hormones. Simulated exposure to traffic noise under controlled conditions elevates both cardiovascular and neuroendocrine activity as a function of sound intensity (Ising, Dienel, & Markert, 1980; Osada, Ogawa, Hirokawa, & Haruta, 1973). Ising's study is particularly interesting because, as in several of the acute noise exposure studies noted earlier, he found that exposure to simulated traffic noise while working had significant effects on both cardiovascular and neuroendocrine levels, especially when mental loads were higher. In one of the more rigorous tests of ambient noise exposure and cardiovascular health, Peterson, J. S. Augenstein, Tanis, and D. G. Augenstein (1981) were able to produce sustained, elevated arterial blood pressure in monkeys exposed for long periods of time to simulated recordings of aircraft and traffic noise played at typical ambient levels ($Leq = 78$). Their work also showed that these monkeys sustained no hearing damage.

Studies of airport noise, which is typically louder and less predictable than road traffic noise, generally find stronger associations between noise exposure and elevated cardiovascular functioning in comparison to the road traffic noise studies. Most studies have focused on children rather than adults, which might also explain the generally more consistent, positive results than those uncovered in the road traffic noise literature.

Knipschild (1977a) found a dose-response relation between community airport noise exposure and hypertension among adult residents in Amsterdam. Two studies of simulated, military aircraft flights at low altitude have shown significant increases in blood pressure among elderly residents (Michalak, Ising & Rebentisch, 1990) and in catecholamines among middle-aged adults (Maschke, Breinl, Grimm, & Ising, 1992). Several studies have found significant relations between exposure to aircraft noise and elevated blood pressure in children (Cohen, Evans, Krantz, & Stokols, 1980; Cohen et al., 1986; Evans, Hygge & Bullinger, 1995; Ising et al., 1990; Karagodina, Soldatkina, Vinokur, & Klimukhin, 1969; Karsdorf & Klappach, 1968; Schmeck & Poustka, 1993). Several of these studies have very thorough statistical controls for socioeconomic status. One study has found no relation between airport noise levels and blood pressure (Cohen, Evans, Krantz, Stokols, & Kelly, 1981), but these data were explained by selective attrition (persons in noisy areas with

the highest levels of blood pressure left the area). Roche, Chumlea, and Siervogel (1982) found no association between ambient noise exposure in suburban communities with no nearby airports or major highways. This study is flawed because of unreliable blood pressure measurement procedures and use of self-reports for noise exposure estimation.

Evans and colleagues (1995) also investigated reactivity to a noise source, as well as chronic neuroendocrine activity levels as a function of community airport noise exposure. As shown in Table 20.1, they found evidence of elevated catecholamine activity, but no shifts in cortisol among elementary schoolchildren living in the flight path of a major international airport. Of further interest, children chronically exposed to noise appeared less reactive to an acute noise source while reading.

Ising and his colleagues found parallel trends for epinephrine, but not norepinephrine, and also found elevated cortisol in two sets of studies with adults that simulated exposure to night-time aircraft operations (Maschke, Ising, & Arndt, 1995). Of additional interest, in one study they generated a dose-response function between elevated overnight hormonal levels and sound intensity levels. Finally, Evans, Bullinger, and Hygge (1998) replicated their cross-sectional aircraft noise and young children's health findings in a prospective, longitudinal study of children living in the vicinity of the new, Munich international airport.

Immune Function

A large number of animal studies have utilized noise as a stressor to investigate altered immune function. The results, like those of the few human studies are quite mixed (Bly, Goodard, & McLean, 1993). Sieber et al. (1992), for example, found that uncontrollable but not controllable noise significantly decreased natural killer cells among healthy male subjects; Weisse et al. (1990) found the opposite pattern with controllable noise causing lymphocyte resistance to mitogens to drop.

Coping Behaviors

An alternative pathway by which noise and other environmental stressors may impact physical health is the exacerbation of substance abuse. Cigarette smoking and alcohol consumption both increase under stress (Cohen et al., 1986). In the presence of loud noise, nicotine ingestion reduces muscle tension (Hutchinson & Emley, 1973) and accelerates habituation (Friedman, Horvath, & Meares, 1974). In a

particularly interesting study, Cherek (1985) demonstrated a dose-response function between cigarette smoking (objective, experimental measures) and controlled exposures to varying noise levels (60–90 dBA).

Psychological Health

Several different types of studies have examined chronic noise exposure and mental health. The first set of studies explored possible relations between psychiatric admissions and aircraft noise exposure with decidedly mixed results. Several studies have found positive correlations between admission rates and high noise exposure (Abey-Wickrama, A'Brook, Gattioni, & Herridge, 1969; Herridge & Chin, 1972; Jenkins, Tarnopolsky, & Hand, 1981; Meecham & Smith, 1977). Nonsignificant relations have been found by Gattioni and Tarnopolsky (1973), and Jenkins, Tarnopolsky, Hand, and Barker (1979) found an inverse relation between noise levels and psychiatric admissions in the same region (Heathrow, to the West of London) utilized by Abey-Wickrama and by Jenkins et al. (1981). Kryter (1990), in a further analysis of some of Jenkins' data, discovered large ethnic differences that might have explained Jenkins' puzzling findings. Many of these studies have poor controls for social class and all are cross-sectional.

Self-reports of psychological distress were unrelated to road traffic noise levels in two cross-sectional studies (Tarnopolsky & Morton-Williams, 1980; Tarnopolsky, Watkins, & Hand, 1980) and in a prospective, longitudinal study (Stansfeld, 1993). The absence of support for a link between road traffic noise exposure and psychological health could be due, in part, to noise measurement. Halpern (1995) found that peak noise levels predicted several indices of psychological health, controlling for socioeconomic status of residents. Mean levels of traffic noise had no mental health correlates. Physician treatment for psychological problems, as well as use of hypnotic drugs, was associated with aircraft noise around Amsterdam (Knipschild, 1977b). Koszarny et al. (1981) demonstrated a similar relation, but only among women. Knipschild and Oudshoorn (1977) also found a clear relation among prescription rates for tranquilizers and aircraft noise over a 7-year period. Moreover, these authors found longitudinal trends in use of hypnotic pharmaceuticals that tracked changes in noise levels in airport impact zones. At the same time, they noted lower and consistently similar utilization rates among quiet neighborhoods of comparable socioeconomic composition. Grandjean, Graf, Lauber, Meier, and Muller (1976) found a dose-response function linking airport noise exposure to self-reported use of sleeping pills and tranquilizers. Watkins, Tarnopolsky, and Jenkins (1981), however, could not replicate the linkages between drug usage and aircraft noise exposure. One study has also uncovered a coarse dose-response function between occupational noise exposure and psychological symptoms among blue-collar workers (McDonald, 1989). Interestingly, in light of earlier work on crowding, social support and psychological health, Mc Donald also noted that impaired interpersonal relationships at work appeared to play a role in the mental health-noise links.

TABLE 20.1
Twelve-Hour, Overnight Neuroendocrine Measures

Variable	Quiet	Noisy
Epinephrine	368.62 ng/hr	526.36 ng/hr
Norepinephrine	766.22 ng/hr	1,108.82 ng/hr
Cortisol	3.62 ug/hr	3.75 ug/hr

Motivation

Interestingly, the initial study of helplessness and human beings utilized inescapable noise as the induction stimulus. Hiroto (1974) demonstrated that short-term exposure to inescapable noise induces helplessness. Adults were exposed to noise or quiet during an initial phase of an experiment. Half of the noise subjects could avoid the noise by learning an avoidance response. For the other half of the noise subjects, the noise was inescapable. The groups were then tested in a similar situation where noise could easily be avoided by a simple manual response. A second series of experiments replicated Hiroto's findings and also demonstrated that the helplessness induced by inescapable noise generalized to persistence on subsequent task performance (Hiroto & Seligman, 1975). Subjects exposed to inescapable noise exhibited significantly greater helplessness in the second testing phase, regardless of the similarity of the helplessness induction and testing phase (Hiroto & Seligman, 1975). Furthermore, the helplessness effects of inescapable noise were greater for external locus of control individuals (Hiroto, 1974). Krantz, Gikass, and Snyder (1974) found similar results in two studies of inescapable versus escapable noise. One final detail of Hiroto and Seligman's work worthy of note is that the learned helplessness effects of inescapable noise were quite similar to the induction of helplessness produced by exposing subjects to insoluble concept formation problems.

A large number of studies, initiated by Glass and Singer's pioneering work on perceived control and stress (1972) have examined performance aftereffects, immediately following exposure to uncontrollable noise. The basic paradigm includes exposing participants to noise while working on a cognitive task for a period of about 30 minutes. The participant then leaves the room and is asked to do another, apparently unrelated task where noise is no longer present (see Cohen, 1980, for an overview of this paradigm). Uncontrollable noise causes deficits in task persistence on puzzles (Gardner, 1978; Glass & Singer, 1972; Glass, Singer, and Friedman, 1969; Percival & Loeb, 1980; Sherrod, Hage, Halpern, & Moore, 1977; Wohlwill, Nasar, DeJoy, & Foruzani, 1976). Work by Glass and Singer (1972) also showed that the controllability, and to a lesser extent the predictability, of the noise is a critical component of these aftereffects. In a test of the external validity of the initial Glass and Singer findings, Moran and Loeb (1977) utilized tape-recorded aircraft noise and found, unexpectedly, that such noise did not appear to induce aftereffects in the laboratory. Percival and Loeb (1980) reasoned that perhaps airport noise, because of its temporal qualities, is rather predictable. Thus, they replicated the original Moran and Loeb finding utilizing the same stimuli, but of particular interest, found that when the aircraft noise bursts were sudden rather than the typical slow onset pattern of an approaching aircraft, negative aftereffects could be reliably produced. Rotton, Olszewski, Charleton, and Soler (1978) also showed that meaningful speech rather than noise could induce the same negative aftereffect. Evans et al. (1996) indicated that these negative aftereffects are amplified if exposure to uncontrollable noise occurs among subjects already under psychological stress. Finally,

Glass and Singer (1972) found that uncontrollable noise interferes with subsequent proofreading accuracy.

A small number of studies has also examined possible relations between chronic noise exposure and susceptibility to helplessness. Evans et al. (1995) adapted the Glass and Singer aftereffects puzzle for young children. They found that children living in high airport noise zones were less likely to persist at solving line tracing puzzles than their quiet community counterparts. Cohen and colleagues (Cohen et al., 1980, 1981) found that aircraft noise-exposed children were significantly less likely to solve a difficult, challenging puzzle than quiet comparison groups. Of particular interest, noise-impacted children were also more likely to simply give up on the puzzle before the allotted 4 minutes had passed. Fifteen percent of children from noisy schools failed the puzzle by giving up in comparison to only 2% of children from quiet schools. It is worth noting that the puzzles were designed and pretested to be fun and engaging to elementary-aged schoolchildren. These effects were replicated by Cohen and colleagues and similar trends were also found for home noise levels (Cohen et al., 1986). Both the Evans and Cohen studies had well-matched SES comparison groups. Moch-Sibony (1984) found very similar results in kindergarten children exposed to higher levels of aircraft noise in Paris. Wachs (1987) also showed that infants exposed to more noise at home manifest less mastery-oriented play as indexed by a standardized observation instrument. Of additional interest, teachers in noisy schools frequently report more difficulties motivating students than do teachers from quiet schools (see Evans & Lepore, 1973b, for a review). Finally, Cohen et al. (1986) uncovered a relation between children's willingness to relinquish choice and chronic noise exposure. Children from noisy schools relative to quiet schools were significantly more likely to allow an experimenter to choose a reward at the conclusion of their experiments rather than make their own choice.

Summary

Both industrial and community studies find no clear, consistent pattern of data on noise and morbidity. Similarly, data on acute noise exposure and altered immune functions are mixed. Although not plentiful, there is a confluence of findings suggestive of noise impacts on in utero development that warrant followup. Several studies point to noise as a factor in elevated smoking.

Acute noise produces short-lived elevations in cardiovascular and neuroendocrine functioning. Recent research suggests, however, that individuals sensitive to noise as well as situations with high workload demands can diminish and perhaps even block such habituation. A plethora of methodologically weak, occupational noise and health studies reveal decidedly mixed findings on noise and blood pressure. Some longitudinal studies indicate small, positive associations between occupational noise exposure and blood pressure elevations. Road traffic noise appears to have no significant impact on blood pressure of community residents, but persons living in the proximity of airports, particularly children, are at risk

for elevated blood pressure. The clinical significance of these elevations is unknown at this time.

Data on noise and psychological health are unclear. The preponderance of poorly designed studies links community noise levels to rates of psychiatric illness. There are better studies indicating some link between community noise exposure and utilization of pharmaceutical hypnotics. Both laboratory and field studies reveal that noise, particularly uncontrollable noise, can contribute to diminished motivation related to learned helplessness. Children chronically exposed to noise may be particularly susceptible to this phenomenon.

DISCUSSION

Application of the construct of psychological stress to examine the role of the physical environment in human health has proven useful in the case of crowding and noise. The primary contributions to date have been the identification of stress-related outcome measures likely to be related to environmental stressors and the preliminary development of a conceptual model for thinking about how and under what conditions noise, crowding, and other environmental stressors might adversely impact human well-being.

Conceptual Issues

A central deficiency has been an inattention to the role of underlying psychophysiological processes or social resources in the environmental stressor–disease link. In searching for answers to the question, why does crowding or noise cause disease?, there are very little data that has tested mechanisms like elevated cardiovascular functioning or diminished self-efficacy. What the data generally show, as depicted in Fig. 20.2, is a broad set of outcome measures independently assessed.

More studies are needed that simultaneously investigate physical or psychological health outcomes and one or more underlying processes in the same sample of individuals. For example, Evans and Lepore (Evans et al., 1989; Evans & Lepore, 1993a; Lepore et al., 1991) showed evidence for the model shown in Fig. 20.3—namely, that high residential density causes deterioration in social support resources, which in turn accounts for the linkage between density and psychological ill health.

There are an unbelievably large number of studies of noise and cardiovascular functioning (principally blood pressure) that have not also looked at some disease endpoint. Similarly, no studies have examined crowding, immune function, and physical morbidity.

Several psychophysiological mechanisms are prime candidates for more in-depth scrutiny as intervening processes that could link environmental conditions to ill health. Alterations in neuroendocrine functioning affect cardiovascular activity, primarily via adrenomedullary action as well as alter immune functioning via adrenocortical pathways (Baum & Grunberg, 1995).

Cardiovascular reactivity is another process warranting analysis. Two viable, competing hypotheses exist. Sustained, chronic exposure to uncontrollable, environmental stressors

like crowding or noise may deplete the organism's ability to respond adequately to challenge with cardiovascular mobilization (Dienstbier, 1989). Alternatively, heightened sensitivity and vigilance from chronic stressor exposure might exacerbate reactivity (Krantz & Manuck, 1984).

Learned helplessness and other motivational processes related to chronic environmental stressor exposure have not been adequately developed. It seems clear that one of the potentially most injurious aspects of chronic environmental stressors is their intractability. Several aspects of motivation and chronic environmental stress warrant additional research. The role of attributional processes, which is well documented in the helplessness literature, has not been applied to environmental stress research. It is clear that attributional processes are salient to environmental stressors like noise and crowding. Noise annoyance is strongly affected by attributions about the origins of noise stimuli, as well as their perceived health impacts (Koelega, 1987). Feelings of arousal induced by personal space invasions (Worchel & Teddlie, 1976), expectancies (Schmidt & Keating, 1979), or informational cues (Langer & Saegert, 1977; Paulus & Matthews, 1980) can all be attributed to crowding or other environmental conditions with varying consequences. The potential interplay among environmental stressors and uncontrollability, helplessness, and negative health outcomes (such as depression) is an area ripe for further study. Motivation or effort to maintain task performance or productivity under suboptimal conditions may be a salient factor, as well, in determining the long-term health consequences of chronic exposure to adverse environmental conditions. Several noise studies both in the laboratory and the field, as well as one crowding study indicate that task performance can be sustained under adverse conditions but at a "cost" of psychophysiological activation. The long-term health consequences of people expending additional effort to do their job when the environment is not optimal is an important and unresearched topic.

Studies of underlying psychosocial processes, such as social support or control, also raise provocative conceptual issues about environment, stress, and coping. Social support and control have each traditionally been conceptualized as exogenous factors that moderate stressor–outcome relations. As can be seen herein, however, chronic exposure to crowding or to noise directly effects social support and control processes, respectively. These psychosocial processes mediate rather than moderate the impacts of these chronic environmental demands. Other chronic stressors may have similar effects on coping resources.

In considering hypothetical mechanisms, it is also prudent to carefully scrutinize the traditional practice of statistically controlling risk factors in environmental epidemiology. For example, several noise and coronary heart disease investigations control for smoking levels. However, what if noise exposure increases smoking as a coping device, as suggested by some studies already reviewed? By statistically partialling out a "risk" factor, a psychologically relevant process that may underlie the noise–health link has been eliminated.

At a more abstract level, the construct validity implications of statistical controls or the practice of random assign-

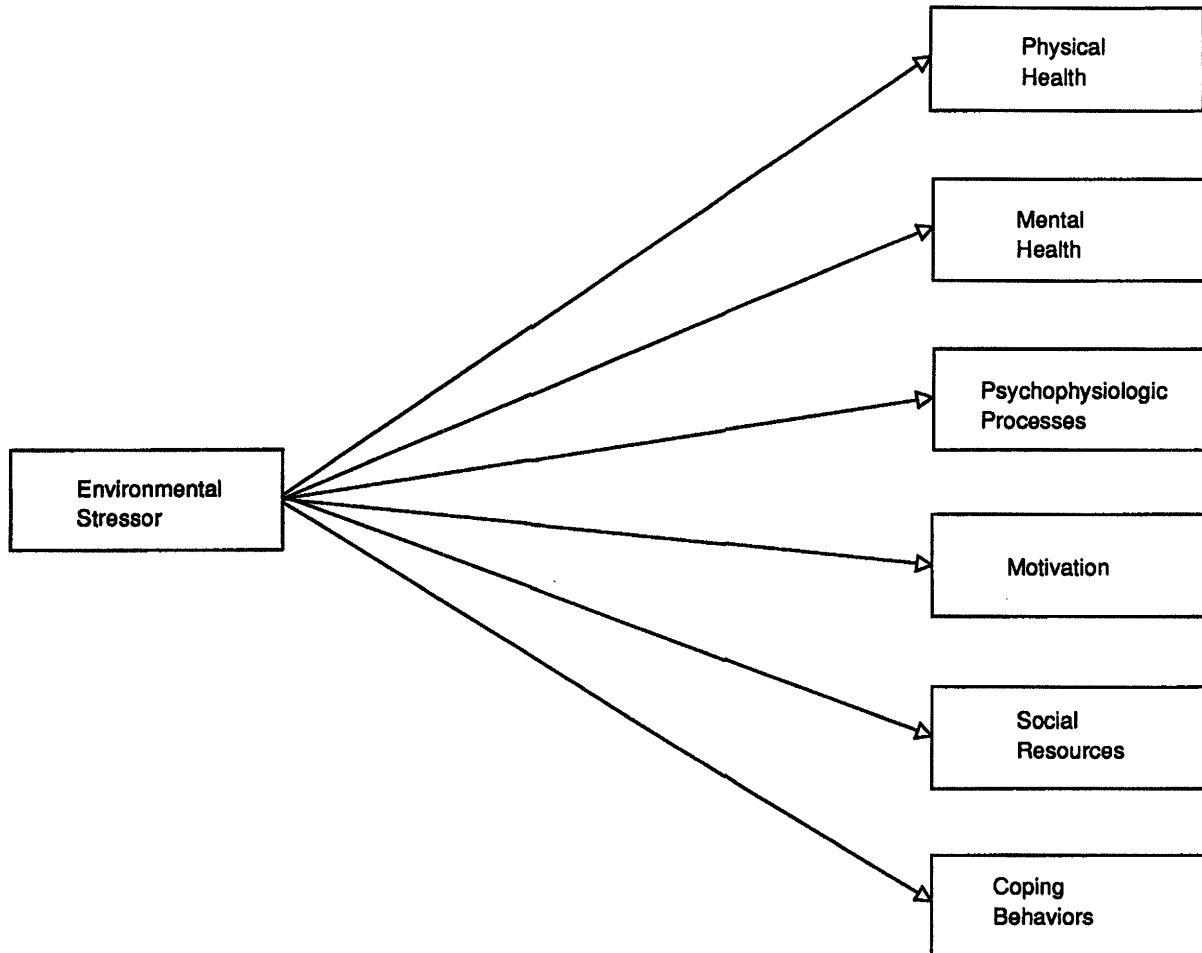

FIG. 20.2

FIG. 20.3

ment in experimental studies of stress and health should be carefully considered. By removing environmental stressors from their natural context (i.e., poverty, other suboptimal environmental factors) for the purposes of study, ecological validity of the stressor–health relation may be distorted. Perhaps crowding and poverty together or noise and certain job requirements together, respectively, lead to pathology. By isolating one independent variable either through statistical or experimental design means for purposes of causal modeling, the actual incidence of adverse outcomes from suboptimal en-

vironmental conditions may be dramatically underestimated (Lepore & Evans, 1996).

It might also be valuable to conceptualize the physical environment not only as a source of stress but also as a source of coping resources (Becker, 1990). Research on coping, like stress, tends to overly focus on intrapsychic mechanisms, missing the potential role of the social and physical environment to promote or interfere with health. For example, research on crowding suggests that floorplan layouts that incorporate greater intervening, hierarchically arranged

spaces, buffer the negative effects of residential crowding on psychological distress (Evans, Lepore, & Schroeder, 1996). Similarly, children in crowded homes who have a place where they can spend some time by themselves appear to suffer fewer negative outcomes (Wachs & Gruen, 1982).

Although children exposed to multiple risk factors are more likely to suffer adverse physical and mental health outcomes, some children are more resilient than others (Rutter, 1987). Bradley and colleagues (1994) found that low residential density was a significant, independent, protective factor among poor, low birth weight babies tested 1 and 3 years later on a wide array of physical and psychological health measures.

Methodological Issues

In addition to some of the conceptual issues associated with statistically controlling for risk factors, statistical approaches that partial out variables in order to "control" for possible confounding effects are also fraught with analytic problems. Statistical models that partial or covary out variables are based on the assumption of no interaction between the independent variable and the potential control variable on the outcome. Controlling for social class, for example, presupposes that noise or crowding do not interact with social class to affect health or well-being. The same statistical problem may occur with controls for certain risk factors, such as family history of coronary heart disease, hypertension status, or age, to name some common examples. Utilization of analysis of covariance or its regression equivalents assumes that the slopes of the respective regression lines between the outcome variable and the independent variable and the covariate (partial b) are parallel (i.e., no statistical interaction). Researchers should not employ covariance or analogous regression procedures to control for risk factors or contextual factors, such as socioeconomic status, without first assessing this basic statistical assumption.

Another analytic issue concerns effect size considerations. When the correlation coefficient between noise exposure and blood pressure, for example, is squared, not a lot of variance is explained. But this is also true if the same is done for cigarette smoking and lung cancer. It is also true that the variance explained in mental health by crowding is on the same order of magnitude as the variance explained by income (Evans et al., 1998; Gove & Hughes, 1983). Critics of the apparently small role of the physical environment in health need to grapple with this issue more in comparative, rather than in absolute, terms.

There is critical need for prospective, longitudinal designs in the field. There is only one crowding study incorporating such a design (Lepore et al., 1991) and just a handful of industrial studies of noise and health that incorporate a longitudinal component. Self-selection into noisy or crowded environments, as well as possible spuriousness, loom as major threats to internal validity in most of the field studies reviewed herein. Too many cross-sectional field studies exist. Furthermore, not enough integrated research programs have examined the same environmental stressor and health in the lab and in the field. The value of integrating lab and field work is illustrated by Cohen and colleagues' work on aircraft noise and

children where laboratory-based concepts and measures were brought to bear on the study of chronic, community noise exposure (Cohen et al., 1986).

Caution is needed in generalizing from aggregate level, epidemiological studies to individual health responses to the physical environment. Several examples of this ecological fallacy were previously reviewed, particularly in crowding field studies, where people per room as indexed by census tract did not yield the same pattern of results as when individual health measures were assessed. Parallel trends were noted in the noise and health literature (Lercher, 1996). One reason aggregate-level comparisons can be misleading is related to exposure estimation. Large degrees of variance in exposure are truncated into a single estimate of exposure when aggregate level data are examined. Furthermore, the actual environment as experienced is even further removed from the exposure metric in comparison to individual residential or work environment assessments.

The problems of exposure estimation and adequate representation of physical stressors in studies are common in the environmental stress literature. Many studies have only gross estimates of actual exposure to the physical stressor. Crowding and noise are typically estimated indirectly and do not account for individual movement throughout the day across settings. One indication of the importance of this issue is found in the noise literature where several studies on industrial noise show that duration of exposure is a critical variable. Similarly, utilization of hearing protection affects noises and health findings in industrial settings. Residential room location can also impact noise exposure (Lercher, 1996). An interesting example of the importance of exposure estimation comes from a recent study by Maxwell (1996) of crowding in preschoolchildren. Children in more crowded day-care centers had greater behavioral and emotional problems only if they also lived in crowded homes.

Moreover, the range of environmental variables in many studies is often truncated and/or the distribution of environmental exposures is badly skewed. Both of these problems strain the general linear model that forms the underlying statistical basis employed in most studies of the physical environment, stress, and health. For example, many studies of crowding have hardly any people in homes with more than 1.5 persons per room. Most laboratory studies expose people to quiet or noise and several community noise studies transform continuous data into a noise/quiet dichotomy. Badly skewed data, as well as use of dichotomous categories, reduce statistical power.

Furthermore, there is some indication of threshold effects for noise and crowding health effects. Recall for example some recent evidence that traffic noise above 65 dBA Leq appears necessary before cardiovascular risk elevates. This nonlinearity also adversely affects statistical power. Studies of traffic congestion and health outcomes indicate that log transformations (Halpern, 1995), or use of indices such as percentage of time at high congestion levels (Evans & Carrere, 1991), predict outcomes significantly better than do mean levels of exposure. This nonlinearity can also appear at the opposite end of the environmental exposure spectrum. Living alone is associ-

ated with psychological impairment as well as low social support (Gabe & Williams, 1987; Galle et al., 1972). Crowding studies that calculate persons per room as the density metric that include people living alone distort the estimate of association between crowding and health outcomes.

Outcome measures are also wanting. Several studies of psychological health employed one item or scales of unknown psychometric properties. Studies of health sorely need standardized, sensitive indicators. Immune function would be a particularly valuable adjunct to environmental morbidity studies. Several studies of blood pressure incorporated one or two readings, often taken in a medical setting. Such data are unreliable and of questionable validity.

Health psychology has demonstrated that individual, biological, and personological characteristics are central to understanding health and disease. A smaller body of work within health psychology has also examined the potential role of sociocultural factors in human health. Hopefully, this chapter has directed attention to the potential direct, indirect, and interactive roles the physical environment can play in health and human behavior.

ACKNOWLEDGMENTS

Preparation of this chapter was partially supported by grants from the National Institutes of Health (1 RO1 HL47325-01) the National Science Foundation (BNS-8920483) and the U.S. Department of Agriculture (Hatch-NY 327407). I am grateful to Jana Cooperman and Tamir Ebbin for bibliographic assistance. I thank Steve Lepore, Paul Paulus, and Shirley Thompson for critical feedback on earlier drafts.

Adjustment to Chronic Illness: Theory and Research

Annette L. Stanton
Charlotte A. Collins
Lisa A. Sworowski
University of Kansas

There are only two health outcomes that are of importance. First, there is life expectancy. Second, there is function or quality of life during the years that people are alive .
—Kaplan (1990, p. 1218)

Most people confront chronic disease, if not in themselves then in those they love. Indeed, more than 50% of deaths in the United States are attributable to cardiovascular disease and malignant neoplasms alone. In addition to their interest in decreasing mortality, health psychologists are dedicated to aiding those who live with chronic disease maintain fulfilling lives. Health psychologists and others have devoted intense energy to identifying psychosocial and behavioral contributors to and consequences of chronic disease. This chapter provides an analysis of current knowledge regarding psychological adjustment to chronic conditions.

Researchers have conducted hundreds of empirical studies to enhance understanding of adaptation to chronic illness. The present literature review focused on pertinent studies of adults with cancer, cardiovascular disease, diabetes, rheumatic diseases (particularly rheumatoid arthritis), and acquired immune deficiency syndrome (AIDS), which are conditions that comprise significant causes of mortality and morbidity and have received substantial empirical attention by researchers in health psychology and related fields. The aim is not to review this voluminous literature in detail. Rather, the focus is on crosscutting issues in the conceptualization of adjustment to these conditions, as well as extant theories and empirical findings regarding determinants of ad-

justment to chronic illness. Further, the discussion concentrates on individual adult adjustment, and the reader is referred to relevant literatures on adjustment to chronic disease in children (e.g., Roberts, 1995), intimate partners (e.g., Revenson, 1994), and families (e.g., Kerns, 1995).

CONCEPTUALIZING ADJUSTMENT TO CHRONIC DISEASE

Sometimes when I wake up in the morning, I forget for a moment that I have cancer. Then it hits me like a ton of bricks and I think, "Will I live to see my little girl graduate from college?" Who wouldn't have these fears?

The doctor brought the psychologist with him when I got my diagnosis. He thought I would fall apart at my third diagnosis of cancer. I figure I'll get rid of it and go on, just like I've done the last two times.

So much positive has come from my experience with cancer. But I've also never been so scared or angry or sad in my life.

I have cancer but it doesn't have me.

These reflections from individuals with cancer¹ represent a sampling of the array of reactions that accompany a diagnosis of chronic disease. These individuals viewed themselves as adjusting well to their disease. What constitutes positive adjustment to chronic illness? Researchers have advanced various conceptualizations of adaptive functioning or health-related quality of life (QOL). Although many researchers explicitly outline their framework for conceptualizing positive functioning, others' definitions are implicit, revealed by their choice of outcome measures in their studies of adjustment to chronic disease. The literature reveals at least five conceptualizations of positive adjustment: successful performance of various adaptive tasks that accompany chronic disease, absence of psychological disorder, relatively low experience of negative affect and/or high experience of positive affect, behavioral/functional status, and appraisals of satisfaction or well-being in various life domains.

Some theorists have defined adaptive tasks in chronic illness, the mastery of which signals successful adjustment. For example, Moos and Schaefer (1984) outlined the illness-related tasks of managing pain and other symptoms, dealing with the hospital environment and treatment, and preserving adequate relationships with medical personnel. More general tasks involve sustaining a "reasonable emotional balance" (p. 10), a sound self-image, and relationships with close others, while preparing for an uncertain future. Taylor (1983), in her theory of cognitive adaptation to threatening events, provided evidence from her study of breast cancer patients that successful adjustment requires adequate resolution of a search for meaning, the ability to retain mastery over one's life, and enhancement of self-esteem. N. M. Clark et al. (1991) suggested that successful self-management of chronic disease requires sufficient knowledge about the disease and its treatment to make informed decisions about health care, the performance of activities to manage the disease, and the application of skills to preserve adequate psychosocial functioning. Relatedly, many researchers focus on the individual's experience of disease- and treatment-related symptoms as indicative of adjustment. For example, the experience of greater fatigue, pain, or nausea compared with others undergoing similar treatments would reflect less positive adjustment.

Researchers also have been interested in documenting the prevalence of psychological disorders (e.g., Cordova et al., 1995; Derogatis et al., 1983; Rosenberger et al., 1993), particularly adjustment disorders, depression, and anxiety disorders in individuals with chronic illness. In these conceptualizations, the relative absence of symptoms is taken as an indicator of good adjustment. It also should be noted that assessment of some relevant symptoms of psychological disorder is complicated by their overlap with symptoms of the chronic disease or its treatment (e.g., D. A. Clark, Cook, & Snow, 1998). For example, fatigue is both a symptom of depression and a common side effect of treatments for cancer; several other somatic symptoms of psychological disorder also are concomitants of chronic disease.

The literature also reveals a focus on affective experience as central to adjustment. Maintenance of relatively low levels of negative affect and, in some studies, high levels of positive affect defines optimal adjustment in these studies. Both general (e.g., state anxiety, global distress) and disease-specific (e.g., fear of cancer recurrence) measures are used. Reviewing the literature on coping with rheumatoid arthritis, Zautra and Manne (1992) found that most studies relied on the absence of negative affect to indicate adequate adjustment. This finding is consistent with the adjustment literature across several chronic diseases.

Functional status and role-related behaviors also can indicate adjustment. Return to work has been used as an adjustment index in many studies of those undergoing cardiac events, for example. Other examples of functional status include mobility, completion of physical rehabilitation, and ability to adhere to medical treatment regimens.

Many researchers view the individual's appraisals of satisfaction in various life domains as the crux of positive adjustment. Some are interested in overall appraisals of life satisfaction, whereas others focus on satisfaction in specific domains. Both general and disease-specific conceptualizations are evident. Often examined are satisfaction or well-being in physical, functional, emotional, and social domains (e.g., Lutgendorf, Antoni, Schneiderman, Ironson, & Fletcher, 1995; Nayfield, Ganz, Moynour, Cella, & Hailey, 1992).

Several points emerge from the examination of the array of conceptualizations of adjustment to chronic illness. First, adjustment to chronic illness is multidimensional, including both intra- and interpersonal dimensions. Within these realms, intraindividual adjustment comprises cognitive (e.g., intrusive thoughts, self-evaluations), emotional (e.g., depression, anxiety), behavioral (e.g., return to work), and physical (e.g., symptom reports) functioning. Interpersonal adjustment often is relevant with regard to both personal relationships (e.g., family, friends) and relationships with health care providers. Further, the dimensions are interrelated. For example, negative emotional reactions (e.g., anxiety) can contribute to functional status (e.g., poor glycemic control) in individuals with diabetes (Lustman, 1988).

Second, consensus exists regarding the centrality of individuals' appraisal of their adjustment. Although other sources of information (e.g., physician report, work functioning) are valuable, they cannot substitute for the individual's own perception of QOL. A complicating factor for researchers in this area is the potential for response shift in individuals' QOL perceptions (e.g., Sprangers, 1996). That is, patients' internalized standards of measurement for QOL may change as they undergo treatment or compare themselves to others who are similarly diagnosed. For example, rather than gauging QOL against premorbid functioning, individuals may shift their standard, concluding, "I'm doing well for someone going through chemotherapy, especially compared to that man in clinic yesterday."

Third, although psychological and physical dysfunctions are central adaptive outcomes, it is important to note that positive adjustment is not simply the absence of pathology. Positive and negative affect, often used as indicators of adjustment

¹All quotes from individuals with cancer in the chapter are from the first author's research program.

to chronic disease, represent two fairly independent dimensions (e.g., Diener & Larsen, 1993). Thus, using only depressive symptoms to indicate QOL will yield only a partial picture of adjustment. A disease that robs life of some of its joys will not necessarily foster intensely negative emotions. In addition to experiencing positive affect, finding positive meaning in the disease experience or attaining personal or spiritual growth also comprise important adaptive outcomes. Further, contributors to positive functioning may not be identical to determinants of negative experience.

Fourth, it is important to consider not only the valences of adjustment dimensions, but also their duration and interference with one's functioning and goal pursuits. Individuals' acute feelings of anxiety and loss on learning that they have a chronic disease may not compromise adjustment, for example, unless these feelings interfere markedly with the ability to make important treatment decisions or they persist long after diagnosis.

Clearly, adjustment to chronic disease is a complex phenomenon. It is recommended that researchers carefully consider their assumptions with regard to what constitutes positive adjustment, tailor their assessments to the theoretical question of interest, recognize that any particular assessment is likely to provide only a snapshot of circumscribed dimensions of functioning, and limit their conclusions regarding adjustment accordingly. Only through accrual of research tapping multiple dimensions of adjustment can a comprehensive portrait of adaptation to chronic disease be achieved.

EMPIRICAL STUDIES OF ADJUSTMENT

How do people with chronic disease fare with regard to psychological adjustment? Both in the psychological and medical literatures, a plethora of studies and reviews address this question. Indeed, Wood-Dauphinee (1996), citing a MEDLINE search of surgical studies from 1989 to 1995, found that abstracts containing the words "quality of life" and reporting standardized measures had increased from 27.4% in 1989 to 1990 to 48.3% in 1993 to 1995. Here, the discussion relies on empirical and meta-analytic reviews of studies addressing adjustment for the five chronic diseases targeted in this chapter, as well as single studies that describe adjustment across patients with different conditions.

van't Spijker, Trijsburg, and Duivenvoorden (1997) conducted a meta-analytic review of 58 studies performed from 1980 to 1994 of psychological sequelae of cancer diagnosis. Focusing on studies that included validated instruments, the authors found that from 0% to 46% of patients qualified for depressive disorder and from .9% to 49% qualified for anxiety disorder across the various studies. Compared to published reference norms for the general population, cancer patients were significantly more depressed (although the effect size was not significant for samples in studies published after 1987), but not significantly more anxious or globally distressed. People with cancer were significantly less distressed, depressed, and anxious than were reference psychiatric patients, and they were less anxious than other medical patient groups.

Several other reviewers of the adjustment literature also conclude that those with chronic illness in general maintain adequate psychological functioning, although a significant minority of patients may be at risk for persistent decrement in function in specific domains. For example, Katz, Rodin, and Devins (1995) reviewed studies of self-esteem in cancer patients. No differences emerged between cancer patients and controls on global self-esteem, but body esteem was impaired in cancer patients who had disfiguring surgery (e.g., head and neck cancer). Reviewing the research on adjustment to coronary events, Ell and Dunkel-Schetter (1994) suggested that the majority of myocardial infarction patients evidence no long-term psychological impairment, although approximately one third may demonstrate long-term impairment in overall psychosocial functioning and quality of life, and a minority experience persistent depressive symptoms. Cox and Gonder-Frederick (1992), in their review of behavioral diabetes research, drew similar conclusions. They suggested that both children and adults diagnosed with diabetes report psychological disturbance following diagnosis, but that adjustment returns to premorbid levels after approximately a year. However, they also reported studies revealing higher rates of psychological disorder (particularly depression and anxiety) in diabetic patients than in the general population. In her review, DeVellis (1995) found that depressive symptoms appear more prevalent in those with rheumatic disease than in people with no chronic illness, although most individuals with rheumatic conditions do not report significant depressive symptoms. Reviewing studies on the psychological impact of HIV/AIDS, Chesney and Folkman (1994) reported an apparent decrease in documented adverse psychological responses to HIV/AIDS over the time the virus has been studied, perhaps owing to advances in medical treatment, counseling interventions, and public awareness. However, they found that disease progression has an important impact on psychological response, with asymptomatic individuals evidencing no clear elevation in anxiety and depressive symptoms, and symptomatic or AIDS-diagnosed individuals evidencing more pronounced distress. Furthermore, women with HIV may experience more depressive symptoms than men with HIV (Ickovics et al., 1999).

Several studies have examined individuals' adjustment across multiple chronic conditions. For example, Cassileth et al. (1984) examined 758 patients with arthritis, diabetes, cancer, renal disease, dermatologic disorders, or depression versus the general public on the Mental Health Index. Psychological status was comparable across patients with different physical diseases and between patients and the comparison group. Patients with chronic disease had more favorable psychological status than did depressed outpatients. Stewart et al. (1989) assessed 9,385 adults at physician office visits in three U.S. cities. Fifty-four percent had at least one of nine chronic conditions (i.e., hypertension, myocardial infarction, congestive heart failure, angina, arthritis, chronic lung problems, back problems, gastrointestinal complaints, diabetes). For eight of nine conditions, patients demonstrated lower functioning in physical, social, and role-related domains, as well as mental health, health perceptions, and bodily pain, compared with those with no chronic disease. However, mental health was the domain least

affected by chronic condition, and the majority of variance in functioning and well-being was not explained by the presence of these chronic conditions.

Two broad conclusions extend from the descriptive literature on adjustment to chronic illness. First, most individuals appear to adjust well to chronic illness, often resulting in psychological adjustment indicators comparable to or slightly below general population norms and more positive than individuals who carry psychological diagnoses. Given that chronic illness presents numerous potential stressors, how can we account for this apparent positive psychological adaptation? Several explanations are possible. Perhaps most individuals are able to muster sufficient internal and external resources in the face of chronic illness to maintain high QOL. These contributors to adjustment are discussed in a subsequent section. Another compatible possibility is that chronic diseases carry the potential for positive as well as negative consequences and that people's ability to extract positive meanings from their disease experience balances any negative consequences. For example, Folkman, Moskowitz, Ozer, and Park (1997), in a study of HIV+ and HIV- caregiving partners of men with AIDS, found that although study participants reported high levels of depressive symptoms, they also evinced positive morale and positive states of mind comparable to general population norms, and they reported experiencing positive meaningful events. A third possibility is that, as mentioned previously, individuals shift their comparison standards as they adapt to disease, so that they evaluate their own adjustment vis à vis their status as a person with arthritis rather than as a healthy person, and they compare themselves to others with arthritis rather than healthy others. Thus, owing to pervasive human tendencies toward positive self-evaluation (e.g., Taylor & Brown, 1988) and toward comparing themselves favorably to others who are under similar threats (e.g., Stanton, Danoff-Burg, Cameron, Snider, & Kirk, 1999; Taylor & Lobel, 1989), they are likely to evaluate themselves as doing very well for "an arthritis patient." Another potential explanation for the apparently positive adjustment to chronic illness is that, rather than potentiating global maladjustment, chronic disease carries more circumscribed impact for most people. For example, Andersen (e.g., B. L. Andersen, B. Anderson, & deProse, 1989a, 1989b; B. L. Andersen, Woods, & Copeland, 1997), in her studies of women with cancer, observed that experience with cancer is more likely to produce "islands" of life disruption in specific realms and at specific points in the disease trajectory than to confer substantial risk for global dysfunction. If only global adjustment is assessed, researchers may miss meaningful points of impact of the disease on psychosocial function.

A second conclusion is that considerable variability is apparent in psychological adjustment, both across studies and across individuals within single studies. Across-study variability is not surprising, given that researchers have used a wide range of measures with samples that vary considerably in demographic attributes and points in the disease trajectory. Moreover, individual variability in reaction to chronic illness certainly is to be expected, given that any particular disease represents multiple stressors (e.g., pain, threat to life, ambig-

ity regarding the future, appearance and functional changes, interpersonal challenges, financial strain), each of which may or may not be pertinent to a specific individual. Such stressors will carry differential relevance, depending on such factors as the individual's goal structure, psychological and contextual resources, and specific coping strategies. For example, individuals whose experience with serious disease saps already scarce environmental and personal resources may be at substantial risk for pronounced life disruption and distress. The next section presents a theoretical and empirical analysis of such factors that may support or hinder individuals as they face chronic illness and thus render them differentially vulnerable to adjustment difficulties.

THEORETICAL PERSPECTIVES ON CONTRIBUTORS TO ADJUSTMENT TO CHRONIC ILLNESS

Many theories of adjustment to chronic illness derive from more general conceptual frameworks regarding adjustment to stressful or traumatic experiences. One of the most prominent among these general theories is that of Lazarus and colleagues (e.g., Lazarus & Folkman, 1984). According to Lazarus, central determinants of adaptive outcomes include personal resources, attributes of the situation, cognitive appraisals, and coping strategies. Although Lazarus and Folkman (1984) discussed preexisting resources and situational attributes, they were more interested in processes initiated by the individual that unfold over the course of the stressful encounter. These include individuals' cognitive appraisals of the potential for harm (i.e., threat appraisal) and benefit (i.e., challenge appraisals) arising from the encounter (i.e., primary appraisals), as well as appraisals of their ability to control or manage the situation's demands (i.e., secondary appraisal). The process of appraisal catalyzes the initiation of coping strategies, which are "cognitive and behavioral efforts to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person" (p. 141). According to Lazarus and Folkman (1984), these cognitive appraisals and coping strategies engaged in response to a stressor substantially determine adaptive outcomes in emotional, social, and somatic realms. Similarly, Moos and colleagues (e.g., Moos & Schaefer, 1993) included in their conceptual model of stress and coping the influences of the environmental system (e.g., life stressors, social resources), the personal system (e.g., demographic and personal attributes), life crises and transitions (i.e., event-related factors), and cognitive appraisals and coping processes on each other and on health and well-being.

Specific theories on adjustment to chronic illness expand on such general conceptual frames. An example is the model of Maes, Leventhal, and de Ridder (1996). They expanded on the Lazarus and Folkman (1984) theory by emphasizing the potentially important roles of contextual factors (e.g., other life events, demographic attributes, cultural and social environment), characteristics of the specific disease situation (e.g., asthma in general versus a specific asthmatic attack), and associated disease representations (e.g. appraisals of the

identity, controllability, duration, causes, and consequences of the disease and symptoms; Leventhal & Nerenz, 1983) in determining coping and adaptation.

As have other theorists, Maes et al. also focused on the influence of individuals' life goals on disease representations and coping processes. The more individuals' central goals in life are threatened by the disease, the more stressful the situation, and the more their appraisals, coping processes, and internal and external resources are challenged. Perceived goal blockage is likely to engender distress and an attempt to cope. In his cognitive-motivational-relational theory of emotion, Lazarus (1991a) revised the conceptualization of primary appraisal to include dimensions of goal relevance, goal congruence, and type of ego involvement. As one woman with advanced cancer stated, "Every time there's a big shift in what I can do, like when I couldn't drive anymore, I get really upset for awhile. I usually try to write out my anger and sadness. Then I eventually start to focus on what I can still do and who I still am, and I'm okay until the next slide and plateau." Thus, coping can be conceived as a goal-directed process. As Lazarus stated (1991a):

The connection between coping and intentions or goals has not been of interest to those working on the coping process. Yet how the person copes depends not only on the coping possibilities and how they are appraised but also on what a person wants to accomplish in the encounter. Moreover, new agendas arise from the ongoing flow of events in the adaptational encounter. More than one goal is apt to be involved in each encounter, and these are apt to change in primacy and salience. (p. 115)

Coping processes can be understood as lower order goals (e.g., express emotions about having cancer) that serve as a path to achieving higher order goals (e.g., maintain emotional balance, live a fulfilling life) (Lazarus, 1991b).

Also relevant with regard to the importance of goals in coping and adaptation is the self-regulation theory of Carver and Scheier (e.g., 1981, 1990, 1998), which they have applied to coping with illness (Scheier & Bridges, 1995). In their view, "illness represents one general and significant class of events that can interfere with the pursuit of life's activities and goals, both those that are health related and those that are not. ... [Illness] can interfere, to a lesser or greater extent, with the general set of plans and activities that give a person's life its form and meaning" (Scheier & Bridges, 1995, pp. 261–262). To the extent that an individual expects to continue successful goal pursuit in the face of having a chronic disease, then initiation of approach-oriented coping strategies are likely. However, if a person expects unremitting goal blockage, then disengagement may ensue. For example, assume that maintaining close family ties is an important goal for Dionne, who has AIDS. If Dionne expects that goal attainment is possible, she is likely to seek support actively from family members, in the best case resulting in the receipt of such aid and consequent feelings of security and caring. However, if she believes that her family sees AIDS as a shameful condition, Dionne may avoid interactions with family or she may not disclose her sta-

tus to them, leaving her feeling isolated and depressed. Of course, another possibility is that Dionne may shift her goals, such that she focuses more on maintaining close relationships in general than on family ties specifically. This example illustrates how goals and goal-related appraisals may determine the nature of the coping process and influence adaptation (see also Affleck et al., 1998).

Both general theories of human functioning and those specific to coping with stressful experiences and chronic disease in particular can serve to guide researchers in their attempt to understand determinants of adjustment to chronic illness. Theoretically grounded approaches, such as those that use the Lazarus and Folkman framework (see, e.g., Smith & Wallston, 1992, on rheumatoid arthritis; Stanton & Snider, 1993, on breast cancer; Pakenham, Dadds, & Terry, 1994, on AIDS), will yield more systematic and substantial advances than will research that is solely empirically driven, just as they will allow researchers not to reinvent the wheel in devising "new" models where established theory already exists. For example, attempts to identify contributors to depression in chronic disease may take as a starting point general theories regarding determinants of depression, as well as extant stress and coping theories. The literature on adjustment to chronic illness would benefit from careful delineation of the central conceptual points at which general and disease-specific theories diverge in their utility for specifying contributors to positive adaptation, meaningful differences among chronic diseases with regard to their impact on adjustment, and how competing theories fare with regard to their differential and combined utility in specifying the most significant influences on adaptation to chronic illness. What follows is an analysis of the state of the empirical literature on determinants of adjustment. The broad conceptual categories in stress and coping theories (e.g., Lazarus & Folkman, 1984; Maes et al., 1996) are used as an organizing framework for this discussion.

EMPIRICAL RESEARCH ON CONTRIBUTORS TO ADJUSTMENT TO CHRONIC ILLNESS

This section aims to provide a sketch of factors that help and hinder individuals as they confront chronic illness. A working model is depicted in Fig. 21.1 (see also Maes et al., 1996; Taylor & Aspinwall, 1996). It should be noted that, to increase readability, not all potential causal paths are displayed, and recursive relations are likely. The contextual factors of the disease itself and the environment are addressed first, followed by consideration of the personal context, including demographic and personality attributes. Cognitive appraisal and coping processes then receive attention.

The Disease- and Treatment-Related Context

Losing my hair, that was the worst part. The nausea wasn't much fun either. They were constant reminders that I didn't have control over my body.

Chronic diseases vary along numerous conceptual dimensions, including controllability, predictability, and severity

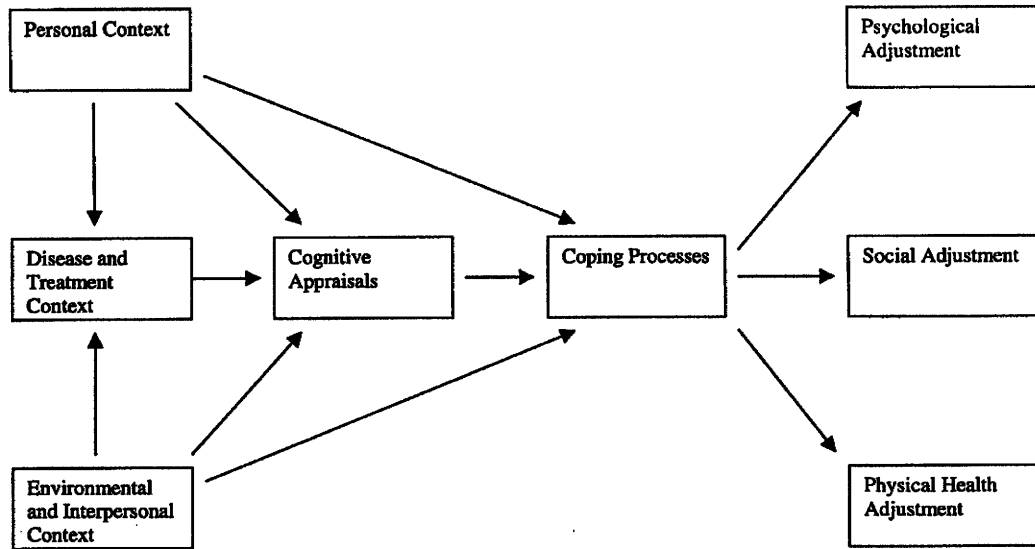

FIG. 21.1. Model of influences on adjustment to chronic illness.

(e.g., lethality, life disruption). Disease- and treatment-specific variables can be mapped at least partially onto these conceptual dimensions. For example, disease course (e.g., progressive or remitting), prognosis, lifestyle change required, side effect-related toxicity and life disruption, and degree of associated pain and disability all vary in controllability, predictability, and severity across different chronic diseases. Even within disease category, it would be a mistake to assume homogeneity. For example, different cancers carry dramatically different prognoses. Adding further to across- and within-disease variability is the fact that, although the disease process itself accounts for much variance in these dimensions, several also are substantially determined by individual factors. What is one person's significant pain may be another person's annoyance. Chemotherapy-induced hair loss may prompt a "Hair by Chemo" t-shirt purchase for one individual and painful social isolation for another. Thus, although disease- and treatment-related factors often are considered exogenous variables in models of adjustment, their existence and impact actually may be influenced significantly by individuals' external and internal resources. Further, individual characteristics and behaviors may interact with disease-related factors to influence adaptive outcomes. Problem-focused coping may be effective only for controllable aspects of a disease, for example.

In light of this complexity, it is a general observation that, when disease- and treatment-specific factors (e.g., prognosis, treatment toxicity, pain) are demonstrated to be related to adaptive outcomes, they often reflect relations of low controllability, low predictability, and high severity with poorer adjustment. Note that many studies do not reveal significant relations of disease-related factors with adjustment. For example, disease stage is related inconsistently across studies to

adjustment to cancer (van't Spijker et al., 1997). Such inconsistent relations between disease-related factors and adjustment may result from the use of small samples and thus insufficient statistical power to detect relations, or from restricted ranges on disease-specific factors, such as low frequency of advanced cancers in a sample. Inconsistent relations also may reflect variability in study participants' experience of or meanings attributed to disease stage. Large-scale and meta-analytic (e.g., Moyer, 1997) studies are necessary to examine the influences of disease- and treatment-related factors on psychosocial outcomes.

Complexity in the determinants and impact of disease-related factors carries several implications for research. First, studies comparing outcomes across diseases will be useful to the extent that they can disentangle mechanisms for obtained effects. For example, the finding that rheumatoid arthritis and systemic blood cancer patients reported more negative affect, less positive affect, and less acceptance of their illness than patients with hypertension or diabetes (Felton & Revenson, 1984; Felton, Revenson, & Hinrichsen, 1984) may reflect differences in perceived controllability or severity of consequences among those diseases. Second, many researchers treat disease-related variables as covariates in analyses. Although this is a reasonable approach, some investigators do not report the magnitude of the relations between the covariates and outcomes, with the result that nothing is learned about the potential impact of disease variables. Investigators also often do not report first testing for interactions of disease-related variables with other predictors before including the variables as covariates. Not only is prior testing of such interactions a statistical requirement of covariance analysis, but it also may yield important findings. For example, disease trajectory may interact with coping processes, such that problem-focused coping may be

more effective during diagnosis and treatment planning than after treatment termination.

Finally, although researchers in adjustment to chronic disease typically have included disease characteristics as predictors of adaptive outcomes, it is clear that these factors also can be conceptualized usefully as dependent variables. For example, identification of factors that contribute to the likelihood of experiencing treatment-related side effects (e.g., the finding that high anxiety and treatment context predict the development of anticipatory nausea during chemotherapy; Redd, 1990) has important applied implications.

The Environmental and Interpersonal Context

I come to this support group because it's the only place that I don't have to put on my "strong" face. People here know what it's like to have a really bad day with cancer.

My husband lost his job and had to take a new one in [another city]. I can't afford to lose my insurance because of the cancer, so I can't quit my job. We have to live apart. He was my mainstay during chemotherapy; I don't know how I'll do without him.

A person lives with chronic disease within an environmental, cultural, and interpersonal context. Such contextual factors have received relatively little empirical attention, with the exception of social support. Even social support typically has been examined from the perspective of the individual (Felton & Shinn, 1992). Although the individual's perspective may be centrally important, examination of the interpersonal context also may yield rich data on adjustment processes. Given their relative emphases in the literature, the focus is on social support and the intimate interpersonal context, although the larger environmental and cultural contexts are mentioned and exemplary references are provided.

The Environmental and Cultural Context. As poignantly illustrated in the quotation from the cancer survivor experiencing job lock, the environmental context (e.g., concurrent life events, chronic strains) may influence adjustment to chronic disease. For example, Evers, Kraaimaat, Geenen, and Bijlsma (1997) found that having more stressful life events was associated with higher anxiety shortly after diagnosis in rheumatoid arthritis patients, but not with distress a year later. Lepore and Evans (1996) argued that coping with one stressor can affect individuals' ability to adapt to a subsequent stressor through interference with their appraisals (e.g., higher evaluation of threat), resources, or motivation to cope with the subsequent stressor. Both stressors external to the chronic disease, such as death of a loved one, and those related to it, such as resultant financial strain, are likely to affect adaptation.

Taylor, Repetti, and Seeman (1997) reviewed characteristics across multiple environments (e.g., community, family, work) that contribute to adverse health outcomes. They concluded that "unhealthy environments are those that threaten safety, that undermine the creation of social ties, and that are

conflictual, abusive, or violent" (p. 411). It is reasonable to suggest that these attributes also would provoke adjustment difficulties in those already contending with chronic disease. In addition to these major chronic environmental strains, it is likely that seemingly more benign environments might prove daunting to the individual with chronic disease. A work environment that was negotiated facily prior to illness may be impossible when a person's concentration and energy level are impaired by medical treatment. As Mechanic (1995) noted, disease-related disability results from "a lack of fit between the capacities of individuals and the environment in which they must function" (p. 1209).

Theoretical and empirical reviews reveal that ethnic and cultural factors also influence illness vulnerability, attention to and interpretation of somatic and emotional changes, a person's actions regarding symptoms, and subsequent interpretations and adaptation (e.g., Angel & Thoits, 1987; Kato & Mann, 1996; Landrine & Klonoff, 1992; K. Young & Zane, 1995). For example, Angel and Cleary (1984) found that Mexican Americans low in acculturation reported more symptoms than non-Hispanic Whites; however, they were less likely to seek care for those symptoms. High concealment of homosexual identity predicted faster progression in HIV-seropositive gay men (Cole, Kemeny, Taylor, Visscher, & Fahey, 1996). Such concealment may reflect an adopted strategy for avoiding social rejection and stigmatization or a marker of inhibited temperament (Cole et al., 1996). Particularly in light of the high mortality rates for chronic diseases in some ethnic and cultural groups (e.g., greater age-adjusted mortality rates in African Americans than Whites for heart and cerebrovascular disease, diabetes and kidney disease, AIDS, and cancer; National Center for Health Statistics, 1996), greater empirical attention to ethnic and cultural influences on causes and adaptive consequences of disease is essential (see Landrine & Klonoff, this volume).

The Interpersonal Context and Social Support.

Social support can be conceived as involving interpersonal transactions that offer emotional comfort, information, concrete aid, or enhanced self-regard (Wills, this volume). Many useful papers are available on the conceptualization and measurement of social support (e.g., Cohen & Wills, 1985; Hobfoll & Vaux, 1993; Pierce, J. G. Sarason, & B. R. Sarason, 1996), as well as the influence of social relationships on physical health outcomes (e.g., Cohen & Syme, 1985; Reifman, 1995; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Although the findings are not without exception (e.g., Bolger, Foster, Vinokur, & Ng, 1996; Revenson, Wollman, & Felton, 1983), reviews of the relation between social support and psychological adjustment to chronic illness suggest that social support in general is related to positive adaptation to several chronic diseases, including rheumatic diseases (DeVellis, Revenson, & Blalock, 1997), cancer (Blanchard, Albrecht, Ruckdeschel, Grant, & Hemmick, 1995; Helgeson & Cohen, 1996), and cardiovascular disease (Shumaker & Czajkowski, 1994). For example, Duits, Boeke, Taams, Passchier, and Erdman (1997) reviewed 17 prospective studies of adjustment to coronary artery bypass graft surgery (CABG). They found that

higher preoperative social support predicted more positive postoperative adjustment. Individual studies demonstrate that the impact of social support may vary as a function of attributes of the provider and recipient, as well as the nature and timing of the support provided. Mechanisms by which social support achieves its effects also are receiving increased attention (e.g., Uchino et al., 1996).

Conceptualizations of social support include its use as a coping strategy, as a coping resource in the environment, and as dependent on personality attributes and coping of the individual (Schreurs & de Ridder, 1997). In their review of studies assessing coping and social support in chronic disease, Schreurs and de Ridder (1997) found that prospective studies consistently revealed that a mechanism by which social support promotes positive well-being is through its effect on approach-oriented coping, thus supporting the beneficial effects of social support as a coping resource. For example, in a 4-year prospective study of cardiac patients, Holahan, Moos, Holahan, and Brennan (1997) demonstrated that higher social support and lower stress in familial and extrafamilial domains predicted greater cognitive and behavioral approach-oriented coping, which in turn contributed to lower depressive symptoms.

It also is clear that the receipt and effectiveness of social support is partially dependent on personal attributes of the recipient and the reactions of others. A role-playing experimental study by Silver, Wortman, and Crofton (1990) demonstrated that cancer patients who reported some distress but maintained a positive attitude received more support from peers than did highly distressed or very well-adjusted patients. In a prospective investigation of rheumatoid arthritis patients, Smith and Wallston (1992) reported that higher helplessness appraisals were associated with passive coping in patients, which in turn was related to lower perceived quality of emotional support, and greater psychosocial impairment and declining self-reported health over time.

Recently, a burgeoning interest in negative aspects of social relationships is apparent in the literature. Behaviors from close others that are insensitive, critical, conflictual, withdrawing, or unreceptive can potentiate adjustment difficulties in chronically ill individuals (e.g., Herbert & Dunkel-Schetter, 1992; Holahan et al., 1997; Lepore & Helgeson, 1998; Manne, Taylor, Dougherty, & Kemeny, 1997), as can the ill individual's perceived inability to live up to the expectations of important others (Hatchett, Friend, Symister, & Wadhwa, 1997). Inadequate relationships with medical staff also can be detrimental to health and well-being. Lerman et al. (1993) reported that 83% of 97 breast cancer patients cited communication difficulties with the medical team and that communication problems predicted heightened distress 3 months later. Even well-intentioned support attempts may provoke negative outcomes in some cases. Support attempts that lead to dependence, obligation, patronization, lack of control, or reinforcement of maladaptive behaviors (e.g., pain behaviors) may impair adjustment in the chronically ill person (e.g., Coyne, Ellard, & Smith, 1990; Kerns, 1995; Revenson, 1994; Romano et al., 1992). Whereas some researchers have found that both posi-

tive and negative aspects of support make unique contributions to adjustment to chronic illness (e.g., Holahan et al., 1997; Revenson, Schiaffino, Majerovitz, & Gibofsky, 1991), others have suggested that the potential harmful effects of negative reactions from the social environment outweigh the benefits of positive support (e.g., Manne et al., 1997).

In addition to considering the potentially positive and negative aspects of social support, researchers point to the importance of the match between what the individual needs over the illness course and what is offered by the social milieu in influencing adjustment (e.g., Cutrona, 1996; Mechanic, 1995; Taylor & Aspinwall, 1990). For example, informational support generally is valued from an expert, either a medical professional or a person who has adjusted well to the same disease, whereas emotional support is valued from family members and friends, as well as from health care providers (e.g., Helgeson & Cohen, 1996; Taylor & Aspinwall, 1990). Even for self-reliant individuals, the rising demands of progressive illness may render instrumental and emotional social support increasingly important, although such demands also may contribute to the erosion of support over time (e.g., Zich & Temoshok, 1990).

Clearly, specific facets of interpersonal relationships can both aid and hinder adjustment to chronic illness, depending on the nature of the support attempt, attributes of the provider and recipient, and demands of the illness. Although the conceptual and data analytic complexities can be daunting, intimate relationships provide rich ground for delineating the complex interplay of factors influencing adaptation for couples (e.g., Revenson, 1994) and families (e.g., Kerns, 1995) within the larger social and environmental sphere (e.g., Lepore, 1997).

The Personal Context

Cancer is not the worst thing that could happen. Things always have turned out well for me, and I think this will, too. Even if the surgery doesn't work, I'm old, I've had a good life. Things will be okay.

Numerous personality and other individual difference characteristics have been tested for predictive utility in adjustment to chronic disease. There are several paths by which stable individual difference variables might affect adjustment (Bolger & Zuckerman, 1995; Costa, Somerfield, & McCrae, 1996; Hewitt & Flett, 1996). An additive model assumes that personality (or other individual differences characteristics) and coping (or appraisal) have independent, direct effects on adjustment. A mediational model involves coping as a mediator between personality and outcomes, such that people high on neuroticism are more likely to cope through avoidance, which in turn predicts poor adjustment, for example. An interactive model implies that personality and coping interact, such that avoidant coping is effective for those low in neuroticism but maladaptive for those high in neuroticism, for example. Here, select demographic and personality attributes that are promising are examined as risk or protective factors in adjustment.

Demographic and Background Attributes. Although not often a focus of studies on adjustment to chronic illness, demographic and other stable premorbid characteristics often are included as covariates or otherwise examined in relation to adaptation. Examples of consistent findings are that younger cancer patients are more likely to be distressed than older patients (van't Spijker et al., 1997); that women report lower quality of life after myocardial infarction (MI) and are less likely to participate and remain in cardiac rehabilitation programs than men (Brezinka & Kittel, 1995; Shumaker et al., 1997); that higher educational attainment is associated with lower disability from rheumatoid arthritis, particularly among men (Leigh & Fries, 1991); and that a premorbid history of psychological disorder confers risk for poor emotional and behavioral outcomes (e.g.; return to work) across several chronic illnesses (Taylor & Aspinwall, 1990).

Methodologically sound research in this area examines potential confounding factors (e.g., women are older and sicker upon first MI than men; Shumaker et al., 1997) and compares findings on the variables of interest to those from the general population (e.g., higher rates of depression in women than men). An important direction for research is to examine mechanisms for obtained results, in order to target interventions productively. For example, are older adults with cancer less distressed than younger adults because they experience less violation of cognitive schemas, they engage in more positive downward social comparisons, and they perceive less attendant blockage of central goals, or is the age difference an epiphenomenon of younger adults' propensity to report greater distress in general?

Personality Characteristics. The five basic factors of personality (i.e., neuroticism, extraversion, openness to experience, agreeableness, conscientiousness) have garnered attention in the broader coping literature (e.g., Bolger, 1990; Costa et al., 1996). For example, neuroticism's association with maladjustment appears to be mediated through use of greater avoidant and less approach-oriented coping (e.g., social support, problem-focused coping; see Costa et al., 1996; Hewitt & Flett, 1996, for reviews). An interactive model of effects of neuroticism and coping on adjustment also has received support (Bolger, 1990). These personality factors have received less attention with regard to adjustment to chronic disease. In a 7-year longitudinal study of adjustment to rheumatoid arthritis, Smith, Wallston, and Dwyer (1995) found that negative affectivity (typically considered equivalent to neuroticism) was empirically distinct from disease impact variables (i.e., pain, functional impairment). Further, controlling for negative affectivity, disease impact was associated uniquely with several components of sick-role behavior (e.g.; information seeking, use of medical treatments) and with some adjustment indices (e.g., life satisfaction, fatigue) but not others (e.g.; depressive symptoms). In another longitudinal study, Affleck, Tennen, Urrows, and Higgins (1992) found that catastrophizing coping partially mediated the relation between neuroticism and chronic negative mood and pain in arthritis patients. Al-

though neuroticism may be an important precursor of coping and other adjustment-related variables, it does not appear to account for the lion's share of the variance in predicting adjustment. Thus, coping is not "just" neuroticism. Rather than being considered merely a nuisance variable in research, however, high neuroticism might be viewed as an immediately identifiable risk factor in those who confront chronic disease, whereupon early intervention can be instituted to diminish maladjustment. The personality factor of conscientiousness also deserves more attention in research on adjustment to chronic disease, as it appears to predict positive physical health outcomes in healthy samples (Friedman et al., 1995).

Dispositional optimism (Scheier & Carver, 1985), a construct reflecting generalized expectancies for favorable outcomes, appears to be a promising predictor of positive adjustment to illness. Moderately negatively correlated with neuroticism but demonstrating discriminant validity (see Carver et al., 1993), optimism has been studied in longitudinal investigations of cancer, coronary heart disease, and HIV. Carver et al. (1993) examined optimism as a prospective predictor of well-being in women undergoing breast cancer surgery. Assessed prior to surgery, optimism was associated positively with approach-oriented coping (e.g., active coping, planning, realistic acceptance) and negatively with avoidant coping (e.g., denial, behavioral disengagement). Controlling for prior distress, optimism predicted lower distress at 3, 6, and 12 months after surgery, relations that were partially mediated through coping strategy use, particularly acceptance, denial, and behavioral disengagement. Stanton and Snider (1993) also found that coping (i.e., cognitive avoidance, positive focus) partially mediated the effect of optimism on distress and vigor prior to surgery for breast cancer, but that optimism did not prospectively predict distress following surgery. Assessed prior to CABG surgery, dispositional optimism correlated positively with problem-focused coping and negatively with denial (Scheier et al., 1989). Moreover, optimism predicted faster in-hospital recovery and faster return to normal life activities 6 months later. In a sample of HIV+ and HIV- men, Lutgendorf et al. (1995) found optimism to be associated with the use of active coping strategies and with lower psychological distress (see also Taylor et al., 1992). These findings suggest that optimism may be an important protective factor in those adjusting to chronic disease, at least in part via promotion of actively engaged coping strategies.

As the foregoing illustrates, investigation of these and other individual difference characteristics (e.g., self-esteem: Katz et al., 1995, and Druley & Townsend, 1998; locus of control: Reich, Zautra, & Manne, 1993; Type A behavior pattern: Denollet & De Potter, 1992) can illuminate risk and protective factors in adjustment to illness. Such factors often can be assessed easily in the earliest phases of diagnosis and treatment. Because interventions are not readily available to modify stable personal dispositions, however, the examination of mechanisms (e.g., coping, appraisal) by which these attributes have their effects also is essential.

Cognitive Appraisals

The most frustrating part is the loss of control, from not being able to work right now to not knowing if the cancer will come back, and not being able to do a lot to prevent it. I hate feeling out of control.

Researchers have studied many sorts of cognitive appraisals in relation to chronic disease (e.g., disease representation; Leventhal & Nerenz, 1983). Here, the focus is on those subsumed in the Lazarus and Folkman (1984) framework.

Primary Appraisal. Primary appraisal, involving the individual's determination of a potentially stressful encounter's significance for well-being through assessments of threat/harm and challenge/benefit in the encounter, plays a pivotal role in stress and coping theory (Lazarus & Folkman, 1984). However, primary appraisal processes have received little empirical attention relative to coping processes, owing in part to lack of consensus regarding conceptualization and measurement. Studies reveal that individuals with chronic medical conditions see the potential for both harm and benefit from their experience (e.g., Stanton, 1991; Stanton & Snider, 1993). For example, a woman diagnosed with breast cancer might judge her experience as involving loss, whereby she must give up a body part; threat, in that her life expectancy and goals for work and family roles may be curtailed; and challenge, as her diagnosis represents an opportunity to reorder priorities and draw closer to her partner. Waltz, Badura, Pfaff, and Schott (1988) found that primary appraisals of threat and harm/loss were important predictors of subsequent anxiety and depression in 372 male cardiac patients. Stanton and Snider (1993) found that, prior to biopsy for breast cancer, women who perceived greater threat to a number of life realms from the potential diagnosis were more distressed. Prebiopsy threat and challenge appraisals did not predict subsequent negative and positive affect on diagnosis or surgery, however. With continued refinement of the primary appraisal construct (e.g., Lazarus, 1991a), it may prove a valuable tool for understanding individuals' goal structures and their assessment of how chronic disease may impede or further central aims.

Secondary Appraisal. In secondary appraisal, the following question may be posed, "What, if anything, can I do about this situation?" Thus, an individual's capacity to manage or change the situation is assessed. Smith and Lazarus (1990) refined the secondary appraisal construct to include cognitive evaluations of accountability for blame/credit, potential for problem- and emotion-directed coping attempts, and expectancies regarding potential for change in the situation. Underlying secondary appraisal, and garnering substantial attention by researchers, is the question of what people can and cannot control in their experience. A central quality of chronic disease is that control over progression and ultimate outcome of the disease is not guaranteed, despite individuals' intense efforts to pursue medical care and implement lifestyle modifications. Thus, the success of primary control

attempts (Rothbaum, Weisz, & Snyder, 1982) is uncertain, although a person may generate the perception of substantial control (e.g., Taylor, Lichtman, & Wood, 1984). Further, across several chronic diseases, individuals are likely to discover controllable aspects of their experience, perceiving greater control over the consequences of their disease (e.g., symptoms, daily management) than over the course of their disease (e.g., rheumatoid arthritis: Affleck, Tennen, Pfeiffer, & Fifield, 1987; AIDS: Thompson, Nanni, & Levine, 1994; cancer: Thompson, Sobolew-Shubin, Galbraith, Schwankovsky, & Cruzen, 1993).

Research demonstrates that control appraisals can influence both the choice of coping strategies and adjustment across time. Findings from the general literature on stress, appraisal, and coping, in which situations of relatively high controllability are associated with more problem-focused coping attempts and low control situations with use of emotion-focused coping (e.g., Folkman & Lazarus, 1980), are mirrored in the chronic disease literature. For example, Folkman, Chesney, Pollack, and Coates (1993), in a longitudinal study of 425 HIV+ and HIV- gay men, found that high perceived control over a self-selected stressful situation was associated with greater approach-oriented coping (i.e., problem solving, information seeking, positive reappraisal), which in turn predicted decreased depressed mood after controlling for prior depressed mood and HIV symptoms.

Another observation from the chronic disease literature is that the specific control domain matters with regard to predicting adaptive outcomes. Several studies have revealed that perceived control over disease consequences (e.g., symptoms) is associated more strongly with positive adaptation than is appraised control over disease course (e.g., Affleck et al., 1987; Thompson et al., 1993, 1994). Further, perceptions of control in specific domains interact with other aspects of the disease to influence adjustment. For example, Affleck and colleagues (1987) found that, in the context of severe rheumatic disease, those who perceived more control over disease course evidenced more mood disturbance, whereas those who perceived more control over disease symptoms reported less mood disturbance. Thus, high control appraisals may be adaptive when the severe threat is controllable but may hinder adjustment when the threat is realistically uncontrollable (see also Helgeson, 1992).

It is clear that control appraisals regarding disease are multidimensional. In adapting to disease, individuals are likely to shift attention from uncontrollable dimensions to aspects of the illness that carry the potential for control and perhaps to additional controllable life goals. Belief that an individual has control in realms that in fact are responsive to control attempts may bolster adaptation. Such findings suggest the importance of differentiating empirically among various potential control domains and of examining precursors of control appraisals.

Coping Processes

I do a bunch of things. I talk to my wife. I get as much information as I can about treatments and the latest research. I rely on my faith. I try to live each day as I want to.

Faced with a chronic disease, most individuals initiate a variety of attempts to manage the associated stressors. Broadly, coping attempts may be directed toward solving the problem at hand (i.e., problem-focused coping) or managing emotions associated with the stressor (i.e., emotion-focused coping) (Folkman & Lazarus, 1980). Thus, a person with AIDS may initiate a complex medical treatment regimen, as well as garnering comfort from friends. Several conceptual and empirical limitations accompany this distinction (e.g., Stanton, Danoff-Burg, Cameron, & Ellis, 1994), however, and researchers have demonstrated that the problem- and emotion-focused coping categories can be subsumed under the higher order classification of approach- versus avoidance-oriented coping mechanisms (e.g., Tobin, Holroyd, Reynolds, & Wigal, 1989). Examples of approach-oriented strategies are coping through seeking social support, active positive reframing, information seeking, problem solving, and emotional expression. Avoidant strategies include denial, distraction, cognitive avoidance, and behavioral disengagement. Yet other processes, such as religious coping, potentially can serve either approach-oriented or avoidant goals.

Reviews of the general literature (Roth & Cohen, 1986; Suls & Fletcher, 1985) suggest that avoidant and approach strategies vary in effectiveness as a function of the temporal sequence and characteristics of stressors. Avoidant strategies temporarily may reduce the effects of acute, severe stressors because they prevent one from becoming overwhelmed when emotional resources are limited. As stress persists, however, approach strategies afford opportunities for actions that may alleviate the stressor or its emotional concomitants.

By definition, chronic disease is a long-term stressor, for which the coping demands and their efficacy may vary over time. Although avoidant coping has been demonstrated useful at circumscribed points, its general untoward impact on adjustment is evident in numerous studies. For example, Levine et al. (1987) found that male cardiac patients high on denial of their illness spent fewer days in the coronary care unit and had fewer indications of cardiac dysfunction during hospitalization than did nondeniers. However, deniers were less compliant with exercise training and had more days of rehospitalization during the year following discharge. Stanton and Snider (1993) found that greater use of cognitive avoidance coping prior to breast biopsy predicted more distress at that point, after cancer diagnosis and after surgery (with initial levels of distress controlled; see also Carver et al., 1993). Reviewers of the chronic disease literature demonstrate consensus in the conclusion that avoidant coping is maladaptive over the long term (e.g., DeVellis et al., 1997, for rheumatic disease; Folkman, 1993, for HIV). Reviewing the literature across several diseases, Maes et al. (1996) concluded that "avoidant emotion-focused coping strategies are related to poor psychological adjustment and poor adherence to medical advice ..." (p. 235). Why is avoidant coping maladaptive? Certainly, avoiding the reality of disease will impair both active problem-focused and emotion-focused coping attempts. Avoidant coping itself may take maladaptive paths, such as excessive drinking or drug use. Further, cognitive avoidance paradoxically may prompt in-

trusion of the threatening material (Horowitz, 1986; Wegner & Pennebaker, 1992), in turn amplifying distress.

In general, research also suggests a complementary advantage for approach-oriented coping strategies in bolstering adjustment to chronic disease (e.g., Fleishman & Fogel, 1994; Holahan et al., 1997). For example, L. D. Young (1992) reviewed the literature on rheumatoid arthritis, concluding, "active, problem-focused coping attempts (e.g., information seeking, cognitive restructuring, pain control, and rational thinking) were consistently associated with positive affect, better psychological adjustment, and decreased depression" (p. 621). However, this chapter concurs with the conclusion of Maes et al. (1996) that the findings for the association of approach-oriented strategies and better adjustment are not as consistent as those for the relation of avoidant coping and poorer adjustment. This difference may occur because approach-oriented strategies (particularly problem-focused approach) may not be effective in the case of uncontrollable aspects of disease, because the utility of approach-oriented strategies is outweighed by the disutility of avoidant strategies when both are examined, or because adjustment indices used typically assess negative (e.g., depression) rather than positive (e.g., life satisfaction) adaptation, which may have differential relations with approach-oriented and avoidant coping (e.g., Blalock, DeVellis, & Giorgino, 1995; Stanton, 1991).

Beyond these associations of higher order coping approaches with adjustment, consistent relations of adjustment with any particular coping strategy are more difficult to discern. However, intensive research on specific coping mechanisms is beginning to prove fruitful, for example, that on social comparison (Buunk & Gibbons, 1997; Taylor & Lobel, 1989), focusing on benefit (Affleck & Tennen, 1996), and emotional processing and expression (Kelley, Lumley, & Leisen, 1997; Stanton et al., 1994, 1997; Stanton & Franz, 1999). Theoretically grounded longitudinal and experimental research that takes into account such factors as the specific problem with which the individual is coping and the relevant adaptive outcomes (e.g., Blalock et al., 1995), the intentionality of the coping effort (Compas, Connor, Osowiecki, & Welch, 1997), the larger interpersonal and environmental context (e.g., Revenson, 1994), and measurement issues in the assessment of coping (Coyne & Gottlieb, 1996) will advance understanding of the process of coping with chronic illness.

FUTURE DIRECTIONS IN RESEARCH ON ADJUSTMENT TO CHRONIC ILLNESS

Obviously, the factors that influence adjustment to chronic illness have been painted in broad strokes, focusing on promising constructs and crosscutting themes. Although this chapter has attempted to provide a modicum of critical analysis of this literature, readers are encouraged to pursue the cited references for deeper examination of issues of particular interest. In addition, the categories of predictors on which this chapter has focused also have been suggested to influence disease onset, progression, and survival (e.g., Epping-Jordan, Compas, &

Howell, 1994; Ickovics et al., 1999; Mulder, Antoni, Duivenvoorden, Kauffmann, & Goodkin, 1995; Scheier & Bridges, 1995). Thus, continued investigation is warranted for understanding factors that bolster and impede both quality of life and disease endpoints.

The review of the literature suggested considerable individual variability in response to chronic disease, within the context of generally positive adjustment. Several risk and protective factors were identified that predicted adjustment consistently across chronic diseases. However, few researchers have compared predictors of adjustment across diseases in single studies. Research identifying meaningful differences among diseases (e.g., degree of life threat, pain, required behavior change), their relations with adaptive outcomes, and mechanisms for differential relations across diseases is warranted. Further, much more is known about predictors of negative psychosocial outcomes than is known about contributors to positive functioning. The literature's prominent focus on negative affect as an outcome has yielded valuable findings. However, in limiting their attention to indicators of maladjustment, researchers may fail to uncover important contributors to positive functioning.

Development and testing of disease-specific theories, continued refinement of stress and coping theories, and comparison of the predictive utilities of competing theories are important venues for further research. Application of other established psychological and biological theories also are proving productive in enhancing our understanding of adjustment to chronic disease (e.g., Andersen, Kiecolt-Glaser, & Glaser, 1994; Andersen et al., 1997; Calfas, Ingram, & Kaplan, 1997; Glaser & Kiecolt-Glaser, 1994; Stanton et al., 1998). Longitudinal research in adaptation to chronic disease allows testing of links among psychosocial and biological variables within a biopsychosocial framework (e.g., Andersen et al., 1994). Theoretical grounding of research is essential in disentangling the complex relations of multiple influences on numerous adaptive outcomes in chronic disease.

The literature review revealed a number of methodologically and conceptually sophisticated studies, allowing for some degree of causal inference regarding determinants of adjustment to illness. It appears that things have moved beyond the point at which atheoretical, cross-sectional research is very useful in this area. Rather, theory-grounded, longitudinal, and experimental designs will illuminate important influences on adjustment, their interactions, and mechanisms by which they have their effects. For example, Reich et al. (1993) discovered significant interactions among demographic (patient age), personality (locus of control), and interpersonal (spouse encouragement of control) variables in predicting the psychological distress of rheumatoid arthritis patients. Another study with arthritis patients revealed interactions between pain level and daily coping strategies in predicting mood (Affleck, Urrows, Tennen, & Higgins, 1992). The Affleck et al. study also is notable in its microanalytic examination of coping processes, an approach especially appropriate for diseases for which coping demands occur on a daily basis (see also Porter & Stone, 1996; Tennen & Affleck, 1996). The complexity of such findings can be daunting, es-

pecially because the nature of chronic illness involves its presentation of multiple strains, which may constantly change shape. However, longitudinal and experimental research will allow more precise identification of contextual and individual factors that promote favorable adjustment and will point the way for tailored intervention.

What implications does research on adjustment to chronic illness carry for intervention? A good example of effective direct application of findings from stress and coping theory is Folkman and colleagues' (1991) coping effectiveness training. Effective in bolstering quality of life in HIV+ men, this approach includes: (a) appraisal training to disaggregate global stressors into specific coping tasks and to differentiate between alterable and immutable aspects of specific stressors; (b) coping training to tailor application of problem-focused and emotion-focused coping efforts to relevant stressors; and (c) social support training to increase effectiveness in selecting and maintaining supportive resources. Other effective psychosocial interventions exist for enhancing quality of life, improving medical regimen adherence, and potentially improving disease endpoints in individuals across several chronic diseases (e.g., Young, 1992, for rheumatoid arthritis; B. L. Andersen, 1992, and Meyer & Mark, 1995, for cancer; Cox & Gonder-Frederick, 1992, for diabetes; Bennett & Carroll, 1994, and Burell, 1996, for cardiovascular disease; Kelly & Murphy, 1992, and Lutgendorf et al., 1997, for HIV; Devins & Binik, 1996, for chronic diseases). Such interventions typically include an emotionally supportive context to address disease-specific worries, information regarding the disease and its treatment, and training in specific cognitive and behavioral coping strategies (B. L. Andersen, 1992). Extant theoretically grounded research on adjustment to chronic disease can refine such interventions through: pointing to effective targets for interventions (e.g., Coyne, 1995, on couple-oriented approaches; Thompson, 1991, for interventions to influence control appraisals; Lanza & Revenson, 1993, for issues in designing social support interventions); suggesting potential mechanisms by which interventions may gain their utility (e.g., through decreasing avoidant coping and increasing approach-oriented strategies); identifying at-risk patients for which interventions may be appropriate (e.g., patients low in optimism, younger cancer patients); and targeting intervention components for maximal effectiveness (e.g., selecting specific coping skills as a function of stressor controllability). Finally, both disease-specific and higher order conceptual dimensions (e.g., controllability) may be useful in understanding adjustment and developing interventions. For example, finding that people are likely to evidence a peak in distress at the point of diagnosis (e.g., Cassileth et al., 1984; Stanton & Snider, 1993) will allow us to know when to intervene. Specification of the underlying factors that confer risk for distress at that point (e.g., perceived low predictability, low control, high disease severity) will offer guidance in how to intervene.

The literature to date offers a foundation for understanding adjustment to chronic illness. However, there is still much to learn about complex determinants of adjustment trajectories and disease endpoints across time, across individuals, and

across disease contexts. Such investigation accrues greater importance in light of the observation that individuals are surviving for many years after diagnosis of diseases once considered rapidly fatal. Ultimately, research conducted by health psychologists should enable more individuals living with chronic diseases to share the cancer patient's sentiment, "I have cancer but it doesn't have me."

Recall Biases and Cognitive Errors in Retrospective Self-Reports: A Call for Momentary Assessments

Amy A. Gorin

Arthur A. Stone

State University of New York at Stony Brook

One of the primary means of obtaining information from participants in behavioral science research is through the use of retrospective self-reports. Research participants are often required to recall both qualitative and quantitative details about prior events, symptoms, behaviors, and psychological processes (Babor, J. Brown, & Del Boca, 1990). Retrospective self-reports also play an important role in clinical practice. Patients are commonly asked to provide information about their health histories, previous affective states, cognitions, symptoms, and health behaviors for use in assessment and treatment. The benefits of retrospective self-reports are numerous: They can be developed quickly, are easy to administer and to complete, tend to have strong face validity (Stone, Shiffman, & DeVries, 1999), and are very economical (Baker & Brandon, 1990).

Until recently, participants' confidence in their own reports was the primary indicator of the accuracy of retrospective recall. As participants are usually quite confident in their own recall, the validity of retrospective self-reports has generally been assumed to be high (Fienberg, Loftus, & Tanur, 1985; Read, Vokey, & Hammersley, 1990). However, research in the field of autobiographical memory questions this assumption. Specifically, a growing body of empirical studies indicates that instead of producing reliable and valid information as once assumed, retrospective self-reports are susceptible to numerous recall biases and cognitive errors

(Jobe & Mingay, 1991; Jobe, White, Kelley, Mingay, & Sanchez, 1990; Thompson, Skowronski, Larsen, & Betz, 1996). According to Ross (1989, p. 342), retrospective recall appears to be "an active, constructive, schema-guided process," which at times is inaccurate. This is not to suggest that retrospective self-reports are meaningless—they undoubtedly provide valuable information about participants' general perceptions of past events and, perhaps, about their future actions. Rather, it appears necessary to recognize their limitations as tools for gathering accurate, detailed, autobiographical facts and to explore alternative means of obtaining such information.

Given researchers' and clinicians' heavy reliance on retrospective self-reports, this chapter has three goals. First, it reviews autobiographical memory processes involved in retrospective self-reporting such as personal memories and generic personal memory. Second, it provides a summary of the types of recall biases and cognitive errors that impact retrospective self-reports. Rather than reviewing all relevant studies in detail, one or two examples of each recall bias are used to highlight the sorts of errors that can occur. Third, it introduces a relatively new alternative to retrospective self-reports, namely, intensive momentary-based assessments, and discusses instances when this approach may be preferable to traditional self-report methods of collecting information.

AUTOBIOGRAPHICAL MEMORY

Autobiographical memory, also known as everyday or ecological memory, refers to memory and knowledge of personal information and experiences (Bruce, 1985; Robinson & Swanson, 1990). It is believed to be organized by a limited number of self-schemata that process personally relevant information in a meaningful fashion, producing a coherent view of the self that may or may not reflect reality. Schemata can center around specific traits (e.g., outgoing vs. shy, dependent vs. independent) or social roles (e.g., student, daughter, etc.) and are believed to be formed through the abstraction of information from past and present experiences (Barclay & Subramariam, 1987).

The types of information organized by self-schemata include *personal memories* (e.g., visual images of specific episodes from the past, such as remembering an argument with a coworker) and *generic personal memory* (e.g., knowledge about the types of instances individuals are likely to experience, such as knowing what it is like to be angry; Brewer, 1994). Recent, low frequency, and/or emotionally laden experiences are likely to be retained as personal memories (White, 1989), whereas other types of experiences tend to fade rather quickly (Engle & Lumpkin, 1992). In contrast to the episodic nature of personal memories, generic personal memory is formed gradually over time as a series of similar events is experienced (Menon, 1994). New and old experiences are automatically integrated (Hawkins & Hastie, 1990) creating a knowledge base that lacks specific time and location indicators (Means, Mingay, Nigam, & Zarrow, 1988).

The present understanding of autobiographical memory processes suggests that retrospective self-reports can be produced in several ways: They can be reproduced from personal memories, reconstructed from generic personal memory, or derived from a combination of reproduction and reconstruction. For example, a person may recall some details of an event from personal memories (e.g., a 30th birthday party) and fill in forgotten details with information from generic personal memory (e.g., general knowledge of what birthday parties entail). The choice of strategy depends in large part on the type of experience to be recalled. Memories of infrequently experienced and/or recent events are likely to be reproduced, whereas memories of events that are commonplace or have been experienced in the distant past are likely to be reconstructed (Blair & Burton, 1987). An exception to this pattern is temporal information (e.g., when an event occurred or how long it lasted), which regardless of retention interval or frequency of event occurrence is almost always reconstructed (Thompson et al., 1996).

Although it was once believed that reproduction was less prone to cognitive errors than reconstruction (see Sudman, Bradburn, & Schwarz, 1996), recent work indicates that both strategies are susceptible to systematic recall biases. In the following sections, the impact of these biases on three broad categories of self-report questions is examined. These categories include previous experiences (e.g., "How did you feel then?"), frequency rates (e.g., "How often have you ...?"), and temporal information (e.g., "When did it occur?").

Within each category, the types of reproduction and reconstruction errors that reduce recall accuracy are discussed.

RETROSPECTIVE RECALL BIASES AND COGNITIVE ERRORS

Previous Experience

Participants in behavioral science research are often asked to recall how they thought, felt, or behaved in the past. Questions can concern either a person's experience at a specific point in time (e.g., pretreatment pain level) or a summary estimate of typical experiences (e.g., average pain level over the past 6 months). Questions pertaining to a specific point in time appear to require participants to reproduce information from personal memories, whereas summary measures presumably require participants to base their answer on generic personal memory or cognitively compute an average of the experiences they reproduce (Stone et al., 1999). Although these types of questions are common in retrospective self-reports, results from numerous studies indicate that participants have difficulty providing accurate answers. For instance, a substantial discrepancy between real-time and retrospective reports was found in Stunkard and colleagues' examination of vomiting among postoperative gastric reduction patients (Stunkard, Foster, Glassman, & Rosato, 1985). Following surgery, patients recorded the number of times they vomited each day in weekly diaries for 6 months. At the end of the monitoring period, they were asked to recall the number of times they had vomited in the week following surgery. Results indicated that for the first postoperative week, patients retrospectively recalled vomiting an average of 12.1 times, whereas their real-time reports produced a much lower average of 3.4 times. This trend of retrospective overreporting continued throughout the 6-month period.

Discrepancies between retrospective and real-time reports have also been documented over shorter time frames. Over a 7-day period, for example, significant discrepancies have been found between retrospective and real-time reports of coping strategies (Ptacek, R. Smith, Epse, & Raffety, 1994) and pain severity (Stone, Broderick, Kaell, & Porter, 1995). Even over a limited 2-day period, retrospective recall of coping strategies has been shown to differ greatly from real-time reports (Stone et al., in press). At retrospective recall, 29% of participants experiencing work or marital stress failed to report a coping strategy they had endorsed during real-time reports recorded during the previous 48 hours.

Reproduction Errors. Why do participants err when retrospectively recalling previous experiences? If a memory is reproduced, recall is likely to be biased by the types of experiences retained as personal memories. The infrequent and/or emotionally laden events that are held in episodic form over time are, by definition, not representative of average experiences. When basing reports on these extreme instances from the past, errors are likely to occur. This bias was demonstrated in a study of emotional recall (Thomas & Diener, 1990) in which participants recorded their mood either four

times a day for 3 weeks or at the end of the day for 6 weeks. Comparisons of summary self-reports completed after daily monitoring with daily mood assessments revealed that participants in both groups retrospectively overestimated the intensity of their positive and negative moods. The authors concluded that participants' responses were based on recall of key emotional events rather than recall of all relevant information. Similar errors have been found in studies of drug use (Hammersley, 1994) and pain severity (Stone, Broderick, Porter, & Kaell, 1997).

Recent events are also more likely to be stored episodically as personal memories than are distal events. Consequently, when participants base their answers on the personal memories they are able to reproduce, their reports are likely to be disproportionately influenced by recent experiences. A comparison of momentary and end-of-day assessments of mood, for instance, demonstrated that retrospective reports were biased toward the most recently experienced emotional state of the day, rather than representing the entire day's mood (Shiffman, 1995). This recency effect has also been observed in studies of pain (Redelemeir & Kahneman, 1996; Stone et al., 1997).

Reconstruction Errors. Similar to the reproduction of experiences from personal memory, reconstruction of information about previous experiences from generic personal memory is prone to error. As generic personal memory is constantly updated by new experiences, one source of information that is particularly salient and likely to bias recall is current state (Jobe & Mingay, 1991). Participants often reconstruct reports of previous experiences by surveying how they feel at the moment of recall. How this information affects retrospective reporting depends in large part on the self-schemata or implicit self-theories participants hold about the stability of their experiences over time (Barclay & Subramariam, 1987; Conway & Ross, 1984). If experiences are believed to remain relatively constant, then participants will likely overestimate the similarity between their current and past states. In contrast, if experiences are believed to change over time, then participants will likely exaggerate differences between current and previous states.

Researchers have found that of the implicit self-theories, beliefs of stability tend to be most common (Ross, 1989). As a result, participants frequently equate their previous experiences with the experiences they are having at the time of retrospective reporting (e.g., Eich, Reeves, Jaeger, & Graff-Radford, 1985; Singer, 1977). Although less common, implicit self-theories of change can also influence participants' reports, particularly when participants expect change due to some sort of intervention or treatment (e.g., Conway, 1989; Conway & Ross, 1984). In a study of hip replacement patients, for example, Mancuso and Charlson (1995) compared actual preoperative health reports with postoperative estimates of the same time period. Retrospectively, only 1% of patients accurately recalled their overall preoperative functioning: The majority of patients (65%) retrospectively rated their preoperation condition as worse than it actually was, exaggerating the amount of improvement they had made following surgery. A similar pat-

tern of results has been found with chronic pain patients undergoing treatment (Linton & Melin, 1982) and patients recovering from prostate surgery and hysterectomies (Aseltine, Carlson, Fowler, & Barry, 1995).

In addition to current state, any other experiences that have occurred between the target event and the recall task are likely to be automatically integrated into generic personal memory. Consequently, participants' retrospective recall is based on both knowledge of past experiences and information about more recent experiences. One area where this poses a significant problem is in the measurement of stress and coping. If a stressful event is assessed after it is successfully dealt with, participants are likely to retrospectively minimize the event's initial stressfulness. This phenomenon, known as "effort after meaning," was first described by G. W. Brown and Harris (1978) and it can significantly bias retrospective reports of stress, coping, and other experiences.

In sum, people have great difficulty accurately recalling their previous experiences at either a specific point in the past or on a summary level. Estimates based on the reproduction of personal memories are likely to be biased by extreme and/or recent experiences. When reconstructing answers, reports are likely to be influenced by current state, implicit theories of stability, and the automatic integration of new and old experiences in generic personal memory.

Frequency Rates

Participants in behavioral science research are commonly asked to provide information about the frequency of various events and experiences. Participants' choice of recall strategy has been demonstrated to be a function of the overall frequency of an event: Information about infrequent events is likely to be reproduced, whereas information about frequent events is likely to be reconstructed (e.g., Blair & Burton, 1987; Menon, 1994). An examination of recall for medical visits by Means and Loftus (1991, Experiment 1) supports this assertion. In this study, participants were asked to recall how many times they had received medical attention in the previous 12 months for allergies, acute injuries, or dental work. After estimating frequency rates, they were asked to indicate how they derived their answers. When only one medical visit was reported, over 80% of participants endorsed reproducing the individual instance from memory as their primary recall strategy. In contrast, when three or more visits were reported, less than 50% of participants reported basing their answers on recall of distinct personal memories. Clearly, as the overall frequency rates increased, the reproduction of information from personal memories decreased. As with recall of previous functioning, the use of both reproductive and reconstructive strategies when answering frequency questions is prone to recall biases and these errors are considered in the following section.

Reproduction Errors. When participants provide frequency information about irregular or uncommon events (i.e., less than three instances within a given recall category), they typically reproduce the relevant instances from personal

memories and then add them to derive their answers (Means, Swan, Jobe, & Esposito, 1994). One type of error that affects reproduction of frequency information is omission (Blair & Burton, 1987). Omission, or the failure to recall an event, is believed to be caused by several factors, most notably inadequate retrieval cues. For instance, Smith, Jobe, and Mingay (1991) asked participants the question, "Altogether, during the past month, about how many times would you say you have eaten (a specific food)?" Prior to answering the question, participants were instructed to either think and take notes about the most recent time they had eaten the food, to think about as many different occasions on which they had eaten the food, or they were given no instructions at all. Omission rates were significantly reduced for participants instructed to think of as many different occasions as possible, suggesting that frequency estimates are influenced by the cognitive context in which they are made.

Length of retention interval has also been shown to be a factor in omission rates. In a study by Mathiowetz (1988), only 2% of medical visits occurring during a week of retrospective reporting were omitted, and approximately 30% of medical visits occurring 6 weeks prior to retrospective reporting were omitted. Omission rates increased by more than 3% with each passing week, providing strong evidence of an association between omission and length of retention interval.

Although less common than omission, errors of commission, or the inappropriate inflation of frequency rates, also affect frequency information reproduced from personal memories (Cummings, Nevitt, & Kidd, 1988). The leading explanation for commission is a phenomenon known as forward telescoping, or the shifting of dates ahead in time (Thompson, Skowronski, & Lee, 1988). Forward telescoping results in overestimation of frequency rates when events are mistakenly imported into the time frame under study. (*Note:* Examples and explanations of telescoping errors are discussed in more detail in the temporal information section). Commission may also be due to source monitoring errors (Johnson, Hashtroudi, & Lindsay, 1993). That is, rate inflation may occur when participants confuse real occasions with instances in which an event was mentally reviewed or verbally discussed (Johnson & Raye, 1981).

Reconstruction Errors. When estimating rates of frequently occurring events (i.e., three or more instances within a given recall category), reconstructive rather than reproductive strategies are likely to be used. Perhaps the most common reconstructive strategy employed when generating frequency information is decomposition (Means & Loftus, 1991; Means et al., 1994). Decomposition involves breaking the time frame of interest into discrete segments, estimating the frequency rate for one segment, and then multiplying that rate by the total number of segments to derive the overall frequency. For example, if asked "How many times in the past month have you exercised?", a participant using decomposition might estimate the number of times they exercised in the past week and multiply that weekly value by four to arrive at a monthly total. To the degree that the event in question is stable over time, this strategy will produce accurate answers. However, for events that do

not show temporal stability, the use of decomposition will produce errors. Returning to the exercise example, there could be many possible reasons why the number of times exercised in the past week may be exceptional and not representative of monthly exercise totals. Thus, depending on the circumstances, decomposition can lead to either accurate responses, overestimation, or underestimation.

Reconstruction of frequency rates can also be biased by normative expectations held in generic personal memory about how often a particular event should or typically occurs (Bradburn, Rips, & Shevell, 1987). For example, when Means and Loftus (1991) asked participants how they derived their frequency estimates of dental visits within the past 12 months, 41% of participants acknowledged basing their answers on the common rule of thumb that you should visit the dentist once or twice a year. Expectations such as this lead participants to anchor and adjust their estimates to ensure they fall within the normative range, consequently limiting the range of values participants are willing to provide as frequency rates.

Just as participants have normative expectations about frequency rates, they also have implicit beliefs about how memory works. One example of this is the common belief that infrequent events are difficult to remember and frequent events are easy to recall (Bradburn et al., 1987). Based on this belief, participants will gauge an event's frequency based on ease of retrieval. If they have difficulty remembering the event (e.g., cannot recall a specific instance or can remember only a few details), they are likely to report it as infrequent. Alternatively, if instances of events are easy to retrieve (e.g., instances come quickly to mind with vivid details), they are likely to be judged as having a higher rate of occurrence (Means et al., 1994). Although this assumption, commonly referred to as the availability heuristic (Tversky & Kahneman, 1974), leads to correct answers at times, equating the level of detail remembered with rate of occurrence can be problematic. A demonstration of this is that specific examples of plane crashes are easier to recall than car accidents, but car accidents occur much more frequently.

In sum, retrospective recall of frequency rates is often biased and inaccurate. If frequency rates are reproduced, they are prone to errors of omission and commission. If they are reconstructed, decomposition strategies, normative expectations, and the availability heuristic are likely to impact their validity.

Temporal Information

Temporal information refers to information about an event's date and/or duration and is often of interest to behavioral science researchers. Unlike previous experiences and frequency rates, temporal information is rarely held episodically in the form of personal memories (Burt & Kemp, 1991). Rather, three lines of evidence suggest that temporal information is almost entirely reconstructed from generic personal memory (Friedman, 1993). First, research participants are not particularly accurate when providing temporal information (Barclay & Wellman, 1986; Thompson, 1982). Cohen and Java (1995), for instance, found that only 50% of health events (e.g., vom-

iting, back pain, and toothaches) occurring within a 3-month interval were retrospectively dated within 2 weeks of their actual occurrence. Second, when given the opportunity, participants tend to shy away from providing exact dates. In a study by Huttenlocher and colleagues (1990), only 23% of participants asked to date a previous in-home interview were willing to venture a guess (Huttenlocher, Hedges, & Bradburn, 1990). Third, when Thompson, Skowronski, and Betz (1993) asked participants to indicate the recall strategies they used to date personal events, less than 18% endorsed reproducing the exact date from memory (Thompson et al., 1993). More frequently, participants reported reconstructing temporal information by relating the event of interest to a general reference period (e.g., summer), basing answers on general temporal schemata (e.g., event happened at work and I only work weekdays), or basing estimates on the clarity of the event memory (e.g., the clearer the memory of the event, the more recently it occurred).

Based on such evidence, a reconstructive model of temporal memory has been advanced, emphasizing the role of generic personal memory (Friedman, 1993; Skowronski, Betz, Thompson, & Shannon, 1991). The model holds that the reconstruction of temporal information is guided by time-related schemata that organize general temporal knowledge (Larsen & Thompson, 1995). One powerful temporal framework is day of the week (DOW) schema, which contains general knowledge about the types of activities a person is likely to be engaged in on a given day of the week (e.g., Monday through Friday work, Wednesday evening class, Saturday morning errands, etc.). Two sources of information indicate that when participants are asked to date an event, their DOW schemas are activated. First, participants consistently perform above chance when identifying which day of the week an event occurred (Skowronski & Thompson, 1990). This is particularly true for events in which contextual information is recalled, presumably because the vivid details facilitate links between events and the DOW schema (Larsen & Thompson, 1995). Second, the error pattern for dating events is unevenly distributed around multiples of seven—indicating that participants tend to err in terms of the given week an event occurred, rather than the day of the week (Huttenlocher, Hedges, & Prohaska, 1992; Skowronski et al., 1991). These two findings suggest that exact dates are not encoded in personal memories but rather are reconstructed from temporal schemas. In this section, a few of the more prominent biases and errors that come into play during temporal reconstruction are reviewed.

Telescoping. Although participants are often correct about the day of week a given event occurred, they can rarely identify an event's exact date. More often than not, an event is forward telescoped and given a date more recent than its actual occurrence (Cohen & Java, 1995; Thompson et al., 1988). This phenomenon has been observed for several types of events ranging from crime incidents (Loftus & Marburger, 1983) to entertainment outings (Huttenlocher, Hedges & Prohaska, 1988). Substantial telescoping was observed, for example, when participants estimated the dates of unique personal events occurring within a 3-month period (Thompson et al.,

1988, Experiment 1). Upon recall, the dates of events occurring at the beginning of the study were shifted forward by an average of 7 days. Examples of reverse telescoping, or shifting an event back in time, are also found in the literature, but are less common (Means & Loftus, 1991; Rubin & Baddeley, 1989; Sudman & Bradburn, 1973). Together, forward and reverse telescoping affect the validity of not only temporal information but of frequency information as well.

The cognitive mechanisms behind telescoping are not well understood (Rubin & Baddeley, 1989). One hypothesis that has been proposed is that the clarity of the memory, or the amount of detail remembered about an event, affects the date it is given (Bradburn et al., 1987). This hypothesis, which appears to be the temporal equivalent of the availability heuristic, posits that when many details are remembered, an event will be dated as occurring recently, and when only a few details are remembered, an event will be dated as occurring in the past. Although one study found support for this hypothesis (N. R. Brown, Rips, & Shevell, 1985), other studies have demonstrated that the magnitude of the telescoping effect is not related to participants' reported clarity of memory or confidence in dating accuracy (Thompson et al., 1988). More work is needed to fully understand the factors contributing to telescoping errors.

Bounding and Rounding. Another interesting phenomenon observed when participants reconstruct dates is bounding. *Bounding* refers to the tendency to restrict estimates to a self-imposed, limited interval. This error was observed by Huttenlocher et al. (1990). When recalling the date of a prior in-home interview, participants tended to self-restrict their estimates to under 60 days, although in actuality several participants were interviewed outside of the bounded interval. The cause of the boundary effect is not clear, but may be due in part to participants' beliefs about what constitutes a reasonable time frame for a recall task.

Huttenlocher and colleagues also noted that when participants were asked to report their answers in terms of the amount of time passed since the interview (instead of giving the exact date), participants tended to respond in terms of prototypic answers, that is, they *rounded* (e.g., weeks or months, rather than exact number of days). Response patterns were unevenly distributed around the values of 7, 10, 14, 21, 30, and 60 days, reflecting a strong tendency to round estimates off to the number of weeks or months elapsed. These values accounted for 70% of participants' response, while in reality they represented less than 10% of the actual values. As with bounding, the source of rounding errors is not known, but may reflect participants' reliance on schemas when answering temporal related questions.

Duration Biases. A series of studies by Burt and colleagues highlights the reconstructive nature of duration estimates. Examinations of both personal and historical events revealed that having no memory for a given event did not significantly increase duration estimate errors (Burt, 1992; Burt & Kemp, 1991). Rather than basing duration estimates on recall of specific personal memories, participants appear to

base their answers on generic personal memory about the event category in question (Burt & Kemp, 1991). For instance, if asked to estimate the length of a friend's visit that is not recalled from personal memories, participants will tend to base their answers on generic knowledge about the typical length of a guest visit. This reconstruction strategy results in errors when the event in question has an atypical duration (Burt, 1993).

In sum, recall of temporal information is almost entirely reconstructive in nature. Participants rely on DOW schemas, as well as general knowledge from generic personal memory, to guide their responses. As a result, temporal estimates are subject to errors such as telescoping, bounding, and rounding.

SUMMARY OF RETROSPECTIVE RECALL BIASES AND THEIR IMPACT

In light of recent work in the area of autobiographical memory, significant biases and errors appear to be inherent in retrospective recall. Both the reproduction of information from personal memories and the reconstruction of information from generic personal memory tend to be inaccurate. Reports based on reproductive strategies are likely to be based on extreme instances from the past and are subject to omission and commission errors. Reports based on reconstructive strategies are likely to be influenced by the integration of new and old information as well as current state, decomposition strategies, and normative expectations. Reports of temporal information are also almost entirely reconstructed, with participants relying on inexact generic knowledge such as DOW schemas to answer temporal questions.

The magnitude of these errors is significant, even over limited retention intervals (e.g., Shiffman, 1995; Stone et al., 1998). In a study of time usage, for instance, participants retrospectively recalled less than 60% of the activities they had engaged in during a 2-hour observation period the previous day (Engle & Lumpkin, 1992). Similar error rates are found in studies with extended retention intervals. Retrospective recall of medication usage over a period of 3 months, for example, revealed omission rates of 40%—an error that could result in potentially serious drug interactions (Cohen & Java, 1995). Recall is even more susceptible to biases and errors as retention intervals expand from months to years. For instance, when hospital CEOs were asked to retrospectively report the type of business strategy they employed 2 years ago, 58% were completely inaccurate (Golden, 1992). Taken together with the work already reviewed, these findings seriously question the ability of research participants or patients to accurately report previous experiences, frequency rates, and temporal information over short and long retention intervals.

Within the past two decades, survey developers have turned to autobiographical memory researchers in efforts to devise ways to minimize recall biases and improve the accuracy of retrospective self-reports (Huber & Power, 1985; Loftus, Fienberg, & Tanur, 1985). This collaborative work has produced several strategies, including instructing participants in the use of retrieval aids such as timeliness and landmarks (Loftus & Marburger, 1983; N. F. Smith, Jobe, & Mingay, 1991), providing participants with more time to respond to answers

(Hammersley, 1994), using bounded-recall interviews (Babor et al., 1990), and increasing participant motivation by stressing confidentiality and giving performance feedback (Baker & Brandon, 1990). Although the effectiveness of many of these techniques has yet to be empirically demonstrated, research in this area suggests many promising ways to limit errors that occur during retrospective self-reporting (see Sudman et al., 1996, for extended discussion).

ECOLOGICAL MOMENTARY ASSESSMENT: AN ALTERNATIVE TO RETROSPECTIVE SELF-REPORTS

An alternative approach to dealing with recall biases has been to move to momentary-based assessment strategies eliminating the retrospective nature of reports. The experience sampling method (ESM) developed by Csikszentmihalyi and colleagues (Csikszentmihalyi & Larsen, 1987) was the first momentary-based assessment approach to focus on behaviors and mental states (for a detailed account of the historical antecedents of momentary assessments in behavioral science research, see Stone et al., 1999). Since the introduction of ESM, behavioral science researchers have used momentary assessment strategies not only to study psychological experiences but physiological variables as well. Stone and Shiffman (1994) coined the term *ecological momentary assessment* (EMA) to reflect the increasing scope of momentary-based assessment approaches. In this section, EMA is defined and a discussion of its strengths and weaknesses as a research tool is provided.

There are three defining characteristics of EMA that differentiate it from traditional self-report measures. First, as its name implies, EMA focuses on what is happening on a momentary basis. Instead of asking participants to summarize their functioning over several weeks, days, or even hours, participants in EMA studies usually record how they feel and what they are doing at the moment of the assessment. For instance, a typical EMA question would be, "On a scale from 1 to 7, please rate how fatigued you are *at this moment*." Unlike retrospective recall, which is often reconstructive, participants' answers to such questions are not likely to be based on generic personal memory. Rather, participants are simply required to report the experiences they are having at that moment.

Second, in contrast to the laboratory and clinical settings typical of retrospective self-report administration, EMA data are collected in the participants' usual environments. Participants carry signaling devices with them throughout their normal daily routine, including while at work and at home. By maximizing ecological validity, EMA minimizes the possibility that reports are an artifact of the testing situation (e.g., white coat hypertension, test anxiety) and, as a result, the data collected are more likely to be representative of participants' typical functioning (Stone & Shiffman, 1994).

Third, EMA differs from retrospective self-reports in terms of its sampling strategy. Although retrospective measures are typically administered only once at the convenience of the researcher or clinician, EMA involves numerous momentary collections per day over a series of several days or weeks. In a typical EMA study, the exact timing of reports are randomly selected in order to ensure a representative and unbiased view

of the phenomenon of interest. Whereas random reports are essential for the study of rapidly changing psychological states, they are not the only sampling strategy available for use with EMA. Depending on the research question at hand, event-contingent (e.g., complete report every time a stressful situation occurs) and time-contingent (e.g., fill out report every 2 hours) strategies can be employed. These are appropriate for the study of relatively rare or infrequent events.

Advantages and Limitations of EMA

In addition to avoiding recall biases and providing a representative view of the phenomenon of interest, the intensive sampling strategy of EMA allows for a detailed analysis of within-subjects effects. Diurnal cycles and the impact of environmental and situational factors on participants' experiences can be explored with EMA data. For example, using an EMA design, diurnal cycles in rheumatoid arthritis patients' pain and fatigue levels have been examined, providing new insights into disease experience (Stone et al., 1997). Variations in outcomes due to environmental and social factors may prove to be an important factor to consider when assessing disease severity and treatment response. Although extremely useful for detailed within-subjects analyses, the multiple reports per person generated through use of an EMA design can also be aggregated across time to examine between-subjects effects. These momentary-based "trait" measures provide summaries of participants' experiences that are not subject to retrospective recall biases.

Although there are many advantages to using EMA, there are also a few notable limitations. Given the intensive nature of the assessment strategy, participant burden is a legitimate concern. Early indicators suggest that completion rates in EMA studies are quite high and missing data are not a significant problem (Ockenfels et al., 1995; Smyth et al., 1996; Stone et al., 1997), but assessments should be brief so as to not add to participants' work load. There also is some concern about possible reactive effects of momentary assessments on participants' daily experiences. By requiring participants to attend closely to their daily experiences, their perception of their own experiences may inadvertently change. Initial work in the area of pain indicates that EMA monitoring does not change participants' perceptions (Cruise, Broderick, Porter, Kaell, & Stone, 1996), however, more work needs to be done to understand the effects monitoring has on participants' daily lives.

In addition to challenging participants, EMA designs pose some problems for researchers. Statistically, the multiple reports per person generated through EMA assessment strategies violate the assumptions of traditional linear modeling. To side step this issue, alternative, and at times complex, methods of analyzing the data need to be employed (see Schwartz & Stone, 1997). EMA can also be financially taxing. Special equipment, including signaling devices (e.g., watches or palmtop computers) and computer programs, are necessary to complete EMA projects.

In sum, although EMA requires extra effort on both the part of researchers and participants, it improves on traditional retrospective self-reports measures in many respects. Most

notably, recall biases and cognitive errors are eliminated. In addition, EMA data are suitable for the examination of individual differences and complex interactions between environmental and psychosocial factors. Given these strengths, EMA is a viable research tool for gathering accurate autobiographical facts.

CONCLUSIONS

This chapter reviews recall biases and cognitive errors that affect retrospective self-reports. The studies examined suggest that the magnitude of retrospective reporting errors are significant and can threaten the validity of information obtained from research participants. Within the past two decades, researchers have begun to develop means of improving participants' reports. These efforts have taken two general forms: improve the accuracy of retrospective reporting through methods such as memory aids and bounded recall, and eliminate the possibility of retrospective recall biases by moving to momentary-based assessment strategies. Both approaches offer ways to improve the accuracy of information gained from self-reports, however, momentary assessments have the additional advantages of maximizing ecological validity and allowing for examination of within-subjects effects such as diurnal cycles and associations between environmental and psychosocial factors. Although ideal for the study of rapidly changing states and frequently occurring events, momentary assessments are not well-suited for all research questions (e.g., studies of extremely rare events). Thus, in addition to the continued development of momentary-based assessment strategies, further research examining autobiographical memory processes contributing to retrospective recall biases is needed. Of particular use would be studies identifying instances when reporting errors are most likely to occur. More work is needed to fully understand the cognitive processes involved in both momentary and retrospective self-reports, but the implications of the existing research are clear: Momentary assessment strategies should be employed whenever possible, and in cases in which the use of EMA is not feasible, the impact of recall biases and cognitive errors on retrospective self-reports needs to be acknowledged.

Burnout and Health

Michael P. Leiter

Christina Maslach
University of California, Berkeley

Work plays a central role in people's physical and psychological well-being. Not only does it provide income and other tangible resources, but it is a source of status, social support, life satisfaction, and self-identity. However, work can also have adverse effects on the individual worker, especially with respect to health (Ilgen, 1990). The risks to physical well-being, in terms of injuries and diseases caused by the job, have long been the concern of the field of occupational health, but it is only recently that more attention has been given to job risk factors for psychological well-being (e.g., Sauter, Murphy, & Hurrell, 1990).

Much of this attention has focused on job stress, which is a general rubric referring to the impact of external job demands (stressors) on the worker's internal experience (stress response), and to the subsequent outcomes of this process. Stress impairs performance by reducing people's capacity for complex physical skills and by impairing cognitive functioning. Stress compromises the immune system, increasing the risk of viral and bacterial infections. The chronic tension associated with stress increases vulnerability to musculoskeletal problems. Empirical evidence has been found for the negative effects of job stress on physical health (especially cardiovascular problems), as well as on psychological well-being (e.g., job dissatisfaction, negative affect). Job stress is also predictive of various behavioral responses, such as lowered job performance, problems with family relationships, and self-damaging behaviors (see Kahn & Byosiere, 1992; Sauter & Murphy, 1995).

WHAT IS BURNOUT?

One type of job stress that has been studied in recent years is *burnout*, which involves a prolonged response to chronic interpersonal stressors on the job (Maslach, 1982; Maslach & Leiter, 1997). The three key dimensions of burnout are an overwhelming exhaustion; feelings of frustration, anger, and cynicism; and a sense of ineffectiveness and failure. The experience impairs both personal and social functioning. Whereas some people may quit the job as a result of burnout, others will stay on, but they will only do the bare minimum (rather than their very best). This decline in the quality of work and in both physical and psychological health can be very costly—not just for the individual worker, but for everyone affected by that person.

Burnout is recognized as a particular occupational hazard for various people-oriented professions, such as human services, education, and health care. The therapeutic relationships that such providers develop with their service recipients can be quite stressful because they demand an ongoing and intense level of personal, emotional contact. Within such occupations, the norms are clear, if not always stated explicitly: to be selfless and put others' needs first, to work long hours and do whatever it takes to help a client or patient or student, to go the extra mile and to give one's all. When such norms are combined with work settings that are high in demands and low in resources, then the risk for burnout is high (Maslach & Goldberg, 1998).

Not surprisingly, burnout has long been an issue of concern for health care occupations (Leiter & Harvie, 1996; Maslach, 1979, 1997; Maslach & Jackson, 1982; Maslach & Ozer, 1995). The caregiving relationship between health worker and patient involves significant emotional experiences. Some of these experiences are enormously rewarding and uplifting, as when patients recover because of the worker's efforts. However, other experiences are emotionally stressful for the health practitioner, such as working with difficult or unpleasant patients, having to give "bad news" to patients or their families, dealing with patient deaths, or having conflicts with coworkers or supervisors. These emotional strains are sometimes overwhelming and lead to emotional exhaustion.

To protect themselves against such disruptive feelings, health professionals may moderate their compassion for patients by distancing themselves psychologically, avoiding overinvolvement, and maintaining a more detached objectivity (a process known as "detached concern"; Lief & Fox, 1963). For example, if a patient has a condition that is upsetting to see or otherwise difficult to work with, it is easier for practitioners to provide the necessary care if they think of the patient as a particular "case" or "symptom" rather than as a human being who is suffering. However, the blend of compassion and emotional distance is difficult to achieve in actual practice, and too often the balance shifts toward a negative and depersonalized perception of patients. A derogatory and demeaning view of patients is likely to be matched by a decline in the quality of the care provided to them.

Many health professionals have not had sufficient preparation for the emotional reality of their work and its subsequent impact on their personal functioning. Thus, the experience of emotional turmoil on the job is likely to be interpreted as a failure to "be professional" (i.e., to be nonemotional, cool, and objective). Consequently, these health workers begin to question their own ability to work in a health career and to feel that their personal accomplishments are falling short of their expectations. These failures may be as much a function of the work setting as of any personal shortcomings; providing good health care may be difficult to accomplish in the context of staff shortages, poor training, or inadequate resources. Nevertheless, health workers may begin to develop a negative self-evaluation, which can impair their job performance or even lead them to quit the job altogether.

Thus, burnout appears to be an important factor in job turnover, absenteeism, and low morale. It is also correlated with various indices of personal and social dysfunction. But the most critical bottom line for burnout is its link to a deterioration in the quality of care or service provided to clients or patients.

A MULTIDIMENSIONAL MODEL OF BURNOUT

Unlike unidimensional models of stress, burnout is best conceptualized in terms of its three core components: emotional exhaustion, depersonalization, and reduced personal accomplishment (Maslach, 1993). According to this model, burnout is an individual stress experience embedded in a context of

complex social relationships, and it involves the person's conception of both self and others.

Emotional exhaustion refers to feelings of being emotionally overextended and having depleted emotional resources. The major sources of this exhaustion are work overload and personal conflict at work. People feel drained and used up, without any source of replenishment. They lack enough energy to face another day or another person in need. The emotional exhaustion component represents the basic stress dimension of burnout.

Depersonalization refers to a negative, callous, or excessively detached response to other people, which often includes a loss of idealism. It usually develops in response to the overload of emotional exhaustion, and is self-protective at first—an emotional buffer of "detached concern." But the risk is that the detachment can turn into dehumanization. The depersonalization component represents the interpersonal dimension of burnout.

Reduced personal accomplishment refers to a decline in feelings of competence and productivity at work. This lowered sense of self-efficacy has been linked to depression and an inability to cope with the demands of the job, and it can be exacerbated by a lack of social support and of opportunities to develop professionally. Staff members experience a growing sense of inadequacy about their ability to help clients, and this may result in a self-imposed verdict of failure. The personal accomplishment component represents the self-evaluation dimension of burnout.

Conceptual Issues

The interrelations among the three components of burnout have been the subject of much theorizing and research. The only measure that assesses all three of these burnout components is the Maslach Burnout Inventory (MBI), so it is considered the standard tool for research in this field (Maslach & Jackson, 1981, 1986; Maslach, Jackson, & Leiter, 1996). There are now three versions of the MBI designed for use with different occupations, which reflects the developing interest in this phenomenon. The original version of the MBI (now known as the MBI-HSS) was designed for use with people working in the human services (including health care). It was in these occupations where the greatest continuing concern about burnout has been evident. A second version of the MBI (the MBI-ES) was developed for use by people working in educational settings. Given the increasing interest in burnout within occupations that are not so clearly people oriented, a third, general version of the MBI (the MBI-GS) has recently been developed. Here, the three components of the burnout construct are conceptualized in slightly broader terms, with respect to the general job, and not just to the personal relationships that may be a part of that job. Thus, the three components are exhaustion, cynicism (a distant attitude toward the job), and reduced professional efficacy (Maslach, Jackson, & Leiter, 1996).

The general version of the MBI was a significant departure from the established focus on the service relationship as the burnout concept was developed (Cherniss, 1980; Maslach,

1982). Almost from the original release of the MBI, researchers used the scale, modified or unmodified, with occupational groups other than public human service providers, including civil servants (Golembiewski & Munzenrider, 1988), military (Leiter, Clark, & Durup, 1994), computer programmers (Lee & Ashforth, 1993), police officers (Burke, 1987), managers (Lee & Ashforth, 1993), and entrepreneurs (Gryskiewicz & Buttner, 1992). These researchers saw that people in these occupations confronted crises in energy, involvement, and efficacy that shared core features with the experiences of human service workers, despite a less intense contact with people. The MBI-HSS did not fully assess burnout outside of human services because of the frequent reference to service recipients in the items; not only did these groups' scores on the MBI-HSS subscales differ from norms established with human service providers, but the factor structure for the MBI was not maintained across other occupational groups. The MBI-GS addressed this problem by developing a variation of the MBI that maintained a consistent factor structure across a variety of occupations including human service providers (nurses) along with a variety of managerial and technical occupations (Leiter & Schaufeli, 1996; Maslach, Jackson, & Leiter, 1996).

Exhaustion is the central quality of burnout and the most obvious manifestation of this complex syndrome. When people describe themselves or others as experiencing burnout, they are most often referring to the experience of exhaustion. In fact, nurses who responded to an advertisement about burnout scored much higher than the average on exhaustion but only moderately higher on the other two aspects of the syndrome (Pick & Leiter, 1991). Of the three aspects of burnout, exhaustion is the most widely reported and the most thoroughly analyzed. The strong identification of exhaustion with burnout has led some to argue that the other two aspects of the syndrome are incidental or unnecessary (Shirom, 1989). However, the fact that exhaustion is a necessary criterion for burnout does not mean it is a sufficient one.

Although exhaustion reflects the stress dimension of burnout, it fails to capture the critical aspects of the relation people have with their work. People do not simply feel exhausted when they experience a mismatch with their job. Exhaustion prompts people to attempt to distance themselves emotionally and cognitively from their work, as can be seen clearly in the human services. The emotional demands of this work exhaust a service provider's capacity to be involved with, and responsive to, the needs of service recipients. Depersonalization is people's attempt to put distance between themselves and service recipients by actively ignoring the qualities that make them unique and engaging people. Recipients' demands are more manageable when they are considered impersonal objects. Outside of the human services, people use cognitive distancing by developing an indifference or cynical attitude when they are exhausted and discouraged. Distancing is such an immediate reaction to exhaustion that a strong relation from exhaustion to depersonalization or cynicism is found consistently in burnout research, across a wide range of organizational and occupational settings (Maslach, Jackson, & Leiter, 1996).

The relation of reduced personal accomplishment to the other two aspects of burnout is somewhat more complex. In some instances, reduced personal accomplishment appears to be a function, to some degree, of either exhaustion, cynicism, or a combination of the two (Byrne, 1994; Lee & Ashforth, 1996). A work situation with chronic, overwhelming demands that contribute to exhaustion or cynicism is likely to erode an individual's sense of accomplishment or effectiveness. Further, the experience of exhaustion or depersonalization interferes with effectiveness: It is difficult for people to gain a sense of accomplishment when feeling exhausted or when helping people toward whom they are indifferent. However, in other settings, reduced accomplishment appears to develop in parallel with the other two burnout aspects, rather than sequentially (Leiter, 1993). Here the lack of efficacy seems to arise more clearly from a lack of relevant resources, whereas exhaustion and cynicism emerge from the presence of work overload and social conflict.

The inclusion of psychological distance in the construct of depersonalization or cynicism, along with professional inefficacy, make burnout much broader than established ideas of occupational stress. The stressful implications of emotional exhaustion are clearly tied to physical well-being, but the other two aspects of burnout are primarily related to psychological and social functioning. Together, the three aspects of burnout provide a rich and productive basis for examining psychological aspects of health in work organizations.

Personal Characteristics of Burnout

Burnout has been studied primarily in postindustrialized nations (United States, Canada, Europe, and Israel), although recently increased interest is being expressed in the syndrome by researchers in other nations. To date, most research on burnout has focused on human service occupations (Cordes & Dougherty, 1993; Leiter & Harvie, 1996; Maslach, Jackson, & Leiter, 1996), with the most frequent reports of burnout occurring among health care workers, teachers, and social workers. There are not substantial differences in burnout levels associated with gender, race, or age. As discussed later, burnout does vary with work conditions, and these may in turn be related to demographic characteristics. For example, in many organizations women have lower status positions relative to men, and they may also report more indicators of burnout due to a diminished quality of their work life. Human service workers in Europe tend to score lower on exhaustion and depersonalization/cynicism (Schaufeli, Maslach, & Marek, 1993; Van Yperen, Buunk, & Schaufeli, 1992). The absence of definite associations between burnout and personal characteristics has focused research and interventions on qualities of work settings.

Engagement With Work

Burnout is one end of a continuum in the relation people establish with their jobs. As a syndrome of exhaustion, cynicism, and ineffectiveness, it stands in contrast to the energetic, involved, and effective state of engagement with work. Recently,

the multidimensional model of burnout has been expanded to this other end of the continuum (Leiter & Maslach, 1998). Engagement is defined in terms of the same three dimensions as burnout, but at the positive end of those dimensions rather than the negative. Thus, engagement consists of a state of high *energy* (rather than exhaustion), strong *involvement* (rather than cynicism), and a sense of *efficacy* (rather than a reduced sense of accomplishment).

This state is distinct from established constructs in organizational psychology such as organizational commitment, job satisfaction, or job involvement. Organizational commitment focuses on an employee's allegiance to the organization, which provides employment rather than to the work itself. The two concepts are related, but the focus of involvement differs. Organizational commitment focuses on the organization; engagement with work focuses on the work itself. Job satisfaction is the extent to which work is a source of need fulfillment and contentment, or a means of freeing employees from hassles or dissatisfiers; it does not encompass the person's relationship with the work itself. Job involvement is similar to the involvement aspect of engagement with work, but does not include the energy and effectiveness dimensions. Engagement with work provides a more complex and thorough perspective on an individual's relationship with work.

The extensive research on burnout has consistently found linear relations of workplace conditions across the full range of the MBI subscales. Just as high levels of personal conflict are associated with high levels of emotional exhaustion, low levels of conflict are strong predictors of low exhaustion. Conversely, high personal accomplishment is associated with supportive personal relationships, the enhancement of sophisticated skills at work, and active participation in shared decision making. These patterns indicate that the opposite of burnout is not a neutral state, but a definite state of mental health within the occupational domain. Whereas the burnout concept describes a syndrome of distress that may arise from enduring problems with work, engagement describes a positive state of fulfillment.

The concept of a burnout-to-engagement continuum enhances the understanding of how the organizational context of work can affect workers' well-being. It recognizes the variety of reactions that employees can have to the organizational environment, ranging from the intense involvement and satisfaction of engagement, through indifference, to the exhausted, distant, and discouraged state of burnout. One important implication of the burnout-engagement continuum is that strategies to promote engagement may be just as important for burnout prevention as strategies to reduce the risk of burnout. A work setting designed to support the positive development of the three core qualities of energy, involvement, and effectiveness should be successful in promoting the well-being and productivity of its employees.

SOURCES AND OUTCOMES OF BURNOUT

The empirical research on contributing factors has found that situational variables are more strongly predictive of burnout than are personal ones. In terms of antecedents of burnout, both

job demands and a lack of key resources are particularly important. Work overload and personal conflict are the major demands, and the lack of such resources as control coping, social support, skill use, autonomy, and decision involvement seem to be especially critical. The consequences of burnout are seen most consistently in various forms of job withdrawal (decreased commitment, job dissatisfaction, turnover, and absenteeism), with the implication of a deterioration in the quality of care or service provided to clients or patients. Burnout is also linked to personal dysfunction, primarily in terms of impaired physical and mental health, although there is some evidence for increased substance abuse as well as marital and family conflicts. Figure 23.1 presents a diagrammatic summary of these major research findings, which have been discussed in a number of recent reviews (see Cordes & Dougherty, 1993; Leiter & Maslach, 1998; Maslach, Jackson, & Leiter, 1996; Schaufeli, Maslach, & Marek, 1993). This chapter concentrates on those findings having to do with health.

Unlike acute stress reactions, which develop in response to specific critical incidents, burnout is a cumulative stress reaction to ongoing occupational stressors. To put it in the terms of Selye's (1967) general adaptation syndrome, burnout is the exhaustion phase, following those of alarm and resistance. In this final phase, after prolonged exposure to stress, the physiological resources are depleted, and irreversible physical damage is caused to the organism. With burnout, the emphasis has been more on the process of psychological erosion, and the psychological and social outcomes of this chronic exposure, rather than just the physical ones. Because burnout is a prolonged response to chronic interpersonal stressors on the job, it tends to be fairly stable over time.

In a similar way, Brill (1984) conceptualized stress as an adaptation process that is temporary and is accompanied by mental and physical symptoms, whereas burnout refers to a breakdown in adaptation accompanied by chronic malfunctioning. This acute versus chronic temporal distinction implies that both concepts can only be discriminated retrospectively when the adaptation has been successfully performed (job stress) or when a breakdown in adaptation has occurred (burnout). In other words, stress and burnout are distinguished more in terms of process than specific physical symptoms (Maslach & Schaufeli, 1993).

Even though the stress literature provides a clear theoretical basis for a relation between burnout and health, such a relation has not been studied extensively. Of the three burnout components, emotional exhaustion is the closest to an orthodox stress variable, and thus it should be more predictive of stress-related health outcomes than the other two components. Exhaustion indicates a depletion of resources and personal energy. An exhausted individual is lacking the necessary resources for making an effective contribution at work as well as those needed to ward off disease and maintain physical well-being. However, the exhaustion may not be high enough to cause such severe debilitation that the person cannot function on the job, or is too sick to work.

Indeed, a consistent finding in burnout research is the correlation between the exhaustion component and various physical symptoms of stress: headaches, gastrointestinal dis-

FIG. 23.1. Model of burnout. Jackson, and Michael P. Leiter. Copyright 1996 by Consulting Psychologists Press, Inc. All rights reserved. Further reproduction is prohibited without the publisher's written consent.

orders, muscle tension, hypertension, cold/flu episodes, and sleep disturbances (Bhagat, Allie, & Ford, 1995; Burke & Deszca, 1986; Golembiewski & Munzenrider, 1988; Hendrix, Summers, Leap, & Steel, 1995; Jackson & Maslach, 1982; Kahill, 1988; Leiter, Clark, & Durup, 1994; Leiter & Harvie, 1996). One study found that emotional exhaustion and a work environment index predicted distinct patterns of health symptoms and behaviors, even after controlling for negative affect and demographic variables. Work environment was most predictive of symptoms and behaviors associated with muscle aches and pains, whereas the exhaustion component of burnout predicted health symptoms related to sleep disturbances and visits to the doctor for cardiovascular complaints (Maslach, Zedeck, Skitka, & Mosier, 1997).

Despite this link between burnout and stress-related health behaviors, there has not yet been any research on relevant health outcomes, such as the utilization of health care services or the filing of workman's compensation claims for stress. There has also been no theorizing to suggest that burnout has a connection to the development or progression of specific diseases, and consequently there is no empirical research on this issue.

In terms of mental, as opposed to physical, health, the link with burnout is much more complex. It has often been presumed that burnout may result in subsequent mental disabilities, and there has been some evidence in support of that view. For example, emotional exhaustion was found to be correlated with anxiety (Corrigan et al., 1994), and higher phases of burnout were associated with worsening scores on a mental health index (Golembiewski & Munzenrider, 1991).

However, an alternative interpretation of such correlations is that burnout is itself a form of mental illness, rather than a cause of it. Much of this discussion has focused on depression, and whether or not burnout is a distinctly different phenomenon. Research conducted during the development of the MBI found burnout to be distinct from, but related to, anxiety and depression (Maslach & Jackson, 1981, 1986). A subsequent analysis (Leiter & Durup, 1994) demonstrated the distinction between burnout and depression in a confirmatory factor analysis of the MBI and the Beck Depression Inventory. This analysis established that burnout is a problem specific to the work context, in contrast to depression that tends to pervade every domain of a person's life. These findings lent empirical support to earlier claims that burnout is job re-

lated and situation specific, as opposed to depression that is general and context-free (Freudenberger, 1983; Warr, 1987).

In their analysis of various conceptualizations of burnout, Maslach and Schaufeli (1993) noted five common elements with respect to mental health. First, there is a predominance of dysphoric symptoms such as mental or emotional exhaustion, fatigue, and depression. Second, the emphasis is on mental and behavioral symptoms more than physical ones. Third, burnout symptoms are work related. Fourth, the symptoms manifest themselves in "normal" persons who did not suffer from psychopathology before. Fifth, decreased effectiveness and work performance occur because of negative attitudes and behaviors.

Based on a similar analysis, Bibeau et al. (1989) proposed some diagnostic criteria for burnout. The principal subjective indicator is a general state of severe fatigue accompanied by loss of self-esteem resulting from a feeling of professional incompetence and job dissatisfaction; multiple physical symptoms of distress without an identifiable organic illness; and problems in concentration, irritability, and negativism. The principal objective indicator of burnout is a significant decrease in work performance over a period of several months, which has to be observable in relation to recipients (who receive services of lesser quality), supervisors (who observe a decreasing effectiveness, absenteeism, etc.), and colleagues (who observe a general loss of interest in work-related issues). Bibeau et al. (1989) also mentioned three criteria of exclusion that allow a differential diagnosis. These subjective and objective indicators of burnout should not result from sheer incompetence (i.e., the person has to have performed quite well in the job during a significant period), major psychopathology, or family-related problems. Also, severe fatigue resulting from monotonous work or a high work load is excluded because this is not necessarily accompanied by feelings of incompetence or lowered productivity. Although this is a provocative proposal for assessing burnout in clinical terms, there has not been any research to establish its validity. Moreover, there is not, as yet, any reliable method for diagnosing burnout at the individual level (Maslach & Schaufeli, 1993).

An issue that has received very little attention in the burnout literature is whether mental dysfunction is a cause, rather than an effect, of burnout. In other words, are people who are mentally healthy better able to cope with chronic stressors and thus less likely to experience burnout? Although not assessing burnout directly, one study addressed this question by analyzing archival longitudinal data of people who worked in interpersonally demanding jobs (Jenkins & Maslach, 1994). The results showed that people who were psychologically healthier in adolescence and early adulthood were more likely to enter, and remain in, such jobs, and they showed greater involvement and satisfaction with their work. Given this longitudinal data set, this study was better able to establish causal relations than is true for the typical correlational studies.

The issue of correlation and causality is familiar but often forgotten, and this is as true for burnout as for other research literatures. Just because one interpretation is plausible does not mean that it is the correct one. To illustrate this point, consider the research on burnout and coping styles, which often

finds a correlation between the different components of burnout and specific coping techniques. For example, problem-focused coping (e.g., making a plan of action, finding compromise) has been correlated with greater personal accomplishment, whereas emotion-focused coping (e.g., ignoring problems, looking for a silver lining, reminding oneself that things could be worse) has been correlated with depersonalization (Bhagat et al., 1995). Similarly, nurses who used more palliative coping (wishful thinking, self-blame, denial/escape) had higher levels of burnout on all dimensions, and those who used more existential coping (finding a sense of meaning and coherence) or preventive coping (trying to reduce anticipated problems) had higher levels of engagement (Ogus, 1995). But which comes first, coping or burnout? Is it that the experience of burnout or engagement causes people to cope differently with stressors? Or, does the use of different coping styles lead them to be more or less burned out? Or, is there some critical third variable that mediates this relationship? The implications of these alternative answers are important both theoretically and practically.

A similar argument can be made with respect to the commonly found negative correlation between job satisfaction and burnout. The overall pattern of the research findings has led some researchers to conclude that, although burnout and job dissatisfaction are clearly linked, they are not identical constructs (Zedeck, Maslach, Mosier, & Skitka, 1988). However, the specific nature of that link is still a matter of speculation. Does burnout cause people to be dissatisfied with their job? Or, does a drop in satisfaction serve as the precursor to burnout? Alternatively, both burnout and job dissatisfaction may be caused by another factor, such as poor working conditions.

HOW DOES BURNOUT HAPPEN?

Inherent to the concept of stress is the problematic relation between the individual and the situation. In the case of job stress, the basic idea is that it is the result of a misfit between the person and the job. Some of the earliest models of organizational stress focused on this notion of job-person fit, and subsequent theorizing continues to highlight the importance of both individual and contextual factors (see Kahn & Byosiere, 1992).

As applied to burnout, this approach proposes that the greater the gap, or misfit, between the person and the job, the greater the likelihood of burnout. However, a new aspect of this approach is the specification of six areas in which this mismatch can take place (Maslach & Leiter, 1997). In each area, the nature of the job is not in harmony with the nature of people, and the result is the increased exhaustion, cynicism, and inefficacy of burnout. On the other hand, when better fit exists in these six areas, then engagement with work is the likely outcome.

The six areas in which mismatches can occur are workload, control, reward, community, fairness, and values (see Fig. 23.2). Each area of mismatch has a distinct relation with burnout and engagement, and an assessment of all six is necessary for a thorough consideration of the impact of the workplace on workers (see Maslach & Leiter, 1997, for a more extensive discussion of these issues).

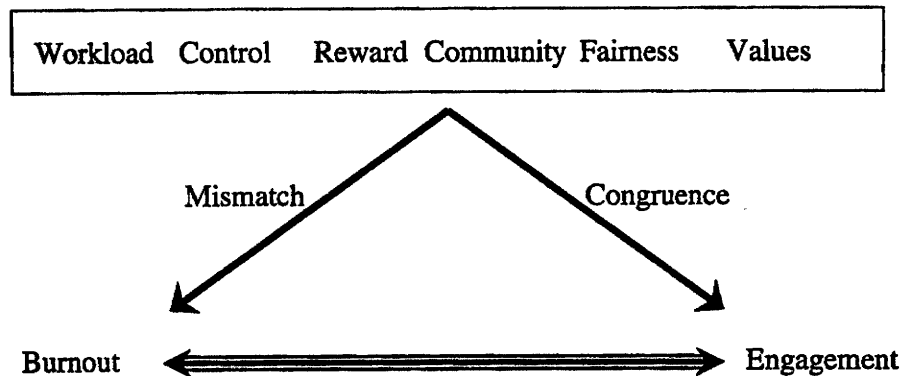

FIG. 23.2. Job-person fit.

Workload. The most obvious, and most commonly discussed, mismatch has to do with overload. Basically, job demands exceed human limits. People have to do too much in too little time with too few resources. They find it difficult to keep up with the rushed pace of work. In many of the human service professions, this kind of overload is a chronic job condition, not an occasional emergency, so there is little opportunity to rest, recover, and restore balance. The resulting burnout can lead to a deterioration in the quality of the work and a disruption of collegial relationships.

The obvious and straightforward relation of chronic work overload with exhaustion is consistently supported in the research as well as in the experience of working people. Both qualitative and quantitative work overload contribute to exhaustion by depleting the capacity of people to meet the demands of the job. The critical point occurs when people are unable to recover from work demands. That is, acute fatigue resulting from an especially demanding event at work—meeting a deadline or addressing a crisis—need not lead to burnout if people have an opportunity to recover during restful periods at work or at home (Shinn, Rosario, Morch, & Chestnut, 1984).

A sustainable workload, in contrast, provides opportunities to use and refine existing skills, as well as to become effective in new areas of activity (Landsbergis, 1988). It builds involvement by opening new opportunities, and by removing concern about work overwhelming personal capacity. A sustainable workload stops the cycle of exhaustion that is a driving force in the experience of burnout for many people.

Control. Another major mismatch occurs when people have little control over the work they do. As human beings, people have the ability to think and solve problems, and want to have the opportunity to make choices and decisions. In other words, they want to have some input into the process of achieving the outcomes for which they will be held accountable. A mismatch occurs when people are constrained by rigid policies and tight monitoring. They do not have much room to improve or customize or innovate—with the result that they do not feel efficacious or responsible for the outcomes.

In contrast, people are more committed to, and derive more satisfaction from, actions that they have freely chosen. The process of making a decision has an enduring impact on employees' experience of participating in organizational life and the responsibility they take for its outcomes. Participative decision making is a cornerstone of job enrichment strategies (Hackman, 1986) as much because of its power to engender commitment as for its capacity to make good use of knowledge and experience within a group of colleagues. Active participation in organizational decision making has been consistently found to be associated with higher levels of personal accomplishment and lower levels of exhaustion (Cherniss, 1980; Leiter, 1992).

Reward. A third type of job-person mismatch involves a lack of appropriate rewards for the work people do. This lack of recognition devalues both the work and the workers. Prominent among these rewards are external ones such as salary and benefits.

Intrinsic rewards (such as pride in doing something of importance and doing it well) can also be a critical part of this area of work life. What keeps work involving for most people is the pleasure they experience with the day-to-day flow of work that is going well (Leiter, 1992). When things are going very well, people experience intrinsic satisfaction continuously in their day-to-day work. An enjoyable workflow supports overall psychological well-being, and physical health as well. The more enjoyable and challenging aspects of work are often the source of recognition from professional colleagues outside of the immediate work setting. The more tedious aspects of work are not only dull in themselves, they crowd out opportunities for engaging in the creative activities that bring professional recognition and reward. Congruence between individuals and organizations regarding material rewards and opportunities for intrinsic satisfaction are an important part of a congruent workplace (Richardson, Burke, & Leiter, 1992).

Community. The fourth job-person mismatch occurs when people lose a sense of positive connection with others in

the workplace. People thrive in community and function best when they share praise, comfort, happiness, and humor with people they like and respect. Unfortunately, some jobs isolate people from each other, or make social contact impersonal. However, what is most destructive of community is chronic and unresolved conflict with others on the job. Such conflict produces constant negative feelings of frustration and hostility, and reduces the likelihood of social support.

Community is evident in social support that can take many forms at work. Generally, support from colleagues is more strongly related with effectiveness, whereas support from supervisors, especially instrumental support that assists people in managing their workload, is more closely associated with lower levels of exhaustion. Regardless of its specific form, social support has been found to be associated with greater engagement (Leiter & Maslach, 1988).

Fairness. A serious mismatch between the person and the job occurs when there is not perceived fairness in the workplace. Fairness communicates respect and confirms people's self-worth. Mutual respect between people is central to a shared sense of community. Unfairness can occur when there is inequity of workload or pay, or when there is cheating, or when evaluations and promotions are handled inappropriately. If procedures for grievance or dispute resolution do not allow for both parties to have voice, then those will be judged as unfair.

A lack of fairness undermines a person's engagement with work and exacerbates burnout in at least two ways. First, the experience of unfair treatment is exhausting. People react with anger, hurt, or anxiety when they are unfairly treated. They obsess on the offensive situation, trying to discover ways of influencing events or forcing another outcome. The personal antagonism toward those who treated one unfairly keeps the emotional upset alive. It can lead to sleep disturbance with the consequential fatigue. Complaining about unfair treatment is emotionally draining, time consuming, and rarely leads to meaningful action. Second, unfair decisions indicate a weak organizational culture in which the personal biases or ambitions of people with authority dominate the allocation of resources and the access to opportunities. It is a sign that neither the espoused values of a well-crafted mission statement nor the personal values of committed staff members drive organizational life.

Fairness in personal contacts with people at work and with the formal decision making and evaluation processes of an organization are critical to maintaining engagement with work. Fairness indicates that individuals and the organization have a common perspective on the work of the organization and the contribution of employees to its mission. Fairness builds the trust that is necessary to support productive involvement with work.

Values. The sixth area of job-person misfit occurs when there is a mismatch between the requirements of the job and people's personal principles. In some cases, people might feel constrained by the job to do things that are unethical and not in accord with their own values. For example, they might have to tell a lie or be otherwise deceptive or not

forthcoming with the truth. In other instances, people may be caught between conflicting values of the organization, as when there is a discrepancy between the lofty mission statement and actual practice.

People become vulnerable to burnout when they experience incongruity between personal and organizational values (Leiter & Harvie, 1997). Sometimes these crises are the result of people realizing that they entered an occupation with mistaken expectations. Often, human service professionals encounter a collapse of the professional mystique in their first job (Cherniss, 1980; Leiter, 1991). They find that the autonomy, power, and satisfaction they anticipated from their careers on the basis of media images or idealistic professional training are unfounded. They encounter public social service organizations whose values are based more on institutional survival or social control than on a sense of community. The resulting value crisis often contributes to burnout.

Changes in the political and economic environments of social institutions in postindustrial societies have increased the frequency and intensity of burnout for people who are established in their careers (Leiter, 1999). In these transitions, the organizational values change abruptly while individuals remain committed to personal values of customer service that were previously supported by the organization. Often, the changes begin with mismatches in one of the other areas of organizational life, but their impact on burnout is most intense when these mismatches lead to value conflict.

Congruency between individual and organizational values build engagement by justifying the energy people put into highly demanding jobs, encouraging involvement, and building effectiveness. Contributing to a meaningful personal goal is a powerful incentive for individuals. When this work contributes as well to the organizational mission, people may be rewarded with additional opportunities for meaningful work. As such, value congruence produces a self-perpetuating dynamic that supports engagement with work.

An Interactive Approach. Problems in one of these six areas of organizational life tend to be associated with problems in other areas. For example, excessive workload often indicates problems in control and autonomy, because much of what people identify as excessive work demands are externally imposed tasks. Professors in research universities rarely complain about the long hours they choose to spend in their research labs, but often grumble about their assigned teaching responsibilities. Similarly, surgeons will freely choose to spend long days in the operating room, but complain bitterly about any new forms or reporting procedure imposed by the hospital.

The areas of community, fairness, and reward all encompass personal relationships among people to some degree. An organization that has a strong and vibrant sense of community is likely to provide recognition for employees' contributions to its success and to treat people fairly as well as with respect. Although it is productive to examine each of these three areas in terms of their unique focus on personal relationships, they are not entirely independent of one another. Currently, it is unclear if some job-person mismatches are more important

than others, or if there is some minimum number that will be more likely to produce burnout, and future research will need to address these and related issues.

To varying degrees, values mediate the relations of the other five mismatches with burnout. At times, some mismatches may have direct implications for an employee's experience of one or more of the three dimensions of burnout. For example, as mentioned earlier, workload can be a direct predictor of exhaustion. In addition to their direct relations with energy, involvement, and effectiveness, the impact of the mismatches is often a function of value conflict. To focus on one potential mismatch, conflicts over control at work often occur when organizations put limits on the professional autonomy of staff members, as when teachers become frustrated with administrative policies that limit their approach to curriculum. These constraints have a much stronger personal impact if they conflict with the teachers' deeply held values about their professional role. For example, a teacher who valued arts education would be more strongly at odds with a back-to-basics policy than would a teacher who valued solid math and literacy skills primarily. Both teachers would be working within a system that constrained their professional autonomy, but only the first teacher would be experiencing value incongruity with the organization. This teacher would be much more susceptible to experiencing burnout.

The mismatches in these six critical areas of organizational life are not simply a list summarizing research findings from burnout studies. Rather, they provide a conceptual framework for the crises that disrupt the relations people develop with their work. This approach emphasizes the social quality of burnout—it has more to do with the organizational context of the job than with simply the unique characteristics of an individual.

ORGANIZATIONAL HEALTH

Burnout provides a perspective on individual mental health that reflects the health of the organizations in which people work. From this perspective, health is not limited to the physical or emotional well-being of individuals, but is evident in enduring patterns of social interactions among people. This is similar to the position of family therapists that it is often more productive to recast difficulties in a troubled family as a breakdown of a social system rather than as the problems of an individual whom the family has identified as the patient. A family problem is one for which each member shares a responsibility. They regain health when all members of the family change the way in which they interact with one another. In an organizational setting, some problems, such as burnout, are better cast as difficulties of the social context of work than as failings of individual employees.

Organizational health is evident throughout the social context in which people work. As with individuals, organizational health requires a reasonable balance of demands with appropriate coping resources. Periods of extreme demand that prompt an organization to work at peak levels are balanced with periods of rest and recuperation within an ongoing context of a readily manageable pace of activity. When this balance is exceeded for a prolonged period, members of the

organization experience the strain on the organizational system: A stressed organization creates strain for its members. This resolution is contrary to the long-term viability and productivity of the organization in a manner similar to a breakdown of an individual's health: The whole individual suffers when any bodily system is under excessive strain. In contrast, engagement with work is associated with a sense of well-being for both individuals and organizations.

Social Versus Individual Perspectives on Burnout

Viewing burnout as a function of the social environment raises the question of individual variation within it. If the impact of the environment is so critical, should not everyone (or no one) in a particular social setting be experiencing burnout? The wide range of burnout responses in any large organization often prompts observers to explain burnout in terms of personal failings, faulty self-concepts, or personality attributes. However, there are other explanations for this variation. First, not everyone experiences the same social environment. Burnout varies according to people's occupational role or their status in an organization. Nurses report consistently higher exhaustion than physicians, although both work very hard in a hospital setting. Managers report a stronger sense of professional efficacy than frontline workers, even though the accomplishments of managerial life are often elusive (Leiter & Harvie, 1998).

Second, people have different values. They bring some of these differences to work with them in the first place. Other differences arise from the unique experiences people have at work or in their personal life. For example, caring for an elderly parent or a chronically ill child may have a profound impact on an individual's values concerning health care, despite many common experiences with colleagues at work. These are important variations in values and experience that could readily affect individuals' experience of burnout without necessarily implying anything about their personality.

Most of the recommended strategies to alleviate burnout have been individual ones—which is particularly paradoxical given that (as mentioned earlier) research has found that situational and organizational factors play a far bigger role in burnout than individual variables (Maslach & Goldberg, 1998). Moreover, there is not much persuasive evidence that these types of self-help, personal stress management techniques are effective—especially in the workplace, where people have much less control of stressors than in other domains of their life. Contrary to this individualistic perspective, any progress in dealing with burnout will depend on the development of strategies that focus on the job context and its impact on the people who work within it.

The close ties of burnout to its social environment point toward organizational interventions. Individually oriented approaches (developing effective coping skills or learning deep relaxation) may help individuals to alleviate exhaustion, but they do not really deal with the other two components of burnout. The use of the complete multidimensional model of burnout focuses attention on the relation between the person and the job situation, rather than either one or the other in isola-

tion. This seems to be a more promising approach for dealing with individual burnout in its situational context. Moreover, a focus on what would promote engagement in the workplace could be a better framework for developing effective interventions than a focus simply on what would reduce stress. The former is more likely to change the job situation, and the latter leads to strategies of changing the person (Maslach & Goldberg, 1998).

Furthermore, the recognition of six areas of job-person mismatch expands the range of options for intervention. For example, rather than concentrating on the area of work overload for an intervention (such as teaching people how to cope with overload, or how to cut back on work, or how to relax), a focus on some of the other mismatches may be more effective. People may be able to tolerate greater workload if they value the work and feel they are doing something important, or if they feel well-rewarded for their efforts, and so an intervention could target these areas of value and reward.

Organizational Interventions

Organizational interventions rooted in ongoing management practices are the most effective and enduring route to alleviating or preventing burnout. They have three critical advantages over individual treatment that people may seek, either on their own initiative or through some sort of employee assistance program. First, organizational interventions have a wider scope. They improve the quality of the work environment for a large number of people, in contrast with the individual focus of most therapy programs. Second, organizational interventions are not solely oriented toward eliminating a problem; they are directed toward improving the effectiveness of the work setting. This quality of organizational interventions increases their duration because they are not an ongoing cost for an organization, but a means of furthering organizational goals of service provision or productivity. Third, organizational interventions focus directly on the work environment rather than implicitly blaming the victims for experiencing problems. That is, they approach burnout as a management problem, not as an individual failing. This perspective shifts responsibility for action to a more powerful sector with greater resources for effecting change in organizational life.

An organizational approach to burnout (Maslach & Leiter, 1997) is much more demanding than individual treatment. For one, many more people must reach agreement on the nature of the problem and the urgency in addressing it than is the case with individual treatment. Often important stakeholders in an organization are committed to opposing perspectives on a problem and its solution, as is evident in many conflicts between management and unions or among professional groups. Second, the information required for cooperative action is not readily available. The staff survey process that assesses burnout, engagement with work, and the six areas of organizational life demands considerable time, collaboration, and sophisticated analysis (see Maslach & Leiter, 1997, for a more extensive discussion of this process).

Designing and implementing interventions that have a lasting impact on burnout and its consequences for health are

a major challenge in large organizations. The six mismatch framework indicates the range of organizational problems related to burnout. The web of relationships among these six areas of organizational life captures the complexity inherent in an organization. The capacity to make effective interventions will grow with increased knowledge about organizational dynamics and their impact on the thoughts and feelings of the people who make up large organizations.

CONCLUSIONS

Burnout is a syndrome of exhaustion, depersonalization, and reduced personal accomplishment in contrast to engagement with work that is characterized by energy, involvement, and effectiveness. Although the sources and immediate consequences of burnout lie within the work environment, burnout compromises the physical health and psychological well-being of people at work and at home. Alleviating and preventing burnout requires an understanding of six critical areas of work environments: workload, control, reward, community, fairness, and values. These six areas of organizational life have a variety of consequences for the way people feel about their work. This interactive view of burnout provides a rich and dynamic approach to understanding the impact of a critical life arena—the work environment—on health.

The health experience of Americans has improved enormously over the course of the 20th century. Communicable and infectious diseases, the major causes of premature death in the United States prior to 1930, have been replaced by chronic illnesses such as heart disease and cancer. Furthermore, age-adjusted mortality from heart disease has decreased from 307.2 per 100,000 in 1950 to 138.3 per 100,000 in 1995. Similarly, infant mortality has decreased from 12.6 per 1,000 live births in 1980 to 7.6 per 1,000 live births in 1995. These changes mean that a majority of people in this country can expect to live a long and productive life. In fact, a child born in 1995 could expect to live 75.8 years compared to 47.3 years for a child born in 1900 (National Center for Health Statistics, 1997).

Unfortunately, these astounding improvements in health status have not affected all Americans equally. Lagging behind are many of the underserved and minority populations (Kington & Smith, 1997; Liao & Cooper, 1995). The ethnic composition of the U.S. population has changed from being primarily White to include a large percentage of African Americans (or Blacks), Hispanics, and Asian and Pacific Islanders. This cultural diversity will continue to increase because of high immigration and birth rates among minority populations. Each ethnic group views health within its own cultural context, which complicates the decision to seek and continue treatment, and to use preventive measures. Additionally, social conditions may put minorities at higher risk

for specific health problems. The purpose of this chapter is to first present basic demographic and health characteristics of the major ethnic groups in this country, and then to describe a contextual model of hypertension in Blacks as an example of how ethnic disparities in health status may occur and be understood.

DISTRIBUTION OF ETHNIC MINORITIES

Although there is a great deal of diversity within ethnic groups, this chapter uses the five general categories as collected and reported by the National Center for Health Statistics (1997): White, Black, American Indian or Native Alaskan, Asian and Pacific Islander, and Hispanic origin. When possible, data is presented by non-Hispanic White and non-Hispanic Black groups. Because there is no consistent agreement on terminology, this chapter uses African American and Black interchangeably throughout.

African Americans, or Blacks, the largest minority group in the United States, number almost 34 million and represent 12.8% of the population (U.S. Bureau of the Census, 1995). During 1994, the African American population grew at a faster rate than the White population (1.5% compared to only 0.8%), but not as fast as the Hispanic population (3.5%). Blacks are projected to be the second largest minority group in this country by 2025 (Fig. 24.1).

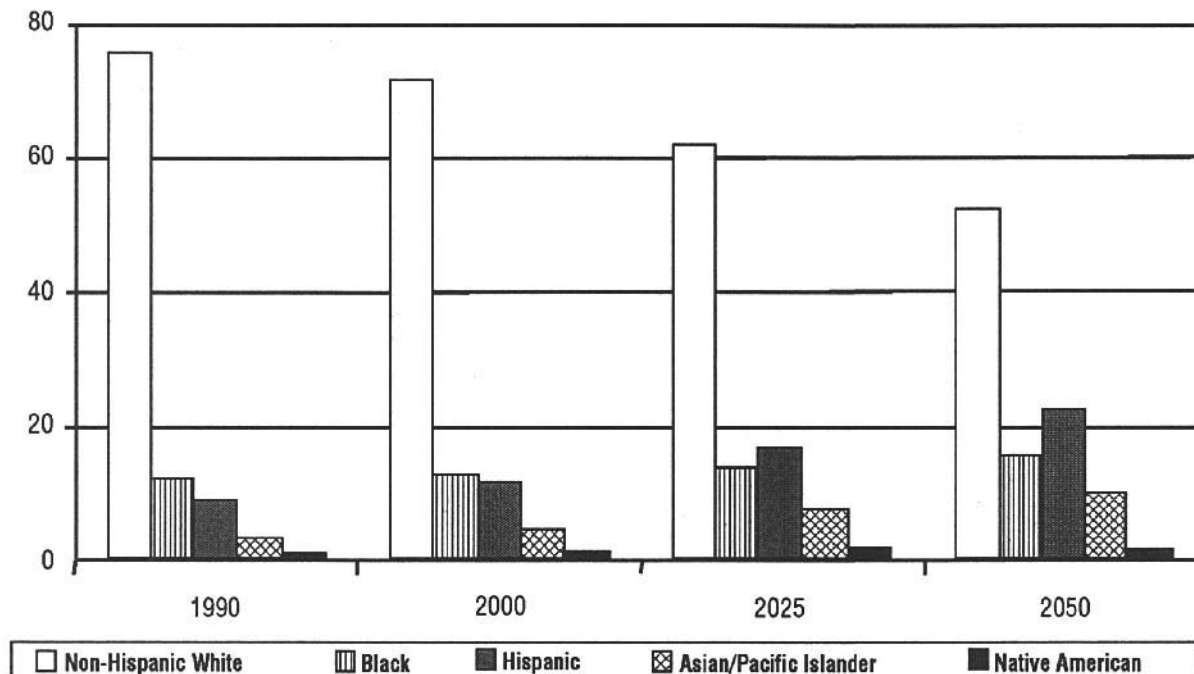

FIG. 24.1

The term *Hispanic* is used to summarize information about people of all races whose ancestry can be traced to Spain, Mexico, Puerto Rico, Cuba, or to any of the Spanish-speaking Latin American countries. The 1990 census enumerated 29.2 million Hispanics classified as Mexican Americans, Puerto Ricans, Cuban Americans, and about 30 additional Hispanic-origin groups aggregated as Other Hispanics (U.S. Bureau of the Census, 1995). Hispanics in the United States represent about 10.9% of the population and are the nation's second largest minority group. However, because of high immigration and birth rates, Hispanics are expected to replace African Americans as the largest ethnic minority group in the United States by 2025.

Asians and Pacific Islanders in the United States number about 10 million (representing 3.7% of the population), and speak more than 30 major languages or dialects (U.S. Bureau of the Census, 1995). The major groups in this category include Chinese, Filipinos, Japanese, Koreans, and Native Hawaiians. Furthermore, about two thirds of the persons in this population group speak their native language at home, and more than 60% of Southeast Asians (Vietnamese, Cambodian, Hmong, and Laotian) have limited proficiency in English. Although a small proportion of the U.S. population, this diverse minority group is expected to increase to more than five times its current size and represent 10.3% of the population by 2050 (U.S. Bureau of the Census, 1995).

Native Americans in the United States number about 2.3 million, just less than 1% of the population. Although this group is expected to grow steadily over the next 50 years, the percent of the population that is American Indian or Alaskan

Native would only rise to 1.1% by 2050, remaining the smallest minority group in the United States (U.S. Bureau of the Census, 1995).

LIFE EXPECTANCY

One measure of the health of a population is its life expectancy, a value that heavily weights early mortality, but does not incorporate quality of life issues. Throughout the 20th century, African Americans experienced substantial improvements in life expectancy, but they still have an estimated life span of 6 to 8 years less than Whites (Table 24.1). For both Whites and African Americans, women live longer than men, resulting in a higher proportion of women alive, especially in the older age groups. The life expectancy at birth for African American men increased 2.2% (or 1.4 years) from 1980 to 1995 compared to a 3.8% (or 2.7 years) increase for White men. The increase in life expectancy for African American women during this same period was identical to that for White women, 1.9% (about 1.5 years; National Center for Health Statistics, 1997).

Although comparable national data are not available for the other ethnic groups, information on residents of Texas suggests that life expectancy at birth for Hispanics is the same as non-Hispanic Whites and higher than non-Hispanic Blacks (Centers for Disease Control and Prevention, 1994; Markides, 1989). Similarly, area-specific studies have found life expectancy for Asian and Pacific Islanders in the United States to be higher than that of Whites. However, data on life expectancy for Asians may be particularly subject to

TABLE 24.1
Life Expectancy at Birth in Years (1980 and 1995)

Year	White		African American

1995	73.4	79.6	65.2	73.9
% change	+3.8	+1.9	+2.2	+1.9

Note: From National Center for Health Statistics (1997).

misclassification and underestimates of the number of deaths within ethnic groups (Gardner, 1994; Hahn, Truman, & Barker, 1996).

Life expectancy for Native Americans is lower than for Whites primarily because of the high death rate for persons under age 45. This higher rate is due to excess mortality from intentional and unintentional injuries rather than from chronic diseases. The death rates for Native Americans are based on death certificate identification of the decedent as a member of this minority group. Unfortunately, it has been demonstrated that many Native Americans have been classified as White on death certificates (Classification of American Indian race on birth and death certificates, 1993; Frost, Taylor, & Fries, 1992; Hahn et al., 1996; Sugarman & Lawson, 1993), thereby artificially reducing the death rate for persons in this group.

MAJOR CAUSES OF DEATH

As shown in Table 24.2, the highest death rate in 1995 is found for Black men (1,016.7 per 100,000). Although most men and women in all ethnic groups experienced a decline in overall mortality rate from 1985 to 1995, the largest decline was among White men (9.6%). Ethnic differences are apparent for mortality, but also for other health indicators such as preventable hospitalizations (Pappas, Hadden, Kozak, & Fisher, 1997).

By examining the top five causes of death (Table 24.3), it is clear that all ethnic groups share some common characteristics in spite of the differences in mortality rates. Among the

leading causes of death for both men and women in most ethnic groups are diseases of the heart and cerebrovascular disease (stroke). A major chronic condition associated with these conditions is hypertension. After heart disease and stroke, the major contributors to the high mortality rate among Black men are HIV infection, violence, and unintentional injuries.

HEALTH STATUS

Unlike identifying the major causes of death, measuring good health is a complicated task. Often health status is simply defined as the absence of disease, even though a complex of physical, social, cognitive, and psychological factors are involved in determining overall health. This chapter uses high blood pressure, or hypertension, as a marker for health status because of its association with the major causes of death and disability for all ethnic groups. Hypertension is usually defined as having a systolic pressure of at least 140 mm Hg or a diastolic pressure of at least 90 mm Hg, or taking antihypertensive medication. About half the people who have hypertension are undiagnosed. Furthermore, only about one fourth of those who know they have the disease have it adequately controlled through lifestyle modification or medication (Havas et al., 1996). Uncontrolled hypertension increases the risk of circulatory diseases (particularly heart disease and stroke), and kidney disease (Burt et al., 1995).

Because it is an important marker of health, questions about hypertension are routinely included in national surveys, thus providing comparable estimates of the prevalence of hypertension for White, African American, and Mexican American subgroups. As shown in Fig. 24.2 and Table 24.4, African Americans have the highest prevalence of hypertension, almost 1.5 times that of Whites, whereas Mexican Americans have an intermediary prevalence (Burt et al., 1995; National Center for Health Statistics, 1997). The percentage of the population with hypertension has decreased between 1976 and 1980 and 1988 and 1994 for Whites and African Americans, but has remained constant for Mexican Americans: The decrease was over 40% among Whites, but less than 30% among Blacks. Consequently, Blacks will continue to experience disproportionately higher rates of morbidity and mortality from heart disease, stroke, and renal disease compared to the other ethnic groups.

Note: A person with hypertension is defined by either having elevated blood pressure (systolic pressure of at least 140 mmHg or diastolic pressure of at least 90 mmHg) or taking antihypertensive medication. From National Center for Health Statistics (1997).

For less than 10% of those with hypertension, there is a definite cause. However, for over 90% of people with hypertension, the cause is unknown and it is termed *essential* hypertension (Frohlich, 1994). Hypertension occurs more frequently among Blacks, older individuals, less educated individuals, those who are obese or have gained weight, those who are physically inactive, and those who use alcohol excessively. Additionally, some individuals with augmented sodium metabolism may develop hypertension (Frohlich, 1994). Because none of these risk factors alone explains a majority of the risk for developing hypertension, it is clear that this disease develops from multiple interacting mechanisms rather than from a single source (Calhoun & Oparil, 1995; Flack et al., 1995). Among the contributors to this disorder are genetic, biological, nutritional, behavioral, social, environmental, and psychological factors.

SOCIAL AND CULTURAL FACTORS RELATED TO HEALTH STATUS

Given the changing demographic makeup of the United States, it is necessary to examine subpopulations within the major ethnic groups that may be at high risk for disease. The rest of this chapter focuses on the development and description of a model that may explain how social and cultural influences interact to affect health status, using the example of hypertension in Blacks. Although this model focuses on Black/White differences in hypertension risk, many elements of the model may be generalizable to other ethnic subpopulations and other health problems.

Contextual Model of Hypertension in Blacks

The contextual model of hypertension in Blacks reflects the contribution of sociology, psychology, and the natural sciences in attempting to systematically understand the key determinants of ethnic differences in the development and mainte-

nance of hypertension. The unacceptableness of unidimensional or strictly genetic accounts of the determinants of hypertension in Blacks is exemplified in the Report of the Secretary's Task Force on Blacks and Minority Health (1986):

Black, in the United States is a sociological category. Some investigators have confused ethnic identity with genetic constitution, simplistically equating them. The heterogeneity of blood pressure levels and hypertension prevalence in Black populations in Africa, the Caribbean, and the Americas casts doubt on the proposition that genetic factors are primarily responsible for the blood pressure excess in U.S. Blacks. ... It becomes clear that any explanation of blood pressure differences between Black populations must take into explicitly account of environmental determinants and influences. (p. 27)

Within the contextual model, hypertension risk factors interact with ethnicity in the context of the environment and culture.

Cardiovascular Reactivity

In recent years, researchers in health psychology and behavioral medicine have explored the role of cardiovascular reactivity as a potential contributor to the high rates of hypertension. *Reactivity* is defined as the magnitude and pattern of acute changes in cardiovascular activity (reactivity) in response to behavioral, social, and environmental stressors. According to Krantz and Manuck (1984), the measurement of reactivity contributes unique information regarding the physiological functioning of the individual beyond that provided by resting or baseline levels alone. The reactivity hypothesis rests on the assumption that acute changes in cardiovascular reactivity to laboratory procedures are analogous to cardiovascular challenges encountered in daily life (Anderson, McNeilly, Armstead, Clark, & Pieper, 1993). Reactivity studies also suggest that exaggerated changes in cardiovascular parameters, which occur when individuals are exposed to behavioral, psychological, or physical challenges precede the development of sustained hypertension (Julius & Schork, 1971). Individuals at risk for hypertension show greater sympathetic nervous system reactivity to stressors. In animal as well as human research, groups at risk for hypertension have shown greater stress reactivity than groups with relatively lower risk. For example, "hyperreactivity" has been observed in Blacks as compared to Whites, in anxious versus nonanxious persons, in anger suppressors versus anger expressors, and in chronically stressed versus nonstressed individuals. Hyperreactivity is thought to be a risk marker for hypertensive risk and may be also directly implicated in the pathogenesis of hypertension.

There have been a substantial number of studies on Black-White differences in autonomic reactivity (Anderson, McNeilly, & Myers, 1992). These studies have been conducted with both children (Dysart, Treiber, Pflieger, Davis, & Strong, 1994; Murphy, Stoney, Alpert, & Walker, 1995) and adults (Anderson, 1989) and have utilized a wide variety of labora-

tory stressors, experimental designs, physiological measures, and population subgroups. Despite the diversity of approaches used, most studies have demonstrated that Blacks show a greater blood pressure reactivity to laboratory stressors as compared to Whites. Perhaps more important, is that the mechanisms responsible for producing the stress-induced blood pressure response may be different in Blacks than in Whites. Blacks have been found to exhibit greater blood pressure reactivity mediated by peripheral vasoconstriction (characteristic of the vascular pattern of reactivity; Girdler, Hinderliter, & Light, 1993; Terrell & Manuck, 1996), whereas the blood pressure response of Whites has shown a greater cardiac involvement (characteristic of the cardiac pattern of reactivity). These results, particularly the heightened peripheral vasoconstrictive responses in Blacks, have been observed among children, adults, normotensives, and borderline hypertensives. It has been most clearly seen in studies using stressors, such as the forehead cold pressor test, that are specifically designed to produce a predominantly vascular pattern of reactivity among Blacks. The studies have not consistently found greater reactivity in Black adults with a positive family history (Anderson, Lane, Taguchi, & Williams, 1989; Anderson, Lane, Taguchi, Williams, & Houseworth, 1989).

Augmented Reactivity in Blacks

Thus far, research using the reactivity paradigm has been largely concerned with describing racial differences in reactivity. The next logical step is to identify the variables that are predictive of heightened vascular reactivity among Blacks. Anderson et al. (1991) noted that physiological and psychophysiological responses obtained in an experimental laboratory are partly a function of the socioecological niche that the individual occupies at that time.

The principal tenet of the proposed contextual model is that the exaggerated peripheral vascular reactivity observed in many Blacks relative to Whites is a function of a number of biological, psychological, behavioral, environmental, and sociocultural factors. The model begins with the premise that in reactivity research, race should be viewed as a proxy for the effects of differential exposure to chronic social and environmental stressors rather than as a proxy for the effects of genetic differences. Black Americans, on average, are exposed to a wider array of chronic stressors than their White counterparts. These chronic stressors interact with nervous system activity, which in turn leads to the release of neuroendocrine substances, including norepinephrine and adrenocorticotrophin hormone (ACTH), augmented sodium retention, and enhanced vasoconstriction. The resulting higher levels of endogenous sodium and ACTH not only increase blood volume but also act to potentiate the vasoconstrictive effects of norepinephrine on the peripheral vasculature. Over time, the repeated stressor-induced episodes of vascular reactivity may lead to structural changes in the vascular wall (e.g., increased wall-to-lumen ratio), which further augments reactivity. If repeated frequently over a number of years, this process has the potential to lead to the development of sustained hypertension. The remainder of

this chapter is devoted to describing each component of this model.

Chronic Stressors and the Social Environment

Many writers view race as a sociological designation that indicates exposure to common life experiences. According to the model presented here, one distinguishing feature of the life experiences between Black and White Americans is exposure to chronic life stressors. As a consequence of historical factors and the continued race consciousness of society, Blacks currently experience a greater array of chronic stressors relative to Whites. These chronic socioecological stressors include, among others, higher unemployment, higher poverty rates and lower income levels, lower status occupations and lower social status, residential crowding, and substandard housing (Bullard, 1994; Farley, 1984; Farley & Allen, 1989; Harris, 1982; McLoyd, 1990). Many of these chronic social and environmental stressors have been associated with hypertensive status among Blacks. For example, socioeconomic status shows a strong inverse relation with hypertension among Blacks (Adams-Campbell, Brambilla, & McKinlay, 1993).

Racial Stress. Racism represents one of the most pernicious forms of chronic psychosocial stress facing African Americans today. A burgeoning body of literature identifies racism as a macrosocial factor contributing to the vast racial disparity of health outcomes found among African Americans and Whites (Jackson et al., 1996; McNeilly et al., 1996). Racial stress has been found to be related to both blood pressure status (Krieger, 1990; Krieger & Sidney, 1996) and cardiovascular reactivity (Armstead, 1991; Armstead, K. A. Lawler, Gorden, Cross, & Gibbons, 1989; Jones, Harrell, Morris-Prather, Thomas, & Omowale, 1996; McNeilly et al., 1995; Morris-Prather et al., 1996).

Historically, African Americans often received severe punitive sanctions for expressing emotions they experienced when exposed to racism. Anger suppression may be a historical coping style that presently serves as a moderator of the interaction between racism and blood pressure status and reactivity. Gentry, Chesney, Gary, Hall, and Harburg (1982) found that males who are high in interracial hostility and who tend to keep anger suppressed have the highest mean diastolic pressure. Krieger (1990) found that Black women who reported usually accepting and keeping quiet about racist treatment were 4.4 times more likely to report being hypertensive than were Blacks who talked to others. Among Whites, this relation did not hold true. In another study, Krieger and Sidney (1996) found that hypertension was significantly higher among working-class Blacks reporting that they typically "accepted" unfair treatment and had not experienced racial discrimination in one of seven situations relative to those reporting that they "challenged" unfair treatment and experienced racial discrimination. Among professional Black adults, systolic blood pressure was 9 to 10 mm Hg higher among those reporting a higher frequency of discrimination

and those reporting that they "accepted" unfair treatment. Black-White differences in blood pressure were partially explained by incorporating variables for exposure and coping styles utilized with racial discrimination.

Armstead (1991) and Armstead et al. (1989) found that anger suppression was related to increased diastolic reactivity to racist stimuli and to a speech stressor. Vascular activation may be end products of chronic anger suppression as a result of coping with racism. Chronic exposure to racial stress may contribute to concomitant changes in the peripheral vasculature in ways similar to other chronic stressors. Anger kinetics may play a role in catecholamine release and subsequent hemodynamic changes associated with racial laboratory stressors.

Lower Socioeconomic Status. The health history of African Americans in the United States is filled with accounts of pervasive disease morbidity and mortality associated with social stratification (Anderson & Armstead, 1995). In U.S. society, social stratification occurs as a function of ethnicity, gender, or socioeconomic status. The term *socioeconomic status* (SES) is typically used to describe stratified inequality in ranking that exists in society. Educational attainment is also one of the strongest predictors of health outcomes in the United States. Higher educational attainment does not consistently bring comparable health benefits for minorities (Pappas, Queen, Hadden, & Fisher, 1993). For example, Blacks have significantly lower SES than Whites by every measure. What is often not recognized, however, is that at most levels of SES, morbidity and mortality rates are higher for Blacks than for Whites (Lillie-Blanton & Laveist, 1996; Williams, 1996).

At present, it is unclear how SES differentially influences hypertension risk behaviors or blood pressure-related knowledge, attitudes, and beliefs of minorities. Stratification and discrimination may directly and/or indirectly interact with socioeconomic status to create a highly vulnerable underclass of African American citizens with poorer overall health, poorer health behaviors, increased daily life stress, and lack of access to health care (Williams, 1992). Lower SES Blacks may not only receive more exposure to environmental risk factors, psychosocial risk factors, and deficits in medical care, but also may be more vulnerable to them. Dressler (1996) found diastolic blood pressure levels were associated with an interaction between lower socioeconomic status and increased exposure to stressful life events.

In the case of essential hypertension, a consistently strong gradient for SES exists, especially for African Americans. Among both Blacks and Whites, hypertension is higher at the lower end of the SES spectrum, yet the relation clearly reflects an interaction of gender, ethnic, and socioeconomic stratification (Adams-Campbell et al., 1993; Williams, 1992).

If SES is linked to hypertension in a causative way, it should be expected that it is also linked to physiological systems relevant to hypertension. One possible biological mediator of SES effects on hypertension effect is cardiovascular reactivity. Carroll, Davey-Smith, Sheffield, Shipley, and Marmot (1997) examined the relation of SES, hostility, and blood pressure reactions to mental stress in British men. They

found that systolic pressure reactivity was positively associated with SES. Higher SES was associated with greater reactivity. Armstead, Anderson, and Lawler (1994) found an interaction between SES and ethnicity for laboratory reactivity to a speech stressor among African American and White women. Lower socioeconomic status Black women demonstrated greater reactivity than White women or higher SES Black women. This indicates that being Black and poor may physiologically predispose individuals to hyperreactivity, which may be a risk marker for essential hypertension.

SES is related to several factors known to enhance reactivity, such as emotional suppression (Armstead et al., 1989; Durel et al., 1989; Johnson, 1989), lower levels of social support (Kamarck, Manuck, & Jennings, 1990), and greater exposure to chronic stress (James & Kleinbaum, 1976). The contextual model of hypertension suggests that lower SES may be an index of exposure to these reactivity-enhancing factors, especially among Blacks, and may serve as a predictor of augmented cardiovascular reactivity in this group. If SES is related to reactivity, then ethnic group differences in SES might partially account for the mixed reactivity results among African Americans and Whites. Calhoun, Mutinga, Wyss, and Oparil (1994) suggest that SES-related stress may cause sympathetic nervous system hyperreactivity by vascular mechanisms.

Socioecological Stressors. Harburg et al. (1973) found that Detroit Blacks residing in neighborhoods high in socioecologic stress, characterized by low SES and high social instability (SIS; defined as high crime and divorce rates), exhibited significantly higher blood pressures than Blacks living in low SES but more stable neighborhoods. Among Whites, socioecologic stress did not influence blood pressure. Similarly, James and Kleinbaum (1976) found that for Black men from age 45 to 54, high stress counties (low SES, high SIS) of North Carolina were associated with significantly higher hypertension-related mortality (e.g., hypertensive heart disease and stroke) than low stress counties. As in Harburg's Detroit studies, no stress-mortality relation was found for White men. In a study of residential crowding, Fleming, Baum, and Weiss (1987) found that individuals living in densely populated neighborhoods had higher blood pressure and greater heart rate reactivity during a challenging behavioral task than those who lived in less crowded neighborhoods.

Family environment is a socioecological stressor that has been found to influence hemodynamic reactivity in children prospectively (Wright et al., 1993). For example, parental reports of greater conflict and control were associated with vascular reactivity among 6- to 8-year-old children at a 2-year follow-up. Thus, not only are Blacks exposed more frequently to chronic stressors, but these socioenvironmental factors may have greater health consequences for Blacks.

Chronic Stress and Vascular Reactivity: Physiologic Mediators

If the differential exposure to chronic stressors is related to acute cardiovascular reactivity as proposed, it should be possi-

ble to identify specific physiological mechanisms linking these phenomena in Blacks. It is proposed that exposure to chronic stressors enhances sympathetic nervous system activity that results in augmented sodium retention and catecholamine release. Augmented sodium retention and catecholamine release may, in addition to increasing blood volume, contribute to the greater vascular responses in Blacks.

Sympathetic Nervous System (SNS) Effects. Of critical importance is whether exposure to chronic stress is associated with this hypothesized physiological scenario. In support of this, research from animal and human studies has demonstrated that exposure to acute and chronic uncontrollable stress may augment resting SNS tone; enhance sympathetic reactivity to acute, novel stressors; elevate plasma levels of catecholamines, ACTH, and opioid peptides; and augment sodium retention (Baum, Gatchel, & Schaeffer, 1983; Davidson, Fleming, & Baum, 1987; Fleming, Baum, Davidson, Reitan, & McArdle, 1987; Koepke & DiBona, 1985; Koepke, Light, & Obrist, 1983; J. E. Lawler, Naylor, & Abel, 1993; Lawler, Zheng, Li, Wang, & Edgemon, 1996; Light, Koepke, Obrist, & Willis, 1983; McCarty, Horwath, & Konarska, 1988).

Studies of reactivity indicate that norepinephrine elicits elevations in blood pressure through vasoconstrictive effects on the peripheral vasculature (Goldstein, 1983). ACTH has been shown to potentiate norepinephrine's vasoconstrictive effects, particularly in humans and animals with reduced renal excretory capacity (Bassett, Strand, & Cairncross, 1978; Strand & Smith, 1980; Whitworth, Coghlan, Denton, Hardy, & Scoggins, 1979), and to augment norepinephrine-induced contractions of a striated muscle (Bassett et al., 1978; Strand & Smith, 1980). Importantly, ACTH also induces sodium and water retention (Lohmeier & Carroll, 1985).

In a series of studies at the University of North Carolina and the University of Iowa, investigators examined the role of stress and sodium retention in dogs and spontaneously hypertensive rats (Grignolo, Koepke, & Obrist, 1982; Koepke & DiBona, 1985; Koepke et al., 1983; Light, 1987). In these studies, animals who were exposed to chronic stress showed significant reductions in sodium and fluid excretion and an associated rise in blood pressure that was mediated by renal sympathetic nerves. In perhaps the first study of stress and sodium retention in humans, Light et al. (1983) discovered that a stressful laboratory task (competitive reaction time) led to decreased urinary sodium excretion in men with risk factors for hypertension (positive parental history of hypertension and/or borderline hypertension) but only if these men showed evidence of high SNS activity as indicated by above average heart rate increases. It has also been found that low intake of dietary potassium enhances vasopressor responses to cold stress in African Americans, but not in Whites (Sudhir et al., 1997). Ionic mediation of reactivity by sodium, calcium, and potassium interactions is implicated, but remains largely unstudied.

Sodium Effects. Several lines of research implicate sodium as a principal physiological mediator of heightened vas-

cular reactivity in Blacks. First, considerable evidence exists that heightened sympathetic activity may induce sodium retention (Weinberger, Luft, & Henry, 1982). Although the dietary sodium intake of Blacks may not be significantly higher than that of Whites (Grim et al., 1980), Blacks excrete less sodium in urine and exhibit greater pressor response to sodium loading (Luft et al., 1979; Luft, Grim, & Weinberger, 1985). Thus, Blacks may be more susceptible to the blood pressure effects of sodium despite a similar dietary intake relative to Whites. Research suggests that sodium may augment cardiovascular reactivity in subjects at risk for hypertension (Ambrosioni et al., 1982; Ambrosioni, Costa, Montebugnoli, Borghi, & Magnani, 1981; Falkner, Onesti, & Angelakos, 1981). Finally, studies in both humans and spontaneously hypertensive rats indicate that sodium may exert its influence on blood pressure via heightened vasoconstriction rather than by increasing cardiac output (Nilsson, Ely, Friberg, Kalstrom, & Folkow, 1985). Therefore, given the influence of the SNS on sodium retention, the greater sodium sensitivity among Blacks, and the effects of sodium on both reactivity and vascular resistance, sodium may be the pivotal physiological mechanism responsible for the observed race differences in vascular reactivity.

How might sodium contribute to increased vascular resistance? Sodium may lead to heightened vascular resistance through its effects on plasma norepinephrine release and action. Although in normotensive individuals sodium loading has been shown to decrease plasma and urinary norepinephrine levels, the opposite effect has been observed for salt-sensitive and hypertensive individuals. In these individuals, sodium loading increases plasma and urinary norepinephrine levels, whereas sodium deprivation has the opposite effect (Koolen & Van Brummelen, 1984; Luft et al., 1979; Takeshita, Imaizumi, Ashihara, & Nakamura, 1982). Furthermore, high sodium intake has been shown to potentiate the effects of norepinephrine on the vasculature (Rankin, Luft, Henry, Gibbs, & Weinberger, 1981), and has also been associated with increased pressor responses to infused norepinephrine in Black hypertensives relative to White hypertensives (Dimsdale, Graham, Ziegler, Zusman, & Berry, 1987). Thus, if Blacks exhibit an exaggerated antinatriuresis, this may lead to an increased release vasoconstrictive action of plasma norepinephrine. This chain of events would increase peripheral vascular resistance in Blacks. Moreover, chronic stressors that stimulate the release of plasma norepinephrine would interact with higher prevailing sodium levels to further stimulate vascular reactivity (Henry, 1988). Deter et al. (1997) found that salt sensitivity was related to increased anger irritation levels and increased reactivity to an information-processing task. They suggested that salt sensitivity, psychosocial, and psychophysiological traits, such as reactivity, interact to play a role in the pathogenesis of hypertension. It is hypothesized that the heightened vascular reactivity observed in Blacks may ultimately result in structural changes (i.e., hypertrophy) in the peripheral vasculature, which in turn may further augment vascular hyperactivity (Folkow, 1982, 1987). A long-term consequence of this process could be sustained hypertension.

In summary, compelling evidence exists that Blacks in American society are systematically exposed to a wider array of chronic social stressors compared to their White counterparts. These stressors involve lower SES, higher rates of poverty, higher unemployment, lower status occupations, exposure to racism, and more crowded and ecologically stressful residential environments. Many have been related to elevated blood pressure and increased hypertension prevalence. Research with humans and animals suggests that exposure to chronic stress may increase tonic SNS activity, acute autonomic reactivity, and urinary sodium retention. Future studies may determine whether the types of stressors that many Blacks are exposed to on a daily basis are related to these potentially pathological sequelae.

Behavioral and Psychological Factors

It is conceivable that chronic social stressors may increase catecholamine release and sodium retention through specific behavioral or psychological factors. Early research demonstrated an association between, anger, Type A behavior, and higher levels of plasma norepinephrine and blood pressure among Whites (Friedman, Byers, Diamant, & Rosenman, 1975). To date, only one study has examined these relations in Blacks (Durel et al., 1989). Although this study yielded nonsignificant relations between norepinephrine and anger for both Blacks and Whites, it did demonstrate positive correlations between anger and cardiovascular reactivity in these individuals.

Several studies have shown that behavioral and psychological factors are linked to elevated blood pressure and hypertension among Blacks (Anderson, Myers, Pickering, & Jackson, 1989; James, 1985). For example, suppressed anger and hostility have been associated with elevated blood pressure and hypertension in both adolescents and adults (Harburg, Blakelock, & Roeper, 1979; Johnson, Schork, & Spielberger, 1987; Johnson, Spielberger, Worden, & Jacobs, 1987). In general, this literature has indicated that Blacks who frequently suppress their anger when provoked, or who express their anger without reflection, have higher resting blood pressure levels than those who routinely express their anger when provoked or who express it only after some reflection (Gentry et al., 1982). Recently, the experience of frequent anger has been related to higher ambulatory blood pressures among Black women while at work (Durel et al., 1989). At this time, research has not examined whether inhibited anger expression is related to sodium excretion or catecholamine release among Blacks.

Another behavioral factor associated with high blood pressure among Blacks is the "John Henryism" behavioral pattern of hard work and determination against overwhelming odds. James, Hartnett, and Kalsbeek (1983) speculated that Blacks who exhibit this type of determination, but who also have few resources to help them achieve their goals, may be at greatest risk for developing hypertension (James, LaCroix, Kleinbaum, & Strogatz, 1984). Furthermore, it has been found that low SES Blacks who are high in John Henryism have a higher percentage of hypertension than persons who

are low in John Henryism or have a high SES (James, Strogatz, Wing, & Ramsey, 1987). Interestingly, no interaction of John Henryism with education or blood pressure has been found for Whites, suggesting, as James and colleagues (1983) noted, that this coping style may be particularly relevant to Black populations.

The behavior of individuals high in John Henryism may actually increase their exposure to stressful social and environmental circumstances. That is, these individuals may continually strive to gain control over their environment in spite of numerous barriers, thereby potentially exposing themselves more frequently to frustrating and stressful situations. Whether this exposure to behaviorally mediated chronic stress results in enhanced SNS and altered sodium regulation remains to be empirically determined. It has been reported, however, that active behavioral coping with acute laboratory stressors enhances sodium retention (Light et al., 1983). It is this active coping with real-life stressors that is the sine qua non of the John Henryism pattern.

Several studies support the notion of active coping as a moderating variable in laboratory reactivity and ambulatory monitoring situational effects. Saab et al. (1997) found that during a speech stressor (active coping), Black men responded with lower blood pressure, cardiac output, and heart rate changes than did White men, White women, or Black women. They also reported more inhibitory-passive coping, hostility, pessimism, and less social support than other groups. Light et al. (1995) found that high effort coping in addition to high job status predicted diastolic blood pressure at work and in the laboratory for both Black and Whites. Job strain coupled with lower status is also implicated in reactivity (K. A. Lawler & Schmied, 1992).

Chronic social stressors may also have other psychological and emotional effects that could potentially influence sodium retention and neuroendocrine release. For example, low income Blacks have been found to report more psychological distress than low or high income Whites and high income Blacks, perhaps due to the combined burden of poverty and racism (Kessler & Neighbors, 1986). Additionally, the stressful residential environments to which many Blacks are exposed (e.g., crowding and crime) are related to stress symptoms, such as anxiety, depression, somatic complaints, lower levels of perceived control, and enhanced sympathetic nervous system activity (Baum et al., 1983; Davidson et al., 1987; Fleming et al., 1987; Schaeffer & Baum, 1984). It has been suggested that urban Black youths have decreased quality and quantity of social support. In fact, African Americans residing in high poverty areas have a higher percentage of people who report being unmarried, having no current partner, and having no best friend compared with those living in nonpoverty areas. These findings on the relative lack of potentially supportive social relationships have also been observed in Whites (Belle, 1982). Social support has been found to have both direct and indirect stress buffering effects on resting blood pressure (Strogatz et al., 1997) and on cardiovascular reactivity (Gerin, Milner, Chawla, & Pickering, 1995; Kamarck, Manuck, & Jennings, 1990; McNeilly et al., 1995).

Biological and Genetic Factors

Although genetic variables have been identified as important in determining sodium excretion in both Blacks and Whites (Luft, Miller, Cohen, Fineberg, & Weinberger, 1988; Grim et al., 1984), epidemiologic evidence suggests that the association of parental history and risk for hypertension may not be as strong among Blacks relative to Whites (R. Stamler, J. Stamler, Riedlinger, Algera, & Roberts, 1979). In fact, no published studies have reported the expected relation between parental history of hypertension and cardiovascular reactivity among Black adults (Anderson et al., 1986; Anderson, Lane, Taguchi, & Williams, 1989; Anderson, Lane, Taguchi, Williams, & Houseworth, 1989; Rowlands et al., 1982), although this relation has been found fairly consistently among Whites (Fredrikson & Matthews, 1990). A possible explanation for these somewhat puzzling findings may be the substantial influence of psychosocial factors in the development of hypertension among Blacks. That is, psychosocial factors, such as chronic stress, may overshadow the influence of parental history such that risk for hypertension and hyperactivity are augmented even in persons with a negative parental history. This could result in a diminished ability to detect differences between parental history groups among Blacks.

Second, although sodium retention has a clear genetic component (Grim et al., 1984), it may also be stimulated by psychosocial stress. To the degree that Blacks, particularly low income Blacks, experience more psychological stress than do Whites or upper income Blacks (Kessler & Neighbors, 1986), they may consequently be more susceptible to inhibited sodium excretion.

Finally, the genetic distinction between Black and White Americans is, at best, ambiguous. It has been noted that the gene pool of American Blacks is comprised of a heterogeneous mixture of genes from genetically diverse populations in Africa (Hiernaux, 1975; Mourant, 1983) and the U.S. Caucasian population (Glass & Li, 1953; Pollitzer, 1958). In fact, Reed (1969) estimated that up to 505 of the genes of Black Americans are derived from Caucasian ancestors, whereas Lewontin and associates (Lewontin, 1973; Lewontin, Rose, & Kamin, 1984) reported that genetic differences between individuals within a race have a substantially greater impact on the total species genetic variation than genetic differences between races. Therefore, although genetic factors no doubt play a role in reactivity among Blacks, their influence on between-race differences is likely to be considerably less.

Coping Resources

Thus far, the chapter has been discussing the various physiological, social, and behavioral factors that may contribute to the augmented sodium retention, greater vascular reactivity, and higher hypertension prevalence among Blacks as compared to Whites. It is important to note, however, that there may be factors inherent in the culture and traditions of Black Americans that may counteract the sympathetic and hypertensinogenic effects of chronic stress. A number of researchers have advocated the view that minorities share many characteristics (contextual,

social, and behavioral) associated with unique intra- and interethnic stress coping mechanisms (Armstead, 1991; Dressler, 1993; Smyth & Yarandi, 1996; Williams, 1996).

According to the contextual model, certain cultural traditions such as strong kinship ties, unique forms of emotional expressiveness, social support, and spirituality could decrease the effects of stress and consequently the effects of stress on SNS activity, sodium retention, and blood pressure level. It has been found, for instance, that resting blood pressure levels among Whites who attend church regularly are lower than among those with less frequent attendance (Graham et al., 1978). It would be of interest to determine whether Blacks exposed to chronic life stressors (e.g., low income Blacks) but who also have a high cultural "buffer" (e.g., strong religious orientation, social support, or an extended family network) exhibit lower tonic SNS activity, lower sodium retention, and lower cardiovascular reactivity than those individuals less connected with cultural resources.

Because of the paucity of coping, stress, vulnerability, and resiliency measures, the complexity of behavior in this population is often misrepresented and misunderstood (Stevenson, 1997). It is important that researchers perform ethnographic studies of culture, stress, and coping in minority populations before making generalizations about psychosocial mediators of cardiovascular reactivity. Furthermore, studies of behavioral risk factors, adaptive behaviors, and maladaptive behaviors are warranted from a culturally sensitive perspective (Bagley, Angel, Dilworth-Anderson, Liu, & Schinke, 1995; Myers, Kagawa-Singer, Kumanyika, Lex, & Markides, 1995). It is imperative to understand how culture and ethnicity may interact with the laboratory environment, the perceptions of laboratory stressors, and the psychological and physiological coping responses to stressors.

TESTING THE CONTEXTUAL MODEL

Directions for Research

The contextual model presented here was designed to provide a stimulus for examining both the basis for racial differences in vascular reactivity as well as for exploring within-race variability in vascular responses among Blacks. Toward these ends, the model suggests a number of testable hypotheses and research questions. Various components of the model could be tested using either field or laboratory methodologies. For example, the model would predict that Blacks who are exposed to higher levels of chronic stress should have higher resting stress hormone levels (e.g., catecholamines, ACTH) and exaggerated responses to novel stimuli, suggesting increased SNS activity compared to Blacks experiencing lower levels of chronic stress. Second, chronic stress should also be positively associated with increased sodium retention (i.e., slower sodium excretion rates) and greater vascular reactivity in Blacks. Third, the combination of chronic stress exposure and behavioral and psychological factors, such as anger suppression and John Henryism, should be positively associated with both increased SNS activity and greater sodium retention. Dietary sodium loading (or saline infusions) should po-

tentiate vascular reactivity in Blacks experiencing chronic stress. Furthermore, macrosocial phenomenon, such as lower SES, residence in socially unstable communities, and chronic exposure to racial stress should be positively associated with increased SNS activity and greater sodium retention. Finally, the contextual model would predict that Blacks with more coping resources (e.g., high social support, strong religious orientation, and racial identity) will show lower SNS activity and decreased sodium retention relative to those with fewer coping resources.

CONCLUSIONS

In summary, according to the proposed model, race is viewed as a sociocultural designation that denotes differential exposure to chronic social stressors. It is proposed that Black Americans are exposed to significantly more chronic social stressors than White Americans. Many of these chronic social stressors have been associated with hypertension prevalence in epidemiological studies. Furthermore, chronic stress has been shown to augment cardiovascular reactivity to acute stress in both animals and humans and to increase sodium retention in SHR. Acute stress has also been demonstrated to increase sodium retention in humans. The essential element of this model is that chronic social stressors that are overrepresented within the Black American population due to historical factors are related to an increase in sodium retention and enhanced reactivity. This altered sodium metabolism and reactivity may be further augmented by biological, behavioral, and psychological risk factors for hypertension and modulated by stress coping resources. It is hoped that this model will serve as a stimulus for further research on the biopsychosocial aspects of autonomic reactivity and hypertension in minorities. Disparity in health status will remain a problem in this country until researchers begin to look at ethnic-specific pathways using this type of contextual modeling approach. This is a challenge directed at researchers to test the applicability of this model to other minority populations.

The Multiple Contexts of Chronic Illness: Diabetic Adolescents and Community Characteristics

Dawn A. Obeidallah
Harvard School of Public Health

Stuart T. Hauser
Judge Baker Childrens' Center, Harvard Medical School, and Josling Diabetes Center

Alan M. Jacobson
Josling Diabetes Center and Harvard Medical School

Adolescents diagnosed with diabetes negotiate at least two worlds of competing demands simultaneously. First, as part of normative adolescent development, they navigate the challenges of individuation, development of behavioral and cognitive autonomy, and intensification of close relationships with friends. In contrast to this push toward independence and greater sense of freedom, successful treatment of diabetes involves changes in diet and exercise habits, monitoring of glucose levels, and administration of insulin (Hauser et al., 1986; Hauser et al., 1997). These paradoxical stressors of adolescence and of disease maintenance contribute to divergent behaviors and somewhat opposing goals for diabetic adolescents and their families.

The diagnosis of diabetes requires a substantial reorganization of families and complicates already nuanced aspects of childrearing (Anderson, 1995; Blechman & Delamater, 1993; Hauser & Solomon, 1985; Reiss, Steinglass, & Howe, 1998). Some families, in response to adolescents' diagnosis of diabetes, step up protection over them by excessively monitoring diet and activities with friends. Such responses may be at odds with the developmental challenges of adolescence and contribute to new tensions between newly diagnosed diabetic adoles-

cents and their parents. In the context of this tension, other social supports, including neighbors and community resources, may take on substantial importance (Powers et al., 1985).

The chronic nature of diabetes, particularly when first occurring during the already complex transition to adulthood, paints a stressful picture for adolescents and their families (Jacobson, et al., 1997; Wertlieb et al., 1990). The burden of these multiple stressors may overtax families' ability to function adaptively. Families that are overtaxed sometimes reach outside the family for assistance, frequently turning to their communities for additional help and support (Powers et al., 1985; Stack & Burton, 1993). The majority of research on diabetic adolescents, however, focuses on the family as the sole social context (Hauser, Jacobson, Benes, & Anderson, 1997), excluding contexts of peers, schools, and most importantly for the purposes of this chapter, communities.

This work is in response to social scientists' calls for further investigations of diabetic individuals with respect to neighborhood and community influences (Glasgow & Anderson, 1995). The basic premise is that families in need, especially those with a child recently diagnosed with diabetes, can draw on the strength of their communities or be undermined by the nega-

tive aspects of their communities; or they can experience both strengths and vulnerabilities from the same community. This chapter sets out to discuss differences between families of diabetic and nondiabetic adolescents. In addition, it addresses the wealth of variability and potential sources of these individual differences within diabetic adolescents.

COMMUNITY CONTEXTS AND ADOLESCENTS

Drawing largely on an ecological-transactional model, the view presented here is that adolescents live within multiple layers of context, each layer influencing and interacting with other layers to create a synergistic force that shapes adolescent development (Bronfenbrenner, 1979; Lynch & Cicchetti, 1998). Specifically, adolescents exist in families embedded within communities functioning in the context of broader macrosystems (e.g., regional norms and values) that occur during certain historical times and periods (Bronfenbrenner, 1986; Dixon & Lerner, 1999; Elder, 1974). These contexts are interdependent and reciprocal: Not only do they contribute to adolescents' and families' experiences, but individuals shape each context. For instance, families of adolescents with diabetes may reach out to their community for help and support. Similarly, neighbors in communities that are more organized and supportive may attempt to reach out to help families in need.

The past two decades have witnessed a resurgence of social science interest in community influences on youth and families (Brooks-Gunn, Duncan, Klebanov, & Sealand, 1993; Burton, Obeidallah, & Allison, 1996; Sampson, 1993; Sampson, Raudenbush, & Earls, 1997; Simcha-Fagan & Schwartz, 1986). Multiple theoretical paradigms regarding community influences on residents' outcomes have been proposed, such as social disorganization theory (Sampson, 1993; Shaw & McKay, 1942), social capital theory (Coleman, 1994), collective efficacy (Sampson et al., 1997), and social control theory (Hirschi, 1969). Accumulating empirical evidence suggests a consistent pattern between characteristics of community social control and social organization, and youth outcomes: Communities with high levels of social control and organization are associated with optimal outcomes for youth. In communities with high levels of control and organization, neighbors look out for one another, anonymity is minimal, and concern for neighbors and the neighborhood is the accepted and practiced norm. Communities with these characteristics tend to boast lower rates of school drop out, teen pregnancy, violent behavior, and drug use.

Sampson (1993) showed that communities with higher levels of social organization and control had lower rates of juvenile delinquency than did less well organized neighborhoods. Interpretations of this link suggest that in communities with high levels of control, neighbors, in a collective and individual sense, organize to enforce the norms they deem valuable, such as low drug use and truancy. Similarly, Elliott and Huizinga (1990) reported that, even after controlling for socioeconomic status, rates of alcohol and drug use were lower in more organized communities. Other studies have shown that neighborhood characteristics have implications for the

effectiveness of violence prevention initiatives as well. The positive effect of prevention programs has been found to be dampened in high risk neighborhoods (Aber, Jones, Brown, Chaudry, & Samples, 1998).

Studies of the neighborhood primarily examine economically challenged youth and communities, and within this circumscribed scope, attend largely to minority youth. This focus underscores the needs of minority youth in economically impoverished situations (Stack & Burton, 1993; Wilson, 1987), connecting these needs and their contexts to youths' functioning (Brooks-Gunn et al., 1993), giving rise to meaningful basic research and valuable policy initiatives. Yet, concentration largely on youth who are economically impoverished leads to a lack of information regarding youth who face other profound challenges. Adolescents confronting the challenges of chronic illness, whether in economically impoverished or more advantaged communities, may experience life in their communities in ways that are unique from their nonchronically ill counterparts. Adolescents with diabetes and their families represent a special challenge to communities, because their needs may be greater than those of other families living nearby. Diabetic adolescents may be more isolated than their neighboring peers, and need additional support from their community.

A recent literature search of key words community—neighborhood, and diabetic or chronically ill youth—was conducted across several databases (September, 1999; psychological abstracts, sociological abstracts, and medline abstracts). This search yielded only a handful of studies examining community influences on diabetic youth. Two studies are from the same research group (Turner-Henson and colleagues). Examining 10- to 12-year-olds with heart disease, asthma, and diabetes, Turner-Henson (1993) showed a relation between mothers' perceptions of neighborhood as resourceful and increased interactions with the community. These results are intuitively appealing and could be expanded on by an exploration of the specifics of what mothers of chronically ill youth found resourceful. In addition, Turner-Henson's work (Turner-Henson, 1993; Holaday, Swan, & Turner-Henson, 1997) included only pre- and young adolescents. As youth traverse adolescence, they interact in their neighborhoods with increasing frequency (Furstenberg, 1993). Consequently, it should be possible to discern more distinct patterns between individual adolescents with diabetes as they move through middle and later adolescent years. In another study, Powers et al. (1985) assessed diabetic, psychiatrically ill, and healthy preadolescents, early adolescents, and middle adolescents. Parents reported on whether their family turns to their community for assistance during difficult times. Results showed that above all other groups of adolescents (i.e., psychiatrically ill and healthy), families of diabetic youth were more active in seeking support from their neighbors and community resources (Powers et al., 1985). The emergent pattern across these studies suggest that families of diabetic youth turn to their neighbors and communities. In addition to parents' subjective reports, new research efforts along these lines could benefit by including adolescents' subjective reports, local health professionals' subjective reports,

and objective indicators of neighborhood characteristics (e.g., U.S. Census Bureau reports, police records). Furthermore, future research should include adolescents and families from diverse ethnic groups in order to explore the influences of cultural values and relative neighborhood advantage or deprivation on diabetic families' use of communities. Explorations could also examine whether families' patterns of seeking community support vary by adolescents' age. In deepening knowledge of these connections, future studies could identify the conditions under which families of diabetic youth are likely to turn to communities, and under what conditions they are least likely to turn to communities for help. It would also be possible to determine whether families of diabetic children living in low resource communities differ in their patterns of use compared to their counterparts living in higher resource communities.

Because youth with chronic illness have not been systematically studied with respect to community influences, it is not clear whether neighborhood characteristics previously identified as promoting optimal outcomes (e.g., lower teen pregnancy, lower juvenile delinquency) would be the same for youth with diabetes. Given the lack of empirical studies in this area, there can only be speculation about the way that communities may be connected to youth with chronic illnesses. Systematic investigation of these links should include not only tests of traditional theories of neighborhood influence (e.g., social organization), but also more recent contemporary innovative theories regarding neighborhood connections (e.g., collective efficacy; Sampson et al., 1997). For instance, tests of collective efficacy could include measures of residents' perceptions of the potential for support from neighbors to determine whether youth with chronic illnesses perceive support differently than their non-ill counterparts. In addition, empirical investigations could assess whether chronically ill youth are more or less responsive to neighborhood support: Are youth with diabetes more or less likely to be influenced by dynamics in their neighborhood? Are diabetic youth more likely to fare better in terms of general adjustment in certain neighborhoods? Are diabetic youth more likely to be compliant with illness-related treatments in certain neighborhoods? How does gender influence these linkages with community support?

STAGE-ENVIRONMENT FIT MODEL AND COMMUNITIES

The thinking regarding the question of optimal community contexts for youth with chronic illness is guided by the stage-environment fit perspective, presented by Eccles and colleagues (Eccles, Midgley, Wigfield, et al., 1993; Eccles, Lord, & Roeser, 1996). The stage-environment fit model uses a developmental perspective (Hunt, 1975), which has at its center the notion that developmentally appropriate contexts promote optimal psychosocial growth. Specifically, this model suggests that positive outcomes result from a match (i.e., a good fit) between the adolescents' developmental stage and the demands of their social context. In contrast, negative outcomes are hypothesized to result from a developmental mismatch (i.e., a poor fit) between an adolescent's developmental stage

and the demands of his or her social context (Eccles & Midgley, 1989). Although the stage-environment fit model was originally proposed to examine links between early adolescents' academic performance and the demands of their school environment (Eccles & Midgley, 1989; Eccles et al., 1993; Eccles et al., 1996), this paradigm has significant implications for understanding youth with chronic illness in context. With the exception of Obeidallah, Hauser, and Jacobson (1999), the majority of the research on the stage-environment fit model has focused exclusively on normative, nonclinical populations. Moreover, although schools and families have been explored as important settings for providing appropriate challenges for adolescents, communities have been all but overlooked.

Findings suggest that highly organized and cohesive communities contribute to better functioning among nonchronically ill youth. It is possible that highly organized and cohesive communities would be linked to better functioning among youth with diabetes. In such neighborhoods, neighboring parents and community leaders could work together to help diabetic adolescents cope with the management of their illness. In addition, in highly cohesive neighborhoods, parents may work collaboratively to prevent local nondiabetic adolescents from alienating or ridiculing youth with diabetes.

On the other hand, communities that are too cohesive may create a situation where diabetic adolescents feel singled-out as a function of their disease and the efforts required for its proper management. What constitutes a good match for adolescents without chronic illness may, then, in fact represent a poor fit for adolescents with diabetes. The complex dance that youth with diabetes engage in—balancing the demands of caring for their disease with the demands of normative adolescent development—may change the expected positive connections between community cohesiveness and adolescents' outcomes. The same community characteristics identified as promoting optimal outcomes among physically healthy adolescents may be the very ones that are deleterious for adolescents with diabetes.

Central to neighborhood's differential influence on diabetic adolescents are issues of control. Kyngas and Barlow (1995) suggest that adolescents who see their parents and the diabetes as controlling may be more inclined to rebel against both. Similarly, it can be argued that highly socially controlled communities act as another restrictive force for diabetic adolescents. Adolescents living in highly controlled and organized neighborhoods, who not only feel overregulated by their disease—and perhaps, by their families' response to their disease—may also feel as if the cohesiveness in their neighborhood is an additional restrictive force. High levels of community social control, which otherwise may be connected to youths' likelihood of experiencing better outcomes, could instead represent another force undermining diabetic adolescents' struggle for independence and autonomy.

It is possible that adolescents who live in highly cohesive neighborhoods would be associated with positive outcomes. Although moderately cohesive neighborhoods may represent the most optimal fit for diabetic adolescents, it is unlikely that neighborhoods characterized by anomie, disorganization, and

utter disarray are better for such youth. In fact, it is likely that neighborhoods characterized by high levels of social disorganization would not be the most optimal environment for any adolescent (i.e., diabetic or otherwise). Often, families in neighborhoods with high levels of social disorganization find that they are isolated from other families and from local services. Unfortunately, isolated families may "face dilemmas in an ever-increasing spiral of difficulty, whereas a family who has supports may turn to others for help" (Palfrey, 1994, p. 29).

Instead of either end of the cohesiveness spectrum, we propose that the most developmentally and disease-sensitive communities are those that are reasonably cohesive, with moderate levels of social organization and control. Neighborhoods with moderate levels of organization and control provide a backdrop of solid connections between neighbors that are not overbearing or excessively controlling. Within a person-environment fit model (Hunt, 1975), it is in such community contexts that adolescents with diabetes have the highest likelihood of successfully negotiating the competing demands of their disease and those associated with normative adolescent development. Testing these ideas empirically involves comparing adjustment indices between youth with and without chronic illness. As predictors, it would be important to include direct objective measures of neighborhoods, such as those provided by U.S. census, local police records of criminal behavior, or other official reports. Optimally, these objective measures could be coupled with subjective reports from adolescents themselves and their family members, and local peers. Additional useful information may be gleaned from key individuals in the neighborhood, such as town leaders and local government officials. Using this multimethod, multireporter approach would facilitate the development of a measure of community cohesiveness and organization. This measure would ideally be continuous so that it would be possible to note whether and where community levels of cohesiveness become problematic for diabetic youth. This approach would not only help researchers understand the experiences of youth with diabetes better, but would also deepen the understanding of the way communities potentially influence nonchronically ill adolescents.

In order to capture developmental issues in context, it is important to assess youth with diabetes over time. Multiple assessments across adolescence could help identify different levels of risk associated with certain community characteristics. Determining whether patterns of risk across adolescence differed for diabetic versus nondiabetic youth would be an interesting and important endeavor. Assessments could begin during preadolescence and continue until early adulthood. Ways to measure developmental status include chronological age, pubertal status, and/or timing. Such developmental markers could be linked to developmental challenges (e.g., interpersonal relationships) and connected to other psychosocial outcomes.

DANGEROUS NEIGHBORHOODS AND FAMILIES WITH DIABETIC YOUTH

Previous research suggests that emotional stress, particularly from an uncontrollable source, may impede functioning at

multiple levels (Allison et al., 1999; Dweck & Light, 1980; Seligman & Maier, 1967). Adolescents living in communities marked by high crime and violence are likely to be living in a stressful context. Stress and its influence on developing systems has particular relevance when considering the impact of dangerous communities on youth with chronic illness.

Concerns related to dangerous neighborhoods supersede issues of socioeconomic status. Neighborhood research has shown that socioeconomic disadvantage is not monolithically associated with community crime (Furstenberg, 1993) or other negative outcomes (Obeidallah, Burton, & Allison, 1999). In regard to adolescents with diabetes, studies examining socioeconomic status and outcomes revealed varied findings: Some research suggests that in lower socioeconomic households, family functioning is compromised after the diagnoses of diabetes is made (Northam et al., 1996), whereas other research indicates that there is no relation between diabetic control and socioeconomic status (Frey & Denyes, 1989; Marteau, Bloch, & Baum, 1987). These two streams of research converge to suggest that socioeconomic status is not necessarily a marker of negative outcomes; instead, other contextual factors, such as levels of community violence and crime, may be more meaningful predictors of outcomes for adolescents with diabetes. In fact, a growing body of research indicates relations between exposure to crime in neighborhoods and youths' development of posttraumatic stress symptoms (Fitzpatrick & Boldizar, 1993; Selner-O'Hagan et al., 1998). Given the dearth of research in this area, however, explorations of the direct effects of socioeconomic status, as well as the interaction between socioeconomic status and community contexts, are necessary in order to best determine these connections.

Despite the theoretical and practical importance of such studies, the relation between community danger and outcomes among youth with diabetes has not been systematically addressed. It is possible, indeed likely, that dangerous communities influence the well-being of adolescents with diabetes. In addition, dangerous communities contribute to the way that parents interact with adolescents. For example, in an effort to guard their young from harm, parents living in dangerous neighborhoods often dramatically increase their control over their children (Burton, 1993; Palfrey, 1994). At its extreme, increased control can take the form of lock-up strategies, wherein children are sent to their rooms immediately following school (Furstenberg, 1993). Families with diabetic adolescents, who may already be acting in overprotective ways in response to the disease, may feel particularly compelled to bolster their protection over their youth in dangerous neighborhoods.

Although tight control may be beneficial for adolescents' physical well-being and safety, it may exact a toll in terms of adolescents' attainment of important developmental needs. For example, the opportunities for development of interpersonal relationships with peers may be undermined among diabetic youth who live in overprotective families in dangerous neighborhoods. Further, this type of overcontrol may lay the planks for acting out or rebelling, possibly unintentionally increasing youths' likelihood of falling into harm's way. Gender

also may play a strong role, with some families stepping-up their protective efforts for their adolescent daughters more so than for their sons. Such differential treatment based on gender may contribute to group differences between girls and boys who have diabetes.

In contrast, some families in dangerous neighborhoods may be overstressed, and in turn, may withdraw from actively working with adolescents in their development of adherence to treatment protocols. In both scenarios, families respond to stresses in their communities and then in turn directly influence adolescents' experiences. The extra complications associated with management of diabetes contributes to the hypothesis that the harmful effects of dangerous communities would be exacerbated among diabetic youth.

COMMUNITIES CONTEXTS, DIABETIC ADOLESCENTS, AND THEIR PEERS

Although the needs of youth with diabetes have been identified by the medical profession, little research has explored the community risks specific to diabetic adolescents. A central risk to youth with diabetes may be through peers in their community. Certainly, there has been a good deal of research exploring the links between diabetic adolescents and their peer groups. Jacobson and colleagues (Jacobson et al., 1990; Jacobson et al., 1997) found that 55% of adolescents did not talk to their friends about their diabetes. Even more striking, 35% of adolescents with diabetes thought they would be better liked if they did not have diabetes. Such a pattern belies adolescents' tendency to want to be similar to other peers, especially during early adolescence. Adolescents who depart from typical maturation may be at increased risk for isolation from peers, have poor self-concept, and experience lower self-esteem. Youth who are socially rejected are those most likely to engage in risky and problematic behavior (Coie et al., 1995; Kupersmidt et al., 1995). Diabetic youth who are excluded from peer groups may be accepted only by those youth who have also been socially rejected. A differential association model (Sullivan, 1996) suggests that adolescents who associate with delinquent peers have an increased vulnerability to engage in risk-taking behavior.

In addition to the individual level risk connected with deviant peers, community attributes may also play a role in increasing diabetic youths' vulnerability to deviant activities. Communities that are socially disorganized and exhibit low social control tend to have a higher proportion of deviant youth compared to neighborhoods that are less disorganized and controlled (Sampson et al., 1997; Simcha-Fagan & Schwartz, 1986). Diabetic adolescents, who may already be vulnerable to peer pressure, and who live in neighborhoods where they have more opportunity to associate with delinquent peers, may find it especially difficult to avoid risk-taking behaviors. Risk-taking behaviors, such as using drugs and smoking, have a far more deleterious effect on diabetic adolescents than their nondiabetic counterparts. This is so because such substances may interact with the disease as well as medication, predisposing these youth for even more significant troubles. Rates of morbidity and mortality show a sharp

increase among drug-using diabetic adolescents compared to their nondrug-using diabetic counterparts and their nonchronically ill peers (Patterson & Garwick, 1998). Thus, community influences may differentially influence adolescents, dependent on their chronic illness status; chronically ill youth may be particularly vulnerable to peer pressure and may experience worse outcomes associated with risk-taking behaviors than their nonchronically ill counterparts.

Additional studies that measure diabetic adolescents' peer networks, including adolescents' perceptions of peers as well as direct assessments of peers themselves, would help close the gaps in an understanding of diabetic adolescents' peer relationships. Through the investigation of diabetic adolescents' peer groups in relation to community characteristics, it is possible to determine the mediating and moderating influences between peers and communities for diabetic adolescents. Peers may mediate connections between community characteristics and diabetic adolescents' experiences—for example, in socially disorganized communities, there may be more delinquent and deviant activity for youth to get involved in. In such contexts, diabetic adolescents who may be socially isolated, may have more opportunity to associate with delinquent peers and engage in delinquent activities. Thus, in the mediating model, the negative influence of troubled communities operates through peers. In a moderating model, delinquent peers would exert a deleterious influence on diabetic adolescents only in contexts where the neighborhood shows signs of disorganization. That is, moderately socially organized neighborhoods would buffer diabetic adolescents from becoming involved with delinquent peers and their activities.

CONCLUSIONS

This work takes an ecosystemic perspective in examining the multiple contexts that adolescents with diabetes traverse. The importance of person-environment match between adolescents, their families, and communities has been discussed. The discussion also has challenged the notion that highly cohesive neighborhoods are the best environments for adolescents with diabetes. It also has described potential pitfalls in dangerous neighborhoods for families and adolescents with diabetes. Finally, the idea has been explored that diabetic adolescents living in troubled neighborhoods may be more susceptible to engaging in risk-taking behaviors.

Underlying the idea of a good fit between communities and adolescents with diabetes is the assumption that adolescents with diabetes may experience their communities differently than do their nondiabetic peers. In particular, it is suggested that what may constitute a good match for nondiabetic youth and their communities may not necessarily include the same ingredients that create an optimal match for diabetic youth. Instead, the possibility is raised that, to the extent to which highly cohesive and organized neighborhoods represent a controlling force, they may be associated with more negative outcomes for diabetic adolescents. This concept is in accordance with earlier work by Reiss, Gonzalez, and Kramer (1984), which suggested that chronically ill family members who were in families with

high levels of family integration and coordination were more likely to die earlier than their counterparts in families that were less cohesive. A moderate level of cohesion in communities would lead to the most optimal match between community characteristics and adolescents with diabetes.

In keeping with an ecosystemic perspective, communities do not simply impact adolescents directly. Instead, community characteristics influence families, and families in turn influence adolescents. In highly stressed communities, families may bolster efforts to protect adolescents from proximal dangers. This healthy wish to protect a child from danger, however, may be exacerbated in families that already engage in protective strategies surrounding the management and care of diabetes. Although increased protection may help adolescents' physical well-being to some extent, it may have the unfortunate consequence of undermining adolescents' attempts at individuation and attainment of other developmentally appropriate goals.

Previous research shows that in neighborhoods with low levels of social organization and control, adolescents' risk of engaging in deviant activity is increased (Furstenberg, 1993). The greater the prevalence of adolescents who engage in delinquent activity, the more opportunity for other adolescents to become associated with delinquent activity. It is suggested that such a situation presents a particularly risky situation for diabetic adolescents. Diabetic adolescents may be more susceptible to trying to "fit in" with peers (Thomas & Hauser, 1997), a situation that exposes them to the negative influence of peer pressure. If this is the case, then adolescents with diabetes who live in neighborhoods with low levels of social organization may be most vulnerable to engaging in delinquent activity. In other words, the relation between socially disorganized neighborhoods and delinquent adolescents may be intensified by diabetic adolescents' increased vulnerability to peer pressure.

Clearly, individual differences among diabetic adolescents exist, creating a mosaic of complex and diverse patterns within this special group. Individual differences occur at multiple layers. First of all, not all youth in the same community are exposed to the same level of community characteristics. Second, among those who are exposed to the same level of a community characteristic, not all will respond in the same way (Cicchetti & Aber, 1998). One line of inquiry relevant to researchers, health practitioners, and policymakers is to identify which community characteristics are associated with better or worse adherence to management of the disease. Within such identified high risk communities, what protects adolescents with diabetes from experiencing negative outcomes? How does gender figure into these models? Are girls or boys more sensitive to community characteristics in terms of their disease management? How would disease management interact with community characteristics to contribute to other outcomes (e.g., pregnancy status, school achievement, drug use)?

Currently, psychosocial predictors of diabetic youths' health status include a patients' adherence and stress (Johnson, 1995). This work suggests that in addition to these individual level predictors, medical health professionals

consider the context in which diabetes will be managed. The full gamut of highly organized to highly chaotic and dangerous neighborhoods has implications for how adolescents manage their disease, as well as for how their families will cope with maintenance. Consideration of the neighborhood context with respect to diabetic adolescents should occur at multiple levels, including the medical level (e.g., pediatricians taking into account the contextual barriers to compliance), research level (e.g., social scientists exploring the potential role of community characteristics on diabetic adolescents' adherence, general well-being, and family processes), and the policy level (e.g., implementing social policy that moves toward creating optimal environments for all youth, with particular attention to those who are chronically ill).

The focus here has been primarily on the broader context of neighborhoods; other contexts, such as schools, also play a significant role in shaping diabetic adolescents' experiences (Delamater, Bubb, Warren-Boulton, & Fisher, 1984). A valuable line of future research is to consider these interlocking contexts in their contribution to diabetic adolescents' development.

Although the aim of this chapter has been to describe communities and adolescents with diabetes, the information presented may be used as a template to better understand those youth who are HIV-positive, have asthma, lupus, cystic fibrosis, hemophilia, or other chronic illness. Discovering convergent themes running through studies of various discrete chronic illnesses and community connections will help researchers ultimately to arrive at a place where new factors, in a new context, can be identified that can enhance adaptation of these special groups of adolescents.

Childhood Health Issues Across the Life Span

Barbara G. Melamed

Barrie Kaplan

Joshua Fogel

Yeshiva University

Drotar et al. (1989) reviewed two decades of child health research and proclaimed the need for a developmental perspective to guide the focus of health promotion. This would also pinpoint where and by whom the site of delivery of services should occur. Some of the factors that make children likely to develop illness are genetic (family history of disease) and environmental (poverty, crowding, lack of nutrition). These factors are difficult to alter. In addition, the mental health of the parents and their level of functioning at the time of their child's incipient illness is likely to determine how soon a child receives access to health care treatment, and how effectively the recommended treatment program can be implemented. For instance, many parents either cannot afford or do not completely understand the concept of prolonged medication even when the symptoms have abated (i.e., antibiotic treatment). Even when parents are psychologically well adjusted there are numerous problems that can exacerbate stress, including:

1. Establishing relationships with medical personnel (Moos, 1977).
2. Coping with medical procedures associated with treatment.
3. Coping with symptoms associated with the condition (whether it is acute or chronic) (Moos, 1977).
4. Coping with the possible separation from parents, other family members, and friends.
5. Coping with the new social pressures such as being labeled as "ill" or having a medical problem.
6. Coping with the limitations that result from a change in lifestyle (e.g., diabetic children must change their diets, asthmatic children must exercise caution during physical activity).
7. Stress of missing school and acclimating during the return to school.
8. Coping with the added burden facing the entire family, including time and money.

Some protection for the child is afforded by certain policy regulations. Unfortunately, access to public health for immunization and inoculation against childhood illness is not as universal as school requirements. Once a child has been admitted to the public school system, further immunizations for new diseases may not be as successful as in the earlier years. In addition, environmentally induced problems exist. Asthma or lead poisoning are difficult to change in the absence of laws protecting children from environmental contaminants. Accidental deaths by falling from heights and seat belt wearing are often prevented only when the absence of window guards and wrong application or absence of seat belts are enforced by penalty. Even in these cases, new incidents of infant death by inappropriate inflation of automobile air bags may confuse parents about the proper precautions. Parents often misunder-

stand safety rule communication and do not provide children with a model of preventive habits.

This chapter focuses on three areas of research as representative of some of the issues that determine whether children can receive adequate care by retraining parents, health care professionals, and policymakers on the importance of prevention across the life span. Studies dealing with issues of illness onset in children diagnosed with asthma will hopefully illuminate issues in self-management across a wide range of chronic illnesses. The issue of organ transplantation has become a serious consideration and will continue to be prevalent in the 21st century. Therefore, it is used as a prototype to discuss issues of decision-making and treatment compliance issues that raise the ethical and practical concerns involved in having this choice. Finally, the issues of prevention of accident, injury, and recognition of the precursors of child abuse are discussed. The chapter attempts to set forth a functional analysis for use by health care professionals to help them see where to focus their efforts, whether it be on prevention, remediation, or teaching self-care behaviors. Future directions for research are specified.

DEVELOPMENTAL ASSESSMENT OF COPING

Differences in Conceptualization and Assessment of Coping

An understanding of coping requires knowing what the task demands of the situation involve, as well as what resources the family has to bring to problem solving. In addition, the mental age of the child must be considered to assess whether the illness problems overwhelm the developmental task of that life period. As others have pointed out, there are few reliable and valid instruments that measure children's coping (Ryan-Wenger, 1992, Wertlieb et al., 1987). The importance of assessment is to determine which coping strategies are most suitable for the numerous stressful events that children and adolescents confront. The difficulty of constructing such a scale and assessing coping mechanisms can be attributed to several causes. There is confusion about the difference between coping mechanisms and coping styles. The two are often used interchangeably, although they relate to different types of behavior. Coping mechanisms are the focus of this chapter and, according to Lazarus and Folkman (1984), the term refers to constantly changing cognitive and behavioral efforts to manage specific internal and external demands that are appraised as taxing or exceeding the resources of the person. Implicit in this definition is the ability to deliberately alter, modify, or adjust both behaviors and thoughts in an attempt to cope with a stressor. In contrast, a coping style is more stable over time and reflects personality characteristics (Lazarus & Folkman, 1984). The definition really demands that the "resources of the person" be considered. This must be applied individually because age as a proxy for developmental ability is known to be deceptive if used without also having knowledge of conceptual level of reasoning and physical maturation or limitations imposed by illness/accident or birth defects.

CHRONIC ILLNESS

Timing Considerations

It is often found that during a critical period at about 6 months to age 3, children separated from a parent due to death, illness, divorce, abandonment, and so on may suffer from attachment problems. This is particularly likely if the children are sick themselves and are in a hospital or another institution with a low staff: children ratio for extended times.

Adaptation to chronic illness is influenced by the rate at which improvements are being made in medical research. For example, adjustment to childhood cancer previously involved providing assistance to families who were anticipating a child's inevitable death. Better survival rates for certain childhood chronic illnesses, including cancer, cystic fibrosis, and AIDS, necessitate new models of continual adjustment to long-term changes in health status.

Despite significant medical advances, chronic illnesses still need to be conceptualized as long-term sources of stress for both children and their families. Long-term health disturbances involve repeated hospitalizations, discomfort, uncertain outcomes, multiple diagnostic procedures, and periodic medical evaluations. Financial resources may be severely strained in families with a chronically ill child, diverting funds from other pursuits. Childhood stress, in turn, may be increased without the additional resources for pursuing special needs educational programs and recreational activities.

Siblings may resent parent's increased attention toward a chronically ill child, especially because sibling conflicts tend to increase during middle childhood. Conflicts are affected by a combination of children's temperaments and parental behavior. Illness changes functioning and roles within the family.

Beliefs about Chronic Illness

Childhood chronic illnesses differ widely with regard to their complexity of medical management. Juvenile diabetes, for example, involves daily adherence to dietary restrictions, blood glucose testing, and insulin injections. Other diseases, such as juvenile rheumatoid arthritis and juvenile diabetes, may involve heightened levels of discomfort. A child may suffer in terms of feeling different from others, which is especially painful in middle childhood.

With their advancing cognitive abilities, children develop more sophisticated notions of cause-and-effect processes in illness development. The cause of illness shifts from being viewed as an external person or action, to an event located within the body. As children's cognitive development matures to include concrete operational thinking, illness representations are altered. Illness beliefs refer to lay understandings of the ways disease processes develop. Children between age 7 and 10 are initially likely to conceive illness in terms of contamination; this implies that an external person, object, or action is responsible for producing illness. Later, children begin to explain illness in terms of internalization. Children, however, have only vague understandings of disease processes at this point.

Additional advances in cognitive development introduce new understandings of the ways illness develops. At approximately age 11, children begin to understand how internal physiological processes are altered to produce disease. The cause of illness shifts from being viewed as an external person or action, to an event located within the body.

Asthma management is the focus of this section, as it is currently the fastest growing epidemic in the United States and is diagnosed in very young children.

ASTHMA

Asthma is the most common disease of childhood and a leading cause of morbidity in adults. Despite significant advances in medical treatment, asthma morbidity and mortality rates have risen dramatically over the past two decades, especially in minority and socioeconomically disadvantaged populations.

Asthma is a lung disease characterized by a variety of features, including airway obstruction or narrowing that is reversible either spontaneously or with treatment. Pathologically, it is characterized as a chronic inflammatory disease of the airways, with a granulocytic-lymphocytic submucosal infiltration, epithelial cell desquamation, and mucus gland hypertrophy and hyperplasia (Wamboldt & Gavin, 1991).

Prevalence

Asthma is the most common chronic disorder of childhood affecting from 4% to 9% of children (Geller, 1996). As many as 50% of the cases are diagnosed before the child reaches age 2. The highest incidence of asthma seems to be from birth to age 4. The estimated prevalence of asthma among children in the United States increased by almost 40% between 1981 and 1988 and is still on the rise. Although the increase occurred mainly among White children, the prevalence of asthma still remains higher in Black children than in White children. Factors that have been implicated in the current rise in asthma prevalence are outdoor air pollution, the decreasing quality of indoor environments as a result of exposure to maternal smoking, and the high levels of dust mites. Other genetic and environmental factors that contribute to the prevalence of childhood asthma are positive family history, male sex, low birth weight, maternal smoking and season of birth (Arshad, Stevens, & Hide, 1993). The increased prevalence of asthma may also be a manifestation of an increase in sensitization among children to inhaled allergens, such as those present in house dust, cat fur, and grass pollen.

Treatment

When asthma is managed properly, hospitalization is rarely necessary. However, about 43% of its economic impact is related to emergency department use, hospitalization, and death, all resulting from the failure of preventive treatment (Milgrom et al., 1996). Current goals of management of asthma are geared toward the relief of obstruction, restoration of oxygenation and ventilation, and prevention of complications. Anti-

asthma medications improve pulmonary function via three primary mechanisms: bronchodilation, protection of the airways from allergen or histamine challenge, and resolution of airway hyperresponsiveness through antiinflammatory properties. Selective beta agonists, corticosteroids, theophylline, and anticholinergic agents have become the most common of the pharmacologic treatments, and fall into the bronchodilator category. Inhalation is the preferred route because it offers rapid onset of action, delivery directly to the airways, fewer systematic side effects and smaller doses than would be required of oral or intravenous routes. In severe cases, intubation and mechanical ventilation are used.

Day-to-day management of symptoms of the illness utilize educational programs involving both the child and the parents. Physician involvement is recommended. Some of the programs include self-charting of symptoms and medication usage. These programs are aimed at increasing self-management knowledge and skills. The parents must understand the use of their children's inhaled drugs, and if they are being used to prevent episodes or relieve symptoms. Prevention by controlling cigarette smoking and dust mites might decrease the severity of symptoms.

Clinical success is determined by the extent to which people adhere to the complex medical regimen involved. Medical regimens for asthma care are particularly vulnerable to adherence problems because of their duration, the use of multiple medication on both routine and pro re nata (prn, as needed) schedules, and the periods of symptom remission (Rand & Wise, 1994). Medical compliance is defined as the extent to which the person's behavior, in terms of taking medications, following diets, or executing lifestyle changes, coincides with medical or health advice (Weinstein, 1995). Some factors that would contribute to a classification of noncompliance are complete failure to obtain or take the prescribed medication, improper taking of medication because of patient misunderstanding of correct dosage and schedule, omission of doses, increasing or reducing dosage or schedule of dosage, and discontinuing therapy before the end of the recommended period. Children are at a particular risk for nonadherence and noncompliance. It has been documented that only about 50% of inhaled medication is taken as prescribed and compliance does not improve with rising severity of illness (Milgrom et al., 1996). This number may be as high as 90% of pediatric asthmatics (Wamboldt & Gavin, 1991). A common problem among children and adolescents is nonadherence with anti-inflammatory inhalers, which are prophylactic and do not yield an immediate improvement in symptoms. Most children are not using proper inhaler techniques, and are not using an appropriate spaced device to maximize medication delivery to the conducting airways. The metered dose inhaler (MDI) is the most commonly used inhalation technique, however, considerable skill and coordination are needed to use it correctly. A study by Boccuti, Celano, Geller, and Phillips (1996) demonstrated that a significant proportion of children with moderate to severe asthma use poor techniques with from 14% to 26% making critical errors. Just because children use it correctly in front of a practitioner, does not mean they generalize it outside the office. Indirect and direct methods of obtaining informa-

tion on accuracy are available. Indirect methods use clinical judgments, self-reports, and asthma diaries. Direct measures include biochemical assays that analyze blood or urine testing to objectively measure levels of medication or byproducts in the body. The downside of these methods is laboratory costs and delay in results. There are now electronic devices such as the MDI, which are attached to aerosol inhalers. These devices record the time at which the inhalers are used, and can track patterns of medication usage over a period of several months. In a study (Milgrom et al., 1996) attempting to evaluate adherence in children with asthma to regimens of inhaled corticosteroids and beta agonists, data were collected electronically by metered dose inhaler monitors and compared with traditional diary. There was a large discrepancy between the diary entries and chronologic records of children. Electronic monitoring demonstrated much lower adherence to prescribed therapy than was reported by patients on their diary cards. This important issue of compliance in children is the dependence on their parents for the knowledge and upkeep of their regimens. The parents of an asthmatic child are frequently faced with complex decisions that have to take into account the child's asthma as well as more general developmental needs (Schwam, 1987). Because parents of asthmatic children are under so much stress, it may be important to measure their quality of life and the quality of life of the children to assess adherence influences. Asthma specific scales for children include the Child Asthma Questionnaire and the Pediatric Asthma Quality of Life Questionnaire (Osman & Silverman, 1996). Other predictors of noncompliance may be the level of the stress of the parent (Parenting Stress Index, Abidin, 1986), and the level of depression in both parents and children. Poor symptom perception may undermine compliance (Wamboldt, 1998). Once stable predictors of noncompliance are uncovered, then practitioners can predict who is at risk. Reliable interventions can lower the chance of exacerbation of disease as well as reduce hospitalizations.

TRANSPLANTATION

Psychologists perform various roles in pediatric organ and bone marrow transplants. Usually, patient-centered consultation involves bedside consultation and other forms of patient contact. Indirect psychological consultation relies just on the referral source without any patient contact. Collaborative team consultation involves interaction with the patient, referral source, and other team members (Resnick & Kruczek, 1996).

The referral sources are usually the primary clinical personnel, such as physicians and nurses. The psychologist should balance the needs of both the patient and clinical personnel (Resnick & Kruczek, 1996). However, collaborative relationships with the referral sources are very important and the psychologist should not use a distant authoritarian manner. Satisfaction by the clinical personnel is strongly related to the diagnosis agreement between the referral source and the psychologist (Olson et al., 1988). Also, a collaborative relationship helps avoid issues of territoriality (Carpenter, 1989).

Transplantation consultation and liaison require special skills. The first skill is a knowledge of the biopsychologic

components along with their associated psychosocial issues. The second skill is an understanding of the hospital culture along with a tolerance for professional ambiguity and intrusions imposed by medical priorities. The third skill is learning to deliver psychological services both formally and informally, with an understanding that patients and their visiting families do not automatically want psychological services. The fourth skill is the ability to translate and communicate psychological principles and interventions that others can understand and even perform (Carpenter, 1989).

Possible roles associated with transplantation patients involve pre- and posttransplant assessment of the patient and family, assisting with coping during and after the procedure, support for the emotional needs of staff members, and sometimes grief work with the family, sibling donor, or staff if the patient dies (Rappaport, 1988).

Behavioral intervention procedures for varying accompanying behavioral problems are often necessary. A chart listing various suggestions for improving behavioral problems is offered by Charlop, Parrish, Fenton, and Cataldo (1987, p. 494).

Stress

Pediatric organ transplantation (OT) can be classified into three phases. The first, or pretransplant, phase includes the weeks and months before admission where the decision for the transplant and then the search for the donor is made. The second, or acute, phase is the inpatient hospitalization, which typically lasts from 1 to 3 months. The third, or the posttransplant, phase is the time that is only relevant for transplant survivors. Posttransplant complication monitoring continues for a few months and medical and neuropsychological monitoring extends to a few years (Phipps, 1994).

Each phase has its own set of stressors. Some pretransplant phase stressors are the family stress of possible sibling donors, which sibling donor is more appropriate, the patient being indebted to the sibling, the waiting period, and the misconception that the patient will acquire the personality characteristics of the donor (Phipps, 1994).

Some acute phase stressors are patient isolation, sterilization, physical restrictions, sensory deprivation, and hospitalization (Andrykowski, 1994; Phipps, 1994; Phipps & DeCuir-Whalley, 1990).

Some posttransplant phase stressors are physical and social isolation, adjustment to society, the patient's appearance, medical procedures, hospitalization, returning to school, treatment-related side effects, extreme dependence on the medical staff, repeated infection, and the possibility of death (Andrykowski, 1994; Bradford & Tomlinson, 1990; Phipps, 1994; Phipps & DeCuir-Whalley, 1990).

A model of family stress in transplantation suggests that initially there is an adjustment phase to the news of the required transplantation. It is viewed as a stressor that interacts with the existing family resources and the perceptions of this stressor. This leads to the adaptation phase where initially they treat everything as a crisis. This leads to a "pile-up." Strategies to deal with this pile-up involve coping methods of

perception of this pile-up and use of existing and new resources (Hare, Skinner, & Kliewer, 1989).

Various patient responses to these stressors are anxiety, depression, withdrawal, anger, hostility, survivor guilt, non-compliance, sleep difficulties, anorexia, paranoia, and acting out (Andrykowski, 1994).

During each of the three phases of OT, appropriate play techniques can ameliorate some patient stress. During the pretransplant phase, children are encouraged to bring their own materials or toys are given to them. During the acute phase, too demanding play activity might be considered intrusive. Instead, minimal participation activities such as reading a story, listening to an audiotape, and viewing a movie is enjoyed. During the posttransplant phase, play interactions can combat the sensory deprivation and social isolation. Tactile activities, such as finger painting or sand and glitter, are helpful. Fantasy play can help to cope with the isolation where the patient can now freely experiment with feelings and situations (Gottlieb & Portnoy, 1988).

Parental Stress. One study showed that mother's stress increased as they moved from the pretransplantation phase to the 1- and 6-month posttransplantation phases. Clinically significant stress was found in 20%, 56%, and 41% of mothers at pretransplantation, and 1-month and 6-month posttransplantation phases, respectively. A greater financial burden, disrupted planning, and caretaker burden stresses were greater at 1 month and 6 months posttransplantation than pretransplantation (Rodrigue et al., 1997).

Another study showed that fathers had lower parenting stress than mothers based on the Parenting Stress Index. This could be either because fathers coped better or fathers were not as involved as mothers. Fathers felt financial stress, disrupted planning of family activities, and increased family burden (e.g., travel restrictions, altering of their schedule to care for the ill child) (Rodrigue et al., 1996).

Posttraumatic Stress Disorder (PTSD). Symptoms of PTSD are common among pediatric OT patients. Denial and avoidance are very common. Reexperiencing of life threats is often not noticed unless the psychologist probes the patient (Stuber, Nader, Yasuda, Pynoos, & Cohen, 1991). Girls are more at risk than boys for PTSD (Wintgens, Boileau, & Robacy, 1997).

Social Support Family members often comprise the social support system. OT patients tend to have fewer friends and active peer experiences. Often the extensive parental social support leads to parental overprotection and patient dependency. Separation anxiety occurs when the patient is separated from the parent (Schweitzer & Hobbs, 1995; Stuber, 1993).

Sometimes social support is not beneficial. If the social support network is too supportive, some patients may feel uncomfortable because they lack control (Littlefield, 1992).

Parental Psychosocial Issues

Parents react to OT issues in different ways. Some parents act in a highly assertive manner that often presents problems to the OT team. Others act underorganized and do not become too involved (Bradford & Tomlinson, 1990).

Preoperative psychosocial issues begin with the initial hospital experience where there is a loss of control, denial of medical reality, and attempted trust building efforts with the hospital staff. The wait at home has concrete issues such as a financial burden with subsequent concerns about the need to get public involvement to raise funds. The parents feel guilt over issues such as the death of the donor, competition for limited organs, and the burden of the informed consent decision for the child. Anger is felt due to a loss of control and a feeling of being forgotten and abandoned (Slater, 1994).

Perioperative psychosocial issues begin with anxiety immediately after the operation. The first 2 weeks are viewed as a possible new beginning. The remainder of hospitalization is a roller coaster period due to the fear of rejection and infection, and the lack of control over the ultimate outcome (Slater, 1994).

Postoperative psychosocial issues begin with the return home where they adapt a new parental role concerning a fear of rejection and death, and a readjustment in family structure (Slater, 1994). One study of parents of bone marrow transplantation (BMT) patients done a year after surgery showed that 37% of the parents had financial concerns, 23% had child-related problems, and 19% had problems sleeping. Very few reported marital or social relationship problems (Sormanti, Dungan, & Rieker, 1994).

Coping

Children can cope with either problem-focused coping (e.g., problem solving, cognitive restructuring) or emotion-focused coping (e.g., social support, problem avoidance, religious belief) (Kronenberger et al., 1996).

One study of children waiting for BMT showed that avoidance and distraction coping were associated with more aggression, anxiety, withdrawal, and depression. Children who coped with religion were less withdrawn, more aggressive, and more depressed. Problem solving and cognitive restructuring were not related to better adjustment. This might be because the severity of BMT overwhelmed the children (Kronenberger et al., 1996).

Developmental Considerations

OT issues are pertinent to child development, especially after a successful transplant. During infancy, the parent should be careful about developing overprotectiveness for the child. Once the child is a toddler, autonomy should be encouraged. Play opportunities should exist with as little restriction as possible, although the parent might be concerned about the

child's frailty. The school-age child should, as much as possible, have a school education to allow for peer interaction. The adolescent should be monitored for risk-taking independent behavior. This can be dangerous if the child forgets to take the immunosuppressant medications or observe the dietary restrictions (Sexson & Rubenow, 1992; Slater, 1994).

Cognitive Functioning

OT can affect cognitive functioning. A successful renal transplant may prevent a downward trend in cognitive functioning associated with end-stage renal disease. Some studies suggest that there are moderate gains (Hobbs & Sexson, 1993; Schweitzer & Hobbs, 1995; Stewart, Kennard, Waller, & Fixler, 1994).

Liver transplants have mixed results concerning cognitive functioning. Some claim there are improvements or no change (Hobbs & Sexson, 1993; Schweitzer & Hobbs, 1995) whereas others claim there are deficits (Stewart et al., 1994).

One study of heart transplant patients showed that they did not have greater cognitive deficits than a cardiac disease/open heart surgery control group (Stewart et al., 1994).

Quality of Life

One study showed that BMT child survivors had good quality of life (physical and psychosocial dimensions of functioning). However, the domains tested were for adults and are of questionable use for children (Powers, Vannatta, Noll, Cool, & Stehbens, 1995).

New measures for determining quality of life have been developed specifically for children. One is a 16-item multiple choice questionnaire in a self-report format using a Likert scale. It takes from 5 to 10 minutes to complete. The children should do it themselves because differences were noted when parents' responses were compared with the children's responses. Each question represents one health-related sphere (e.g., mobility, friends, vision). This test was validated on 12- to 15-year-old adolescents waiting for OT. The young adolescents rated the positive spheres of breathing, friends, mobility, and mental function as most important. They rated the negative sphere of death as the most important followed by unconsciousness as the next worst. These OT patients had more problems with breathing, eating, and elimination than the control group (Apajasalo, Sintonen, et al., 1996).

Another quality of life measure was developed for 8- to 11-year-old children surviving OT. It has 17 dimensions and is in the form of a structured interview. It takes from 20 to 30 minutes to complete. The OT patients had more problems eating, eliminating, and concentrating than the control group (Apajasalo, Rautonen, et al., 1996).

Adherence

Lack of adherence can cause a successful OT to fail. This issue is quite serious. One study showed no adherence problems for children under age 2. However, 73% of preschoolers

(age 2–6), 82% of school-age children (age 7–12), and 40% of adolescents (age 12 and up) had adherence problems (Phipps & DeCuir-Whalley, 1990). Another study showed that 50% of adolescents do not always take their medication (Schweitzer & Hobbs, 1995).

Some factors associated with poor adherence are poor self-esteem, family conflict, and multiple family stressors (Wainwright & Gould, 1997). One study showed that informative support (advice or personal feedback) and emotional support (caring, sympathy, love) by fathers were negatively related to adherence to the immunosuppressant medications of azathioprine and cyclosporine. It is possible that this occurred either because the fathers only became involved due to the poor adherence or perhaps this occurred because this was the way the child was attempting to gain control (Foulkes, Boggs, Fennell, & Skibinski, 1993).

Future Directions

Many OT studies rely on small sample sizes (Schweitzer & Hobbs, 1995). Future research should focus on more prospective studies that use larger sample sizes. A possible solution is for multiple investigators in different hospitals to collaborate in their research. This will offer more concrete and valid information on the effects of OT on children.

INJURY PREVENTION

Injuries are an important health issue for children. Injury is the third leading cause of death in the United States and the leading cause for children, adolescents, and young adults (Irwin, Cataldo, Matheny, & Peterson, 1992). Previous research has presented confusing and conflicting results on the determinants of childhood injuries, particularly psychosocial predictors. In an analysis of 532 pediatric patients at a prepaid clinic during 12 months, it was found that four factors independently associated with the risk of at least one treated injury: high activity level, high rate of pediatric utilization for noninjury-related visits during the follow-up period, occurrence of a treated injury during the preceding year, and a negative attitude toward medical care providers by the child's mother. Mothers who work more than 15 hours a week outside the home and who have more life events in the preceding year are more likely to have children with serious injuries. Thus, Horwitz, Morgenstern, DiPietro, and Morrison (1988) concluded that these characteristics must be targeted for stressed families.

Adolescents

In a study (Kolbe, 1990) conducted by the Centers for Disease Control, the behaviors that contribute most to adverse health and social outcomes were grouped into six categories: behaviors that result in unintentional and intentional injury such as motor vehicle accidents, homicide, and suicide; drug and alcohol use; sexual behaviors that result in sexually transmitted diseases, including human immunodeficiency

virus infection or unintended pregnancy; tobacco use; dietary behaviors that contribute to adult morbidity and mortality; and physical inactivity.

Adolescents are more prone to athletic injuries and suicide than children at other developmental periods. In a study (Baumert, Henderson, & Thompson, 1998) surveying high school students in grades 9 through 12, athletes and nonathletes were found to differ in specific health risk behaviors. Adolescent athletes appear less likely to smoke cigarettes or marijuana, more likely to engage in healthy dietary behaviors, and less likely to feel bored or hopeless.

Peterson and Brown (1994) reviewed the literature on unintentional injuries in children. They pointed out the similarities between factors predicting both unintentional injuries and child neglect. It was not until the 1980s that the focus shifted from the physical environment to sociocultural and personal factors, including the immediate environment and the skills and abilities of the parents. A deficit in problem solving and a failure to provide appropriate supervision appear to be difficult constructs to measure as both involve a lack of response. In coming up with a working model to encompass all of the etiological factors for child injury, they provide both caregiver-based and child-based variables. Several studies showed that stress contributes to risk of child injury. Thus, families who exist in poverty, chaos, crowding, and residence change have a higher chance of having a vulnerable child. Social isolation may increase caregiver stress, particularly in young single mothers. Maternal depression may be a particularly critical injury risk factor (Garbarino et al., 1991).

A recent study (Kramer, Warner, Olfson, Ebanks, Chaput, & Weissman, 1998) of the offspring of depressed parents found that there is an increased susceptibility to specific medical conditions and hospitalization relative to the depression status of both the parent and the offspring. The study revealed that the offspring depression status was associated with a history of general medical problems and hospital visits only among those offspring who also had a depressed parent. The association was demonstrated for genitourinary disorders, headaches, respiratory disorders, and hospitalizations. Parental depression without considering offspring depression was limited to a report of unconsciousness in the offspring and may be related to an increased prevalence of accidents resulting from inadequate parental monitoring among depressed parents. These findings were consistent with a longitudinal study of children of depressed parents (Billings & Moos, 1985). They found that the offspring of depressed parents had more general medical problems, more health risk factors (i.e., smoking, drinking, and drug use), and poorer functioning than children of nondepressed controls. It was further found that having a parent with a lifetime measurement of depression even if it had remitted, still presents a risk for medical problems. In the two-generation study, it was found that a history of depression in both the offspring and the parents was necessary to exhibit a significant association between depression and medical problems. However, these results may be due to either genetic or environmental influences or both. There is some association between allergies and depression, which may mean that both dysfunction in the adrenergic and

cholinergic systems may predispose people to both atopic disorders (e.g., allergy and asthma) and some forms of depression. This may be passed on genetically, thus producing the medical comorbidity only among those with two generations of depression.

CONCLUSIONS

Thus, within each of the areas of research reviewed, it is important to consider the parents' state of stability, ongoing stressors in the home, and the children's developmental age in the assessment and treatment programming of the health care team. The first task of a functional analysis would be to view the problem within the framework of what developmental tasks need to be accomplished during the next 5 years of the child's life. Differences between independence struggles and age capacities will indicate how involved the parent should be in the implementing of the medical program. Often compliance can be improved by educational discussions and nonthreatening guidance of parents in more appropriate problem solving. In the case of adolescents, they may be encouraged to modify the program to fit in more with their life style and identification needs. Especially in the area of suspected child neglect when too many visits to the emergency room with accidents or asthmatic attacks occur, the parent needs to feel believed and not evaluated or blamed for the injury or failure of medical compliance. A team approach by the hospital staff and health consultants would allow better supervision and more constructive individualization of programs as multiple input will pinpoint strengths and weaknesses in each individual involved in the care of children. When parental depression is lifelong, it may be necessary to encourage an independent evaluation of the suffering parent so that medication and social support from the other spouse may be improved. In impoverished environments due to dysfunctional families, low access to health care, poverty, crowdedness, or environmental hazards, the school could serve as an entry point for mobilizing community resources.

Social Influences in Etiology and Prevention of Smoking and Other Health Threatening Behaviors in Children and Adolescents

Richard I. Evans
University of Houston

In his widely cited review of psychosocial approaches to smoking prevention, Flay (1985) commented on the brevity of the time line of prevention research:

Four generations of research on psychosocial approaches to smoking prevention have been conducted within less than one half of a human generation (indeed, less than one decade). Given this, remarkable progress has been made in an important area of health psychology and public health. ... Research on smoking prevention ... has evolved more systematically and progressed further than most other areas of health promotion. (p. 482)

For more than four decades, it has been my privilege to be an active participant-observer in the research processes just described (Evans, 1998), and the present chapter presents an historical perspective from that frame of reference. There is growing evidence that the components of smoking prevention programs may also be applicable to addressing the prevention of use of alcohol and other drugs as described, for example, by Glynn, Leukefeld, and Ludford (1985), and may be, at least, a basis for AIDS prevention interventions as well.

In examining the history of smoking prevention efforts, one first encounters the approach of conventional wisdom that high fear arousal is perceived as the major device for discouraging children and youth from beginning to smoke. As Janis and Feshbach (1953) suggested in their now classic

study, high fear arousal to encourage a health protective behavior (oral hygiene) does have some impact on short-term changes in such behavior but may not impact on truly long-term changes. For example, Marston (1970) reported that immediately after a heart attack (certainly high fear arousal), individuals may change their lifestyles to minimize high risk behaviors (e.g., diet, smoking) to avoid a recurrence, but, over time, may return to many of their original risk-taking behaviors. So, even under conditions of intense fear, as pointed out in earlier research by Evans (1979), permanent changes in health habits may not occur. In fact, in the most recent report on smoking rates among adolescents, Johnston, Bachman, and O'Malley (1995) reported that most students in 8th, 10th, and 12th grades perceive a "great risk" in smoking, even in the face of increasing prevalence of smoking among these students. Further discussion of this report is addressed later in this chapter.

Because of the persistence of conventional wisdom concerning the effectiveness of "scare tactics" to prevent health threatening behaviors, a more detailed examination of fear arousal as a mechanism for instituting modification of behaviors may be instructive at this point. In his extensive review of the fear arousal literature, Higbee (1969) pointed out that no blanket statement could be made concerning the value of fear arousal as a persuasive device. However, this review suggested a basis for several interesting hypotheses that relate to the effects of various levels of fear arousal from minimal to

high, effects of fear-arousing communications over time, and combining fear arousal with other persuasive devices in targeted behavior modifications. The value of testing such hypotheses was supported by Janis (1967); Evans, Rozelle, Lasater, Dembroski, and Allen (1970); and Sutton (1982). Some studies that have examined some of these hypotheses concerning the role of fear arousal are used as examples in prevention of health threatening behaviors in adolescents.

As it became increasingly evident that fear arousal in itself, that is, simply emphasizing the negative effects of engaging in a particular health threatening behavior was not enough (Evans, 1979), investigators sought to expand their prevention strategies. Janis and Feshbach (1953), in the study mentioned earlier, reported that the combination of a minimal fear approach with general toothbrushing instructions was more effective in increasing the incidence of toothbrushing among adolescent subjects than a strong fear appeal alone. Subsequently, Leventhal, Singer, and Jones (1965) challenged the relative importance of fear arousal in itself as a motivator to change a health-related behavior. In a study involving persuasion to submit to tetanus inoculations, these researchers found that providing highly specific instructions on how to obtain such inoculations, without depending solely on the fear of contracting a life threatening disease, was more effective in motivating individuals to engage in this specific prevention behavior than the effects of fear alone.

Our University of Houston Social Psychology/Behavioral Medicine Research Group pursued the problem of the relative effectiveness of fear arousal in a series of basic studies in preventive dentistry with young adolescents (Evans et al., 1970). Results of these studies indicated that exposing the students on only one occasion to elaborated instructions and the modeling of specific oral hygiene behaviors (without fear or positive appeals) resulted in significantly more effective oral hygiene behavior. General oral hygiene instructions coupled with a positive appeal were almost as effective. Effective, but significantly less so, were fear appeals coupled with merely general oral hygiene instructions. Furthermore, it was found that simply testing subjects at irregular intervals, possibly perceived as monitoring, was almost as effective as the various persuasive messages. When the short-term study was extended over time, behavior changes were maintained (Evans, Rozelle, Noblitt, & Williams, 1975). In order to cross-validate self-reports of toothbrushing, a procedure not present in the Janis and Feshbach (1953) study, a chemical indicator of cleanliness of teeth, was employed (Evans, Rozelle, Lasater, Dembroski, & Allen, 1968). This cross-validation procedure was later generalized to smoking prevention studies as the research group developed the "pipeline procedure" to increase the validity of self-reports of cigarette smoking (Evans, Hansen, & Mittelmark, 1977). Incidentally, this was not a "bogus" pipeline, as often incorrectly stated in descriptions of this procedure. Actual, rather than bogus, measures of nicotine in blood assays were used.

Approaches to prevention of smoking, which incorporated some elements of fear arousal that have been used extensively, but with only limited success, include the information model and the affective model described by Edmundson,

McAlister, Murray, Perry, and Lichtenstein (1991). The information model is based on the assumption that providing adolescents with factual information about a potentially destructive behavior such as smoking or drug use, will prevent them from engaging in the behavior. Such information may be presented in a variety of ways such as didactic lectures by a classroom teacher, videotapes and films, posters and pamphlets, or guest speakers who are experts in the area. Despite evidence that indicates this approach to be largely ineffective (Goodstadt, 1978; Thompson, 1978), it remains the approach of choice of many school-based smoking prevention programs according to Murray, Davis-Hearn, Goldman, Pirie, and Luepker (1988). Programs based on the "affective model" stress more global attitude changes directed at such factors as enhanced self-esteem, improved decision making and goal-setting, and often do not include specific information about health risks of smoking (Glynn et al., 1985). Little evidence exists in support of the application of this model for effective prevention (Hansen, Johnson, Flay, Graham, & Sobel, 1988; Tobler, 1986).

The limited effectiveness of fear-arousing information, even in earlier investigations, led our Research Group to consider alternate conceptual foundations for prevention interventions. During the early 1970s, as a research component of the National Heart Center at Baylor College of Medicine, the research group was challenged by the notion that even without being directly exposed to any systematic prevention program, most young adolescents at that time were aware of the dangers of smoking, including long-term health consequences such as heart disease and cancer. As elementary schoolchildren, they often utilized such information in an attempt to persuade their parents to quit smoking. At about the time they entered junior high school, however, many began to smoke. Fear of the consequences induced by knowledge of the dangers of smoking appeared to be insufficient to prevent its onset among many young adolescents exposed to social pressures to engage in the behavior, as even currently appears to be the case as was suggested in the Johnston et al. (1995) report.

However, because of conventional wisdom related to the value of fear arousal as a persuasive device, it was not surprising that a survey of junior high school smoking prevention programs revealed that most programs focused almost completely on fear-arousing messages. They emphasized the long-term effects of smoking such as heart disease or cancer without consideration for the present-oriented rather than future-oriented time perspective of young adolescents (Mittelmark, 1978). The programs rarely reflected feedback from target groups in their designs and seemed to ignore previous research on the effective use of media. A critical problem was the lack of any form of systematic evaluation of these programs. A series of focused interviews was conducted with a large population of seventh-grade students (Evans, Raines, & Hanselka, 1984). These interviews suggested that various levels of peer pressure, models of smoking parents, and smoking-related messages in the mass media that featured attractive smokers, seemed for many adolescents to outweigh concerns about the dangers of smoking.

Inferences from this study suggest that three overall considerations may be important in examining the effect of social influence on the decision to smoke:

1. Sources of social influences: These may include peers or friends, siblings, parents, admired public figures, perceived social norms, and social climate.
2. Mechanisms of social influence: These may be overt (direct social pressure such as from peers) or covert (effects of modeling).
3. Susceptibility to social influences: These may include various intrapersonal characteristics (e.g., self-efficacy, risk-taking, optimism or pessimism) and social cognitions (perceptions).

A pilot study was conducted that supplemented messages addressing the health consequences of smoking with information concerning social pressures that might impact young adolescents to begin smoking, together with training in specific skills to resist these pressures (Evans et al., 1978). More recently, this has been described as "resistance skills training." Considering the results of this pilot study, a prevention program based on an incorporation of such social influences was developed and evaluated. The social inoculation model, as it was described, appears to have guided much of the prevention research for the past two decades. Referring to the work of the Houston Group (Evans, 1976, 1983, 1984; Evans et al., 1984; Evans et al., 1981; Evans & Raines, 1982), Edmundson et al. (1991) stated:

The social influences model recognizes smoking in adolescents as primarily a social behavior. This model includes the following four components: (1) information on the negative social effects and short-term physiological consequences of tobacco use; (2) information on the social influences that encourage smoking among adolescents, particularly peer, parent, and mass media influences; (3) correction of inflated normative expectations of the prevalence of adolescent smoking; and (4) training, modeling, rehearsing, and reinforcing of methods to resist those influences and to communicate that resistance to others, particularly peers. (p. 154)

The evolution of social influences models has drawn on various concepts in psychology. Bandura's (1977) social learning theory was particularly relevant in early formulations of the social inoculation model. As applied to the initiation of smoking, the theory suggested that children might acquire expectations and learned behaviors vis-à-vis smoking through observation. They might learn vicariously that smoking appears to relieve tension or anxiety. Vicariously learned expectations of the positive and negative consequences of cigarette smoking could be important factors in the ultimate decision regarding smoking behavior. Bandura's (1982, 1989, 1995; Evans, 1989a) more recent development of the concept of self-efficacy, which further explicates this notion, has become central to some current models of smoking and drug use cessation such as the stage theories developed by DiClemente et al. (1991), although Bandura (1995) has some

reservations concerning stage theories, even as they integrate the concept of self-efficacy. This social inoculation model, which involved inoculating adolescents with the knowledge and social skills to resist various social pressures to smoke, may be regarded as a behavioral application of McGuire's (1961) cognitive inoculation model. McGuire's (1968) communication-persuasion model, essentially an information-processing analysis, proved to be useful as a guide for the utilization of the social inoculation concept involved in the development and delivery of prevention programs.

To discuss more fully the components of the social inoculation model, it should be pointed out that it considered both the socioenvironmental and personality or intrapersonal determinants that contribute to the complex of influences that encourage the use of harmful substances. Implicit in the model was the conception that as children reach early adolescence, they experience greatly increased vulnerability to social pressures to engage in risk-taking behaviors, greater mobility, and greater freedom from adult authority figures. Experimentation with personal identity and lifestyle choices, which marks this period of development, could include use of tobacco or other harmful substances, and conflicting expectations could override both personal beliefs and parental or family values. This model identified smoking, or use of alcohol and other drugs, both as a form of rebellion against authority including risk-taking, and as part of a new and different lifestyle for adolescents during the early teenage years. For example, it might predict the initiation of smoking for children as young as age 10 or 11. In fact, it might be noted here that in the 1970s, as the original social inoculation studies (which addressed smoking) were being planned, smoking initiation reflected an upward trend from the elementary grades to high school (Johnston, Bachman, & O'Malley, 1979; Thompson, 1978), with a significant shift in rate of the initiation of smoking when entering junior high school. Thus, we chose to begin our prevention intervention with seventh-grade students. Even preliminary results from the current NIDA-supported Middle School Drug Prevention project (Evans, 1994) indicate that 31.8% of the subjects had initiated at least some cigarette smoking at or before they were 11 years old.

Variations of the social influences-based models that have been involved in the formation of prevention programs have appeared to be, at least initially, quite effective in preventing the use of harmful substances as reported by a number of investigators including Best et al. (1984); Biglan, Glasgow, et al. (1987); Biglan, Severson, et al. (1987); Ellickson, Bell, and McGuigan (1993); Flay, d'Avernas, Best, Kersell, and Ryan (1983); Flay et al. (1987); McAlister, Perry, and Maccoby (1979); McAlister, Perry, Killen, Slinkard, and Maccoby (1980); Pentz et al. (1989); and Perry, Killen, Slinkard, and McAlister (1989). The cognitive behavioral model, which expands the social influences model with additional problem-solving, decision-making, and self-control methods, has also been the basis for prevention programs that have produced initial positive results as reported by Kendall and Hollon (1979); Gilchrest, Schinke, and Blythe (1979); Schinke and Blythe (1981); and Schinke and Gilchrest (1983). The life skills model developed by Botvin and Eng

(1982) and Botvin, Eng, and Williams (1980) incorporates components of the social influences model and the cognitive behavioral model, with a particularly strong emphasis on training adolescents to cope with social challenges. This program also appears to have produced promising results.

Other possibly relevant conceptual areas in psychology that were described in the 1979 Surgeon General's Report on Smoking in Children and Adolescents (Evans, Henderson, Hill, & Raines, 1979) might be utilized in programs designed to prevent the use of harmful substances. Included here would be Festinger's (1957) theory of cognitive dissonance used in explorations of conflict between health beliefs and the initiation of health threatening behaviors such as smoking, and the Jessor and Jessor (1977) multideterminant conceptual structure of problem behavior, which had been successful in predicting age-graded problem behaviors that are considered to be acceptable in adults but not in adolescents. The latter model has been incorporated into several longitudinal research designs, for example, the work of Sherman, Chassin, and Presson (1979) and Sherman et al. (1982). These investigators attempted to explain the onset of smoking and the transition in status from nonsmoker to smoker. Ajzen and Fishbein (1970) and Fishbein and Ajzen (1975) proposed a framework for predicting behavioral intentions, which were assumed to mediate and thus predict subsequent overt behavior. For example, this model, which has been applied with some success in studies of alcohol use in adolescents (Schlegel, Crawford, & Sanford, 1977), also appears to lend itself to empirically testable hypotheses that could tease out important components of the development of smoking behavior. Henderson's (1979) small-scale study of smoking in a population of ninth-grade students, based on Fishbein's and Ajzen's (1975) model, provided a provocative basis from which more elaborate investigations employing such models could be pursued within structural equation or causal models (Dill, 1981). Subsequent investigators also developed interventions directed toward altering some of the situational and intrapersonal determinants of smoking (Botvin et al., 1980; Hurd et al., 1980). Other investigators began focusing on mediators of the initiation of the use of harmful substances such as modifying perceptions of social norms as well as directly addressing mediators such as peer pressure (Sussman, 1989).

In recent years, as researchers began working within the framework of structural equation modeling (SEM) and path analyses, they began to address the question of synergism. That is, to what degree does the initiation of use of one harmful substance trigger the initiation of use of another substance? A syndrome of problem behavior initiation may be present that includes the use of tobacco, alcohol, and illegal drugs together with other risk-taking behaviors (Elders, Perry, Ericksen, & Giovani, 1994). It appears that adolescents often engage in more than one risk behavior during this stage in their lives. Even though the specific risk behaviors may differ, the common thread for all adolescents may be exposure to such risk factors. Researchers in prevention began to recognize that all prevention programs, however different in focus (e.g., avoiding tobacco, illegal drugs, and alcohol; preventing pregnancy and sexually transmitted diseases; prevention of

violence), may all be connected by the same set of factors that enhance adolescents' susceptibility to engage in high risk behaviors. Vega, Zimmerman, Warheit, Apospori, and Gil (1993) suggested that distribution of risk factors is similar among ethnic groups even if the susceptibility to those risk factors may differ. Risk taking may begin with one risk behavior such as cigarette smoking and progress to other more risky behaviors as the student gets older. Kandel and Yamaguchi (1993) suggested that cigarette smoking itself is a risk factor for illegal drug use and that there is a predictable pattern of engaging in harder and harder drugs. Such hypothesized synergism among the use of various drugs must be considered in prevention programs (Stall, McKusick, Wiley, Coates, & Ostrow, 1986). Another recently emerging area of problematic behavior is excessive gambling among adolescents (National Research Council, 1999), which also appears to be operative within the context of co-morbid substance use behaviors (Evans, 1999).

Longitudinal research designs employing confirmatory factor analysis and SEM, such as the research group and others are employing in current or past investigations, should help identify multiple indicator latent variables and possible causal relationships among the use of various substances and other health-risk behaviors. Drawing on preliminary findings from the NIDA-supported Middle School Drug Prevention Study currently underway (Evans, 1994), it has been noted that drug use profiles (by ethnicity and race) indicate that such profiles differ within a tri-ethnic sample in terms of the sequence of the use of various health threatening substances:

- Among middle school Whites: cigarettes, hallucinogens, inhalants and steroids.
- Among middle school African-Americans: intravenous (IV) drugs, marijuana, and smokeless tobacco.
- Among middle school Latinos: cigarettes, cocaine, inhalants, IV drugs, marijuana, and steroids.

These preliminary analyses suggest that the synergistic pattern involving the use of various substances may differ among ethnic and racial groups and should be considered in prevention programs. Such profiles add a level of complexity to the conceptualization of gateway substances. In particular, this research appears to suggest that there is no general gateway substance, but rather that gateway substances may differ among various individuals and groups.

At least three theoretical possibilities exist concerning synergism in the use of health threatening substances: (a) nonsynergism (i.e., there is no tendency for persons engaging in particular risk behaviors to be engaging in other such behaviors); (b) simple synergism that describes persons engaging in particular risk behaviors as tending to engage in other risk behaviors without a specific causal sequence in the initiation of such behaviors; and (c) gateway synergism, as demonstrated in the Kandel and Yamaguchi (1993) study in which persons engaging in particular risk behaviors tend to engage in other risks, with certain risk behaviors leading causally to the initiation of others. Although risk behavior synergism has been reported by some investigators who utilized cross-sectional data (Biglan et al., 1990; Hingston, Strunin, Berlin, &

Herren, 1990), the lack of data available from sound prospective investigations precludes distinguishing between simple and gateway synergism. So a general guideline is not clearly developed concerning whether interventions should focus on the prevention of the use of one harmful substance or should address various harmful substances simultaneously.

The issue of AIDS prevention must now be seriously considered within this context. Because of the current concern about risky sexual behavior, including exposure to HIV among adolescents, one could hardly undertake a drug use prevention investigation without recognizing the relation between drug use and sexual behavior. Teenage sexual activity within the context of drug use may well result in impairment of responsible decision making that would otherwise lead to the practice of "safer sex" (Adler, Kegeles, Irwin, & Wibbelsman, 1990).

According to Evans, Getz, and Raines (1991), this relation between HIV risk, drug use, and sexual behavior may be a complex, reciprocally reinforcing, biopsychosocial phenomenon. Despite their increasing knowledge of the dangers of drug use and unprotected sexual behaviors, as would be expected based on earlier studies of the use of harmful substances, many young adolescents still initiate such behaviors (Miller, Turner, & Moses, 1990; Morrison, 1985). When theory is marshaled to explain such phenomena, possible perspectives are reflected in some variant of Rational Choice Theory or Subjective Expected Utility Theory (Gilbert, Bauman, & Udry, 1986; Luker, 1975; Weisman et al., 1991). These theories could also be utilized to examine the decision-making process involving cost-benefit analyses of alternative behaviors. Another investigation currently being conducted by the research group employs a planned behavior-action control perspective that pays close attention to the role of social influences in the use of harmful substances as related to at-risk sexual behavior. Consistent with the discussion of sexual behavior presented by Weismann et al., it can be inferred that the initiation of drug use is best regarded as relationally determined, that is, not only does it require the presence of another person (at least for it to constitute an HIV risk), but the actions of that other person occur within a social context having impact on the quality of one's decision-making processes vis-à-vis drug use.

While suggesting that teenage sexual behavior can be interpreted as rational (Lowenstein & Furstenberg, 1991), it can be argued that sexual activity in the context of drug use can result in the derailing of a decision process that might otherwise lead to the practice of safer sex as described by Adler et al. (1990). If Dryfoos' (1990) estimate is correct, that 25% of the adolescent population is using alcohol or marijuana heavily and is engaging in unprotected sexual intercourse, we might infer that this same proportion is at high risk for contracting HIV. Her estimation that underprivileged African-American and Hispanic adolescents, particularly those who are falling short academically, are overrepresented in this high risk group is consistent with epidemiological data linking drug use, early sexual activity, race or ethnicity, and AIDS prevalence (Miller et al., 1990; Strassberg & Mahoney, 1988). These findings appear to be supported by early results from a

current study dealing with a study population that fits the profile of adolescents at high risk for both substance abuse and HIV-risk sexual behavior.

A study by Kirby (1997), which assessed curricula used for preventing sexual risk behavior, suggests that AIDS prevention programs might be based on social learning or social influence models such as social inoculation, even as such models have been utilized in drug use prevention programs. Such AIDS prevention programs focus on reducing specific risk-taking behaviors. They are interactive, provide training for teachers who are taught about social influences such as peer pressure and the media, and finally, focus on specific group norms and behaviors.

Another significant problem that should be addressed is the at-risk status of minority youth. For example, in the NIDA supported study previously described, differences among minority groups in incidence of use of various substances represent critical information that must be considered. Prevention programs must be sensitive to the distinctions that are present when there is a focus on minority populations. For example, as indicated earlier, my research has demonstrated a correlation between the use of certain substances and particular ethnic or racial affiliation. As shown in Tables 27.1 and 27.2, data from the studies described earlier indicate some significant differences in use among three ethnic groups. For example, African-American adolescents tend to report smoking less than Whites and Hispanics, while some Hispanic populations report a more frequent use of inhalants than do other groups. A properly conducted prevention intervention program must be sensitive to such differences in frequency and patterns of use to ensure that the most effective indigenous message is presented to all groups. The value of "cookie cutter" programs merely based on data from primarily White subjects are clearly subject to question.

Although use of substances and the prevention of such use among members of the majority population have been widely studied (Bell & Battjes, 1985; Glynn et al., 1985), few large-scale studies have targeted minority populations. Among these are investigations conducted by Botvin (1986), Schinke et al., (1988) and Orlandi (1986). Minority and low socioeconomic status generally are considered important risk factors for substance abuse although the relationships are complex (Dryfoos, 1990; Pentz, Trebow, Hansen, MacKinnon, 1990).

A large number of the young African-American and Hispanic, as well as White, adolescents living in the target area of one of my current investigations, and those in investigations such as reported by Botvin (1986), are routinely confronted with high drug availability and may have limited skills to cope with explicit and implicit social influences to use these drugs. This type of environment may well exemplify the "drug abuse crisis" described in earlier research (Evans, 1989b), and most recently cited by the Columbia University Drug Addiction Center (Merrill, 1995) as the most critical problem faced by children and adolescents, and provides a strong rationale for implementing such investigations in such target areas.

Another issue confronting prevention researchers is that high dosage-high frequency, truly long-term prevention pro-

TABLE 27.1

Percentage Reporting Use of Various Drugs × Ethnicity
Among Middle School Students in Grades 6 Through 8
(N = 2,446)

	Whites (45%)	African American (36%)	Mexican American (20%)
Alcohol	61%	42%	54%
Beer	58%	50%	60%
Cigarettes	48%	32%*	54%
Cocaine	3%	3%	5.3%
Downers	4%	2%	3%
Hallucinogens	7%	2%*	6%
Inhalants	17%	7%*	20%
IV drugs	2%	2%	2%
Marijuana	12%	18%	21%
Smokeless tobacco	21%	6%*	12%
Speed	5%	3%	7%
Steroids	4%	2%	1%
Ecstasy	2%	1%	2%

*Significantly less reported use than other ethnic groups.

grams and their benefits, in terms of cost-effectiveness, must be considered because the effects of short term interventions often wash out (Murray, Pirie, Luepker, & Pallonen, 1989). As indicated earlier, Johnston et al. (1995) reported an increase in smoking among 8th and 10th graders. Botvin, Schinke, and Orlandi (1995) elaborated on this point when they stated the following:

Follow-up studies designed to provide data concerning the durability of the prevention effects produced by social influence approaches have reported positive behavioral effects lasting for up to 4 years (Elder et al., 1993; Luepker, Johnson, Murray, & Pechacek, 1983; McAlister et al., 1980; Murray et al., 1989; Telch, Killen, McAlister, Perry, & Maccoby, 1982). Efforts to establish the durability of prevention effects for longer than 3 or 4 years have been disappointing. Data from several longer term follow-up studies have shown that these effects gradually decay over time (Flay et al., 1989; Murray et al., 1988), suggesting the need for continuing intervention or booster sessions. Because little is known about the nature and timing of booster interventions or the extent to which social influence approaches may require further refinement, additional research is needed. (p. 171)

On this issue, Bandura (1995) suggests a possible prescription for higher dosage interventions:

TABLE 27.2

Percentage Reporting Use of Various Drugs × Ethnicity
Among High School Students in Grades 9 Through 12
(N = 2,190)

	Whites (49%)	African- American (33%)	Mexican- American (18%)
Alcohol	84%	70%	78%
Beer	80%	69%	75%
Cigarettes	66%	40%*	65%
Cocaine	6%	2%	10%
Downers	6%	2%	5%
Hallucinogens	15%	2%a	15%
Inhalants	15%	4%*	18%
IV drugs	2%	1%	1%
Marijuana	30%	27%	40%
Smokeless tobacco	34%	5%*	20%
Speed	13%	1%*	8%
Steroids	3%	1%	2%
Ecstasy	6%	1%	5%

*Significantly less reported use than other ethnic groups.

Researchers are applying promising prevention models in school settings under severe constraints well suited to undermine their effectiveness. The general conclusion is that these approaches work in the short run, but their effects dissipate over time. There are several problems with this indiscriminate verdict. Informative evaluation research requires assessment of quality of implementation. Otherwise, there is no way of knowing whether weak results reflect a deficient model, or deficient application of a good one. Outcome studies of school-based programs rarely provide data on adequacy of implementation. Journal editors should insist that outcome studies include sound data on quality of implementation. School-based applications are probably long on didactics, but short on personal enablement. By enablement I do not mean a stock set of refusal tactics. Rather, it involves equipping children with skills and efficacy beliefs that enable them to regulate their own behavior and manage the diverse pressures in interpersonal relationships for detrimental conduct. Meta-analyses show that the more children practice exercising regulatory control, the more successful they are in resisting detrimental health habits. (p. 10)

Although this "washing out" of the effects of many of the prevention programs may account for only some of the variance related to the increase in smoking among children and ad-

olescents, this now challenges the overall effectiveness of prevention programs over the last several years. Johnston et al. (1995) speculated that one reason for this increase in smoking is that smokers attractive to teenagers are once again being frequently "modeled" in the media. It is also possible that, as has been discovered in recent years, schools have been less enthusiastic about smoking prevention programs because over all, substance abuse curricula are in place with little modification of their content despite the changing face of the psychosocial influences to which adolescents are exposed. Ellickson et al. (1993) pointed out, however, that even with equivocation concerning long-term effectiveness of prevention programs, any successful delay of engaging in high risk behavior results in a lowered risk of contracting an STD, being in a car wreck, or other consequences of high risk behavior that can result in poorer health and higher treatment costs. The longer onset is delayed, the more success will be gained in avoiding illness and psychosocial effects attached to high risk behavior. If initiation can be delayed long enough, will the adolescent's high risk avoidance behavior carry over into adult decision making about health choices? If success is achieved in changing social norms, these same messages must be communicated within the community as well as in the school or social setting where adolescents may initially be exposed to the messages. Considerable evidence of the value of this is apparent as more and more institutions and communities are committed to limiting exposure of nonsmokers to smokers.

Strategies for monitoring prevention programs with appropriate modification of their content over time would appear to be one major step that might be taken to address the alarming findings in the Johnston et al. (1995) report. In fact, we are currently exploring in our major longitudinal investigations the effect of high dosage prevention interventions throughout the tenure of prospective investigations. Other investigators are also responding to this problem of washing out of early effects of prevention programs in a similar manner. Future prevention research should consider:

1. Synergism among an array of health threatening behaviors.
2. Differences in frequency of patterns of use of harmful substances among various ethnic and racial groups.
3. The need for high dosage truly long-term continual prevention interventions.
4. Promote the involvement of school, communities, and mass media in modifying group norms and behaviors (including eliminating youth targeted content in cigarette ads), so that norms and displays of models of the use of cigarettes and use of other substances become an increasingly less effective stimulus for the initiation of such behaviors by adolescents.

Health, Behavior, and Aging

Ilene C. Siegler

Lori A. Bastian

Hayden B. Bosworth
Duke University

Health psychology has always been sensitive to age as an important construct because the distributions of diseases by age are not random and are important in determining the psychological impact of different diseases. Epidemiology, on the other hand, studies age as a prominent risk factor for disease. Both are important in understanding the set of associations in health, behavior, and aging.

The psychology of adult development and aging looks at persons aging normally, some with and some without specific diseases, to examine the ways disease influences the aging process. Health psychology studies individuals with specific physical illnesses and seeks to understand how the aging process might modify the impact of that disease (Siegler & Vitaliano, 1998). The psychology of adult development and aging and health psychology are two subdisciplines of psychology that have multidisciplinary partners. The multidisciplinary aspects of studying aging are part of gerontology and limited to studying primarily the elderly, whereas the medical aspects of aging are studied as a postgraduate branch of medicine called geriatrics (Hazzard, Bierman, Blass, Ettinger, & Halter, 1994; Maddox et al., 1995). Behavioral medicine is a multidisciplinary approach to understanding problems in health psychology that interact with the same problems in psychosomatic medicine (Blechman & Brownell, 1998; Matthews, in press).

Handbooks are common in the psychology of adult development and aging. In each of the Handbooks there has been a "health psychology" chapter (Deeg, Kardaun, & Fozard, 1996; Eisdorfer & Wilkie, 1977; M. F. Elias, J. W. Elias, & P.

K. Elias, 1990; Siegler & Costa, 1985). As a group, they provide excellent reviews of the relevant literature that need not be repeated here. As part of a set of master lectures on adult development and aging, Siegler (1989) was given the "health psychology" assignment and tried to conceptualize the intersection of health, behavior, and aging as developmental health psychology. This chapter reflects an updating of that initial effort and focuses on emergent findings in the past 10 years and aims to be illustrative rather than exhaustive.

Understanding the issues in health, behavior, and aging first requires discussing what has been a central question in the field: What is normal aging? Second, some important methodological ideas are reviewed from the psychology of adult development that will be useful in health psychology. The chapter then takes up the issue of a life-span developmental versus "phase" theory view of a developmental health psychology. It then considers some new data and thinking about women's and men's health in middle and later life, and reviews the findings from some recent empirical studies that show the excellent results from the synergy of developmental and health psychology.

WHAT IS NORMAL AGING AND HOW IS IT DIFFERENT FROM DISEASE?

This question drove the initial longitudinal studies of normal aging, such as the Duke Longitudinal Study (Busse et al., 1985). Shock's (see Shock et al., 1984) initial observations were essentially correct, that some, albeit rare, individuals

age without the typical declines (as was shown by a careful testing of participants in the Baltimore Longitudinal Study of Aging, BLSA) and normal aging itself is a relatively benign set of processes (Williams, 1994). This is not to say that older persons do not have health problems or that the probability of health problems does not increase with age. But rather, when they do, they can be attributed to a particular disease process rather than just the passage of time. The resulting problems then could be considered the fault of a chronic disease process that is not rapidly fatal, but treated, and remains as a companion for the rest of life. Thus, it seems "unfair" to blame aging. It used to be that normal aging was accepted and disease treated. However, current cohorts raised on such slogans as "Better living through chemistry" are trying to treat normal aging as well.

A table taken from a recent NIA publication summarizes what the Baltimore Longitudinal Study of Aging (BLSA) teaches about normal aging (NIA, 1996).

Definitions of normal aging are a moving target and change as a function of individual's risk modification behavior and effective treatments. Thus, Table 28.1 is true today; but future research may point out changes for future cohorts. As new cohorts age, they may well be different from current middle-aged and elderly persons. As is discussed later, psychology of aging has spent considerable time understanding these shifting patterns of aging.

METHODOLOGICAL CONCERNS FROM PSYCHOLOGY OF AGING

Psychology of aging has made major contributions in the explanation of the meanings of age, period, and cohort and important factors in understanding development (Baltes, 1968; Schaie, 1965; Schaie & Herzog, 1985). Here, the focus is on the implications of developmental designs for health psychology.

Period/Time Effects

The definition of a period, or time effect, is a societal or cultural change that may occur between two measurements that present plausible alternative rival explanations for the outcome of a study (Baltes, Reese, & Nesselroade, 1988; Schaie, 1977). In order to specifically describe a period, or time effect, in health and disease, these effects are described in terms of new diagnostic tools or medical therapies that present plausible alternative rival explanations for the outcome of a study.

The introduction of the prostate-specific antigen (PSA) test in 1987 is an example of the effects of period/time effects accounting for age-related changes in detecting prostate cancer. With the increased use of the PSA test as a diagnostic tool for prostate cancer, there is now an increasing number of prostate cancers being diagnosed among older adults that would not have been diagnosed based on previous diagnostic techniques (Amling et al., 1998). Because prostate cancer prevalence rates increase with age, researchers studying longitudinally the relation between age and onset of prostate cancer would have to account for the introduction of this relatively new diagnostic tool.

TABLE 28.1
What is Normal Aging?

Individuals age at extremely different rates. In fact, even within one person, organs and organ systems show different rates of decline. However, some generalities can be made, based on data from the Baltimore Longitudinal Study of Aging. It is important to remember that these statements do not apply to all people.

Heart. It grows slightly larger with age. Maximal oxygen consumption during exercise declines in men by about 10% with each decade of adult life and in women, by about 7.5%. However, cardiac output stays nearly the same as the heart pumps more efficiently.

Lungs. Maximum breathing (vital) capacity may decline by about 40% between age 20 and 70.

Brain. With age, the brain loses some cells (neurons) and others become damaged. However, it adapts by increasing the number of connections between cells—synapses—and by regrowing the branch-life extensions, dendrites, and axons that carry messages in the brain.

Kidneys. They gradually become less efficient at extracting wastes from the blood. Bladder capacity declines. Urinary incontinence, which may occur after tissues atrophy, can often be managed through exercise and behavioral techniques.

Body Fat. The body does not lose fat with age but redistributes it from just under the skin to deeper parts of the body. Women are more likely to store it in the lower body—hips and thighs—while men store it in the abdominal area.

Muscles. Without exercise, estimated muscle mass declines 22% for women and 23% for men between age 30 and 70. Exercise can prevent this loss.

Sight. Difficulty focusing close up may begin in the 40s; the ability to distinguish fine details may begin to decline in the 70s. From age 50 on, there is increased susceptibility to glare, greater difficulty in seeing at low levels of illumination, and more difficulty in detecting moving targets.

Hearing. It becomes more difficult to hear higher frequencies with age. Hearing declines more quickly in men than in women.

Personality. After about age 30 personality is stable. Sudden changes in personality sometimes suggest disease processes.

Information is becoming made available quicker and improvements in diagnostic techniques and treatments are increasing in frequency. This is a benefit for the population, but it makes research more difficult, particularly if an intervention is in process and new information or changes in medical procedure is being made and available to the public at-large. Subsequently, health psychologists are going to have to become more aware and flexible in the way they deal with these increasing period/time effects. An example of researchers adapting to historical or period effects has been the ongoing Women's Health Initiative study, in which information on estrogen use is being collected (Matthews et al., 1997). Since the design of this large observational and intervention study in the late 1980s (Roussow et al., 1995), there has been an increased number of data to suggest that the influence of estro-

gen is related to long-term benefits, such as preventing or delaying osteoporosis, heart disease, and Alzheimer's disease (Jacobs & Hillard, 1996). More recently, researchers have identified newer selective estrogen receptor modulators (i.e., Raloxifene and lower doses of conjugated estrogen (0.3 mg) that may be as effective as the more traditional 0.625 mg Premarin but with fewer side effects (Delmas et al., 1997; Bastian, Couchman, Nanda, & Siegler, 1998; Genant et al., 1997). The increase in awareness of the possible association of estrogen and diseases, such as Alzheimer's disease, and the addition of newer therapies may have altered women's perception and experiences with hormonal replacement medication and influence study observations.

Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) information is being made readily available, which is quickly influencing treatment outcomes. AIDS and aging were once mutually exclusive conditions: The AIDS epidemic began in young adults and they died before they had time to age (Justice & Whalen, 1996). Much has happened since 1982, when the first Centers for Disease Control (CDC) definition of AIDS was published. Better therapies, specifically protease inhibitors, have changed HIV infection to be a chronic condition (Flexner, 1998; Hogg et al., 1998). Given the current success of these therapies, more HIV infected persons should be expected across the life span. It will be necessary to learn how to adjust management for specific populations, such as the elderly. More may be learned about the immune function and aging while treating HIV infection and AIDS in various age groups.

As researchers move from studying diseases cross-sectionally and move toward examining the disease path and as they continue to apply this acquired information to interventions, they will need to better understand period and time effects and the ways they may influence ongoing studies.

Is the Age at Disease Onset Important?

An area often neglected in the study of aging and disease is whether the development of a particular disease in young adults has the same etiology or recommendations for treatment, as among older adults. For example, a disease that is influenced by age of onset is prostate cancer. The risk of prostate cancer increases faster with age than any other form of cancer (National Cancer Institute, 1991). After age 50, both mortality and incidence rates from prostate cancer increase almost exponentially. Ninety-five percent of cases of prostate cancer are diagnosed in men between age 45 and age 89, with a median age at diagnosis of age 72 (Winkelstein & Ernster, 1979). There is widespread clinical impression among physicians treating prostate cancer that the disease is more virulent and rapidly progressive in younger men (Meikle & Smith, 1990) and as a result treatment options vary based on the age of onset. More invasive procedures are used for later stages at earlier age of onset than at comparable stages at later age of onset.

Depression is another example in which age of onset is an important factor in understanding the etiology and subsequent treatment. Depression in the elderly is a serious medical condi-

tion that is underdiagnosed and undertreated (NIH, 1992). A common approach to characterizing depression has been to study its risk factors and presentations according to age of first onset. This method dichotomizes depression into early-onset depression and late-onset depression, generally using the range from age 50 to 60 as a cut-off point (Steffens, Hays, George, Krishnan, & Blazer, 1996). Late-onset depression is more frequently associated with structural brain changes and cerebrovascular disease, and early-onset depression seems to be more influenced by family and genetic factors (Coffey, Figiel, Djang, & Weiner, 1990; Figiel et al., 1991). Clinically, patients with late-onset depression show more loss of interest, less pathological guilt, more psychosis, and more generalized anxiety (Krishnan, Hays, Tupler, George, & Blazer, 1995). There is also evidence that late-onset depressives may be more refractory to antidepressant treatment than patients with early-onset depression (Hickie, Scott, Wilhelm, & Brodaty, 1997) and suffer higher mortality rates (Philbert, Richards, Lynch, & Winokur, 1997).

Age of Disease Onset by Gender Interaction. Not only is age of disease onset an important issue to consider when examining the relation between aging, disease, and behavior, but the consideration of how gender interacts with age of disease onset is just as important. This is particularly the case for coronary heart disease because clinical manifestations of coronary heart disease (CHD) occurs among women on average 10 years later than for men, with the occurrence of myocardial infarction being almost 20 years later (Wenger, 1995).

An example of the importance of considering gender in terms of age of onset interaction is provided in the Framingham study, which is a 30-year follow-up examining a number of specific risk factors for CHD by age group and gender. Results from the study indicate that the majority of significant associations between risk factors and CHD apparent in younger men and women remain significant in older age groups, but not consistently in both sexes. Systolic blood pressure and vital capacity, for example, both demonstrate strong risk associations for CHD in younger men and women and the association increases for older men, but decreases for older women (age 65–94). The effects of diastolic blood pressure are strong risk associations for CHD in younger adults and the effects decrease in older adults, particularly among older women. The risk association for serum cholesterol, cigarettes, relative weight decreases the risk of CHD in older adults, whereas blood glucose increases the risk of CHD (Harris, Cook, Kannel, & Goldman, 1988).

Another gender interaction is diabetes. At all ages, but especially in premenopausal women, diabetes mellitus is a far more powerful risk factor of CHD for women than for men (Barrett-Connor, Cohn, Wingard, & Edelstein, 1991). Adult onset diabetes, in the Nurses' Health Study was associated with a three- to sevenfold increased risk of a cardiovascular event, with this risk amplified by associated risk factors (Manson et al., 1991). The mechanisms imparting risk among diabetic women are uncertain, but may include lipid abnormalities, hypertension, fibrinogen abnormalities, and the upper body obesity syndrome, all of which are common

concomitants of diabetes mellitus. Further, after age 45, women are twice as likely as men to develop diabetes (Wenger, 1995).

Usefulness of a Life Span Perspective

In the psychology of adult development and aging, it is almost a matter of catechism that development needs to be understood in a life span perspective. Is this true in developmental health psychology as well? Two areas of research that have gotten attention in the past 10 years are the tremendous increase in the numbers of centenarians and the role of hormone replacement therapy (HRT) as an antidote to aging for women. Both research areas argue for lifespan development within particular phases, not as a continuous process.

Centenarians and the role of health and aging.

Centenarian status is not easy to predict from earlier in the life cycle. It sounds trite to say that one must live until 80 or 90 to get to be 100; but it is not at all obvious from a group of very old people, who will be the rare person to get all the way to 100. This not only makes them very hard to locate and to study, but also to describe. In studies that require cognitive testing, centenarians are generally seen as expert survivors (Poon, Johnson, & Martin, 1997). When the full population of living centenarians is studied, the variances are extreme in both physical health and cognitive functioning (Forette, 1997).

HRT and the Logic of Estrogen-Related Disease

Until recently, women's health research has mainly focused on reproduction and cancers unique to women. Given that the incidence of chronic diseases in women increase after menopause (a marker of midlife), it is logical to use the terminology pre- and postmenopausal to describe adult women's health. The postmenopausal period extends beyond age 50 and can be divided into three additional phases based on the incidence of chronic diseases. As shown in Table 28.2, women's health can be described in four phases: Phase 1—premenopause; Phase 2—postmenopause (age 50–64) with the development of diseases such as breast cancer; Phase 3—postmenopause (age 65–79) with the development of diseases such as heart disease; and Phase 4—postmenopause (age 80 and up) with the long-term development of diseases such as osteoporosis and Alzheimer's dementia.

The terminology "estrogen-related diseases" can be used to organize and describe diseases associated with estrogen. Although some of these diseases, such as osteoporosis, heart

disease, endometrial cancer, and breast cancer are well established to be associated with estrogen in women (Col et al., 1997; Colditz et al., 1995; Grady et al., 1992; Grady, Gebretsadik, Kerlikowske, Ernster, & Petitti, 1995; Newcomb & Storer, 1995), other diseases like Alzheimer's dementia and colon cancer have been reported to be associated with estrogen but are generally considered more controversial (Kawas et al., 1997; Nanda, Bastian, Hasselblad, & Simal, 1999; Paganini-Hill & Henderson, 1996; Potter, 1995). Estrogen-related diseases can be used as a shorthand to represent the potential HRT may have on the public health of women. A much better understanding of how estrogen is related to these and other diseases can be expected because of anticipated results from the Women's Health Initiative (WHI; Rossouw et al., 1995). Reported to be the largest study of women's health in the world, WHI researchers have compiled a battery of psychological measures in addition to the longitudinal assessment of disease incidence as outcome measures (Matthews et al., 1997).

Conversely, there is not a clear marker of midlife in men. However, there may be a role for discussing phases of diseases in men's health as well. Like estrogens, androgen levels decrease with age and have a broad range of effects on sexual organs and metabolic processes. Androgen deficiency in men older than age 65 leads to a decrease in muscle mass, osteoporosis, decrease in sexual activity, and changes in mood and cognitive function (Swerdlow & Wang, 1993) leading to speculation that there may be at least two phases of chronic diseases related to androgen levels in men. Whether men over age 65 would benefit from androgen replacement therapy is not known. Any potential benefits from this therapy would need to be weighed against the possible adverse effects on the prostate and cardiovascular system.

EMERGENT FINDINGS ON AGING AND HEALTH/DISEASE

The literature has matured in this area as investigators have started to ask important questions about how age interacts with other factors to try to look at the potential mechanisms that relate psychosocial factors to disease outcomes. Kop (1997) provided an interesting theoretical statement. He argued that psychosocial factors, such as hostility and socioeconomic status are important in understanding the risks of heart disease only under age 55. Whether this turns out to be true requires significantly more empirical verification. However, it is consistent with findings reported by House et al. (1992), suggesting from survey data that the number of chronic conditions

TABLE 28.2
Women's Health in Four Phases Based on Peak Incidence of Estrogen-Related Disease

	Phase 1 Premenopausal	Phase 2	Phase 3	Phase 4
Age	< 50	50–64	65–79	80 and older
Diseases	Reproductive concerns Breast cancer	Breast cancer Endometrial cancer	Heart disease Cerebrovascular disease	Osteoporosis Alzheimer's dementia

reported by individuals stratified by SES and age indicated that the average number of conditions for an older person, age 75+, in the upper social class was the same as for a middle-aged person (around age 45) in the lower social class strata.

Jennings et al. (1997) studied middle-aged men (age 46–64) from the Kuopio study to ask empirical questions about the role of age, disease (hypertension), and medication on cardiovascular reactivity and found that there are no simple answers. All three of the factors have effects of reactivity. Thus, the role of age in studies of health psychology needs to be determined paradigm by paradigm, and disease by disease.

Kaplan (1992) reported on data from the Alameda county study to ask if risk factor modification undertaken in later life has an impact on mortality—the answer is a definite yes. When those over age 70 in the Alameda county study were followed for 17 years, current smoking, physical inactivity, consuming more than 45 drinks per month, being more than 10% underweight or 30% overweight, and having a low social network index were associated with mortality, whereas marital status, race, and SES were not.

The Role of Health-Related Quality of Life

Clinicians and policymakers are recognizing the importance of measuring health-related quality of life to inform patient management and policy decisions, but researchers have been a little slower to examine this outcome. An understanding of what determines good health outcomes is highly valued by patients and is necessary in order to maintain function and, therefore, improve health-related quality of life (Stewart et al., 1989). One reason why researchers have chosen not to consider health-related quality of life as an outcome measure is that this concept misleadingly suggests an abstract philosophical approach, whereas most approaches used in the medical contexts do not attempt to include more general notions such as life satisfaction or living standards and instead concentrate on aspects of personal experience that might be directly related to health (Fitzpatrick et al., 1992). Nevertheless, despite the proliferation of instruments and the theoretical literature devoted to the measurement of health-related quality of life, no unified approach has been devised for its measurement, and little agreement has been attained on what it means (Bergner, 1989; Gill & Feinstein, 1994; Spilker, Molinek, Johnson, Simpson, & Tilson, 1990).

Although, health-related quality of life has not been clearly defined, it is important to begin to consider outcomes other than mortality and morbidity, particularly as life expectancy continues to increase and chronic diseases are becoming more prevalent. Health-related quality of life is important for measuring the impact of chronic disease (Patrick & Erickson, 1993). It will be interesting to see if Baby Boomers have the same patterns as earlier generations. Physiologic and clinical measures provide information to clinicians, but they often correlate poorly with functional capacity and well-being (Guyatt, Feeny, & Patrick, 1993). For example, in patients with chronic heart and lung disease, exercise capacity in the laboratory is only weakly related to exercise capacity in daily

life (Guyatt et al., 1985). Another example of health-related quality of life instruments improving assessment is that these instruments have been shown to be better than conventional rheumatologic measures as predictors of long-term outcomes in rheumatoid arthritis in terms of both morbidity and mortality (Leigh & Fries, 1991; Wolfe & Cathey, 1991).

There is evidence of great individual variation in functional status and well-being that is not accounted for by age or disease condition (Sherbourne, Meredith, & Ware, 1992). The field of health psychology needs to consider health-related quality of life because a commonly observed phenomena that two patients with the same clinical criteria often have dramatically different responses. For example, two patients, with the same range of motion and even similar ratings of back pain, may have different role function and emotional well-being. Although some patients may continue to work without major depression, others may quit their jobs and have major depression. Thus, health-related quality of life is often a better index of the impact that health has on functioning than diagnostic or clinical criteria. It, however, does not have the same etiologic significance as a verified diagnosis according to standard criteria.

CONCLUSIONS

Aging has taken on a higher profile given the demographic revolution due to increased longevity (Qualls & Abeles, in press). Interest in aging issues is often due to a concern with the health, disease, and disability of the elderly population (Siegler, in press). As the demographic revolution occurs, it is important to note that the number of adults with diseases will continue to increase (prevalence), but because of improvements in diagnostic tools and treatments, will be able to live longer. However, despite the fact that there will be increasing numbers of people with chronic diseases, the incidence of certain diseases continues to decline. This demographic revolution, however, is spread unevenly around the world (Murray & Lopez, 1996).

The writing of this chapter has led to three conclusions that summarize current thinking on health, behavior, and aging:

1. Gender and age interact in important ways during adult life and aging. This is especially true in terms of diseases such as AIDS, coronary artery disease, and cancers. In the last decade, gender differences in the etiology and treatment of diseases have been illuminated. These differences have provided the impetus to create a women's health medical specialty. Examples have been presented in this chapter of gender differences and similarities across the adult life span.

Several studies have examined the issue of differences in health care use between men and women. Landmark studies identified a gender disparity in the diagnosis and treatment of chest pain and CHD (Tobin et al., 1987). This study has led to further studies demonstrating sex differences in the rates of cardiac catheterization and coronary artery bypass surgery (Ayanian & Epstein, 1991). These studies have

changed the way medical students are taught about evaluating chest pain and have resulted in the reporting of other gender disparities on such topics as renal transplants (Held, Pauly, Bovbjerg, Newmann, & Salvatierra, 1988) and HIV/AIDS (Bastian et al., 1993). The recognition that there is a need to improve the training of clinicians in women's health, has led to the development of a new interdisciplinary specialty in women's health (Wallis, 1992). One consequence of the focus on women's health has been the widening of the definition of health to include social interactions, domestic issues, mental health, and reproductive function (Litt, 1997).

2. Life span development is theory, which at the present time, is not practical given the state of the science. Researchers are able to use data at one phase of the life cycle to inform them about developments in adjacent phases and periods approaching 40 years.
3. Survival as a quantity of life measure is different than quality of life measures. Although there is a growing emphasis to include health-related quality of life as an additional outcome measure other than morbidity and mortality for health-related interventions, and that health-related quality of life is a useful discriminator among different population segments, and is an important predictor of health and health behaviors, the field still needs to alleviate a number of measurement-related issues and difficulties. The continued efforts to identify those content areas and response dimensions that likely will provide the best discrimination among populations and the greatest sensitivity to change are essential to enable health psychologists to guide future health policy and resources.

Informal Caregiving to Older Adults: Health Effects of Providing and Receiving Care

Lynn M. Martire

Richard Schulz

University of Pittsburgh

The provision of ongoing care to an impaired older friend or relative is often a stressful experience that impacts the mental and physical health of the caregiver. Because caregiving sometimes has severe consequences for the health of the caregiver, and because these individuals are an invaluable resource to the rapidly growing population of older adults, research on caregiving has burgeoned over the past two decades. The important role of health psychology in this area of research is demonstrated by the fact that many of the advances made in understanding the consequences of caregiving have resulted from the application of theoretical models and methodologies borrowed from this field.

This chapter first briefly describes the nature and prevalence of informal caregiving to impaired older adults. The second and third sections review the evidence for the effects of caregiving on the individual who provides care and the older adult who receives that care, respectively. The latter focus on the consequences of informal care for the older adult represents a relatively new direction in caregiving research that has important linkages to other literatures in social and health psychology. Because providing care to another person is not always bad for the caregiver, and receiving care is not always good for the care recipient, the second and third sections describe both the negative and positive consequences of providing care and receiving care. Finally, the chapter concludes by highlighting the interactive nature of helping and being helped and the need to address the perspectives of both the caregiver and care recipient in future descriptive and intervention research.

OVERVIEW OF INFORMAL CAREGIVING TO OLDER ADULTS

One unfortunate consequence of growing older is the increased difficulty in carrying out everyday activities such as driving, shopping, and preparing meals (instrumental activities of daily living, IADLs), or even personal care activities such as bathing and dressing (activities of daily living, ADLs). For many older adults, this difficulty stems from illnesses such as arthritis, heart disease, and diabetes, the most chronic health problems of older men and women (Benson & Marano, 1994). Such difficulty with everyday activities, often referred to as functional disability, eventually progresses to the point where the older adult needs assistance from others.

Although the likelihood of becoming disabled increases with age, the functional ability of the older adult population is actually characterized by much variability. Of the 95% of U.S. adults from age 65 to 74 who live in noninstitutionalized settings, only 11% are ADL or IADL impaired. This percentage rises to 27% for those from age 75 to 84, and 60% of those over age 85 experience some amount of disability (Manton, Corder, & Stallard, 1997). Investigations utilizing several different national data sets have shown that between 1982 and 1994, the proportion of the population age 65 and older that was disabled decreased slightly (Crimmins, Saito, & Reynolds, 1997; Manton et al., 1997). Despite the relatively low rates of disability before age 85 and the modest improvements in the physical functioning of older adults in general, the contrasting dramatic growth in the proportion of the population that is older will re-

sult in a predictable increase in the number of disabled older adults in the future. Thus, as the number of older adults continues to grow, so will the number of older adults who have difficulty with everyday activities and who need and receive assistance from informal caregivers.

Some amount of functional disability in the older adult population is due to cognitive impairment. Conservative estimates indicate that 2.1 million adults age 65 or older are cognitively impaired and this number is projected to rise to 3.2 million by the year 2015 (U.S. General Accounting Office, 1998). It is estimated that approximately 2.1 million of these individuals will need active assistance with personal care.

National household surveys show that the prevalence of informal caregiving is indeed high and has grown substantially in the past 10 years. Using a relatively restrictive definition of caregiving (i.e., helping an older adult with at least two IADLs or one ADL), a 1988 survey estimated that there were seven million caregiving households in the United States (American Association of Retired Persons [AARP] and the Travelers Foundation, 1988). Applying this same definition of caregiving, the number of caregivers in 1996 had grown to 21.3 million, or triple the number in 1988 (National Alliance for Caregiving and the AARP, 1997). It is likely that this number includes caregivers to older adults with acute health problems as well as caregivers to older adults with long-standing health conditions. Regardless, this number illustrates that caregiving is a growing national concern.

Given the prevalence of caregiving, a logical question to ask is: Who are the informal caregivers to older impaired adults? Most older adults receive assistance from their spouse. But, when the spouse is no longer alive or is unavailable to provide assistance, adult children usually step in to help. Adult daughters and daughters-in-law are more likely than sons and sons-in-law to provide routine assistance with household chores and personal care over long periods of time (e.g., Horowitz, 1985) and they also spend more hours per week in providing assistance (e.g., Montgomery, 1992). Although caregiving tasks are sometimes divided among several family members or friends, the more typical scenario is that the majority of care is provided by one family member.

DETRIMENTAL AND BENEFICIAL EFFECTS OF PROVIDING CARE TO AN IMPAIRED OLDER ADULT

Theoretical Models of the Effects of Caregiving

Caregiving is an activity that is rich in contextual variability because of the differences among caregivers in their personality attributes and life circumstances as well as among care recipients and their health conditions. The complexity of the context of caregiving mandates the use of theoretical models to guide the design and interpretation of studies in this area. One of the most basic ways to conceptualize the caregiving experience is in terms of a framework for interactions between the individual and the environment (Elliott & Eisdorfer, 1982). The three elements of this model include a

potential activator or stressor, an individual's reaction to the activator, and the consequences of that reaction. In the context of caregiving, potential activators or stressors stem from the care-recipient's functional disability or cognitive impairment, whereas reactions are the transient physiological or psychosocial responses to specific activators (e.g., increased negative affect) and consequences are the prolonged or cumulative effects of these reactions (e.g., risk for infectious disease or clinical depression). This basic model has been elaborated and applied to a number of caregiving contexts, including caregivers of spinal cord injured persons, stroke victims, dementia patients, the chronically mentally ill, cardiac patients, and cancer patients (e.g., Aneshensel, Pearlin, Mullan, Zarit, & Whitlatch, 1995; Haley, Levine, Brown, & Bartolucci, 1987; Pearlin, Mullan, Semple, & Skaff, 1990; Schulz, Tompkins, & Rau, 1988).

One recent iteration of a stress-process model that links environmental demands to health outcomes may be particularly applicable to elder caregiving (Cohen, Kessler, & Gordon, 1995). This model has been modified for this chapter (see Fig. 29.1). As applied to elder caregiving, environmental demands include providing instrumental assistance and emotional support in response to the older adult's disability. If individuals perceive these demands as threatening and also view their coping resources as inadequate, they perceive themselves as under stress (e.g., Lazarus & Folkman, 1984). The appraisal of stress is presumed to trigger physiological, affective, behavioral, or cognitive responses that place the individual at increased risk for mental and physical health problems.

This model also allows for the possibility that individuals may feel they have the capacity to deal with caregiving demands and thus appraise these demands positively (Kramer, 1997; Lawton, Kleban, Moss, Rovine, & Glicksman, 1989). This appraisal may in turn lead to positive physiological, affective, behavioral, or cognitive responses, and decreased risk for mental and physical health problems. It is important to note that this second pathway has less empirical support than the first but has also received less attention.

Although the physiological, affective, behavioral, and cognitive responses to caregiving are important outcomes in their own right, Fig. 29.1 shows that they can also be conceptualized as mediators in this process because they help to explain how caregiving experiences are manifested in altered mental or physical health status. Examples of cognitive mediators of the relation between caregiving experiences and mental health include an enhanced or eroded sense of control or mastery over events occurring in life, and changes in self-esteem. For example, stressors encountered in providing assistance to an impaired older adult may result in symptoms of depression or anxiety by giving caregivers the sense that they cannot master challenges such as those posed by caregiving. Mediators of physical health outcomes are most likely to be physiological or behavioral and include altered immune response, cardiovascular reactivity, and changes in preventive health behaviors. To the extent that caregiving stress compromises immune or cardiac functioning or prohibits self-care activities, the caregiver is placed at increased risk for infectious and chronic illnesses.

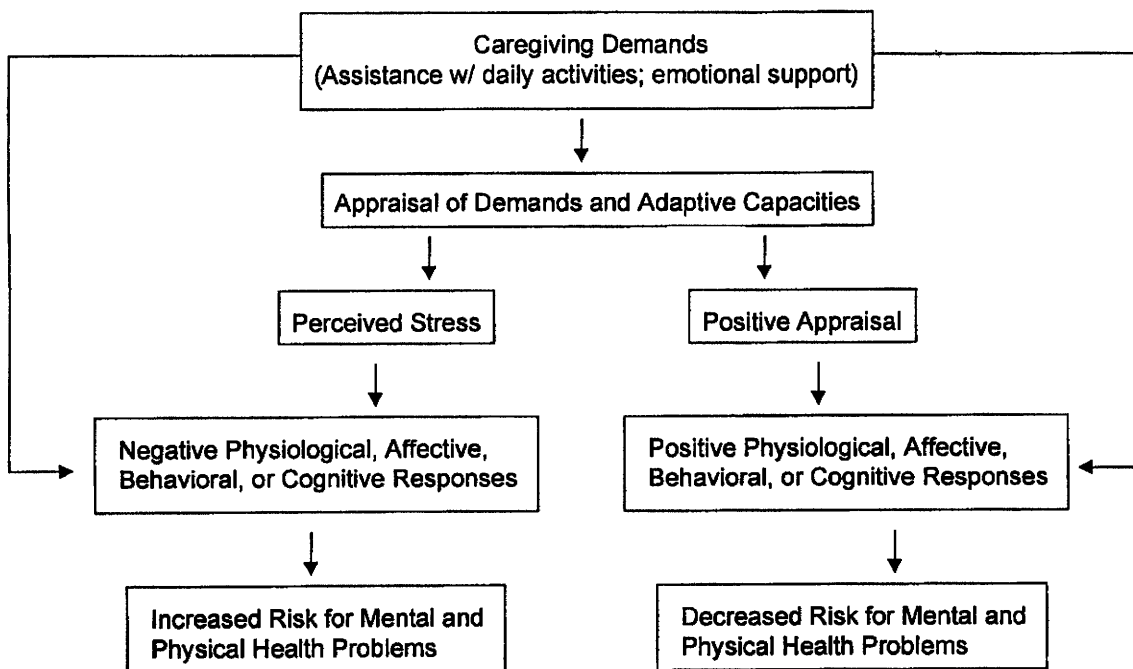

FIG. 29.1. A model of the health effects of elder caregiving. Adapted from Cohen et al. (1995).

Although not represented in this model, other factors have been identified as moderating or conditioning factors in the caregiving stress process. Moderators of caregiving stress indicate the conditions under which the negative impact of stress on health is likely to be strongest and thus aid in the identification of health risk factors. A search for moderators of caregiving stress has been motivated in part by the recognition that there is much variability in the way individuals respond to caregiving. For example, caregivers may experience negative mental and physical health effects that last for an extended period of time (e.g., after cessation of caregiving due to death or placement of the care-recipient) or, alternatively, may adapt to the stress of caregiving even while it persists.

One proposed moderator of caregiving stress is emotional or instrumental support to a caregiver from the spouse, other family members, or friends. It has been suggested that the effects of caregiving stress on mental and physical health are buffered (i.e., lessened) when caregivers receive high levels of support from others. Other proposed moderators or buffers of caregiving stress include the caregiver's use of adaptive coping strategies; a high quality relationship between caregiver and care-recipient; personality characteristics of the caregiver such as greater perceived control or mastery, optimism, and low neuroticism; and greater financial resources of the caregiver. It is important to note that several factors, such as perceived control or mastery and the quality of the relationship between caregiver and care-recipient, may explain how caregiving experiences affect mental and physical health as well as condition the effects of caregiving experiences on

health (i.e., act as both mediators and moderators of caregiving experiences).

Three features of the model depicted in Fig. 29.1 are important to point out. One critical feature is that the appraisal of caregiving demands is not necessary in order for these demands to place the individual at increased or decreased risk for negative health outcomes. This is illustrated by the arrows directly linking demands to negative and positive responses. For example, caregivers may not feel burdened by caregiving but respond negatively by neglecting their own needs such as eating regularly or going to the doctor. The second feature concerns the existence of many possible feedback loops. Although the model as specified is primarily unidirectional, it is recognized that dealing with stressors is a complex, dynamic process in which responses at one stage of the model may subsequently feed back to earlier stages. Finally, the reciprocal nature of the relation between psychological problems and physical disorders (Cohen & Rodriguez, 1995) suggests that the effects of caregiving stress on physical health may be mediated by changes in mental health or vice versa (Hooker, Monahan, Bowman, Frazier, & Shifren, 1998; Wright, Clipp, & George, 1993).

Although this chapter focuses on the provision of care to older adults, it is important to note that much of the model presented in Fig. 29.1 is also applicable to caregivers of chronically ill individuals of other ages, such as a parent providing care to a child with cystic fibrosis or an individual providing care to a middle-aged adult with spinal cord injury. That is, there are many similarities across such caregiving situations

in terms of caregiving stressors and rewards, mental and physical health outcomes, and mediating and moderating factors in these processes (Quittner, Glueckauf, & Jackson, 1990; Schulz & Quittner, 1998). However, each age group and patient population is likely to pose distinct caregiving demands as well as challenges for the caregiving researcher. For example, the factors of care-recipient age and kin relationship between caregiver and care-recipient are often confounded, making it difficult to disentangle the role that each of these factors might play in the type of help provided and in the mental and physical health outcomes experienced.

Detrimental Effects of Caregiving

Several different approaches have been used to examine the negative effects of elder caregiving. One strategy has been to compare caregivers to noncaregivers or to population-based norms. More commonly, investigators have focused solely on caregivers and examined the extent to which the care-recipient's level of disability, or the appraised stressfulness of providing assistance, affects such outcomes as the caregiver's health. Prior research has typically focused on the most stressful caregiving situations. Thus, many studies have focused on the effects of providing care to an older adult with Alzheimer's disease or other dementing illness. Dementia caregiving poses some of the most difficult challenges faced by caregivers because it involves watching the care-recipient become progressively intellectually impaired and requires managing a variety of unpredictable asocial and problematic behaviors.

Several reviews of the literature have been conducted recently in regard to caregiving to older adults who suffer from Alzheimer's disease or another type of dementia (e.g., Schulz, O'Brien, Bookwala, & Fleissner, 1995) and caregiving to older adults who are physically or cognitively disabled (e.g., Schulz, Visintainer, & Williamson, 1990; Wright et al., 1993). The remainder of this section reviews general conclusions from these articles, as well as findings from a select number of studies conducted since these articles were published. The most common sociodemographic and psychosocial correlates of health outcomes are described, and evidence is provided for a few factors that have been shown to function as moderating or mediating factors in the relation between caregiving stress and health. Findings are also reviewed from studies examining the effects of caregiving on individuals' work and leisure activities and their relationships with family members.

Mental Health Outcomes. Depressive symptoms have been the most frequently examined indicator of mental health in caregiving research. Depressive symptomatology has been assessed with self-report instruments such as the Center for Epidemiologic Studies-Depression Scale (CES-D; Radloff, 1977) and the Beck Depression Inventory (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961), as well as through clinical interviews using measures such as the Hamilton Depression Rating Scale (Hamilton, 1967). Other mental health indicators that have been examined include anxiety, life satisfaction, and psychotropic medication use.

Overall, there is overwhelming evidence that caregiving is associated with poorer mental health (e.g., Schulz et al., 1995). Caregivers often have elevated levels of depressive symptomatology and higher prevalence rates for clinical depression and anxiety than population norms or noncaregivers. Not surprisingly, caregivers also use antidepressants and anti-anxiety medications more often than noncaregivers. The majority of the most recently published studies also provide evidence for poorer mental health among caregivers than noncaregivers (e.g., Haley et al., 1995; Jutras & Lavoie, 1995; Rose-Rego, Strauss, & Smyth, 1998).

It is important to note that these mental health consequences of caregiving have likely been overestimated to some extent due to the sampling strategies used in prior research. Caregivers have been most commonly recruited from support groups and social service agencies, resulting in samples that are likely to be more distressed than the general population of caregivers. Only a few studies have used population-based samples (e.g., Grafstrom, Fratiglioni, Sandman, & Winblad, 1992; Moritz, Kasl, & Ostfeld, 1992; Schulz et al., 1997). Based on their finding in a population-based sample that only slightly more than half of spousal caregivers reported experiencing mental or physical strain as a result of caregiving, Schulz and colleagues (1997) concluded that studies utilizing samples of distressed or strained caregivers may have overestimated the negative mental health effects of caregiving.

Several recent studies and reviews have examined differences in the mental and physical health effects of caregiving according to gender and ethnicity. Few gender or ethnicity differences have been found in regard to physical health. However, studies have generally shown that Black caregivers report less burden and depressive symptomatology and greater life satisfaction than White caregivers (e.g., Haley et al., 1995; Hinrichsen & Ramirez, 1992; Lawton, Rajagopal, Brody, & Kleban, 1992; Miller, Campbell, Farran, Kaufman, & Davis, 1995) and these differences in adjustment do not appear to be explained by greater severity of objective caregiving stressors or sociodemographic variables (Haley et al., 1995). In regard to gender differences in the mental health effects of caregiving, most studies have found that greater caregiving burden and emotional distress are reported by females than males (see review by Miller & Cafasso, 1992), even when there are no differences in functional impairment of the care-recipient or caregiver involvement in care. However, these findings raise the issue of whether these differences reflect the fact that women in general report higher levels of depressive symptomatology than do men. One recent study addressed this issue by comparing the well-being of husband and wife caregivers as well as noncaregiving husbands and wives. This study demonstrated that caregiving wives were more depressed than caregiving husbands but that there were no differences between noncaregiving husbands and wives, suggesting there is something specific to caregiving that leads to greater depression in women than in men (Rose-Rego et al., 1998).

Other correlates of poorer mental health include greater caregiving stress and poorer self-rated physical health of the caregiver. Problem behaviors of the older adult are often the most frequently endorsed stressor of dementia caregiving and

there is evidence that this factor is more strongly related to caregivers' depression than provision of assistance with daily tasks (Schulz et al., 1995). Also, lower socioeconomic status, being a spouse, and sharing a residence with the older adult are caregiver characteristics consistently related to greater depressive symptoms (Meshefedjian, McCusker, Bellavance, & Baumgarten, 1998; Schulz et al., 1995; Wright et al., 1993). Caregivers who have higher levels of neuroticism and lower levels of mastery not only tend to have more depressive symptoms but also report that their care-recipient has greater difficulty with IADLs (Bookwala & Schulz, 1998).

Some attention has been given to identifying factors that mediate the relation between caregiving stress and mental health outcomes. There is evidence that the effects of stress on mental health may be explained by the caregiver's cognitive responses. That is, an eroded sense of mastery and self-esteem as a caregiver has been shown to explain the process by which caregiving stress results in more negative affect (Franks & Stephens, 1992). In addition, there is evidence from two recent studies that the quality of the relation between the caregiver and care-recipient can operate as an explanatory variable in the stress and depression relation. The first study showed that the presence of problem behaviors in the patient was associated with greater depression in the caregiver because such behaviors were detrimental to the quality of the relation between the patient and caregiver (Lawrence, Tennstedt, & Assmann, 1998). A second study of adult child caregivers demonstrated that the relation between the parent's cognitive impairment and the caregivers' depressive symptoms was explained by increased conflict between the parent and adult child (Townsend & Franks, 1995).

The factor that has most frequently been examined as a potential moderator of caregiving stress and mental health is social support to the caregiver; however, there are conflicting findings in regard to the benefits of such support. Emotional support from an adult daughter caregiver's social network has been shown to buffer the negative effects of behavior problems and assistance with daily activities on depressive symptoms (Li, Seltzer, & Greenberg, 1997), and instrumental support in the form of paid assistance to the care-recipient with personal care and household tasks has been shown to buffer the effects of problem behaviors on caregivers' depressive symptoms (Bass, Noelker, & Rechlin, 1996). However, neither emotional nor instrumental support buffered the negative effects of caregiving stress on emotional health in other investigations (e.g., Aneshensel et al., 1995; Franks & Stephens, 1996). The quality of experiences in noncaregiving domains has recently been shown to be a conditioning factor in the caregiving stress process. For adult daughter caregivers who are married, have children living at home, and are employed, high levels of stress in their experiences as mothers exacerbated the negative effects of caregiving stress on life satisfaction and high levels of rewards in the employee role buffered the negative effects of caregiving stress on depression (Stephens & Townsend, 1997). In addition, spousal and adult child caregivers who had a close relationship with their care-recipient prior to onset of Alzheimer's disease were shown to feel less burdened by caregiving than those whose relationship was not close (Williamson & Schulz, 1990). One

recent study revealed that the caregiver's psychological resources are also beneficial in the context of caregiving stress, in that high levels of mastery in caregiving buffered the negative effects of the care-recipient's problem behaviors and functional disability on caregiver's depression (Miller et al., 1995).

Physical Health Outcomes. Although traditionally given less attention than mental health outcomes, research on the physical health effects of caregiving has been more common in the past several years. Evidence continues to accumulate that caregivers are at risk for physical health problems. Schulz and colleagues concluded that the most consistent evidence for the negative effects of caregiving on physical health has been found for self-reported global health, in that caregivers perceive their health to be worse than noncaregivers. At the time of that review, there was mixed evidence for differences in health care utilization between caregivers and noncaregivers and little evidence for differences in other health behaviors such as following a proper diet and exercising (Schulz et al., 1995). However, a recent study of a large population-based sample of mostly nondementia caregivers showed that individuals whose spouse was ADL impaired did not find time for exercise, had inadequate rest, did not take enough time to rest when sick, and forgot to take their medications, more often than noncaregivers (Burton, Newsom, Schulz, Hirsch, & German, 1997). These self-reports of global health, physical symptoms, and health behaviors should be viewed cautiously because emotional distress exerts a significant influence on such reports.

Research on the physical health effects of caregiving has advanced because of the recent focus on objective physiological indicators of health such as immune functioning (e.g., natural killer cell activity) and metabolic functioning (e.g., high density and low density lipoprotein, HDL and LDL, cholesterol and insulin levels). At the time of the review by Schulz and colleagues (1995), only a few studies had examined caregivers' immune functioning. Studies published since that review support the hypothesis that caregivers have compromised immune functioning (e.g., Castle, Wilkins, Heck, Tanzy, & Fahey, 1995; Esterling, Kiecolt-Glaser, Bodnar, & Glaser, 1994; Kiecolt-Glaser, Glaser, Gravenstein, Malarkey, & Sheridan, 1996; Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995). For example, caregivers of relatives with Alzheimer's disease have an impaired immune response to influenza virus vaccination relative to matched controls (Kiecolt-Glaser et al., 1996) and also show impaired wound healing relative to controls (Kiecolt-Glaser et al., 1995). In regard to metabolic functioning, one recent study of spousal caregivers revealed that older male caregivers had a significantly larger body mass index and were more obese than controls and female caregivers showed a greater increase in weight than controls over a 15- to 18-month period of time, putting them at risk for higher lipid levels, high blood pressure, cardiovascular disease, and arthritis in weight-bearing joints such as the hips and knees (Vitaliano, Russo, Scanlan, & Greeno, 1996). Nondiabetic spousal caregivers to dementia patients also have significantly higher insulin levels than

gender-matched spouses of nondemented older adults (Vitaliano, Scanlan, Krenz, Schwartz, & Marcovina, 1996).

The effects of caregiving on physical health are not as consistent or as strong as those observed for mental health (Schulz et al., 1995; Vitaliano, Schulz, Kiecolt-Glaser, & Grant, 1997). One explanation for this discrepancy is that physical health effects may take longer to emerge and thus may not be as salient as mental health effects until the caregiving role has been occupied for a long duration or even until after this role has been relinquished. However, once the effects on physical health emerge, they may be long lasting, as demonstrated by studies showing altered immune response several years after cessation of caregiving due to bereavement (e.g., Esterling et al., 1994).

Common correlates of poorer physical health in dementia caregivers are more depressive symptoms, less social support, and greater cognitive impairment of the care-recipient (Schulz et al., 1995). In addition, caregiver characteristics such as lower socioeconomic status, being older, and sharing a residence with the care-recipient are fairly consistently related to poorer physical health for caregivers (Wright et al., 1993). In terms of mediating factors in the stress and physical health relation, indicators such as immune response and health behaviors may explain how caregiving stress results in illness conditions and symptoms; however, little attention has been paid to systematically testing such models in the context of caregiving.

There is recent evidence that perceived control conditions the effects of caregiving on preventive health behaviors. Spousal caregivers with a strong sense of control over events in life report getting more rest than caregivers with a weak sense of control (Burton et al., 1997). Instrumental support in the form of assistance with caregiving tasks has been shown to buffer the effects of caregiving stress on perceptions of global physical health and deterioration in health as a result of caregiving (Bass et al., 1996; Franks & Stephens, 1996). High levels of emotional and instrumental support also are associated with better immune responses for dementia caregivers, suggesting that support may buffer the negative effects of caregiving stress on immune response outcomes (Esterling, Kiecolt-Glaser, & Glaser, 1996).

Although mental and physical health are the main outcomes examined in research on the effects of caregiving, there are a variety of other consequences of caregiving. For most caregivers, this activity reflects just one aspect of their lives in that they have many other interests and demands outside of caregiving. Therefore, researchers have examined how caregiving affects other family and nonfamily domains of an individual's life. One particular line of research in this area has focused on adult daughter caregivers, prompted by the recognition that much informal care is provided by adult daughters and daughters-in-law and that these middle-aged women may be particularly burdened by caregiving because of competing demands for their time and energy. Due to demographic trends of the past few decades in delayed child-bearing and increased workforce participation of women, many midlife women in the United States have children living at home and are also employed outside the home. Reflecting

these trends, the results of a recent national survey showed that the typical caregiver is a married woman in her mid-forties who works full time, and 41% of caregivers have one or more children under age 18 living in their household (National Alliance for Caregiving and the AARP, 1997). In general, research findings indicate that other social roles occupied by caregivers such as spouse, parent, and employee have the potential to add to the caregiver's burden, but they also may provide crucial financial and psychosocial resources for sustaining the provision of care.

The following sections review findings from studies that have examined the effects of caregiving on work and leisure activities and relationships with family members. Such outcomes may be most usefully conceptualized as mediating factors in that they may explain how the burden or stress of caregiving is ultimately manifested in poorer mental and physical health for the caregiver. Much of the work reviewed here focuses on women caregivers who have multiple social roles.

Work and Leisure Activities. Results of a national survey show that 64% of caregivers are employed at least part time, and this percentage rises to 76% for caregivers between age 35 and 49 (National Alliance for Caregiving and the AARP, 1997). Early on, researchers interested in the consequences of combining caregiving and employment focused solely on occupancy of the employment role as a correlate of caregiver health outcomes. In general, these studies showed that employed caregivers experienced less caregiver strain and better mental health than those who were not employed (e.g., Giele, Mutschler, & Orodnenker, 1987; Miller, 1989; Skaff & Pearlin, 1992), and this finding did not seem to be due to less provision of care by employed than nonemployed caregivers. This finding is probably explained by advantages that paid employment seems to have for all adults, such as greater financial resources, respite from family demands (including elder caregiving), and the greater social contact and social support that is gained in the workplace.

More recent research on employed caregivers has moved beyond role occupancy to focus on experiences in the workplace and in caregiving that may be important determinants of caregivers' health (e.g., Martire, Stephens, & Atienza, 1997). Several studies have shown that experiences in caregiving can negatively spill over into work (e.g., Barling, MacEwen, Kelloway, & Higginbottom, 1994; Neal, Chapman, Ingersoll-Dayton, & Emlen, 1993; Scharlach, 1994; Stephens, Franks, & Atienza, 1997). For example, employed caregivers report that due to caregiving responsibilities they are often exhausted at work or unable to concentrate, disrupted at work, or miss work. There is evidence that such negative spillover from caregiving to work is a mechanism that explains how the stress of caregiving becomes manifested in greater depressive symptomatology for the caregiver (Stephens et al., 1997).

Individuals who provide care to an impaired elder also experience changes in their leisure and social activities. Caregivers have been shown to be more restricted than noncaregivers in their ability to socialize with friends, participate in group or organized activities, exercise or participate in

sports, and go out for dinner or a show (e.g., George & Gwyther, 1986; Haley, Levine, Brown, Berry, & Hughes, 1987), and studies have demonstrated that this restriction can be a direct result of the stress of caregiving (e.g., Kinney, Stephens, Franks, & Norris, 1995; Miller & Montgomery, 1990; Stull, Kosloski, & Kercher, 1994). Less social activity often means that caregivers have less opportunity to interact with, and obtain support and advice from, others. For some caregivers, such limitations in access to available social resources may explain how caregiving is harmful to mental health. A study of spousal caregivers of cancer patients found that the effect of caregiving stress on depressive symptomatology was explained by restriction in the caregiver's daily and social activities (e.g., going shopping and visiting friends; Williamson, Shaffer, & Schulz, 1998).

Relationships With Family Members. Providing ongoing care to an impaired elder puts a strain on relationships with others. The most obvious relationship affected by caregiving is the one between the caregiver and older adult. However, most of the research in this particular area has focused on the effects of caregiving on a marriage (e.g., Stephens & Franks, 1995; Suito & Pillemer, 1992). Husbands are a crucial source of support to adult daughter caregivers, and thus the potential negative effects of caregiving on the caregiver's marriage are important to examine. In one study of married adult daughter caregivers, three quarters reported that caregiving prevented them from spending time with their husband and two thirds reported that worrying about caregiving responsibilities had interfered with their relationship with their husband (Stephens & Franks, 1995). Such negative spillover of caregiving into marriage was associated with greater depressive symptomatology for the caregiver.

Providing care to an older relative also has the potential to create problems with other family members such as siblings. Conflict with family members often centers around the caregiver's perceptions that he or she is not receiving enough assistance from siblings or that siblings do not appreciate the caregiver's efforts, and such conflict is related to greater depressive symptoms for the caregiver (e.g., Semple, 1992). Such family conflict may be especially likely for adult child caregivers and their siblings, who frequently disagree about how the parent should be taken care of and who will help with particular tasks. In fact, married caregiving daughters report that siblings are the greatest source of interpersonal stress in regard to caregiving (Suito & Pillemer, 1996).

Beneficial Effects of Caregiving

The caregiving health effects model presented at the beginning of this section specified that the demands posed by caregiving may not always be appraised as stressful, allowing for the possibility of positive physiological, affective, behavioral, or cognitive responses to caregiving demands (Fig. 29.1). Unfortunately, the positive aspects of caregiving have received far less attention than the negative. Reflecting the novelty of this area of research, the majority of studies on the

positive aspects of caregiving have been published in the past 10 years (Kramer, 1997). As noted by others, lack of attention to the positive aspects of caregiving may seriously skew perceptions of the caregiving experience and limit the ability to enhance theories of caregiver health (e.g., Kinney & Stephens, 1989; Kramer, 1997).

Caregivers often report positive experiences as a result of providing ongoing care to an older adult. When asked to describe the experience of caregiving, the majority of caregivers (57%) use positive words such as "rewarding," "happy," and "enjoyable" (National Alliance for Caregiving and the AARP, 1997). The specific rewards from caregiving that individuals refer to include the comfort of knowing that relatives are well cared-for and an increased sense of mastery from meeting the challenges of caregiving (e.g., Lawton et al., 1989; Miller, 1989; Stephens, Franks, & Townsend, 1994). One recent study provides indirect evidence that rewarding aspects of caregiving may benefit caregivers' mental health. A study of spousal caregivers of older adults who were in the early stages of physical disability showed that increased task assistance over time was related to decreased anxiety and depression for the caregiver, suggesting that being able to help a spouse may have beneficial effects for the caregiver when the recipient has low to moderate levels of disability (Beach, Schulz, & Jackson, 1997).

Providing care to a parent may also be an important part of an individual's identity. One recent study found that the majority of adult daughters and daughters-in-law reported that being a caregiver was highly central to how they saw themselves (Martire, Stephens, & Townsend, 1997). Through caregiving, spouses and adult children can also derive added meaning from life by perceiving caregiving as a positive experience in which a new perspective is gained and they become more resilient people (Noonan & Tennstedt, 1997).

Research on the positive aspects of caregiving has been advanced conceptually by the finding that positive or rewarding experiences of caregiving do not merely represent a lack of stressful or problematic experiences (e.g., Lawton et al., 1989; Riedel, Fredman, & Langenberg, 1998). That is, stressful and rewarding aspects of caregiving do not seem to represent opposite ends of a single continuum but rather reflect two distinct dimensions. In fact, caregiving rewards have been shown to predict mental health outcomes even after controlling for the effects of caregiving stress (Noonan & Tennstedt, 1997; Stephens et al., 1994). Despite the fact that positive and negative experiences are two distinct dimensions of caregiving, the effects of caregiving rewards or satisfaction on health do not seem to be as strong as the negative aspects of caregiving. In some instances, caregiving uplifts have not been shown to be related to better well-being (e.g., Kinney & Stephens, 1989; Sheehan & Nuttall, 1988), and in other studies such positive experiences have only been related to positive indicators of mental health such as life satisfaction (Martire et al., 1997; Stephens et al., 1994). These findings have prompted others to conclude that the positive aspects of caregiving are very important for many caregivers but do not result in significant containment of stress over time (e.g., Aneshensel et al., 1995). Contradicting this point, a recent

study showed that greater caregiving rewards such as feeling needed and seeing that the care-recipient received high quality care buffered the effects of caregiving difficulties on perceived burden (Riedel et al., 1998).

To summarize this section on the health effects of caregiving, fairly strong negative effects of caregiving on mental health have been demonstrated in past research, whereas evidence for negative physical health effects of caregiving is sparse but accruing. Such research is critical because caregivers who are burdened are more likely to relinquish caregiving by placing their relative in a long-term care facility or passing on responsibility to another caregiver (e.g., Montgomery & Kosloski, 1994). Much of the responsibility for informal elder care falls to middle-aged family members who have other family and work responsibilities. Although much has been made of the burden that such individuals may feel, it is important to keep in mind that additional roles may also serve as psychosocial and financial resources that help to relieve the stress of caregiving and ensure that the caregiver can continue to provide care. Although frequently burdensome, providing care to an older adult can also be a fulfilling experience and the positive dimensions of caregiving may even offset the problematic aspects.

The health effects of caregiving may be less pronounced in studies that do not focus on highly distressed caregivers such as those individuals providing care to an older adult with Alzheimer's disease or another type of dementia. In addition, many of the effects of caregiving, particularly the physical health effects, may take years to emerge. Although studies on the effects of caregiving on health over time are becoming more common (e.g., Goode, Haley, Roth, & Ford, 1998; Schulz & Williamson, 1991; Vitaliano, Russo, et al., 1996), prospective studies are still very rare. Researchers need to study caregivers over longer periods of time and, more importantly, continue to follow them through important caregiving transitions such as institutionalization and death of the care-recipient (e.g., Skaff, Pearlin, & Mullan, 1996). It may be that individuals who have predisposing mental or physical health problems are at highest risk for experiencing health problems during caregiving (Redinbaugh, MacCallum, & Kiecolt-Glaser, 1995). This possibility makes it important to assess the caregiver's mental and physical health status prior to taking on the caregiving role.

BENEFICIAL AND DETRIMENTAL EFFECTS OF RECEIVING INFORMAL CARE

The extent to which an individual's health is affected by caregiving has direct implications for the amount and quality of assistance provided to the older adult. Thus, caregiving research has addressed the welfare of the care-recipient, albeit indirectly. However, it is critical to assess the more proximal effects of receiving care. Possibly one of the most important reasons for this focus is that the older adult's responses to assistance in turn affect the amount and quality of future care from friends and family members. To date, the effects of receiving care have been paid far less attention than the effects of providing care to an ill older adult and thus there is much to

learn about the extent to which care is or is not well-received, and why. Recognizing this, researchers have broadened their investigations to focus on the effects of receiving as well as providing care (e.g., Newsom & Schulz, 1998).

The greater focus on the caregiver in past research is in part due to the fact that many studies have focused on caregiving to older adults who suffer from cognitive impairment due to Alzheimer's disease, stroke, or other dementing illnesses. Problems associated with assessing the perspective of cognitively impaired elders include difficulty in recruiting these individuals and obtaining valid and reliable information from them in regard to the care they receive and their level of distress (Cotrell & Schulz, 1993; Spencer, Tompkins, & Schulz, 1997). However, it is important to keep in mind that the majority of older adults who receive informal care are cognitively intact, and even individuals with mild to moderate cognitive impairment are often capable of articulating their feelings and concerns. Furthermore, for those care-recipients who are severely cognitively impaired, alternative research methods such as proxy reports can be used to obtain a picture of the care-recipient's views (e.g., Logsdon & Teri, 1995).

Theoretical Models of the Effects of Care Receiving

Little attention has been paid to developing or testing theoretical methods that specify how receipt of assistance with daily activities may lead to an impaired older adult's increased or decreased risk for additional mental and physical health problems and the mechanisms that explain how this process occurs. Is there variability in the extent to which assistance from others is viewed as helpful by the older adult? Does receiving assistance have significant effects on an older adult's mental and physical health beyond the effects of their present disability? Recent evidence suggests that the answers to these questions may be affirmative. In one study, 60% of stroke patients reported at least one unhelpful action by the spouse when an attempt was made to help with daily activities (Clark & Stephens, 1996). Another study found that 40% of older care-recipients reported emotional strain in response to help they received from their spouse and this strain predicted greater depressive symptomatology for the recipient 1 year later (Newsom & Schulz, 1998).

The concept of person-environment fit may be useful in understanding the health effects of receiving care. According to this framework, psychological adjustment is a function of the degree of fit between aspects of the environment and the individual's personal characteristics (e.g., E. Kahana, B. Kahana, & Riley, 1989). Although the concept of person-environment fit has typically been used in an attempt to understand how older adults adjust to different physical environments (e.g., Parmelee & Lawton, 1990), it may also be helpful in terms of thinking about how such individuals adjust to their social environment. The degree of fit between assistance provided and the older adult's needs or preferences for assistance may determine whether such assistance is perceived as helpful or unhelpful.

The caregiving health model presented earlier has been adapted as a first step toward developing a model of the health

effects of care receiving (see Fig. 29.2). In this model, receipt of assistance with daily activities (i.e., instrumental support) and illness-specific emotional support are conceptualized as experiences that are appraised by the care-recipient as either helpful or unhelpful, depending on whether or not such support fits the recipient's needs or preferences. Similar to the caregiving model, the appraisal of assistance as unhelpful is presumed to result in negative physiological, affective, behavioral, or cognitive responses that place the older adult at increased risk for exacerbated or additional mental and physical health problems. Alternatively, assistance from others may be perceived as helpful and thus lead to positive responses associated with a decreased risk for exacerbated or additional mental and physical health problems.

A likely indicator of mental health to be affected by the quality of instrumental and emotional support from others is the recipient's experience of depressive symptoms (e.g., Cohen & Wills, 1985). It is well known that chronic illnesses, particularly those involving pain, put older adults at risk for depression (e.g., Williamson & Schulz, 1992). Responses to receiving support are likely to put a patient at a further increased or decreased risk for depression. One aspect of physical health that is likely to reflect the effects of receiving support is the older adult's level of functional disability. That is, the extent to which assistance is helpful or unhelpful is likely to affect older adults' future ability to carry out daily activities on their own or with minimal help from others (Baltes & Wahl, 1992).

Cognitive responses have been proposed as likely mediators of the relation between receipt of care and mental health problems such as depressive symptomatology. It has been

suggested that emotional support and instrumental assistance contain self-relevant messages for recipients that may apply generally to their life or to coping with illness. Specifically, theorists have proposed that self-evaluations of domain-specific efficacy may explain the positive or negative effects of support to older adults on their mental health (Antonucci & Jackson, 1987; Bandura, 1997). Support from others also may cause recipients to feel more or less autonomous (i.e., self-governing) or competent (Ryan & Solky, 1996), which may in turn affect their mental health. Responses that may mediate the relation between receipt of care and disability are most likely to be cognitive or behavioral in nature and include following a proper diet, using assistive devices, and obtaining medical care. It seems particularly plausible that assistance received from informal caregivers has an impact on the extent to which older adults take care of their own health. As noted by others, family members often serve as a source of motivation and advice for the older adult who is attempting to develop or maintain self-care behaviors and are also very involved with interactions between the older adult and the medical care system (e.g., Prohaska, 1998).

Findings from the field of social psychology offer specific hypotheses in regard to moderating factors or conditions under which support does or does not fit an older adult's needs or preferences or has positive or negative effects on mental and physical health. Much of this evidence regarding recipients' reactions to help has been obtained in experimental studies with individuals who were not acquainted with each other, rather than more naturally occurring helping situations between close friends or family members. Researchers have demonstrated that a recipient's reactions to help received

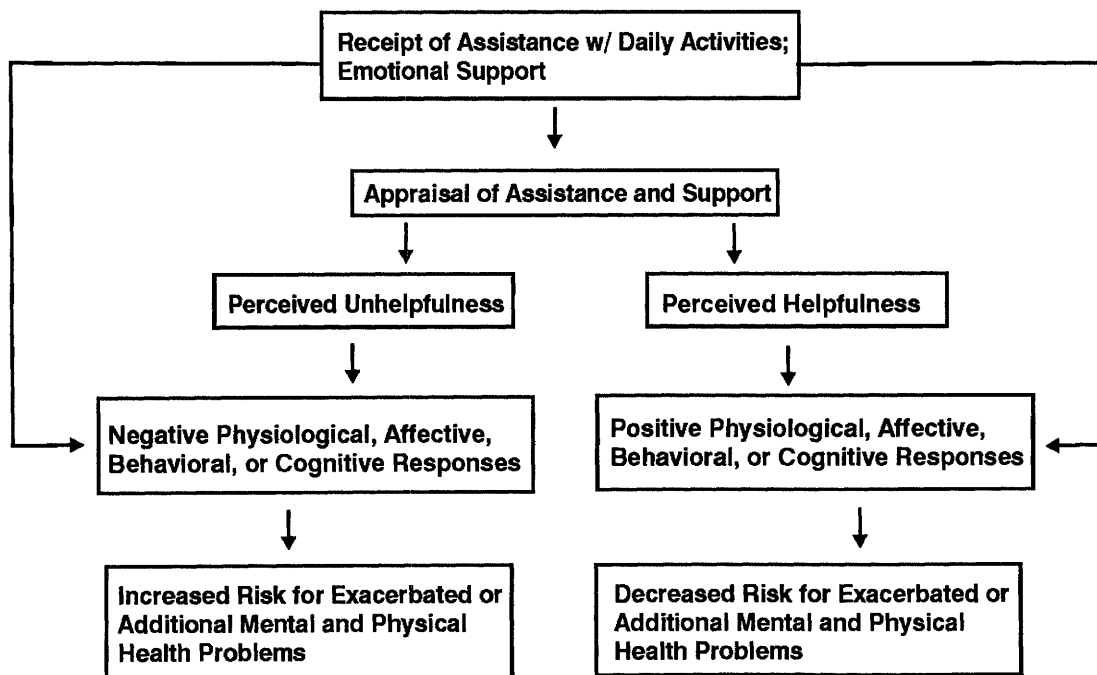

FIG. 29.2. A model of the health effects of elder care-receiving. Adapted from Cohen et al. (1995).

from others are often determined by multiple factors that fall under three general categories: characteristics of the support provider (i.e., the caregiver), characteristics of the support recipient (i.e., the care-recipient), and characteristics of the provided support (i.e., emotional support and assistance with activities of daily living; see reviews by Fisher, Nadler, & Whitcher-Alagna, 1982; Nadler & Fisher, 1986).

Applying this general framework to the impaired older care-recipient, one characteristic of caregivers that may be important in determining the recipient's reactions to support is their relationship to the older adult. For example, it may be more difficult for some older adults to accept support from an adult child than from a spouse. Characteristics of the recipient that may be important in determining the perceived helpfulness of emotional support and instrumental assistance include level of perceived control or desire for control, level of self-esteem, and the importance of carrying out tasks independently (e.g., Daubman, 1995; Nadler & Fisher, 1986). Characteristics of provided support that have received the most empirical attention as determinants of recipients' reactions to support include the type of support, the amount of support, and the timing of support (e.g., DePaulo, Brittingham, & Kaiser, 1983). To this list of potential moderating factors, a fourth must be added—the quality of the relationship between the caregiver and care-recipient. We believe that relationship quality is a factor that is likely to be important in determining the recipient's responses to assistance.

There are three specific points to be made about the model presented in Fig. 29.2. First, as is true for the literature on the health effects of caregiving, some research on recipients' reactions to assistance does not assume that task assistance and emotional support have to be appraised as helpful or unhelpful by the recipient in order for health effects to occur (see arrows directly linking task assistance and emotional support to negative and positive responses). Some studies examine the relation between the amount of received assistance and the care-recipient's well-being without assessing the perceived helpfulness of such assistance (e.g., Silverstein, Chen, & Heller, 1996). A second important feature of Fig. 29.2 relates to the possibility that receipt of care might be associated with positive mental health outcomes but negative physical health outcomes, or vice versa. For example, studies focusing on chronic pain patients and their families have demonstrated that assistance from family members is associated with more positive affect for the patient but also increased disability and pain behaviors (Kerns & Weiss, 1994). Finally, as was true for the caregiving health effects model presented earlier, much of the model presented in Fig. 29.2 is applicable to not only different patient populations but also to young and middle-aged care-recipients.

Beneficial Effects of Care Receiving

As noted at the beginning of this chapter, the benefits to older adults of receiving assistance from family members are many and include less assistance from paid helpers and delayed institutionalization. Simply put, assistance from family members enables older adults to live independently

for a longer period of time. Most of the advantages of receiving care from family and friends are assumed and not examined empirically.

There are additional potential advantages to receiving informal care beyond reduced health care costs and delayed institutionalization. One benefit is the opportunity to become closer to family members. For older adults who are primarily receiving care from an adult child, this contact provides the opportunity for both individuals to gain a new appreciation of each other and the time they have left together (Walker, Martin, & Jones, 1992). The same principle is true for older adults who are primarily receiving care from a spouse. Moreover, when older husbands and wives both suffer from chronic illness, increased closeness may result from mutual assistance.

Several studies provide empirical evidence for the benefits of receiving care. Having instrumental support available if needed has been shown to prevent a decline in older adults' health-related feelings of self-efficacy (i.e., perceptions that staying healthy depends on factors under one's own control) over a 3-year period (McAvay, Seeman, & Rodin, 1996). Such feelings of efficacy are critical in terms of maintaining health and functional ability (Bandura, 1997). In addition, older adults receiving assistance from others with daily activities have been shown to be more likely to engage in self-care activities such as using assistive devices or special clothing and avoiding harmful activities (Norburn et al., 1995). The manner in which support is offered can also be beneficial to the care-recipient. One research program has looked at the extent to which family members provide autonomy support, defined as being able to take recipients' perspectives and encourage them to be more self-directed (Ryan & Solky, 1996). This approach has recently been applied to nursing home residents in a study showing that assistance from family members and nursing home staff that supported a sense of autonomy was related to greater life satisfaction for the care-recipient (Kasser & Ryan, in press).

Detrimental Effects of Care Receiving

An accumulating literature has documented the negative consequences that occur when an ill older adult's family members are critical or hostile in their actions or communications (e.g., Rook, 1984; Stephens, Kinney, Norris, & Ritchie, 1987) or even abusive (e.g., Pillemer & Suito, 1992). However, actions or communications that are intended by the provider to be supportive may also backfire and have negative rather than positive effects on the recipient (Burg & Seeman, 1994). For the purposes of both description and intervention, it may be just as important to determine why well-intended actions are unhelpful as it is to examine correlates of hostile or critical actions by family members toward their ill older relatives.

For individuals dealing with a chronic illness, seemingly supportive efforts of significant others such as offering advice, avoiding discussion of the illness, and becoming highly involved in the patient's life, are often reported as unhelpful (Dunkel-Schetter, Blasband, Feinstein, & Herbert, 1992). In addition, patients agree that family and friends sometimes make suggestions that are unhelpful or upsetting, or find it

hard to understand the way the patient feels (Revenson, Schiaffino, Majerovitz, & Gibofsky, 1991). Consistent with these findings, a recent study of older stroke patients and their spouses showed that the most frequently mentioned unhelpful actions were being critical of the patient's attempts at recovery, underestimating or overestimating the patient's abilities, and not providing assistance correctly (Clark & Stephens, 1996).

Mental Health Outcomes. As in the literature on the mental health effects of caregiving, studies on the mental health effects of receiving care have primarily focused on depressive symptoms as the outcome of greatest interest. Clark and Stephens (1996) examined the effects of both helpful actions (e.g., general assistance with activities such as cooking, housework, and transportation, and showing love or affection) and unhelpful actions and found that only the latter were predictive of the patient's greater depressive symptomatology, controlling for the patient's level of functional disability. Another study of older women with osteoarthritis and their husbands examined negative reactions to receiving instrumental or emotional support from the husband and how these reactions related to depressive symptoms and life satisfaction after controlling for the patient's level of functional disability and amount of instrumental or emotional support received (Martire et al., 1998). Patients who felt they had little control over the assistance they received from their husband or who felt less competent in carrying out tasks on their own as a result of this assistance experienced more depressive symptoms and less life satisfaction. Similarly, patients who felt more rejected (undermined or put down) as a result of their husband's attempts to be emotionally supportive experienced more depressive symptoms and less life satisfaction.

Much has been written about the potential problems that may emerge when a family member becomes overly involved in the welfare of a chronically ill patient (e.g., Coyne, Wortman, & Lehman, 1988). Several studies that focus on older adults (who may or may not have been disabled) have provided empirical evidence for these detrimental effects of overinvolvement. Older adults receiving high levels of emotional support have been shown to have a less internal locus of control at a later point in time, suggesting that too much support can erode feelings of control (Krause, 1987). In addition, emotional and instrumental support received from adult children was shown to be associated with less depressive symptomatology up to a threshold point, beyond which more support was associated with more depressive symptoms (Silverstein et al., 1996). This nonlinear effect of support on well-being was particularly pronounced for older adults who were unmarried and had low expectations for support from their children, suggesting that too much assistance is particularly problematic for older adults who may believe that adults should provide support to their children and not vice versa. In another study, receiving ADL assistance from adult children was positively related to older adults' depressive symptoms, even after controlling for health-related factors (Lee, Netzer, & Coward, 1995). In this study, older adults who gave more support to their children than they received were the least depressed.

Findings from a separate program of research suggest that the perception that one is being overwhelmed may be more important than the actual amount of overhelping (Thompson & Sobolew-Shubin, 1993; Thompson, Sobolew-Shubin, Graham, & Janigian, 1989). In this research on stroke patients, overprotection was assessed in terms of not letting the patient do things that could be done independently, taking over the patient's responsibilities unnecessarily, and shielding the patient from upsetting or frustrating situations or events. Patients who felt overprotected by their family caregivers for these reasons were found to be more depressed even after controlling for the severity of the stroke. Overprotection was not related to quantity of support, suggesting that overprotection was not simply the equivalent of providing too much assistance. Although it has often been suggested that overhelping or overprotection is detrimental to an older adult's mental health because it makes the recipient feel less efficacious, competent, or independent (e.g., Krause, 1995), investigators have yet to examine such explanatory or mediating mechanisms empirically.

The findings of several studies directly address the issue of person-environment fit. The common approach used in these studies is to examine the interaction between amount or nature of assistance and personality characteristics of the recipient. A recent study of spousal caregiving dyads focused on amount of assistance from the spouse, personal characteristics of the care-recipient, the extent to which care-recipients experienced mental or emotional strain from receiving assistance with ADLs and IADLs, and the care-recipient's level of depressive symptomatology. Recipients with lower self-esteem and lower mastery reported more strain as a result of receiving care, especially those who received high levels of ADL and IADL assistance from the spouse. Insufficient help was found to be associated with more care-receiving strain for those with low perceived control but was associated with less strain for those with high perceived control, suggesting that individuals with high levels of perceived control prefer lesser amounts of assistance (Newsom & Schulz, 1998). Moreover, greater care receiving strain predicted more depressive symptomatology for the recipient 1 year later.

As further evidence for person-environment fit, one study showed that older adults who have an internal locus of control (i.e., perceive that events in their lives are primarily under their control) and whose social network encourage them to be reliant on others for support experience poorer mental health, whereas individuals with an external locus of control experienced better mental health when receiving this same type of support (Reich & Zautra, 1991). Another study by the same investigators revealed that older adults who were encouraged to be self-reliant at a time when they had a significant increase in activity limitations experienced poorer mental health (Zautra, Reich, & Newsom, 1995). Finally, although not focused specifically on older adults, one study found that women who appraise rheumatoid arthritis as a challenge (rather than a threat) experience more depression when they receive high levels of instrumental, emotional, and informational support from their husband (Schiaffino & Revenson, 1995).

Physical Health Outcomes. Little attention has been paid to whether or not the receipt of care has negative effects on the older adult's physical health beyond their existing health condition, and virtually no attention has been paid to explanatory or conditioning factors in this process. One common suggestion is that the actions of others can be unsupportive in the sense that they can foster a sense of dependency or incompetency in the older adult that contributes to poorer physical functioning (Baltes, 1988). Evidence for this hypothesis has been found for older adults receiving assistance from nursing home staff as well as individuals receiving assistance from family members (Baltes & Wahl, 1992). Another study found that instrumental support in the form of assistance with tasks and provision of information was associated with increased risk for onset of new or recurrent disability in a sample of highly functioning older men, suggesting that receipt of support may have led to reduced confidence in the ability to carry out tasks independently and decreased effort in this regard (Seeman, Bruce, & McAvay, 1996).

Although not necessarily focusing on caregiving situations, the chronic pain literature has documented the impact that family members' actions can have on the functioning of an individual suffering from conditions such as low back pain, headaches, and osteoarthritis. A number of studies have shown that family members unintentionally reinforce pain behaviors and inactivity in chronic pain patients by acting solicitously toward the patient (i.e., providing assistance even when it may not be needed) (e.g., Romano et al., 1992; Turk, Kerns, & Rosenberg, 1992).

To summarize this section on the health effects of care receiving, the positive aspects of receiving care have for the most part been assumed and not evaluated empirically. However, there is evidence from several different literatures that emotional support and task assistance from informal caregivers, although usually well-intended, can sometimes backfire and have negative rather than positive effects on the older adult care-recipient. Less is known about the extent to which receiving care affects an older adult's mental and physical health beyond the effects of his or her preexisting disability. Studies have not yet begun to address the roles of gender and ethnicity in the mental and physical health effects of receiving care. Furthermore, although a fair number of studies reviewed here were prospective in nature, most focused on general samples of older adults receiving instrumental support as broadly defined (e.g., McAvay et al., 1996; Silverstein et al., 1996) rather than ill or disabled older adults receiving illness-specific emotional support or task assistance (e.g., Schiaffino & Revenson, 1995; Zautra et al., 1995). Prospective studies focusing on the latter group may be most useful in terms of exploring the ways the health effects of receiving care change as a result of such factors as health transitions of the care-recipient or a change of primary caregiver.

As noted at the beginning of this section, research on the effects of receiving care is important because the recipient's response to assistance is an important determinant of the quality of future care, as well as future help-seeking behavior and reciprocity (DePaulo et al., 1983). As is true for the caregiving literature, an interesting question is whether the negative or

positive aspects of receiving assistance have a greater impact on health. Furthermore, what are the conditions under which an older adult is better off receiving care from formal (i.e., paid) caregivers than from family or friends?

CONCLUSIONS

This chapter demonstrated that the perspectives of both the caregiver and the older adult care-recipient are important to consider in investigations of the health effects of informal caregiving. Moreover, evidence was provided that there are negative and positive aspects to both caregiving and care receiving. However, by organizing the review to focus separately on the caregiver and care-recipient, it may be falsely concluded that health effects of caregiving and care receiving are best viewed in isolation from each other. Therefore, this chapter concludes with a discussion of the interactive nature of helping and being helped.

Table 29.1 depicts four mental and physical health effect scenarios for the elder caregiving dyad. As illustrated, both the caregiver and care-receiver may experience positive health effects (cell 1) or negative health effects (cell 4) from the provision and receipt of care. Obviously, the first scenario is the optimal situation, whereas the fourth cell represents a scenario which should be of particular concern to researchers and policymakers. The second cell represents a health "trade-off," whereby the caregiver experiences negative health effects but the care-recipient benefits from received assistance. This may be the most typical scenario of the four, and is illustrated by findings from a study of married men recovering from myocardial infarction (MI). In this study, the wife's protective buffering (i.e., protecting the spouse from upsetting events and taking over tasks and responsibilities) was associated with the husband's increased efficacy in recovering from an MI but was also associated with her increased distress (Coyne & Smith, 1991). The third cell of Table 29.1 depicts another possible tradeoff whereby the care-recipient's health suffers as a result of receiving assistance but the caregiver benefits from the provision of assistance. One way that this scenario may occur is when the caregiver underestimates the older adult's abilities and provides more assistance than needed, thereby making the caregiver feel positively about his or her efforts but also causing the older adult to be more dependent on the caregiver for assistance in the future (e.g., Clark & Stephens, 1996).

TABLE 29.1
Typology of Dyadic Mental and Physical Health Effects
of Informal Caregiving

Health Effects on the Care-Recipient	Health Effects on the Caregiver	
	Positive	Negative
Positive	1	2
Negative	3	4

The health effects illustrated in Table 29.1 also serve to bring another issue to the forefront. Obviously, health effects experienced by the caregiver and care-recipient do not exist in isolation from each other. The mental and physical health of each member of the caregiving dyad likely affects the mental and physical health of the other individual, a phenomenon often referred to as contagion. Several recent studies have demonstrated that the mental health status (e.g., depressive symptomatology) of a married older adult has a significant impact on the mental health of their spouse, even after taking into account the spouse's physical health status (Bookwala & Schulz, 1996; Coyne et al., 1987; Tower & Kasl, 1995). This picture emerges over many years, making it difficult to determine the causal ordering of such effects.

Evidence for the negative effects of informal caregiving on both the caregiver and care-recipient suggests that psychosocial interventions that are designed to improve the caregiving situation should target both the caregiver and care-recipient. To date, interventions have primarily been targeted at lessening the burden and subsequent negative health effects of informal caregiving through such approaches as education, support groups, counseling or psychotherapy, in-home respite programs, and free-standing or institutional adult day-care programs. Other literatures examine the efficacy of psychosocial interventions for improving the quality of life of specific chronic illness populations, such as individuals with arthritis, visual impairment, terminal illness, and individuals recovering from stroke or myocardial infarction. To date, there are only a handful of studies evaluating the efficacy of psychosocial interventions targeted at both members of elder caregiving dyads, in the context of conditions such as visual impairment (e.g., Horowitz, November 1997), osteoarthritis (e.g., Keefe et al., 1996) and psychiatric illness (e.g., Sherrill, Frank, Geary, Stack, & Reynolds, 1997; Teri, Logsdon, Uomoto, & McCurry, 1997). Clearly, there is a need for research of this kind.

Psychosocial interventions should target caregivers through efforts to relieve their burden as well as education in regard to providing the best assistance and support to the older adult. Given the importance of autonomy and control issues to many older adults, interventions aimed at getting nursing home staff to be more autonomy-supportive may be usefully applied to informal caregivers (Baltes, Neumann, & Zank, 1994). Care-recipients can be targeted through efforts to help them find the best ways to communicate the need for help, and education in regard to how their illness affects their caregiver. Of course, the most thorough psychosocial intervention would also target the older adult's primary health care provider in an attempt to improve communication between this individual and both the patient and caregiver and subsequently improve the quality of care provided to the patient (Council on Scientific Affairs, American Medical Association, 1993). An added benefit of multitargeted psychosocial interventions in the context of informal caregiving is that findings from this research can inform models of the health effects of caregiving and care receiving by identifying mediating and conditioning factors in these processes.

Marci Lobel

State University of New York, Stony Brook

Pathik D. Wadhwa

University of Kentucky College of Medicine

From the time of its inception, health psychology has accumulated a strong record of research on psychological aspects of various diseases such as heart disease and cancer. In contrast, the field has not delved much into reproductive health. Research in nursing, public health, and medicine has been conducted on the biopsychosocial aspects of infertility, contraception, abortion, miscarriage and stillbirth, on prenatal genetic screening and health behaviors, on labor and delivery, and on maternal and infant health in general. Such issues are prime research topics for attention by health psychology, as any quick reading of the available literature indicates. This chapter focuses on pregnancy and birth specifically, although this is only one of a plethora of important, underresearched topics in reproductive health.

A central event in most women's reproductive life cycles is the prenatal period culminated by the birth of a child. During these 9 months, numerous well-established changes in physiology take place. These changes are accompanied by psychological changes that are not as well documented, nor are the interrelations of the physiological changes to psycho-

logical factors well mapped out as yet. The effects of pregnancy on mood or affect, social resources, coping processes, and various behaviors are highly variable from woman to woman depending on her circumstances and her condition. To what extent are women anxious about having a first or a subsequent birth? Does prenatal anxiety vary as a function of her available coping resources? Do women with close relationships with the father of the baby have better health and well-being in pregnancy than women who do not have this relationship? Are certain personal characteristics such as self-esteem associated with positive prenatal health behavior? Does the way a woman perceives and copes with challenges in her pregnancy influence her emotional adjustment or her infant's health? What are the mechanisms accounting for relations of maternal psychosocial factors and maternal, fetal, and infant outcomes? These are the kinds of health psychology questions that can be considered in building a better understanding of pregnancy.

Pregnancy is an ideal condition for study by health psychologists for many reasons. First, it has a clear-cut and finite

time frame. Second, millions of women experience it annually. Third, many of the issues such as the prevention of infant mortality are international in scope. Finally, evidence for interactions of mind and body are numerous. For example, it is known that having a companion present during labor to provide support has beneficial effects on labor outcomes (Kennell, Klaus, McGrath, Robertson, & Hinkley, 1991; Sosa, Kennell, Klaus, Robertson, & Urrutia, 1980). It is also well established that behaviors such as smoking, diet, and adherence to medical regimens have effects on fetal growth and infant health (McCormick et al., 1990). Emerging research also indicates that life stress and its emotional effects are risk factors for adverse birth outcomes for mother and infant. It is this latter topic—prenatal stress processes and effects on birth outcomes—that is the central focus in this chapter. By studying stress processes in pregnancy, the many interactions of psychological, sociocultural, and biological systems and their effects on birth outcomes can be examined. More specifically, the mechanisms accounting for the links between stress and birth outcomes are unknown, and can be probed within a broad-based stress framework.

PREGNANCY AND STRESS

Although biological perspectives sometimes view pregnancy as a physical stressor to the body, there are limitations of such models for studying pregnancy. For one, the human body has many adaptive mechanisms to ensure the health of mother and fetus (Amiel-Tison & Pettigrew, 1991). In fact, pregnancy is best conceptualized as a normative developmental transition involving changes of many kinds that may or may not be perceived as stressful. This may be especially true in a first pregnancy. A woman's social network may change, with her family and marital relationships growing stronger or more strained. She may develop new friendships with other expecting mothers or parents, and become less close with others who do not have children. Emotions may range over the course of pregnancy from happy to anxious, "blue," or sad. Behaviors such as abstinence from smoking, alcohol, and drug use, and regular prenatal care, healthy diet, and moderate exercise may differ markedly from prepregnancy behaviors. Variability in these issues among women is even greater in second, third, or further pregnancies, as a function of the experiences of earlier pregnancies and the conditions of the current one. Understanding the variability in responses to pregnancy and determining the factors that predict such variation is one goal of the research.

MULTILEVEL STRESS MODELS AS APPLIED TO PREGNANCY

Many factors at different levels of theoretical analysis influence the degree to which a woman experiences particular changes, emotional responses, and events in pregnancy. These levels include sociological, cultural, familial, dyadic, and individual. For example, maternal socioeconomic status has been shown to influence substance use, prenatal care utilization, and diet, as well as stress levels in pregnancy (Feldman, 1997;

Gazmararian, Adams, & Pamuk, 1996; Kramer, 1998; Moore et al., 1991). Ethnic and cultural differences have been found in attitudes about a particular pregnancy, about pregnancy in general, and in health behaviors (Schaffer, Velie, Shaw, & Todoroff, 1998; Scrimshaw, Zambrana, & Dunkel-Schetter, 1997; Zambrana & Scrimshaw, 1997; Zambrana, Scrimshaw, N. Collins, & Dunkel-Schetter, 1997). Some of these factors—socioeconomic indicators, attitudes toward pregnancy, and health behaviors, in particular—have been shown in turn to influence rates of medical complications and outcomes such as prematurity and infant birthweight (J. W. Collins, Herman, & David, 1997; Gudmundsson, Bjorgvinsdottir, Molin, Gunnarsson, & Marsal, 1997; Safonova & Leparsky, 1998; Zimmer-Gembeck & Helfand, 1996). Age also plays a part, with teenage pregnancy creating a vulnerable group of women for whom prenatal changes are perhaps the most stressful and pose the most risk (McAnarney, 1987). For example, teens are at high risk for substance use and inadequate health care in pregnancy (Kosher, Lee, Goss, Heilemann, & Stinson, 1998). Marital status has also been found to be important to pregnancy processes and outcomes, with married women at lower risk of many adverse outcomes (Ahmed, 1990; Arntzen, Moum, Magnus, & Bakketeig, 1996; McIntosh, Roumayah, & Bottoms, 1995). Psychosocial mechanisms such as availability and receipt of support of all kinds are likely explanations for these marital effects.

At the individual level, a host of factors such as maternal personality, coping style, and coping resources influence the degree and rate of changes in pregnancy and outcomes. For example, women with high perceived control or mastery appear to have better pregnancy outcomes (Rini, Dunkel-Schetter, Sandman, & Wadhwa, 1999). Women who cope with challenges in pregnancy in certain ways (e.g., Yali & Lobel, 1999), and who have ample resources to cope (e.g., Dunkel-Schetter, Sagrestano, Feldman, & Killingsworth, 1996), also appear to fare much better. For example, naturally occurring social support has been associated with larger birth weight infants and with fewer labor complications (N. L. Collins, Dunkel-Schetter, Lobel, & Scrimshaw, 1993).

Variability in response to pregnancy may also be due to biological factors such as genetic predisposition, obstetrical and gynecological history, and state of prepregnancy health. Possible pathways between psychosocial factors and outcomes such as maternal complications or infant health include processes at many biological levels of analysis that range from systemic (endocrine and immune processes) to molecular (gene expression). Historically, pregnancy has been studied at only single levels of analysis, but current trends in perinatal research are toward multilevel analyses in which biological, psychological, and sociocultural factors are examined jointly.

In short, there are many factors at many different levels of analysis that influence exposure to stress in pregnancy, appraisals of stress, emotional responses to stressors, and effects of them on mental and physical health outcomes. Furthermore, these factors interact and work together in complex causal sequences in their effects on maternal, fetal, and infant outcomes. Thus, a broad biopsychosocial approach to

understanding pregnancy and birth, similar to that found in much of health psychology, is appropriate in this context, and offers avenues for productive research.

This chapter overviews some of the biopsychosocial interrelationships in pregnancy and birth with special attention to stress processes. Stress processes are inherently biopsychosocial and provide a useful entry point to the broader arena of study. It begins with a review of the mainly descriptive research on the prevalence and variability of emotional responses in pregnancy. The next section lays out the array of potential pregnancy and birth outcomes that may be studied. Because of their significance as health issues, special attention is devoted to length of gestation, preterm delivery, and to low birth weight. To provide some groundwork for examining links between stress and these particular outcomes, the etiology of preterm delivery and low birthweight is also briefly discussed. Next, the chapter reviews recent evidence regarding stress as an independent risk factor for adverse outcomes. The next section is devoted to mechanisms or pathways that may account for stress–birth outcome effects. Two general mechanisms are discussed: physiological pathways and behavioral pathways. Following the discussion of mechanisms, two moderators of stress outcome effects are examined. These are coping processes and social support processes. Inasmuch as there is very little research on coping, this topic is treated briefly. In contrast, there is both a solid existing research literature and a growing body of work on social support in pregnancy; thus this topic is covered in some depth. The section on social support provides a brief conceptual basis for the study of support in pregnancy, and then reviews research on the relation of social support to birth outcomes.

EMOTIONAL RESPONSES IN PREGNANCY

Some experts have suggested that heightened levels of estrogen and progesterone in pregnancy make pregnant women more emotionally vulnerable, although the impact of hormones on prenatal mood has not been established empirically (Leifer, 1980). For the most part, prenatal emotion has not been examined as a topic in its own right, but rather it has been described in the coverage of other topics, mainly in studies focusing on the impact of maternal emotion on birth outcomes or on postpartum adjustment (cf. Leifer, 1980). In these studies, mean levels of emotion are often not reported, and when reported, are not usually compared to population means, or otherwise given meaningful interpretation (e.g., Affonso, Mayberry, Lovett, & Paul, 1994; Brooke, Anderson, Bland, Peacock, & Stewart, 1989; Chalmers, 1983; Farber, Vaughn, & Egeland, 1981; Kalil, Gruber, Conley, & Syntiac, 1993). Furthermore, of the limited number of studies of women's emotional state during pregnancy, a fair portion were published 20 or more years ago. These studies may offer an inaccurate view of emotions in pregnant women of today due to important societal changes that are likely to have altered the experience of pregnancy. For example, more pregnant women are in the workforce now than in previous decades, which has affected societal views of pregnancy and the way pregnant women view themselves (Horgan, 1983; Lobel, 1998). Al-

though the tendency to treat pregnancy as a sickness has receded over the last few decades (Seegmiller, 1993), pregnancy has been increasingly medicalized. Most women now routinely undergo prenatal tests such as ultrasonography, amniocentesis, chorionic villus sampling, and alphafetoprotein testing. There is conflicting evidence about whether such testing, and the greater availability of medical interventions, provides reassurance to pregnant women or focuses their attention on the number of things that can go wrong (Diaz & Lobel, 1998; Tunis & Golbus, 1991). Because of these changes, research must be fairly current to accurately represent the emotional state of pregnant women today.

Three types of studies comprise the research literature on prenatal emotion. One type, which includes many of the older studies, examines the prevalence of various indicators of psychopathology in pregnant women and compares these to population norms. Studies of psychosis, suicide, and admission to psychiatric hospitals have generally found that these are less common in pregnant than nonpregnant women, and in those who do experience psychiatric disorders, a history of disorder prior to pregnancy is often present (reviewed by Elliott, 1984; Leifer, 1980). A second type of study, comprised of qualitative interviews with pregnant women, is the primary source of data on positive emotions (e.g., Mercer, 1986) and on emotional fluctuations in pregnancy. The media and other popular sources often depict pregnant women as displaying what one best-selling women's health guide calls "dramatic emotional changes" (Carlson, Eisenstat, & Ziporyn, 1996). Qualitative reports suggest that a portion of women do experience emotional lability during pregnancy (Leifer, 1980; Mercer, 1986), but there appears to be high interindividual variation. Furthermore, it is unknown whether emotional lability is any more common in pregnant women than in other groups. More controlled studies with repeated measures over the course of pregnancy are needed to examine emotional states in pregnant women and appropriate comparison groups.

A third type of study has employed standard measures of emotion in pregnant women, occasionally comparing sample means to population norms. Studies of this type have focused almost exclusively on negative emotions, particularly anxiety and depression, although "distress" (e.g., Hedegaard, Henriksen, Sabroe, & Secher, 1993) and "tension" (e.g., Elliott, Rugg, Watson, & Brough, 1983; Mercer & Ferketich, 1988) have been measured in a few studies. These quantitative studies of prenatal state anxiety and prenatal depression yield information about normative levels of negative emotion in pregnant women and to some extent about stability and change in negative emotion over the course of pregnancy.

Prenatal State Anxiety

Studies using standardized measures such as the State–Trait Anxiety Inventory (STAI; Spielberger, 1983) have produced extremely similar estimates of prenatal levels of state anxiety, and the levels reported are close to published norms for these instruments for nonpregnant women (e.g., Crandon, 1979; Molfese, Bricker, Manion, Beadnell et al., 1987; Pagel, Smilkstein, Regen, & Montano, 1990;

Park, Moore, Turner, & Adler, 1997). Thus, on average, pregnant women in these studies do not appear to experience elevated anxiety. However, study participants have been mostly socioeconomically advantaged, White, and married or partnered. There is conflicting evidence about whether anxiety is greater in women of lower socioeconomic status or in other demographically at-risk groups (e.g., Norbeck & Anderson, 1989a; Pond & Kemp, 1992).

There is a high degree of interindividual variability in anxiety in these studies. For example, variation from the mean by approximately 10 or 11 points on the STAI appears to be common in samples of pregnant women, and is approximately equal to the standard deviation derived from population norms. Thus, levels of anxiety in both pregnant and nonpregnant women commonly range within a spread of approximately 20 points (10 points below the mean to 10 points above), which constitutes about a third of the entire STAI response range. In essence, these data indicate that there are fairly large differences in anxiety from woman to woman, whether pregnant or not.

A few studies have assessed anxiety at multiple time points, providing a way to examine whether prenatal anxiety is stable across the 9-month period. These studies also enable determination of whether using single assessments offers valid estimates of prenatal emotion. Although studies employing repeated measurement have utilized samples of quite different composition, there is an impressive convergence of evidence that state anxiety is fairly stable across pregnancy (Elliott et al., 1983; Lobel & Dunkel-Schetter, 1990; Norbeck & Anderson, 1989a; Perkin, Bland, Peacock, & Anderson, 1993; Zax, Sameroff, & Farnum, 1975). One of the most methodologically rigorous and comprehensive of these investigations was conducted among married, working-class urbanites in Britain (Elliott et al., 1983). For the sample as a whole, no significant change in anxiety was observed across pregnancy. However, the authors noted that variance in individual patterns of change was "striking." That is, some women did experience changes in anxious emotion, although as Elliott et al. cautioned, these patterns of change are difficult to interpret and individual variation across pregnancy was not associated with any particular maternal characteristics.

Three older studies have been cited frequently as demonstrating variation in anxiety levels during pregnancy, but on close examination, they offer little evidence to support this claim (Edwards & Jones, 1970; Gorsuch & Key, 1974; Lubin, Gardener, & Roth, 1975). For example, Lubin et al. found an exceptionally small (1.5 points out of a 21-point range), but statistically significant, difference between anxiety in the second trimester compared to the first or third trimesters using one measure. But they found no difference on a second standard measure of anxiety between trimesters. Furthermore, anxiety in this sample was low and comparable to population levels. The remaining two studies found small changes in anxiety over time, but neither study examined whether the changes were statistically significant. For participants in both of these studies, anxiety scores at virtually every time point were well within one standard deviation of the population norm.

To summarize, across samples with great variability in socioeconomic status, racial characteristics, marital status, medical risk, and parity, a consistent pattern of temporal variation in anxiety over the course of pregnancy does not appear to exist. Women experience normal levels of anxiety throughout their pregnancy, although a minority of women experience some changes over time. However, even for these women, there does not appear to be a consistent pattern of variation associated with the progression of pregnancy.

Prenatal Depression

As with data on anxiety during pregnancy, information about depression is available almost exclusively from investigations conducted for other purposes. These studies, less numerous than those of anxiety, concur that most women do not experience clinical levels of depression during pregnancy. The more recent studies indicate that mean scores on the Beck Depression Inventory, the most common measure used, are below cutoffs for mild depression (Cameron et al., 1996; Molfese, Bricker, Manion, Beadnell et al., 1987; O'Hara, Zekoski, Philipps, & Wright, 1990; Steer, Scholl, Hediger, & Fischer, 1992). Older studies (reviewed by Kaplan, 1986) and those using other depression measures (Elliott et al., 1983; Lubin et al., 1975; Mercer & Ferketich, 1988; Neter, Collins, Lobel, & Dunkel-Schetter, 1995; Perkin et al., 1993; Rofe, Lewin, & Padeh, 1981) also find that the majority of women do not report depression. Similarly, in the few studies examining prenatal depression at multiple time points, it appears to be fairly stable for the majority of women (Cameron et al., 1996; Chapman, Hobfoll, & Ritter, 1997; Elliott et al., 1983; Lubin et al., 1975; and see review by Kaplan, 1986), although there are notable exceptions (e.g., O'Hara et al., 1990).

O'Hara and colleagues (1990) have demonstrated the importance of distinguishing between major depression, minor depression, and depressive symptomatology or dysphoric mood in pregnant women. They found that pregnant women are not more likely to exhibit clinically notable levels of depression (minor or major) than nonpregnant women, but they do experience more depressive symptomatology, especially in late pregnancy. Thus, according to these results, pregnant women are likely to experience some emotional distress during the last trimester, but not at levels considered harmful or requiring clinical intervention.

The next section considers the specific pregnancy and birth outcomes that may be influenced by emotional state during pregnancy, as well as by the other psychosocial and psychobiological factors mentioned earlier.

PREGNANCY AND BIRTH OUTCOMES

The study of stress processes in pregnancy involves a wide continuum of possible variables and outcomes for study. These can be broadly classified by the time of their occurrence into *prenatal*, *labor and delivery*, and *postpartum* periods. This developmental continuum can be extended to include prepregnancy conditions such as infertility and, at the other end of the continuum, parenting and child development

outcomes. Factors of interest during pregnancy can be further classified into maternal factors versus fetal and neonatal factors (see Table 30.1). *Maternal prenatal* variables include prenatal affect and well-being and maternal complications such as gestational diabetes and pregnancy-induced hypertension. *Maternal labor and delivery* outcomes include variables such as length of labor, mode of delivery, use of analgesia and anesthesia, and dysfunctions of labor. *Maternal postpartum* variables include postpartum depression, postpartum medical complications such as maternal hemorrhaging, and parenting variables such as difficulty in breastfeeding or caring for the infant. *Fetal variables* include growth and development parameters and fetal neurobehavioral maturation. *Infant outcomes* (at and after birth) include birth complications and infant health and behavior. Another important infant outcome is *birth weight*, which is described further later.

An outcome of special interest cuts across these categories because it involves both mother and fetus (i.e., the maternal-fetal unit), as well as pregnancy and delivery. This outcome is the *timing of delivery*, also referred to as *length of gestation*. *Preterm birth* (delivery before 37 weeks gestation) is one of the major causes of *low birth weight* (less than or equal to 2,500 grams). Fetuses with less time in utero have less time to grow and develop normally. Thus, infants born preterm, especially very preterm (under 35 weeks), are more likely to be low in birth weight. Low birth weight infants in turn are at risk for many complications medically and developmentally (Newnham, 1998; Thompson et al., 1997). Most notably, very low birth weight babies are at significantly higher risk for infant mortality. Preterm delivery and low birth weight are among the largest contributors to infant mortality (McCormick, 1985). Thus, infant mortality, low birth weight, and preterm delivery constitute

important targets for programmatic public health efforts (Alexander, 1998; Berendes, Kessel, & Yaffe, 1991; Paneth, 1995; Shiono & Behrman, 1995).

Of special interest in studying pregnancy and birth in the United States is the nation's very high rate of low birth weight (and preterm delivery) relative to other industrialized nations. The United States compares unfavorably to 36 countries reporting infant mortality data to the World Health Organization (25th), with 8.4% of infants born at low birth weight in the United States each year. This rate has been climbing steadily over the past 10 years, and there are stable and important demographic differences with rates of low birth weight as high as 13% in non-Hispanic Blacks, 9.4% in Puerto Ricans living in the continental United States, and closer to 6% in other groups (David & Collins, 1997). Similarly, rates of preterm delivery are disproportionately high in non-Hispanic Blacks (Rowley, Hogue, Blackmore, Ferre, Hatfield-Timajchy, Branch, & Atrash, 1993).

Very low socioeconomic status is one contributor to risk of low birth weight in the United States, but it does not appear to account for all the variation among groups in the population (Frisbie, Biegler, deTurk, Forbes, & Pullum, 1997). Psychosocial factors have shown impressive power to predict variation in birth weight when demographic differences such as age, education, income, and race/ethnicity are controlled (Copper et al., 1996; Goldenberg et al., 1991; Herrera, Salmeron, & Hurtado, 1997; Paarlberg, Vingerhoets, Passchier, Dekker, & Van Geijn, 1995; Orr et al., 1996; Shiono, Rauh, Park, Lederman, & Zuskar, 1997; Zimmer-Gembeck & Helfand, 1996). Thus, biopsychosocial models of birth weight and preterm delivery are currently the most accepted and most researched models in this area, having edged out narrower biomedical models some time ago. Work has focused on the link

TABLE 30.1
Schema for the Clarification of Outcomes in Perinatal Research

Developmental Continuum	Maternal	Fetal and Infant
Prepregnancy	Ob-Gyn conditions (e.g., infertility)	(Not applicable)
Prenatal (prepartum)	Pregnancy loss Medical complications Neuroendocrine, immune, and hemodynamic parameters Affect and well-being Health behaviors	Fetal growth Neuroendocrine, immune, and hemodynamic parameters Fetal neurobehavioral development
Labor & Delivery (intrapartum)	Analgesia Mode of delivery Abnormal labor Gestational length and preterm delivery	Fetal distress Neonatal complications (respiration, asphyxia) Infant birthweight
Post-birth (postpartum and first years of life)	Medical complications Depression & "blues" Caregiving/parenting Breastfeeding	Infant health Infant development

between psychosocial factors (especially stress) and preterm delivery and low birth weight. These outcomes are the focus of the following review on stress and birth outcomes.

THE ETIOLOGY OF PRETERM DELIVERY AND LOW BIRTH WEIGHT

The etiology of preterm delivery is not well understood (Adams, Sarno, Harlass, Rawlings, & Read, 1995; Moore et al., 1994), although it is believed that early delivery may occur as a result of more than one disorder or pathway. There are at least two categories of preterm birth that appear to have somewhat different etiologies (Berkowitz, Blackmore-Prince, Lapinski, & Savitz, 1998; Meis, 1998). *Spontaneous preterm birth* appears to account for approximately three quarters of all preterm births and may be accompanied by preterm labor or preterm rupture of membranes (Klebanoff, 1998). Early labor or rupture of membranes may occur due to infection or other causes (Bryant-Greenwood, Millar, Yamamoto, Bogic, & Tashima, 1998). *Indicated preterm birth* accounts for the remaining one quarter of preterm births. These result from complications leading to mandated delivery by either Caesarian section or labor induction with or without Cesarean section. Studies of preterm delivery may look at whether the delivery occurred at less than 37 weeks, or they may use a more stringent criterion such as 35 weeks. Other research examines *gestational age* (also referred to as *gestational length*) in weeks (or days) as a continuous variable. Similarly, studies of *low birth weight* may examine infants of 2,500 grams or less, or may use the more stringent category of *very low birth weight* infants of 1,500 grams or less. They may also examine the continuous distribution of birth weight in grams.

At least two processes appear to be intertwined here. The length of gestation and the weight of the infant are highly correlated, typically sharing approximately 10% to 30% variance. This reflects the fact that the etiology of low birth weight involves processes that contribute to fetal growth and growth retardation independent of preterm delivery. In order to disentangle the processes leading to preterm delivery from those leading to fetal growth retardation, birth weight as an outcome variable must be examined after controlling for the length of gestation. Very little research has addressed this issue in analyses. Research on either of these two endpoints (PTD and LBW) is useful in understanding the possible contribution of stress to adverse outcomes of pregnancy and research that takes both length of gestation and birth weight into account is especially valuable.

STRESS AS AN INDEPENDENT RISK FACTOR FOR ADVERSE OUTCOMES

Since the 1970s, many empirical studies have been published addressing the role of stress in preterm delivery, infant birth weight, and related outcomes. Studies in the past 10 years have been the most sophisticated with larger samples, better measures, and more controlled analyses that address the issues of confounding and independence of any effects of

stress. This is a very rapidly developing area of research with growing interest in medicine and public health.

However, differences in design and samples across investigations continue to make it difficult to compare results. For example, characteristics of samples vary in the nationality, ethnicity, social class, risk status, and parity (birth history) of pregnant women. The number and timing of prenatal assessments varies from single assessments at various times in gestation to repeated assessments, most often in the second or third trimester. Few studies conduct assessments in the first trimester, which may be a particularly vulnerable time for effects of stress on some birth outcomes (e.g., birth defects). At the same time, early prenatal assessment creates biases in sampling because socioeconomically disadvantaged women are much less likely to be in prenatal care at this point (Gazmararian et al., 1996). Most studies conduct prenatal assessments late in pregnancy with the advantage of lowering attrition and loss prior to collection of labor and delivery data. The disadvantage of this approach is that women delivering preterm can then be missing prenatal data by virtue of having already delivered their infants. Thus, the issues involved in selecting a research design are very complex and are important to consider in evaluating the research.

Conceptualizations of stress have been quite diverse in this literature, including assessments of stress exposure, emotional responses, and appraisals of stress (Lobel & Dunkel-Schetter, 1990). Self-report methods are the norm, due mainly to the difficulty of measuring stress more objectively, but there are also advantages of a phenomenological approach to studying stress (Cohen, Kessler, & Gordon, 1995; Lazarus & Folkman, 1984). Life events and state anxiety are the constructs most often assessed, but measures of depression and generalized distress also appear in the literature. In addition to these, quite a few studies have focused on occupational stress and physical strain or exertion (see Woo, 1997, for a review). This work is relevant but not as well developed as research on life stress. Nonetheless, distinguishing physical exertion from psychological stress is very important to understanding mechanisms. Adverse outcomes may result from physical strain in strenuous daily activities or from perceiving that the demands of life stressors exceed people's coping capacity. It is unlikely that physical strain and appraised stress have the same effects on physiology and outcomes of pregnancy.

Finally, many studies include other constructs such as mastery or self-esteem in approaches to understanding stress and birth outcomes. Sometimes these psychosocial variables are combined with stress variables into broader psychosocial risk indices (e.g., Nuckolls, Kaplan, & Cassel, 1992). It can be argued that this strategy maximizes empirical predictive power at the expense of theoretical clarity, which is only obtained by examining stress variables and related moderators and mediators separately.

Existing research has not yet focused on chronic stress and its effects on pregnancy, despite plausible mechanisms whereby chronic stress might influence both fetal growth and preterm labor and delivery. Some work has included an instrument assessing perceived stress (PSS; Cohen, Kamarck, & Mermelstein, 1983; Cohen & Williamson, 1988). Although

not designed to assess chronic stress per se, this instrument appears to capture the extent to which a woman feels overwhelmed by stress from any and all sources, unable to cope with or control the stress, and emotionally distressed. This scale has been associated with both gestational length and birth weight (Lobel, Dunkel-Schetter, & Scrimshaw, 1992; Zambrana et al., 1997). Additional research incorporating direct approaches to the study of chronic stress in pregnancy (Lepore, 1995) would be very valuable.

Several review articles have been published, each addressing certain aspects of the literature on stress and birth outcomes (Istvan, 1986; R. P. Lederman, 1986; Levin & DeFrank, 1988; Lobel, 1994). Some address stress as a risk factor for low birth weight specifically (Brooks-Gunn, 1991; McAnarney & Stevens-Simon, 1990). In a comprehensive review on the determinants of low birth weight, Kramer (1987) concluded cautiously that "stress and anxiety may provoke pre-term labour in some susceptible women" (p. 684), and they are important risk factors to study along with physical activity, maternal employment, antenatal care, and genital tract infection.

Since the publication of this review, newer evidence strengthens the case that stress is a risk factor for preterm labor and delivery. Approximately 20 studies on stress and preterm delivery, most of which are well controlled, have appeared since 1986. For example, Nordentoft et al. (1996) studied 2,432 Danish women at 20 weeks gestation using the most sophisticated life events assessment methods available (i.e., those of Brown & Harris, 1978). They found that severity of life events was associated with preterm delivery after controlling for education, age, and cohabitation. Similarly, Hedegaard, Henriksen, Secher, Hatch, and Sabroe (1996) found that the presence of one or more highly stressful life events during pregnancy was associated with risk of preterm delivery in 5,873 Danish women studied prospectively. Together these studies and others provide fairly convincing evidence that life event exposure may pose a risk for preterm delivery, although the risk ratios were relatively small.

Other studies using measures of stress other than life events support the role of stress in the etiology of preterm delivery. In a multicenter study of 2,593 women in the United States who were assessed at approximately 26 weeks gestation, a two-item stress measure (part of a larger psychosocial risk index) was significantly associated with preterm delivery after controlling for race, age, marital status, insurance, education, and substance abuse (Copper et al., 1996). The two items were "There is a great deal of nervous strain associated with my daily activities" and "In general, I am very tense and nervous." The content of this measure raises the question of whether stress as a risk factor is based in environmental circumstances or is more reflective of personality predispositions of women. That is, the risk may lie either in the exposure to stressors or in the patterns of appraising and responding to stressors. Some contribution from each is expected within a transactional model of stress (Lazarus & Folkman, 1984). However, this issue has been addressed to some extent.

Lobel, Dunkel-Schetter, and Scrimshaw (1992) studied 130 pregnant women from early gestation throughout preg-

nancy with assessments at every prenatal visit. Multiple measures of stress (including life events, state anxiety, and perceived stress) were included in each assessment. Structural equation modeling methods were used to combine stress variables into a latent factor, providing the advantages of minimizing the effects of measurement error and using a common core of shared variance among stress measures as the predictor of outcomes (Lobel & Dunkel-Schetter, 1990). The best latent factor to represent stress was composed of state anxiety, perceived stress, and ratings of perceived distress from life events. The total number of life events (or exposure alone) did not correlate with the latent factor or with outcomes. However, the latent stress factor predicted both birth weight and gestational age at delivery after controlling for medical risk factors including smoking.

In a subsequent study, Wadhwa, Sandman, Porto, Dunkel-Schetter, and Garite (1993) included a more contextually based measure of stress in which anxiety and concerns about the pregnancy were assessed in questionnaires administered to 90 pregnant women. In contrast to more general stress or anxiety measures, a 5-item index assessing *pregnancy anxiety* was most significantly associated with risk of early labor and delivery. Recently, these results have been replicated in studies in which life events, state anxiety, perceived stress, and pregnancy anxiety were measured in structured interviews with two samples of pregnant women. In both samples, results indicate that pregnancy anxiety is an important component of stress in predicting preterm delivery (Dunkel-Schetter, 1998). For example, Rini et al. (1999) found that pregnancy anxiety and state anxiety were moderately intercorrelated. When modeled as a latent factor, this anxiety factor predicted length of gestation in a sample of 230 women (half Hispanic and half non-Hispanic White) after controlling for the effects of obstetric and sociodemographic risk factors.

In addition, this study distinguished psychosocial resources (i.e., self-esteem, mastery, and dispositional optimism) from stress variables by assessing the former with standard scales and combining the scores into a latent factor. Labeled *personal resources*, this factor significantly predicted birth weight. Thus, stress was associated with length of gestation and not with intrauterine growth, whereas personal resources (mastery, self-esteem, optimism) were associated with birth weight and not length of gestation. Prior studies reporting significant associations between stress and birth weight or intrauterine growth have not controlled for personality factors or personal resources such as these, nor have they addressed the issue of confounding of different psychosocial constructs in multivariate analyses (e.g. Goldenberg et al., 1991). Possible mechanisms explaining these effects are discussed in the next section, but briefly, it seems likely that different mechanisms are involved. Neuroendocrine and immune pathways are implicated in the stress-preterm findings in the literature, whereas behavioral pathways appear to be more promising in linking personality (or personal resources) and birth weight. As noted earlier, pinpointing the mechanisms responsible for links between psychosocial factors and birth outcomes is critical.

MECHANISMS OF STRESS-BIRTH OUTCOMES EFFECTS

There are two major classes of mechanisms through which psychosocial factors such as stress influence health in humans: a direct, physiological pathway mediated primarily by central and peripheral stress responses of the nervous, endocrine, and immune systems; and an indirect, behavioral pathway mediated by health-related behaviors such as smoking, alcohol and drug abuse, nutrition, exercise and physical activity, and reduced compliance or adherence to other aspects of health care. Each of these possible mechanisms is discussed in the context of the effects of maternal psychosocial factors on pregnancy outcomes.

Physiological Mechanisms

The responses of the nervous, endocrine, and immune systems to psychological stress are well-established (see, e.g., Axelrod & Reisine, 1984; Herbert & Cohen, 1993, for reviews) and have been proposed as central mechanisms linking psychosocial factors to health outcomes (Chrousos & Gold, 1992; McEwen, 1998). Several researchers have suggested that stress-related responses of the neuro-immuno-endocrine axis during pregnancy may contribute to adverse outcomes such as preterm birth, fetal growth restriction/low birth weight, and neurodevelopmental deficits. For instance, elevated levels of hypothalamic, pituitary, and placental stress hormones have been implicated in the initiation of preterm labor and delivery (Hobel, Dunkel-Schetter, & Roesch, 1998; McLean et al., 1995; Wadhwa, Porto, Garite, Chiciz-DeMet, & Sandman, 1998). The immunosuppressive effects of stress and hypothalamic-pituitary-adrenal (HPA) activation may increase susceptibility to infection (DeSouza, 1993; Jemmot & Locke, 1984), which in turn plays a role in the etiology of premature rupture of membranes and preterm birth (Garite, 1994; Lockwood, 1994; Romero et al., 1994). Vasoconstriction and hypoxia in response to sympathetic-adrenal-medullary (SAM) activation decrease uteroplacental perfusion, and may thereby contribute to fetal growth restriction and low birth weight (Cosmi, Luzi, Gori, & Chiodi, 1990; Myers, 1975; Shepherd, Stanczyk, Bethea, & Novy, 1992).

Stress-related processes involving the nervous, endocrine, and immune systems may also play an important role in embryonic and fetal brain development (Glover, 1997). Normal brain development requires precise interactions between environmental signals and genes that regulate cell differentiation, migration, and circuit formation. Experimental studies using animal models have demonstrated that intrauterine environmental influences, including alterations in the biochemical milieu effected by stress, stress hormones, immune products, and vascular dynamics, can modulate cell fate choice and neuronal growth, with permanent consequences for cognitive, affective, and behavioral outcomes over the life span (Wadhwa, 1998).

To date, there have been very few systematic investigations of these physiological processes as potential mediators of the prenatal stress and pregnancy outcome link in humans.

A few studies have examined the association between catecholamines and anxiety at the onset of labor (e.g., R. P. Lederman, E. Lederman, Work, & McCann, 1985), and between catecholamines and physical activity during pregnancy (e.g., Katz, Jenkins, Haley, & Bowes, 1991). In one study (Dorn, Susman, & Petersen, 1993), a sample of 40 pregnant adolescents was assessed during the middle and latter part of gestation and postpartum. Subjects with an increase in cortisol levels across a 40-minute period measured before 20 weeks gestation and again at 2 to 3 weeks postpartum had fewer symptoms of anxiety and depression than subjects with no cortisol increase. There was, however, no relation between cortisol and symptoms of anxiety or depression at the 34 to 36 week gestation assessment. In a sample of 54 adult pregnant women, maternal plasma levels of the principal pituitary-adrenal stress hormones (adrenocorticotropin hormone, ACTH; β -endorphin, bE; and cortisol) measured at the beginning of the third trimester of pregnancy were significantly correlated with psychosocial factors. Subjects reporting higher levels of prenatal stress had higher plasma levels of ACTH and cortisol, whereas subjects reporting higher levels of social support had lower plasma levels of ACTH and cortisol. After controlling for the effects of factors known to influence hormone levels during pregnancy, including gestational age, circadian variation, and obstetric risk, a combination of maternal psychosocial and sociodemographic factors accounted for 36% of the variance in ACTH, 13% of the variance in cortisol, and 3% of the variance in bE (Wadhwa, Dunkel-Schetter, Chiciz-DeMet, Porto, & Sandman, 1996). Another study addressed the link between maternal psychosocial factors and immune parameters. In a sample of 72 pregnant women, high levels of stress and low or inadequate social support were associated with depression of lymphocyte activity (Herrera, Alvarado, & Martinez, 1988).

With reference to fetal outcomes, again, a very small number of studies have examined the relations between maternal psychosocial factors and fetal physiology. Recently, a series of longitudinal studies were conducted by DiPietro and colleagues to study the functional development of the fetal central nervous system over the course of gestation and to identify risk factors for neurodevelopmental delays (DiPietro, Hodgson, Costigan, Hilton, & Johnson, 1996a, 1996b). In these studies, the sequence and characteristics of fetal neurobehavioral development and maturation (i.e., fetal autonomic, motoric, state, and interactive functioning) were assessed serially at six time points between 20 and 38 weeks gestation. Findings indicated that chronic maternal psychological distress was significantly associated with delayed and impaired neurobehavioral maturation of the fetus—that is, greater maternal stress was associated with reduced fetal heart rate variability and reduced coupling between fetal heart rate and movement (DiPietro et al., 1996a, 1996b). In another study of 37 women, maternal levels of trait anxiety were significantly associated with uteroplacental and fetal blood flow. Using measures of pulsatility index (PI) derived from doppler flow studies of the umbilical and fetal middle cerebral artery at from 37 to 40 weeks gestation, results indicated that fetuses of mothers with high trait anxiety had significantly higher PI values in

the umbilical artery, significantly lower PI values in the fetal middle cerebral artery, and a significantly lower cerebro-umbilical PI ratio (signs of fetal hypoxia and compensatory redistribution of blood flow to the fetal brain; Sjostrom, Valentin, Thelin, & Marsal, 1997).

Finally, one study with a sample of 40 low risk pregnant women examined maternal blood pressure responses to a laboratory-based behavioral stressor (interactive arithmetic task) during pregnancy. Infant birth outcomes were subsequently obtained from medical records. Results indicated that mothers with greater psychophysiological stress reactivity (in this case, larger diastolic blood pressure responses to behavioral stress) delivered infants with significantly lower birth weights and decreased gestational age (McCubbin et al., 1996).

Two sets of issues warrant consideration when thinking about physiological mediators of the effects of maternal psychosocial factors in pregnancy. First, progressive changes that occur in maternal physiology over the course of gestation may produce changes in the typical pattern of biological responses to stress. For example, neuroendocrine alterations in pregnancy, which are characterized by the evolution of a transient endocrine unit, the placenta, and by modification of negative feedback mechanisms, result in a significant and progressive increase in plasma concentrations of HPA and placental hormones (corticotropin-releasing hormone, CRH; adrenocorticotrophic hormone, ACTH; beta-endorphin, β E; cortisol; estrogens; progesterone) over the course of gestation (Petraglia, Florio, Nappi, & Genazzani, 1996). These increases of peripherally circulating hormones may exert inhibitory influences on the hypothalamus and pituitary, and thereby attenuate endocrine responsivity to exogenous stimuli (Goland, Conwell, Warren, & Wardlaw, 1992; Schulte, Weidner, & Allolio, 1990). Similarly, cardiovascular alterations in pregnancy, which include a progressive diminution of the sensitivity of baroreceptor reflex mechanisms and an increase in plasma volume with advancing gestation (Monga & Creasy, 1994), may result in a blunted sympathetic (noradrenergic) response to exogenous stimuli (Barron, Mujais, Zinaman, Bravo, & Lindheimer, 1986).

Consistent with this premise, studies of physiological reactivity in pregnancy have reported attenuated responses to exogenous challenges. For instance, pregnancy has been associated with blunted sympathetic-adrenal-medullary responses, including vascular responses to norepinephrine and epinephrine infusion (Nisell, Hjemdahl, & Linde, 1985); blunted heart rate and catecholamine responses to physical maneuvers such as standing, upright tilt, isometric handgrip, and cold pressor (Barron et al., 1986; Nisell, Hjemdahl, Linde, & Lunell, 1985a, 1985b); blunted plasma renin activity response to thermal stress (Vaha-Eskeli, Erkkola, Scheinin, & Seppanen, 1992); and blunted blood pressure responses to physical and mental challenges (Matthews & Rodin, 1992). Attenuated HPA responses have also been reported in late gestation, including ACTH and cortisol responses to administration of exogenous CRH in humans and baboons (Goland et al., 1992; Schulte et al., 1990). A recent preliminary study of maternal physiological responses to behavioral stress (speech/math task) at various gestational ages

suggested, first, a progressive attenuation of the maternal psychophysiological stress response over the course of gestation, and second, that the degree of attenuation was accounted for in substantial part by maternal baseline stress hormone levels, namely, ACTH and cortisol (Wadhwa, Sandman, Chicz-DeMet, & Porto, 1997). At present, the function of these changes is not known, but these advances in stress pathophysiology research appear to be important to untangling the mechanisms involved in stress-outcome links.

The second set of issues relates to the ontogeny of fetal development. Fetal growth and development is a logarithmic process, with rapid mitosis at early stages and cellular hypertrophy and accumulation of fat, glycogen, and connective tissue later in gestation (Lockwood & Weiner, 1986). It is well-established that there are several sensitive or critical periods in development. The presence or absence of a particular experience at a critical period in the life cycle may exert an extraordinary and dramatic influence over structure and/or function well beyond that point in development. There may be critical periods during pregnancy when the developing fetus is especially vulnerable to pre- and perinatal insults (Bornstein, 1989; Dunkel-Schetter & Lobel, 1998). For example, the effects of hypoxia on the developing fetus not only depend on the severity and duration of hypoxia but also on the time period during gestation when hypoxia occurs. Although the effects of equivalent degrees of chronic hypoxia during early and late gestation on fetal growth restriction may appear to be similar in magnitude, hypoxia experienced early in gestation produces greater fetal nervous system disability than hypoxia experienced later in gestation, when mechanisms to evoke the brain-sparing effect have developed and are in place (Amiel-Tison & Pettigrew, 1991; Wadhwa, 1998). For these reasons, psychobiological interactions in models of pregnancy should not only incorporate explanations of mechanisms through which maternal signals are relayed to the placenta and/or fetus, but they should take into account alterations in maternal psychophysiological responses over the course of gestation and the fetal developmental time line.

Behavioral Mechanisms

The effects of prenatal health-related behaviors such as poor eating habits, smoking, alcohol, and drug abuse on fetal development are well-documented. An increased risk of spontaneous abortion, fetal growth restriction, preterm delivery, and cognitive and motor deficits of the central nervous system are among these (Abrams, 1994; Andres & Jones, 1994).

An emerging literature supports a significant role for psychosocial variables such as prenatal stress and depression in countertherapeutic health behaviors in pregnancy. For example, many studies between 1975 and 1997 examined the associations between maternal psychosocial factors and smoking, alcohol, or drug abuse in human pregnancy (Barnet, Duggan, Wilson, & Joffe, 1995; Borrelli, Bock, King, Pinto, & Marcus, 1996; Bresnahan, Zuckerman, & Cabral, 1992; Hutchins & DiPietro, 1997; McCormick et al., 1990; Pritchard, 1994; Zuckerman, Amaro, Bauchner, & Cabral, 1989). Most studies rely on self-reports of health behaviors, but a very small

number include biological screens such as cotinine assays for smoking or toxicological assays for alcohol and other illicit drugs. Psychosocial factors examined in these studies include social support, depression, stress, maternal personality (self-esteem, locus of control, hostility, coping style), and whether the pregnancy was intended or unintended.

Approximately 80% of the studies reported significant associations between maternal psychosocial factors and prenatal health behaviors. Higher levels of prenatal stress or depression were associated with increased incidence of risk posing behaviors. Higher levels of social support were associated with decreased incidence of these behaviors. Among personality and individual difference variables, higher levels of self-esteem, locus of control, and an intended pregnancy were associated with decreased incidence, and higher levels of hostility and defensive coping style were associated with increased incidence of these behaviors, respectively. In addition to these correlational findings, emerging evidence suggests psychosocial factors such as stress, depression, and partner support may play an important role in the success of prenatal intervention programs to reduce the incidence of these behavioral practices (Ingersoll, Lu, & Haller, 1995; Wiemann & Berenson, 1998).

Overall, this literature provides strong support for the hypothesis that psychosocial factors are related to one or more of the risk posing behaviors in human pregnancy both because of the consistency of findings and because of methodological strengths of studies including the range of populations studied. The study samples were representative of the general population, and ranged from middle-class, married, Anglo women to low socioeconomic class, single, African American women and teenagers. The majority of the research is prospective and studies assess both psychosocial factors and health behaviors at one or more times during pregnancy.

MODERATORS OF STRESS-BIRTH OUTCOME EFFECTS

Not only is stress ubiquitous in the course of living, but pregnancy entails a number of changes that women may find stressful, as described earlier. However, the fact that pregnant women on average do not experience high levels of emotional distress suggests that intervening factors moderate the influences of prenatal stress on women's emotional state. These factors may account for individual differences among pregnant women in levels of prenatal anxiety and depression. Coping, or the way that women manage problems during pregnancy, is one likely factor. Social support is another commonly studied resource that may facilitate successful adaptation. Existing research on coping and social support in pregnancy is described next. It must be noted, however, that research on coping in pregnancy is in its infancy, whereas there is a considerable body of work on social support in pregnancy.

COPING IN PREGNANCY

A large number of studies substantiate that people who cope successfully with stressful situations are least likely to experi-

ence negative mood; conversely, maladaptive coping exacerbates or increases negative mood. The predominant view of coping is that it includes anything people do to manage problems or emotional responses, whether or not successful (Carver & Scheier, 1994; Lazarus & Folkman, 1984; Pearlin & Schooler, 1978). Despite a voluminous literature on coping within other health contexts, studies of coping in pregnancy have been rare.

Although this research is limited, the findings provide a fairly clear picture of the impact of the three most commonly studied types of coping: avoidance, problem solving, and positive appraisal. *Avoidant coping*, which involves behavioral or cognitive disengagement from problems, is associated with greater emotional distress in pregnancy (Hansell, 1993; Martinez, 1989; Perez, 1982; Spirito et al., 1991; Yali, 1998; Yali & Lobel, 1999). This corroborates a large body of work demonstrating the deleterious emotional impact of avoidant coping in a variety of populations (e.g., Aldwin & Revenson, 1987; Fleishman & Fogel, 1994; Stanton & Snider, 1993). Avoidance may exacerbate emotional distress in pregnant women because ironically, people often become preoccupied with the thoughts that they attempt to suppress, and because the inhibition of thoughts, feelings, and behaviors can cause autonomic arousal (cf. Lobel, Yali, Zhu, & DeVincent, 1998). Also, the use of avoidant coping requires sustained effort to screen out stressor-relevant cues (cf. Lazarus & Folkman, 1984); this can be taxing and is likely to deplete pregnant women's already limited physical energy. Avoidant coping may have harmful nonemotional consequences as well. For example, women who use avoidant coping may neglect to get appropriate assistance or necessary medical attention.

A second type of coping, labeled *problem solving, active coping, or approach-oriented coping*, tends to be effective in nonpregnant populations (e.g., Aspinwall & Taylor, 1992; Folkman, Lazarus, Dunkel-Schetter, DeLongis, & Gruen, 1986), but the evidence in pregnancy is mixed (see Hansell, 1993; Martinez, 1989; Spirito et al., 1991; Yali, 1998; Yali & Lobel, 1999). One reason is that active ways of coping may lead to an increased focus on problems, some of which may not be remediable in pregnancy. For example, Yali and Lobel (1999) found that women at high medical risk who coped by preparing for the baby (e.g., acquiring furniture and supplies) were emotionally worse off than women who did not cope in this way. They reasoned that this type of coping focuses attention on the baby, which is distressing among women whose pregnancy may not result in a healthy child. Although problem-focused coping strategies such as preparation are associated with positive outcomes in some stressful situations (Compas, Malcarne, & Fondacaro, 1988; Holahan & Moos, 1990, 1991; Roth & Cohen, 1986), they may not be efficacious for people facing imminent or severe threats (cf. Bolger, 1990; Carver & Scheier, 1994). Thus, coping through preparation and other types of problem solving may be more adaptive for pregnant women at low medical risk. This possibility has yet to be tested empirically.

Positive appraisal is the only type of coping that has consistently been associated with lower distress in pregnant women (Barth & Schinke, 1983; Perez, 1982; Spirito et al.,

1991; Yali, 1998; Yali & Lobel, 1999). This way of coping involves viewing a stressful situation positively, emphasizing what can be gained or what benefits might accrue from it. Positive appraisal has been shown to be an adaptive form of coping in a variety of populations undergoing stressful events (Dunkel-Schetter, Folkman, & Lazarus, 1987).

Issues of measurement are important considerations in research on prenatal coping. Standard versions of coping instruments such as the Ways of Coping, or the COPE (Carver, Scheier, & Weintraub, 1989; Folkman & Lazarus, 1985), may not be appropriate for use in pregnant women because they do not capture the situationally specific ways in which women may manage the strains and challenges of being pregnant and they contain some items inappropriate in the context of pregnancy. To address this issue, Lobel and colleagues developed a pregnancy-specific coping instrument that has been used in two samples of pregnant women of different socioeconomic, racial, and other composition (Lobel et al., 1998; Yali, 1998; Yali & Lobel, 1999). The Prenatal Coping Inventory (PCI) includes items from standard coping measures and items that pregnant women endorsed during open-ended interviews and pilot testing. Similar factors were derived from factor analyses of the PCI in both samples. These include factors reflecting preparation for motherhood, avoidance, positive appraisal, and prayer. The first three correspond to categories of coping that have been identified in the few previous studies of pregnant women. Prayer, a type of coping not examined previously, was the most frequently reported type of coping used by women in both of these studies. Unexpectedly, use of prayer was associated with increased emotional distress. The authors suggested that the type of prayer practiced by study participants may have been a form of rumination, which typically produces unfavorable emotional consequences (Nolen-Hoeksema, 1991; Nolen-Hoeksema & Morrow, 1993; Park & Cohen, 1993). The high reliance on prayer in these two studies in conjunction with its adverse impact highlight the value of further research on this coping strategy among pregnant women.

Although it serves as a useful starting point, several important questions about the impact of coping and the psychological mechanisms involved have yet to be addressed. For example, are pregnant women who cope with stress adaptively at lower risk for adverse birth outcomes? Conversely, does maladaptive coping with stress in pregnancy increase risk? What leads women to select and exercise particular ways of coping? Researchers have begun to look at the latter question by examining the role of disposition, or individual traits, and the role of appraisal, or the way that pregnant women evaluate their situation. They find that women who are dispositionally optimistic and those who view their pregnancy as controllable select more efficacious ways of coping, and thereby experience lower emotional distress (Yali, 1998). However, virtually nothing is known about how other types of dispositional characteristics or appraisal influence coping in pregnancy. Knowledge about these factors may help clinicians identify women at emotional risk in pregnancy and give us useful information about the sorts of coping training that might be effective for particular groups of women.

SOCIAL SUPPORT AND RELATIONSHIPS IN PREGNANCY

The birth of an infant is a major life event and transition for parents, and usually influences many others close to the baby's mother. By virtue of the ties of kinship, the extended families of both parents are often intricately involved in the pregnancy and may be major sources of support for the pregnant woman. Close interpersonal relationships and the social support derived from them influence how individuals cope with stress. Thus, these are important topics in the study of pregnancy (Berthiaume, David, Saucier, & Borgeat, 1998; Dunkel-Schetter et al., 1996; Elbourne & Oakley, 1991; Nuckolls et al., 1972). This chapter focuses primarily on the supportive aspects of close relationships and does not address other relationship issues such as marital satisfaction, intimacy, and commitment (for a review see Berscheid & Reis, 1998).

Although the association between social support and health has been well-documented (Cohen & Syme, 1985; House, 1987; B. R. Sarason, I. G. Sarason, & Gurung, 1997), research on the role of specific relationships and the mechanisms that might account for their association with healthier pregnancies has been limited. This section has reviewed correlational pregnancy research on global support, on specific sources or providers of support, on various functions or types of support, and on negative aspects of social relationships. The chapter concludes with a review of research on supportive interventions and on mechanisms whereby support may influence outcomes.

The term *social support* has been principally defined as either *available* or *perceived support*, or alternatively as *received* or *enacted support*. These terms differentiate between support individuals believe to be available if they should need it and the amount of support that they actually receive or report to have received (Barrera, 1986; Dunkel-Schetter & Bennett, 1990; Gottlieb, 1985). Beyond the distinction between perceived and received support, social support has been further categorized in many different (although not mutually exclusive) ways. For example, support can be distinguished by *function* or *type* of support (emotional, informational, instrumental). Other distinctions such as *global versus specific* support (support for general stressors or specific stressors) have also been used. Finally, categories may be created by focusing on who is providing the support (or *source of support*; e.g., spouse, family, friends, doctors, and medical staff). These different categories can be fit into a hierarchy with the general approach (received or perceived) as the primary dimension. Within each, the dimension of source of support can be distinguished and finally different types or functions of support can be embedded within each source (Schwarzer, Dunkel-Schetter, & Kemeny, 1994). For example, emotional support received from baby's father, or perceived emotional support from baby's father can be studied, and either received or perceived support can be studied with reference to family or friends.

As documented by a number of reviews (cf., Dunkel-Schetter et al., 1996; R. P. Lederman, 1995; Paarlberg et al., 1995; Scholl, Hediger, & Belsky, 1994), social support and

close relationship processes play an important role in both the psychological well-being of pregnant women as well as in determining the course of labor and birth outcomes. A large number of correlational and experimental intervention studies have shown that, in general, social support is related to lower levels of stress, anxiety, and depression during pregnancy (Albrecht & Rankin, 1989; N. L. Collins et al., 1993; Clifford, Weaver, & Hays, 1989; Gurung, Dunkel-Schetter, Collins, & Hobel, 1998; MacDonald, Peacock, & Anderson, 1992; O' Hara, 1986; Thorpe, Dragonas, & Golding, 1992; Tilden, 1983; Zuckerman, Amaro, Bauchner, & Cabral, 1989). For example, Zuckerman et al. (1989) examined the effects of different types of support on depressive symptoms in a low income multiethnic sample and showed that total support was negatively related to reports of depressive symptoms. More recently, Berthiaume et al. (1998) interviewed 350 French Canadian women at the beginning of their second semester of pregnancy and found that satisfaction with social support was significantly related to lower levels of prepartum depression, as were employment and self-esteem.

In work on social support in pregnancy, several constructs have been conceptualized and measured and the best ways to combine these measures of social support have been investigated (e.g., N. L. Collins et al., 1993; Gurung et al., 1998). For example, Gurung et al. (1998) used structural equation modeling to compare competing models of support in pregnancy. Three main types of support (perceived, received, and network), two primary sources of support (friends/family and baby's father), and three major functions of support (tangible, informational, and advice) were measured. The best fitting model was one with two factors (one for each source of support), each with received and perceived support measures included and that collapsed across the type/function measures. The empirical validity of conceptualizing support primarily by source is also consistent with similar analyses of support measures and concepts in other contexts (e.g., men with HIV, Schwarzer et al., 1994).

SPECIFIC SOURCES OR PROVIDERS OF SOCIAL SUPPORT IN PREGNANCY

Past pregnancy research has both focused on different sources of support (Gurung et al., 1998; Davis, Rhodes, & Hamilton-Leaks, 1997; Sagrestano, Feldman, Rini, Woo, & Dunkel-Schetter, in press), and examined the positive and negative implications of perceiving or receiving social support from specific relationships or sources (Cramer & McDonald, 1996; Zimmermann-Tansella, Bertagni, Siani, & Micciolo, 1994). The major comparison is between support transactions at the level of a dyad (e.g., support provided to the baby's mother from the baby's father), versus at the level of a network or group (e.g., support provided by friends and family). Yet a different set of studies has focused on the impact of support from professional sources (e.g., nurses and doctors; Blondel, 1998).

The baby's father has been a critical focus of attention, and his role as a major source of support has been reported in a number of different studies (Casper & Hogan, 1990; N. L. Collins et

al., 1993; Giblin, Poland, & Ager, 1990; Lantican & Corona, 1992; Zayas & Busch-Rossnagel, 1992). Social support from baby's father has been shown to significantly influence outcomes such as prenatal care utilization and emotional distress (e.g., Gurung et al., 1998; Hobfoll & Leiberman, 1987; Kalil et al., 1993; MacDonald et al., 1992; Norbeck & Anderson, 1989b; Norbeck, Lindsey, & Carrieri, 1981; Norbeck & Tilden, 1983; O'Hara, 1986; Tietjen & Bradley, 1985). For example, Sable, Stockbauer, Schramm, and Land (1990), in a sample of 1,464 women, showed that support from the baby's father was a stronger predictor of prenatal care than was support from others. Women who were at a greater risk for receiving inadequate prenatal care were African American, less educated, poor, had unwanted pregnancies, higher parity, and perhaps most importantly, were single (see also, Giblin et al., 1990).

Support from the baby's father has been found to be especially important among certain ethnic groups (e.g., Zambrana et al., 1997). For example, in a study of acculturation and psychosocial risk factors in pregnant Mexican American and Mexican immigrant women, Zambrana et al. (1997) found that support from the baby's father was associated with significantly less stress, less substance abuse, and more positive attitudes toward the pregnancy. These results further indicated that acculturation was a significant factor in relationship status, with Mexican-immigrant women being more likely to live with and be married to the baby's father than the more acculturated Mexican American women.

In contrast to the baby's father, support from the family does not seem to be as significant a predictor of pregnancy outcomes. Although the expected positive associations of family support with outcomes such as well-being and birth weight are seen, the relation with the initiation of health care, even among low income groups who might depend more on their families for material support, is not as uniform (Dunkel-Schetter et al., 1996; St. Clair, Smeriglio, Alexander, & Celantano, 1989; St. John & Winstin, 1989; Zambrana, Hernandez, Dunkel-Schetter, & Scrimshaw, 1991). However, this relation may vary depending on the age and ethnicity of the pregnant women. For example, Turner, Grindstaff, and Phillips (1990) found that family support is especially crucial for pregnant teenagers. Specifically, teenagers who reported higher levels of family support had babies with higher birth weights and experienced less postpartum depression. Similarly, Boyce, Schaefer, and Uitti (1985) showed that pregnant teenagers who perceived their family to be more helpful had fewer neonatal complications.

Studies of ethnic minority groups in the United States show that for some groups (e.g., African Americans, Latinas) the family is a critical source of support in pregnancy, particularly female relatives (Knouse, 1991; Zuniga, 1992). Mexican American families tend to live in close units with extensive bonds to other family units and the extended family serving as the primary source of support (Chilman, 1993, Keefe, Padilla, & Carlos, 1979). Similarly, the family is the most important source of support to African Americans (Cauce, Felner, & Primavera, 1982; Miller, 1992). In one of the most cited studies of ethnic differences in support, Norbeck and Anderson (1989b) measured life stress, social support, anxiety state, and

substance use at mid- and late pregnancy in Hispanic, European American, and African American low income women. They found that none of the social support measures were significant predictors of gestational age, birth weight, or gestation and labor complications when the sample was analyzed as a whole. However, for African Americans, lack of social support from the woman's partner or mother was a significant predictor of gestational complications and of the likelihood of prolonged labor and cesarean section complications. For Whites, social support was significantly related to length of labor and to drug use, although high levels of social support were associated with longer labor. Similarly, White women with high stress and high support from relatives also had more delivery complications. None of the support measures were statistically significant predictors of complications or birth outcomes for the Hispanics.

In a direct test of ethnic differences in social support, Sagrestano et al. (in press) analyzed data from two multiethnic prospective studies of 246 and 504 African American, Latina, and non-Hispanic White pregnant women, and found strong ethnic differences in support from family and friends. Multivariate analyses of ethnic differences controlling for sociodemographic variables showed that African American women reported receiving the most support from family followed by Latinas and White women. However, White women reported more family members in their social networks than did Latinas. Furthermore, Latinas reported higher quality interactions with family.

How do the effects of support from different sources compare? In a recent study designed to answer this question, Gurung et al. (1998) compared the support received from the baby's father with that received from her friends and family in an ethnically diverse sample of 480 women (African American, Latin American, and non-Hispanic White). Various types of support measures were assessed at multiple time points before the birth, together with standard measures of depression and anxiety. Different sources of support were associated with different outcomes. Specifically, social support from the baby's father predicted significantly less anxiety but not significant differences in depressed mood. Support from the mother's friends and family were significant predictors of maternal depressed mood, but did not predict anxiety (cf. Kalil et al., 1993). Social support from the baby's father predicted maternal changes in anxiety independent of sociodemographic variables such as age, ethnicity, and SES and individual difference measures such as mastery and coping. This difference in support effects by source is consistent with the theory and some results in the social support literature indicating that support is most effective when there is a match between the type of support a person needs and the type provided (e.g., Cutrona, 1990) for support to be effective. Others discuss the existence of an optimal support provider for different specific needs (Cantor, 1979; Litwak, 1985).

Taken together, these results present a compelling set of findings for pregnancy researchers and health psychologists, suggesting that different sources of support cannot be thought of as interchangeable. Support from the baby's father has been shown to be significantly related to less stress, anxiety and de-

pression, better utilization of prenatal care, and better birth outcomes even when other sources of support are available. Focusing on support from specific sources (e.g., partners and spouses) has greatly advanced the understanding of stress and coping with chronic and terminal illnesses like cancer and AIDS (e.g., Hays, Turner, & Coates, 1992; Helgeson & Cohen, 1996). Similarly, the documented positive impact of support from the baby's father on pregnancy outcomes opens up new avenues of research in which the father may be more central. Furthermore, studies with greater emphasis on close relationship processes and those that include both the pregnant mother and the baby's father in their designs, currently an uncommon procedure in prenatal research, will undoubtedly prove to be highly effective in advancing prediction of psychological, labor, and birth outcomes in pregnancy. In summary, whereas support from the baby's father seems generally effective, support from friends and family is only effective for certain samples, such as teenagers and certain ethnic groups (including African American and Latinas).

FUNCTIONS OR TYPES OF SOCIAL SUPPORT IN PREGNANCY

Three functional aspects of social support have been most commonly studied and primarily as received support: instrumental (tangible or material) support, informational (or advice) support, and emotional support. Some studies on pregnancy included analyses of several functions of support. For example, Norbeck and Tilden (1983) compared the different functions of support in a group of low risk pregnant women and found moderating effects of instrumental support and indirect effects of emotional and informational support on pregnancy outcomes. Low support was detrimental, although the effects varied as a function of stress level. Women who reported high stress during pregnancy and low levels of instrumental support experienced more infant and gestation complications (e.g., premature labor and poor infant status), whereas women who reported low tangible support in the context of low stress during pregnancy reported more labor and delivery problems (e.g., prolonged labor and cesarean delivery).

N. L. Collins et al. (1993) measured four types of social support (material aid, assistance with tasks, advice and information, and the amount of listening) and computed partial correlations between the four types and four outcomes (birth weight, abnormal labor, postpartum depression, and a 5-minute Apgar) controlling for many factors. Results indicated that a relation between greater support and higher Apgar scores was due to receipt of prenatal task and informational support rather than emotional support. Furthermore, the association of social support with labor progress was primarily a function of task and material support. Finally, although an overall index of the four types of support did not relate to depression, women who received more material support tended to be less depressed after childbirth.

In general, evidence suggests that different types of support are likely to be beneficial in pregnancy, although it is important to factor in the context and stressfulness of the

situations in which it is offered (Dunkel-Schetter, Blasband, Feinstein, & Herbert, 1992).

NEGATIVE ASPECTS OF CLOSE RELATIONSHIPS IN PREGNANCY

A discussion of the association between close relationships and psychological well-being and health outcomes during pregnancy cannot be complete without a consideration of the negative aspects of relationships. Whereas a majority of past research has emphasized the health promoting effects of social support, there has been rising concern that the absence of negative social interactions may be even more important for mental health (Cutrona, 1996; Schuster, Kessler, & Aseltine, 1990). Emerging findings from research in the area of marital conflict and close relationships suggests that support from romantic partners and families can have negative as well as positive consequences (Pasch & Bradbury, 1998; Ramsey, Abell, & Baker, 1986; Rook, 1992). Cramer and McDonald (1996) interviewed 42 young low income mothers and found that although family assistance helps many teenagers who have to cope with the challenges of poverty and childrearing, such support was perceived to entail conflict, stress, frustration, and disappointment due to interpersonal tensions, conflicting interests, or relatives with limited ability to provide support. They also found a consistent discrepancy between the young mother's high expectations and her support network's lower performance. Rhodes and Woods (1995) found similar results in a study of 157 pregnant minority teenagers whose network members were the sources of interpersonal problems (including criticism, intrusiveness, conflict, and disappointment) and support. These studies illustrate the frequently noted dual nature of supportive relationships, that is, their capacity to be beneficial and harmful.

Evidence of the darker side of close personal relationships also comes from newer literature on violence during pregnancy (Ballard et al., 1998; McFarlane, Parker, & Soeken, 1996a). Although no pregnancy outcome was consistently found to be associated with violence during pregnancy in a review by Petersen, Gazmararian, Spitz, and Rowley (1997), one study (McFarlane, Parker, & Soeken, 1996b) found that abuse during pregnancy was a significant risk for low birth weight as well as maternal low weight gain, infections, anemia, smoking, and use of alcohol and drugs (see also Parker, McFarlane, & Soeken, 1994). Of greater importance is the fact that abuse and violence during pregnancy appear to be quite common. A review by Gazmararian et al. (1996) indicates that the prevalence of violence during pregnancy ranges from 9% to 20%. Similarly, McFarlane, Parker, and Soeken (1996b) found that the prevalence of physical or sexual abuse during pregnancy was high (16%). Estimates of violence in women in general are generally somewhat lower than these rates. In fact, family violence may be a more common problem for pregnant women than some conditions for which they are routinely screened and evaluated. One correlate of violence in pregnancy seems to be an unwanted pregnancy. Gazmararian et al. (1995) showed that women of all socioeconomic groups with unwanted pregnancies had 4.1 times the

odds of experiencing physical violence compared to women with pregnancies that were wanted. In studying close relationships in pregnancy, and the potentially beneficial social support they can provide, pregnancy researchers must consider the negative sides of these relations as well.

SUPPORT INTERVENTIONS IN PREGNANCY AND OUTCOMES

In contrast to the correlational work on close relationships in pregnancy, the majority of studies assessing the influence of professional support are experimental, with interventions utilizing either nurses, social workers, midwives, or other trained medical practitioners. Three extensive reviews of the intervention literature (Blondel, 1998; Elbourne & Oakley, 1991; Elbourne, Oakley & Chalmers, 1989) agree that there was a trend toward better birth outcomes (e.g., lower preterm delivery), more positive affect, higher satisfaction with antenatal care, better communication with medical staff, and fewer gestation and labor complications in the intervention groups, although in general the reviews note considerable methodological problems in the literature despite many promising findings.

More recent studies are among the most rigorous and these are therefore mentioned briefly despite some remaining concerns with methodological issues. Studies assessing social support interventions have documented improvements in birth weight (e.g., Heins, Nance, McCarthy, & Efid, 1990; Oakley, Rajan, & Grant, 1990; Olds, Henderson, Tatelbaum, & Chamberlin, 1986), prenatal mortality (e.g., Sokol, Woolf, Rosen, & Weingarden, 1980) utilization of labor and delivery interventions (Oakley et al., 1990), and infant health (e.g., Olds et al., 1998). Norbeck, DeJoseph, and R. T. Smith (1996) used focus groups to develop culturally relevant standardized face-to-face interventions that provided the support usually provided by the participants' mother or male partners. One hundred and fourteen at-risk African American women were randomly assigned to the control group or the support group. The rate of low birth weight (LBW) was 9.1% in the social support intervention group compared to 22.4% in the control group. Similarly, Rogers, Peoples-Sheps, and Suchindran (1996) evaluated the impact of an intervention using paraprofessionals to provide social support to pregnant teenagers through home visits. The support focused on helping the teenagers better use the resources provided by network members, and also consisted of advice and the provision of emotional support. The intervention group consisted of 1,901 primiparous teenagers in intervention counties who were compared to 4,613 teenagers from counties in which the program was not offered. Results indicated that the intervention teenagers initiated prenatal care earlier and were less likely to have a preterm birth. Olds et al. (1998), conducted two randomized trials of prenatal and infancy home visitation using registered nurses and involving four prenatal visits. In contrast to women in a control group, nurse-visited women showed improved maternal caregiving and better health care behaviors. Furthermore, among women who smoked, those who were nurse-visited had 75% fewer preterm deliveries.

Interventions have also been shown to have some long-term effects. In one study, Oakley, Hickey, Rajan, and Rigby (1996) compared the health of 255 women who were offered a social support intervention provided by midwives during pregnancy with 254 controls who received normal care only. The participants were followed up at 6 weeks, 1 year, and 7 years. At the 7-year follow-up, factors such as child and mother health, child development, and health and welfare service use were assessed. Results showed that mothers and infants in the intervention group had significantly better physical and psychological health than those in the control groups 7 years after the intervention. The development of better social support interventions in pregnancy and methodologically rigorous evaluations of them is critical.

PATHWAYS BETWEEN PRENATAL SUPPORT AND BIRTH OUTCOMES

The general finding that social support and personal relationships have beneficial effects on the psychological well-being of the pregnant mother and on labor, delivery, and birth outcomes still leaves unanswered the question of the pathways or mechanisms of the social support effect. The two main models of support–outcome relations have been the *direct effects* model and the *stress buffering* model. If support truly was a moderator of stress effects on outcomes of pregnancy, then there should be evidence for the stress buffering model. However, most of the correlational studies provide fairly consistent evidence that prenatal social support has main effects on birth weight (Hoffman & Hatch, 1996; Molfese, Bricker, Manion, & Yapple, 1987; Norbeck & Tilden, 1983; Reeb, Graham, Zyzanski, & Kitson, 1987; Zacariah, 1996). For example, Turner et al. (1990) measured perceived social support from family, friends, and romantic partner in a study of 243 pregnant teenagers and found that family support had a significant direct effect on birth weight adjusted for length of gestation.

This support for main effects notwithstanding, theories have tended to emphasize the buffering model in which social support is protective primarily or solely for those in stressful circumstances (Norbeck & Anderson, 1989b; Norbeck & Tilden, 1983; Nuckolls et al., 1972). Nuckolls et al. (1972), for example, showed that life stress and social support interacted such that among high stress women, high social support was associated with fewer complications but there was no effect of social support in low stress women. The stress buffering process conceivably operates either during the appraisal process to reduce stress appraisals or, for events appraised as highly stressful, at the time of coping.

The absence of much comparison of the two models in prenatal social support research (i.e., main effect and buffering or interactions with stress) is due to two trends in this literature. First, comparisons of effects is hampered by the fact that studies testing for main effects of social support do not usually measure stress and test for buffering. Second, different conceptualizations of support make comparisons of findings across studies difficult. Although no clear patterns can be seen in the pregnancy literature, the social support literature on other health populations suggests that network measures

of support tend to have direct effects whereas measures of emotional support tend to have buffering effects (Pierce, I. G. Sarason, & B. R. Sarason, 1996). This may be worth following up in pregnancy research.

In terms of mediators, there are many ways in which social support could promote positive pregnancy outcomes other than by buffering stress, including promoting adaptive health behaviors. To date, a few pregnancy studies have explored the relation between social support and health behaviors such as drinking, smoking, and substance use (Aaronson, 1989; Albrecht & Rankin, 1989; Ramsey, Abell, & Baker, 1986). For example, Giblin et al. (1990) in a sample of African American pregnant women and MacDonald et al. (1992) in a sample of British pregnant women, both found that social support reduced the incidence of maladaptive health behaviors such as smoking and alcohol consumption. Given the links between these maladaptive health behaviors and negative pregnancy outcomes (Archie, 1992), health behaviors appear to be important mediators of the effects of social support in pregnancy on outcomes.

The fact remains that social support in general benefits some people, in some situations, and under some conditions (Coyne & D. A. Smith, 1991; Dakof & Taylor, 1990; Sandler & Lakey, 1982), and the key for health psychologists is to identify which people do best under what conditions. The research on the effects of a companion during labor provide a good example of this issue. The presence of a supportive woman, or *doula*, during childbirth has been associated with significantly shorter labor and fewer complications during delivery (Kennel et al., 1991; Sosa et al., 1980). However, studies investigating the effects of the presence of the baby's father during delivery have been ambiguous (e.g., Henneborn & Cogan, 1975). Studies designed to pinpoint moderators of the effects of support in labor have revealed that the personality of the women in labor plays a major part in their distress during labor and delivery; the presence of the baby's father benefited only those women high in anxiety and who were more dependent (Keinan, Ezer, & Feigin, 1992; Keinan & Hobfoll, 1989). The inclusion of measures of constructs such as this can help to formulate new directions in pregnancy research.

CONCLUSIONS

The scope of this chapter is quite broad, but a unifying focus is the role of stress as an independent risk factor for adverse outcomes of pregnancy. In order to scientifically study this issue properly, there needs to be an appreciation of the multiple levels of analysis involved as both antecedents and consequences of stress, and also an understanding of the outcomes of interest and their etiology. Having covered these issues, albeit briefly, research on the pattern of emotions in pregnancy was reviewed. Such research is of descriptive use in and of itself, and it also sets the stage for considering the links between stress and birth outcomes, particularly because the predictive components of stress appear to be emotion-based. Research on stress and outcomes was reviewed. It was suggested that anxiety, and pregnancy anxiety, in particular may be the most risk-posing components of stress for preterm de-

livery. Mechanisms, both physiological and behavioral, were elaborated in light of current research findings. Two possible moderators of stress, coping behavior, and social support were covered in separate sections. Research on coping behavior in pregnancy is in its infancy, but promising new directions are emerging. Research on social support in pregnancy is much more developed, although support appears to operate more as a resource (with main effects on outcomes) than as a stress buffer (i.e., moderator). Understanding potential moderators is an important step in eventually intervening to improve maternal, fetal, and infant outcomes.

What are some promising directions for future research? Regarding stress as an independent risk factor for adverse outcomes of pregnancy (especially preterm delivery), the following directions merit attention: (a) What types of stress are most potent? A comparison of chronic and acute stressors is warranted and may be informed in part by emerging research on chronic stress and allostatic load (McEwen & Stellar, 1993) in which biopsychological mechanisms are proposed whereby chronic stress may lead to poor health outcomes. (b) To what extent is stress exposure, versus emotional responses to stress, responsible for risk in pregnancy? This is an open issue with important implications for understanding mechanisms. Some combination of the two may prove to be most detrimental. (c) When in pregnancy is stress most potent? The timing of stress in pregnancy is a key issue, and it is not yet known whether there are vulnerable periods for risk of preterm delivery or low birth weight, and it is not known whether a particular duration of exposure to stress is necessary for adverse effects (i.e., thresholds exist). If vulnerable periods or threshold levels of exposure exist, these might be different for various outcomes (e.g., preterm delivery, low birth weight). Understanding the precise timing of stress in predicting specific adverse effects is essential to planning any intervention efforts.

With respect to emotions in pregnancy, future research might focus on the following issues: the nature of the emotions studied; the confounding of emotion measures with somatic complaints common in pregnancy, and the distinction between mean levels of emotion and individual variation.

Few studies have distinguished traditional emotions from pregnancy-specific worries, concerns, or fears. Yet there is considerable theoretical and empirical value in measuring pregnancy-specific concerns (Elliott et al., 1983; Glazer, 1980; Levin, 1991; Rini et al., 1999; Roesch, Dunkel-Schetter, & Hobel, 1998; Wadhwa et al., 1993; Yali & Lobel, 1999). Women may experience a number of specific concerns about their pregnancies and babies, and these tend to change in content and strength across pregnancy. Better understanding of these contextually based emotions and their associations with traditional emotional states, such as anxiety, is an important issue for future research.

Regarding measures of emotion, many of the standard measures typically used contain somatic indicators of negative emotion, including fatigue, changes in appetite, decreased sexual interest, or sleep disturbance, which can produce inflated negative emotion scores because women usually experience these symptoms in the course of a normal pregnancy (cf.

Kaplan, 1986). Some researchers have resolved this problem by removing items with somatic content from measures such as the Beck Depression Inventory (e.g., Chapman, Hobfoll, & Ritter, 1997; O'Hara, Zekoski, Philipps, & Wright, 1990), but a number of studies examining prenatal mood have not used corrected measures. The validity of standard depression measures in pregnancy and postpartum is unknown and should be addressed in future research.

The distinction between mean differences in emotion and individual variation over time in pregnancy is one of the most important issues raised by this body of research. As Elliott et al.'s (1983) work demonstrates, a sample of women might not differ in emotion on average—either over time or relative to a comparison group—although individual members of the sample might experience substantial changes in their emotions over the course of pregnancy, or might experience levels of emotion that are different from the comparison group. For this reason, it is useful for researchers to provide more detailed information than the standard tests of between-group differences. Ipsative approaches have rarely been used and may be quite useful in targeting women at risk. More research designs with repeated assessment of emotions and stress in pregnancy are also needed.

Regarding social support, an important goal for further study is to develop a better understanding of when support is beneficial and when it is not, and to specify the conditions under which each holds true. One direction is to consider various sociocultural milieus in which women experience pregnancy. In studies of predominantly Hispanic and African American pregnant women, some important differences have been observed between groups in support, as well as attitudes and behaviors in pregnancy (Sagrestano et al., in press; Zambrana et al., 1997; Zambrana, Dunkel-Schetter, Collins, & Scrimshaw, 1999). Furthermore, there is a relative dearth of research concerning support processes in pregnancy in Asian families. Like Hispanics, Asian Americans (Chinese, Japanese, Indian, Korean among others) are also known for their collectivist values and strong family orientations (Gaines, 1997; Gurung & Mehta, 1998). For example, in Indian families it is not uncommon for the pregnant woman's mother-in-law, rather than her mother, to move into her son's home to help her daughter-in-law during gestation and to help take care of the baby after it is born. To what extent does this attenuate the stressfulness of pregnancy for Indian American women? Asians and Asian Americans of various origin raise new categories of empirical questions for further research. Moreover, the broader domain of sociocultural influences on stress processes in pregnancy is an exciting opportunity for interdisciplinary research.

Another issue in the support arena is the need to gain more than simply the pregnant woman's perspective on prenatal support conditions. By studying multiple perspectives, including that of the baby's father, researchers may gain a multifaceted and more accurate view of support relationships than by assessing the maternal perspective alone. This direction raises new questions: Do the pregnant woman and her partner agree about how much support he provides? What characteristics of fathers enable them to be better prenatal support providers? Do

individual differences such as the mother's level of mastery, or relationship characteristics such as marital satisfaction, influence how much support is given by the baby's father during pregnancy? These questions can be optimally answered by involving both parents in research designs.

There are two further research directions that should be mentioned. Interestingly, they concern the generation before, and the generation after the pregnant mothers that are being studied today. With reference to earlier generations, newer research on intergenerational risk factors has developed in conjunction with research on ethnicity and socioeconomic status in pregnancy. For example, a recent study by Coutinho, David, and J. W. Collins (1997) examined a transgenerational data set of Illinois vital records to test whether parental birth weight was related to infant birth weight among African Americans and Whites born between 1989 and 1991. The authors found that parental birth weights were important risk factors for low birth weight (LBW) in both ethnic groups. However, the effects were particularly dramatic in African Americans for whom the rate of LBW among those born to LBW mothers was 17.9% compared to 10.8% among African Americans born of non-LBW mothers (rates for Whites were 8.5 and 4.8, respectively). Similarly, a Dutch study by Lumey and Stein (1997) of women born between 1944 and 1946 during a Dutch famine found evidence of long-term biologic effects of maternal intrauterine undernutrition, extending even into the next generation (Lumey & Stein, 1997). Emanuel (1997) highlighted some of the research directions suggested by these remarkable findings. A similar set of results is emerging with respect to preterm delivery. Porter, Fraser, Hunter, Ward, and Varner (1997) found that risk of preterm birth was higher among mothers who were themselves born before 37 weeks gestation. With respect to the focus of this chapter, these intergenerational effects suggest that a number of socioeconomic, cultural, and psychosocial factors may have long-term influences on maternal health and on the health of subsequent generations. Health psychology has much to bring to an understanding of these provocative and important issues.

A second future direction concerns the offspring of the pregnant women studied today. Work suggests that prenatal experience may have important consequences for the length of gestation and the growth of the fetus. Little research, however, has extended the paradigm to look at the influence of prenatal factors on infant health and well-being during infancy, childhood, adolescence, or adulthood. Hypotheses can be derived from current research concerning the consequences of prenatal stress for health and well-being of the offspring across the life span (Wadhwa, 1998). An evolving view is that the blueprint for brain development is not contained in genetic makeup alone, but is the result of a dynamic process involving interactions between genes and environment. The prenatal environment is the earliest setting in which such interactions may occur. Researchers working with animal and human models of pregnancy are discovering in numerous ways that the influence of the prenatal environment on brain and nervous system development may have far-reaching consequences for the cognitive and emotional functioning of the offspring later in life.

These possibilities open up a new horizon for researchers interested in biopsychosocial models of pregnancy.

In conclusion, the study of stress in pregnancy and its many ramifications is a large research arena with numerous exciting frontiers. Biopsychosocial approaches to the study of pregnancy and birth are accepted across disciplines, and interdisciplinary research collaboration is essential. Health psychology is in a unique position to contribute to this endeavor in the next millennium.

ACKNOWLEDGMENTS

This chapter draws from the results of Christine Dunkel-Schetter's collaborative research with Curt Sandman, Ph.D., Calvin Hobel, M.D., and Pathik Wadhwa, Ph.D., M.D. This program of research has been supported by several joint grants (NIH R01 HD28413, NIH R01 HD28202, NIH R01 HD29553). During the development of this chapter, R. Gurung was supported as a postdoctoral fellow by the UCLA Training Grant in Health Psychology (MH 15750), P. Wadhwa was supported in part by NIH grant R29 HD33506, and M. Lobel was supported in part by NIH grant R29 NR03443. The authors would like to thank Christine Rini for her valuable comments on this chapter and Sarah Roper for her assistance in the preparation of the chapter. Dunkel-Schetter would also like to acknowledge the contributions of Nancy Collins, Ph.D., Pam Feldman, Ph.D., Susan Scrimshaw, Ph.D., Grace Woo, Ph.D., and Ruth Zambrana, Ph.D.

Women's Health Promotion

Barbara K. Rimer
National Cancer Institute, Rockville, MD

Colleen M. McBride
Duke University Medical Center

Carolyn Crump
University of North Carolina

Health promotion has been defined by Green and Kreuter (1990) as the combination of educational and environmental supports for actions and conditions of living conducive to health. Within this broad definition, health promotion includes such diverse health promoting behaviors as appropriate nutrition, smoking prevention and cessation, exercise, stress management, and screening for prevalent diseases (e.g., cancer). Because women can expect to live longer than ever before, their lifelong health habits will become more important. Fletcher (1995) observed, "Many of the deadliest conditions for women are stopped not only by knowing more molecular medicine but knowing better how to help our patients to shed unhealthy habits and adopt healthy ones."

It is important that health promotion for women not be seen as a set of isolated recommendations and activities but within an integrated framework (Rimer, 1995b) that addresses the potential synergistic effect of both good and bad health habits (Lane, Macera, Croft, & Meyer, 1996). As an example, quitting smoking reduces the risk of three major killers of women—cancer, heart disease, and stroke—as well as other conditions and diseases like the complications of diabetes. Decreasing dietary fat may not only decrease the risk of heart disease but also breast and colon cancers. And regular exercise may reduce not only the risk of heart disease and osteoporosis but also of breast and colon cancers. Health habits interact in other ways as well. For example, there is evidence that smokers may be less likely to get mammograms and regu-

lar exercise (Orleans, Rimer, Salmon, & Kozlowski, 1990; Rimer et al., 1990; McBride, Curry, Taplin, Anderman, & Grothaus, 1993), and women who practice more health promoting behaviors report a more favorable health status (Lane et al., 1996). Neither health behaviors nor their consequences exist in a vacuum.

An assessment of women's health habits and risk factors indicates that there is much room for improvement. Currently, nearly 25% (more than 22 million women) of women are current cigarette smokers, 20% have cholesterol of 240 mg/dl or greater, 20% have high blood pressure, and 35% are obese. Moreover, 73% of adult women do not report regular participation in aerobic exercise, and minority women and those with lower levels of education are the most likely to be sedentary. Most women still are not getting regular mammograms or colorectal cancer screening. Clearly, the need for effective women's health promotion has never been greater.

Solutions and programs must be appropriate for women, that is, reflect the psychological, social, economic and political realities of women's lives. Ruzek and Hill (1986) stressed the need for positive health information reflective of women's own experience of health and illness. Consequently, effective health promotion strategies must be drawn from a continuum of interventions that can be applied not only at the individual, family, and organizational levels but also at the community and policy levels (Chesney & Ozer, 1995). Interventions also must reflect life-span needs and concerns unique to women. More-

over, the health promotion agenda of younger women will be different from those who are peri- or postmenopausal.

This chapter focuses on the proven, accepted dimensions of health promotion, including diet, smoking, exercise, and cancer screening. Each section includes a brief epidemiologic overview summarizing relevant prevalence data and the rationale for the recommended behavior as well as a summary of the continuum of relevant intervention research targeted to women or that has special implications for women. The goal is to review briefly not only what health promoting behaviors are recommended for women but also to summarize the evidence for effective interventions that promote healthy behaviors for women. It becomes evident that far too little is known about how to influence health promotion, especially among certain categories of women (e.g., ethnic minorities and older women). Often, studies that include both men and women lack the power to reach firm conclusions about gender-specific efficacy. Moreover, unless programs are designed with women's needs as a foundation, they may not succeed. As Chesney and Ozer (1995) cautioned, women are not a homogeneous group. Strategies for health promotion should, but rarely do reflect the socioeconomic status (SES), racial, cultural, and age diversity of women.

The first half of this chapter examines health behavior changes (including reducing dietary fat, smoking cessation, and increasing physical activity) that are essential to promoting women's health. The second half of the chapter examines screening behavior in the areas of breast, cervical, and colon cancers.

DIET

Dietary Risk Factors for Women

Diet is an important risk factor in the development of cardiovascular disease and cancer. Consistent evidence suggests that a diet high in fat is positively associated with hypercholesterolemia, which is a key risk factor for heart disease. In particular, diets high in saturated fats increase levels of low density lipoproteins (LDLs) that appear to be most important in the development of atherosclerosis in both women and men (Rich-Edwards, Manson, Hennekens, & Buring, 1995). Women with blood cholesterol levels over 265 mg/dl have a two times greater risk of developing heart disease compared to those with levels under 200 mg/dl (Packard, 1985). Although cholesterol levels among Americans have been declining, 20% of adult women have cholesterol levels over 240. Moreover, during menopause women experience a steep increase in their average cholesterol level due in large part to their decreasing estrogen levels (Busch, Fried, & Barrett-Connor, 1988).

Dietary factors have a somewhat more complex association with cancer risk (Doll, 1996; Willett, 1995). Two large epidemiologic studies of women, the Nurses Health Study conducted with over 120,000 female nurses and the Iowa Women's Study conducted with over 30,000 women, found that consumption of red and processed meat products (Willett

et al., 1995) was associated with as much as a twofold increase in women's risk of colon cancer. However, neither of these large studies of women or five other studies have found a relation between total dietary fat or saturated fat consumption and increased risk of breast cancer (Hunter et al., 1996). In contrast, the evidence of a protective effect of fruit and vegetable consumption is consistent and overwhelming, with more than 200 studies indicating significantly reduced risk of cancers of the breast, cervix, and colon among women (Block, Patterson, & Subar, 1992; Doll, 1996; Willett, 1995). Evidence for the protective role of fiber independent from that of fruits and vegetables is as yet inconclusive, with case control studies indicating stronger effects than prospective studies (Willett, 1995). Thus, reduction of dietary fat and increased consumption of fruits and vegetables are essential components of health promotion programs for women.

Diet and Overweight

Diet has an indirect effect on women's health through its influence on body weight. Eating a diet high in fat is positively associated with overweight and obesity (Romieu et al., 1988). Lifetime weight gain of as little as 5 to 8 kg after age 18 increases women's risk for coronary artery disease (Willett et al., 1995). It is encouraging that even modest weight loss, on the order of 10% of initial body weight, can improve blood pressure, lipid profiles, glucose, and insulin (Wing & Jeffery, 1995; Wood, Stefanick, Williams, & Haskell, 1991). Approximately, 35% of American women are overweight, defined as 20% above their ideal weight (Kuczmarski, Flegal, Campbell, & Johnson, 1994). Although the prevalence of overweight has increased for the American population as a whole (Kuczmarski et al., 1994), it is consistently highest among women, particularly African American and Hispanic women, and those with low socioeconomic status (Jeffery & French, 1996; Kuczmarski et al., 1994). Data from the most recent National Health and Nutrition Examination Survey (NHANES III) indicate that 33% of White women, 49% of African American women, and 48% of Mexican American women are obese, that is, they are 30% or more above ideal body weight (Manson & VanItallie, 1996). Being obese substantially increases women's risk of hypertension, hyperlipidemia, Type II diabetes, and coronary artery disease, as well as postmenopausal breast cancer, cancers of the endometrium, and gall bladder (Manson & VanItallie, 1996).

Consistent evidence demonstrates that the average American's weight increases steadily with age (Manson & VanItallie, 1996). For women, pregnancy has been suggested as an important determinant of this lifetime weight gain (Boardley, Sargent, Coker, Hussey, & Sharpe, 1995; D. E. Smith et al., 1994). In a large multisite coronary risk factor study of young adults, women who became pregnant experienced greater weight gains (2-3 kg) over a 5-year follow-up than women who remained nulliparous. African American women gained almost twice as much weight as did White women (D. E. Smith et al., 1994). Interventions that encourage women to maintain an optimal weight over the life span are a necessary component of health promotion efforts for women.

Dietary Practices

The average American consumes a diet consisting of approximately 36% of calories from fat (U.S. Department of Health and Human Services, USDHHS, 1991). Current recommendations are that dietary fat should be limited to 30% of total calories and that individuals should consume from 20 to 30 grams of fiber per day (USDHHS, 1991). Data from the Behavioral Risk Factor Survey indicate that fewer than one quarter of American women reported behaviors that comply with these national dietary guidelines (Serdula et al., 1995). For example, of the almost 14,000 women surveyed, about half reported eating only one to two servings of fruits and vegetables per day in contrast to the five recommended servings. Rates of consumption are even lower among African American (Serdula et al., 1995) and Hispanic women (Subar et al., 1995). Although many women are not in full compliance with current dietary recommendations, three quarters of the women who were surveyed in 114 worksites reported they were either preparing to, were active in or were maintaining dietary changes of decreased fat and increased fiber (Glanz et al., 1994). However, low income and less educated women were consistently less inclined to be considering or to have adopted healthy dietary practices than those with higher socioeconomic status (Balcazar, Castro, & Krull, 1995; Glanz et al., 1994; Jeffery & French, 1996).

Cultural factors have a complex influence on women's likelihood of adhering to dietary guidelines (Balcazar et al., 1995). Two studies have indicated that less acculturated Mexican American women were less likely to avoid foods high in fat and more likely to consume high calorie foods than highly acculturated women. However, these same less acculturated women consumed more fiber than highly acculturated women. The health promoting and health compromising components of different ethnic diets must be considered in health promotion activities.

It has been widely argued that for women, dietary practices are deeply enmeshed with their concerns about body weight (Brownell, 1991). Studies of adolescents in particular indicate that girls believe more strongly than boys in the benefits of a healthy diet for weight control and improving their appearance (Gracey, Stanley, Burke, Corti, & Beilin, 1996). Often, this translates into unhealthy dieting practices that in their most extreme form can lead to eating disorders, including anorexia and bulimia. More prevalent, however, is women's reported dissatisfaction with their weight (de Castro & Goldstein, 1995; Sobal, Nicolopoulos, & Lee, 1995), ongoing restriction of calorie intake (de Castro & Goldstein, 1995), and active dieting (Horm & Anderson, 1993) as compared to men. African American women, although heavier on average than women of other racial ethnic groups, do not appear to have the same level of weight concerns or a high prevalence of dieting (Horm & Anderson, 1993). Thus, the presence or absence of weight concerns, other personal motivators, as well as the cultural and socioeconomic environment, are important considerations in effecting dietary behavior change among women.

Barriers and Facilitators to Dietary Change

Factors that influence dietary change can be categorized as those that predispose and enable the initial adoption of behavior change and those that reinforce or maintain these changes (Green & Kreuter, 1990). Knowledge of the fat and fiber content of foods, beliefs in a diet-disease connection, being motivated, and perceiving benefits to dietary change all have been noted as factors that predispose individuals to reduce their dietary fat (Bowen, Fries, & Hopp, 1994; Glanz et al., 1994; Gracey et al., 1996; Kristal et al., 1995). Enabling factors, such as access to low fat food choices in community, school, and worksite settings, perceived norms, and social support favoring low fat diets have also been positively associated with reductions in dietary fat (Bowen et al., 1994; Kristal et al., 1995). Comparison of the relative contribution of these predisposing and enabling factors have shown that predisposing factors are better predictors of dietary intentions, self-efficacy, and likelihood of reducing dietary fat than are enabling factors (Kristal et al., 1995). Others have shown synergism between these factors with women's motivation to make dietary changes particularly enhanced if they have support for such changes from their friends (Kelsey et al., 1996).

In the longer term, factors such as feelings of wellness and a development of a distaste for fat that occur subsequent to dietary fat reduction have been positively associated with maintenance of fat reduction (Urban, White, Anderson, Curry, & Kristal, 1992). In contrast, feelings of deprivation with respect to food choices are important deterrents to maintenance. Moreover, women who have made dietary changes also cite increased time for meal planning, preparation, and costs of low fat menus as additional deterrents to long-term maintenance of dietary changes (Urban et al., 1992). Thus, interventions that enhance motivation, as well as the perceptions and experienced benefits of healthy dietary practices, have the greatest likelihood of success. Moreover, recommended dietary changes must be incorporable into women's daily lives, be within their economic means, and include foods that are accessible and palatable to multiethnic and low income communities.

Interventions to Promote Healthy Diets

Intensive health promotion interventions that target the individual for dietary change have had some success. The Women's Health Trial, a multicenter feasibility study to lower dietary fat among women, demonstrated that relatively dramatic reductions in dietary fat can be achieved among highly motivated women (Insull et al., 1990). A sample of 300 women from age 45 to 69 was randomized either to a control or intervention group. Women assigned to the intervention attended small group sessions over a period of a year. Sessions were led by a nutritionist who instructed women how to choose low fat foods, modify recipes, self-monitor fat intake, and develop individualized low fat eating plans. Women in the intervention group experienced a mean reduction in dietary fat from 39% at baseline to 21% at the 6-month follow-up. In contrast, women in the comparison group experienced a nonsignificant reduc-

tion in fat from 39% to 38%. Significant treatment effects were maintained over 24 months of follow-up.

Women's influence over the dietary practices of their families is also evidenced by results of the Women's Health Trial. Husbands of the women who participated in the trial experienced reductions in dietary fat that were comparable to those of their wives (White et al., 1991). Moreover, because women place more value on, and are at more advanced stages of readiness to adopt healthy eating patterns than men (M. K. Campbell et al., 1994; Curry, Kristal, & Bowen, 1992; Glanz et al., 1994; Gracey et al., 1996), they are likely to be the most receptive to dietary interventions. Family-focused dietary interventions that engage both children and their parents, primarily mothers, to participate in home-based nutrition education activities and increase physical activity also have had success (Crockett, 1987). These family-based interventions represent an important area for further research.

Tailored health education materials that provide the optimal characteristics of intensive and interactive interventions, but are relatively inexpensive and easily disseminable, hold promise for application to dietary interventions. Using standard questionnaires and computer algorithms, the content of written materials can be tailored to the factors most salient to a woman's dietary practices. Using these techniques, M. K. Campbell and colleagues (1994) evaluated a one-time mailed nutrition information packet with a sample of predominantly female family practice patients. Materials included in the nutrition information packet were tailored to the participant's stage of readiness, dietary intake, motivation, self-efficacy, and barriers to dietary changes. Those who received the tailored packet were significantly more likely to have used the materials, and reported significantly greater decreases in dietary fat intake than those who received nontailored and control materials (M. K. Campbell et al., 1994). In contrast, other targeted approaches that have not customized materials to psychosocial variables have had less success in influencing dietary fat reductions (Bowen et al., 1994).

Larger scale environmental and health marketing interventions that are characteristically less intensive but have broader reach have also been evaluated. Worksite-based interventions that encourage employees to implement changes in the worksite environment, such as increasing availability of low fat food items in vending machines, have had limited success (Glasgow, Terborg, Hollis, Severson, & Boles, 1995; Sorenson et al., 1998). However, initial results of the Working Well worksite trial have indicated a nonsignificant downward trend in dietary fat consumption and significant increases in fruit and vegetable consumption among intervention participants compared to those in the control worksites (Sorenson et al., 1996). Motivating employees to participate in intervention activities and to support each other's efforts to make dietary changes has been difficult (Glasgow et al., 1995). Sorenson and colleagues (1998) have extended the traditional worksite model to include a family involvement component. This intervention is being tested in 22 community health centers that employ a large proportion of low income women who live in the surrounding community. The family component includes a learn-at-home program, annual family newsletters,

and family festivals to encourage a home environment that is supportive of worker's attempts to change their eating patterns. Preliminary results indicate that consumption of fruits and vegetables was positively associated with household support. This worksite project and eight other interventions to increase fruit and vegetable consumption are part of the national Five A Day program that is being funded by the National Cancer Institute (Havas et al., 1994). The program objective is to promote a simple, positive message: Eat five or more servings of fruit and vegetables daily as part of a low fat, high fiber diet (Heimendinger, Van Duyn, Chapelsky, Foerster, & Stables, 1996). The Five A Day program is being conducted in partnership with the food industry, including supermarkets, restaurants, food merchandisers, and suppliers. The retailers and their suppliers participate by displaying the Five A Day logo on eligible products, incorporating the program message in print and broadcast advertisements, and sponsoring taste tests and supermarket tours. The impact of these efforts is currently being evaluated.

Diet Summary

Adoption of healthy diets is a central tenet of health promotion for women. The combination of individual, family-based, and environmental interventions to promote decreased dietary fat, and increased fruit, vegetable, and fiber consumption, has shown promise. However, personal motivators and stage of readiness to adopt dietary changes, as well as the sociocultural contexts of minority and low income women must be considered in the design of dietary interventions. Recent advances in health communication strategies that enable tailoring message content to the needs of specific groups may help to expand the reach and appropriateness of dietary interventions to important demographic subgroups of women.

CIGARETTE SMOKING

Smoking is the leading preventable cause of death for women. It is estimated that 140,000 women die annually of smoking-related causes (Blumenthal, 1996). About 80% of female lung cancer and a comparable proportion of heart disease in the United States is attributable to cigarette smoking (Rich-Edwards et al., 1995; Shopland & Burns, 1993). Disturbing increases in rates of initiation among adolescent girls (USDHHS, 1994) and relatively low rates of cessation among adult women smokers, particularly heavy smokers, make understanding smoking behavior and identifying interventions that are most appropriate for women an important health promotion priority.

Health Effects of Smoking for Women

Smoking significantly increases women's risk of heart disease, stroke, chronic obstructive pulmonary disease, and cancers of the lung, bladder, nasopharynx, and esophagus (Rich-Edwards et al., 1995). Recent evidence suggests that dose for dose, women may be more susceptible to tobacco carcinogens than men (Zang & Wynder, 1996). Moreover, specific to

women are the legion of negative reproductive health-related effects of smoking that include: infertility, which is measured as delay in time to conception (Daling, Weiss, Spadoni, Moore, & Voigt, 1987); ectopic pregnancy (Stergachis, Scholes, Daling, Weiss, & Chu, 1991); spontaneous abortion (USDHHS, 1989); pelvic inflammatory disease (Marchbanks, Lee, & Peterson, 1990); amenorrhea (Pettersson, Fries, & Nillius, 1973); earlier onset of menopause (Willett et al., 1983), which is a risk factor for osteoporotic fractures; as well as cancers of the endometrium and uterus (USDHHS, 1990). Moreover, smoking and use of oral contraceptives significantly increase the risk of myocardial infarctions among women over age 35 (USDHHS, 1990). There is also growing epidemiological evidence of the association between smoking and the development of cervical cancer. A review of 30 studies noted positive associations generally ranging from a two- to fourfold increase in risk (Winkelstein, 1990). Evidence of measurable levels of nicotine and cotinine in the cervical fluids of women smokers supports the biological plausibility of smoking as a risk factor for cervical cancer (Hellberg, Nilsson, Haley, Hoffman, & Wynder, 1988).

Physiological Effects of Nicotine on Women

At equivalent levels of nicotine intake, women metabolize nicotine more slowly than men (Fant, Everson, Dayton, Pickworth, & Henningfield, 1996) and therefore experience higher sustained blood levels of nicotine. This slower metabolism is thought to enhance the reinforcing properties of smoking (Fant et al., 1996). Moreover, evidence suggests that there are also racial differences in nicotine metabolism (Wagenknecht et al., 1990), which may further increase the dependence properties of nicotine for minority women. Clinical evidence of greater perceptions of muscle tension (Epstein, Dickson, McKenzie, Russell, 1984) and reaction time (Knott, 1991) that have been associated with nicotine deprivation in women compared to men suggest that women may derive greater physiologic benefits from nicotine. Although there appear to be no gender differences in the severity of symptoms experienced during nicotine withdrawal, it has been suggested that women experience withdrawal differently than men (Fant et al., 1996), with women reporting more depressive affect and cigarette craving than men (Svikis, Hatsukami, Hughes, Carroll, & Pickens, 1986).

There is consistent evidence that nicotine increases the metabolism of smokers as evidenced in smokers weighing less on average than nonsmokers (Perkins, 1994). The majority of smokers who quit gain from 5 to 10 pounds, with up to 15% of quitters gaining 25 or more pounds (Kawachi, Trois, Rotnitzky, Coakley, & Colditz, 1996; Williamson et al., 1991). The stronger metabolic effects of nicotine in women may place them at greater risk of gaining weight and cause them to gain more weight than their male counterparts (Perkins, 1994; Williamson et al., 1991). Moreover, a consistent dose-response relation has been observed with heavier smokers gaining more weight with cessation than lighter smokers (Kawachi et al., 1996; Williamson et al., 1991).

Women who smoked 15 or more cigarettes per day were four times more likely than women who smoked less than 15 cigarettes to gain 13 kilograms or more after quitting (Williamson et al., 1991).

Patterns of Smoking Among Women

Despite widespread public awareness of the multiple health risks associated with smoking, one out of every four girls under age 18 is a smoker and more than 25 million American women smoke (Blumenthal, 1996). Whereas the last two decades have seen an overall decrease in smoking prevalence, the rate of smoking has declined much more slowly among women than among men (Husten, Chrismon, & Reddy, 1996). If current trends continue, smoking rates of women will overtake those of men by the year 2000. Smoking rates are highest, approaching 30%, among women of reproductive age (18–44 years; Husten et al., 1996). Rates of smoking are particularly high among young White women with a high school education or less and low income. Cessation rates are lower among African American women (30% have quit) compared to White women (43% have quit; Stotts, Glynn, & Baquet, 1991). Minority and young women who have low rates of self-initiated cessation are also underrepresented in formal smoking cessation programs. A greater proportion of women than men are precontemplators, that is, not considering quitting smoking within 6 months and have lower self-confidence that they could quit if they were to try (Schorling, 1995; Tessaro et al., 1997). However, the debate continues regarding whether or not women are less likely to be successful at quitting when they try than men, with some evidence suggesting that women are more likely than men to relapse (Nides et al., 1995) and others indicating no gender differences (Garvey, Bliss, Hitchcock, Heinold, & Rosner, 1992; Hill et al., 1994; Husten et al., 1996). Regardless, rates of relapse are very high, both among self-quitters (Garvey et al., 1994) and those who participate in formal cessation programs (Pirie et al., 1992).

Barriers to Smoking Cessation For Women

Weight concerns (i.e., a strong desire to stay thin and fear of weight gain) have been suggested to be key factors that influence women to take up smoking (Camp, Klesges, & Relyea, 1993; French, Perry, Leon, & Fulkerson, 1994) and keep them from quitting (Garvey et al., 1994; Klesges et al., 1988). Lack of awareness of the health effects of smoking has been indicated as an important barrier to cessation among African American women (Manfredi, Lacey, Warnecke, & Buis, 1992; Schorling, 1995). Fear of irritability and depression, loss of an important pleasure, and perceiving smoking to be beneficial for stress management also have been widely reported as barriers to cessation among both White (Sorensen & Pechacek, 1987) and minority women (Ahmed, D. R. Brown, Gary, & Saadatmand, 1994; Manfredi et al., 1992; Shervington, 1994; Tessaro et al., 1997). This is particularly true among low income women who report few available resources for dealing with the life stresses associated with eco-

conomic disadvantage (Manfredi et al., 1992; Shervington, 1994). Living with other smokers or being married to a smoker is an important barrier to cessation for women (Garvey et al., 1992; Murray, Johnston, Dolce, Lee, & O'Hara, 1995). Moreover, the lack of a strong social network and living in a low income environment characterized by high rates of smoking and weak norms supporting smoking cessation reduce African American women's likelihood of and success at cessation (Manfredi et al., 1992). Confidence in ability to quit (Gritz, Berman, Bastani, & Wu, 1992; Hill et al., 1994), intrinsic motivators such as health concerns and desire for self-control (Curry, Wagner, & Grothaus, 1991), and social support from family, friends, coworkers, and spouses regardless of their smoking status (Cohen & Lichtenstein, 1990; Hill et al., 1994), have been positively associated with success at quitting.

Smoking Cessation Interventions for Women

Interventions specifically designed for women smokers have attempted to address the role of weight concerns as an inhibitor to cessation and long-term maintenance. A randomized trial tested nicotine gum or a behavioral weight control program each alone, or in combination as adjuncts to an intensive group cessation intervention for weight concerned women smokers (Pirie et al., 1992). The intervention integrated accepted cognitive and behavioral coping strategies for quitting smoking, changing eating behaviors, and developing a walking program. The weight gain prevention intervention was highly attractive to women smokers. Nicotine replacement reduced postcessation withdrawal symptoms (Hatsukami, McBride, Pirie, Hellersteadt, & Lando, 1991) and initially decreased postcessation weight gain (Pirie et al., 1992). However, the tested adjunctive components failed to increase cessation rates or long-term weight gain. Evaluation of a similar but more intensive intervention that included as part of the most intensive component an individualized aerobic exercise plan not only failed to increase cessation rates but had higher rates of relapse than the control condition (Hall, Tunstall, Vila, & Duffy, 1992).

Results of these two studies have led some to conclude that interventions requiring simultaneous changes in diet, smoking, and exercise may overburden individuals who are trying to quit smoking. Further, it is suggested that change in one behavior may undermine success in another behavior change. For example, calorie restriction may enhance the reinforcing properties of nicotine, thus, making cessation more difficult (Hall et al., 1992; Perkins, 1994). Recent evidence that women's weight gain is relatively small in the month after quitting (McBride, French, Pirie, & Jeffery, 1996) suggests that weight gain prevention adjuncts do not necessarily need to be provided coincident with cessation interventions in order to be effective. Moreover, weight concerns increase steadily during the 12 months after cessation (McBride et al., 1996). Thus, as has been suggested elsewhere (Gritz et al., 1992), weight-related adjuncts could be provided in the months after cessation.

Interventions designed to evaluate the benefit of physical activity for smoking cessation among women have also had mixed results. An earlier study found no advantage in decreasing relapse rates and actually increased reports of tension and anxiety among women quitters who participated in nine activity sessions that emphasized a walking/jogging activity plan as compared to two comparison groups (Russell, Epstein, Johnston, Block, & Blair, 1988). However, adherence to the intervention as indicated by posttreatment fitness levels appeared to be low. A more intensive intervention that required women to participate in multiple weekly sessions of aerobic activity for 3 weeks prior to their quit date reported more positive findings (B. H. Marcus, Albrect, et al., 1995). Although cessation rates were higher in the exercise group, achieving compliance with a comparable intensive intervention may be difficult in real-world settings given the results of the earlier trial (Russell et al., 1988). Recent data based on over 9,300 women smokers in the Nurses Health Study indicate that moderate levels of physical activity minimize postcessation weight gain for women (Kawachi et al., 1996). Thus, evaluations of interventions that promote less rigorous exercise regimens are needed.

In response to decreasing participation rates in group cessation programs and smokers' preferences for self-guided cessation interventions, several innovative randomized trials have evaluated minimal self-help cessation interventions provided in an outreach format to "nonvolunteer" smokers. Typically, these interventions have included some combination of written self-help guides (Gritz et al., 1992; Curry, McBride, Grothaus, Louie, & Wagner, 1995), personalized feedback (Curry et al., 1995), and outreach telephone counseling (Curry et al. 1995). Although these outreach approaches have been well-received by smokers, they have not resulted in uniformly higher quit rates than those observed in untreated control groups or than national secular trends. However, of the minimal strategies tested, telephone counseling has shown the greatest potential particularly among smokers who, prior to being called, were not thinking about quitting (Curry et al., 1995). It has been argued that the effectiveness of these proactive approaches might be enhanced if they were provided within the context of a meaningful health event or clinical context (Curry et al., 1995).

Women are higher utilizers of health services, particularly in their reproductive and childrearing years. Moreover, women's childbearing role creates unique physical, social, and clinical contexts for smoking cessation interventions. For example, social awareness of the health risks of smoking to the fetus makes pregnancy a "teachable moment" of enhanced motivation for smoking cessation (Floyd, Rimer, Giovino, Mullen, & Sullivan, 1993). Provision of minimal cessation interventions—such as self-help booklets, advice to quit from a health care provider, and counseling either face to face or via the telephone—have been shown to substantially increase rates of cessation during pregnancy, particularly in middle income women (Ershoff, Mullen, & Quinn, 1989; Sexton & Hebel, 1984). However, with a few exceptions (Windsor et al., 1985), clinic-based interventions with low income pregnant smokers have had far less favorable results (Kendrick et al., 1995).

Moreover, these interventions have had little or no impact on high postpartum relapse rates (Ershoff, Quinn, & Mullen, 1995). Several randomized trials testing relapse prevention interventions that include self-help guides and telephone counseling adjuncts in late pregnancy and early postpartum are currently underway (McBride, Curry, Lando, & Pirie, 1994). Cessation interventions based in pediatric, family planning, and WIC clinics that serve a high proportion of women of childbearing age (Secker-Walker, Chir, Solomon, Flynn, & Dana, 1994) have also been evaluated (Kendrick et al., 1995; Severson, Andrews, Lichtenstein, Wall, & Akers, 1997; Wall, Severson, Andrews, Flynn, & Dana, 1994). However, these clinical settings offer special challenges due to high patient volume and limited provider resources to implement cessation interventions (Kendrick et al., 1995; Wall et al., 1994).

Community-based smoking cessation interventions that have included quit contests, outreach recruitment to cessation services, and policy initiatives have been somewhat disappointing (COMMIT, 1995; Lando et al., 1995). These interventions have had the greatest impact on lighter smokers, who are also most likely to quit on their own (COMMIT, 1995). The fact that rates of cessation among heavy smokers have not been influenced by these approaches suggests that more intensive intervention programs may be necessary for this recalcitrant group of smokers.

Smoking Summary

High rates of smoking among women make the development and evaluation of effective smoking cessation interventions a health promotion priority. The unique barriers to quitting reported by women suggest that interventions must address weight concerns, stressful lifestyles, and more healthful ways to cope with negative moods and depression. More work is needed to design and evaluate interventions that encourage smoking cessation simultaneous with behavior changes (e.g., increasing exercise) that can enhance the potential for long-term maintenance of cessation.

Women's greater use of health services presents multiple opportunities for providing cessation interventions to women in clinical settings. However, organizational and system barriers to these interventions present major obstacles to widespread adoption of these approaches. Community-wide interventions could accelerate secular trends in cessation, particularly among light smokers. However, these approaches are likely to be ineffective for highly addicted smokers.

PHYSICAL ACTIVITY

Health Effects of Physical Activity

A sedentary lifestyle is associated with death from coronary heart disease, colon cancer, and diabetes (Powell, Thompson, Caspersen, & Kendrick, 1987; USDHHS, 1996); in contrast, a physically active lifestyle reduces morbidity associated with multiple chronic diseases and improves the quality of life (Bouchard, Shephard, & Stephens, 1994; Paffenbarger et

al., 1986). Overall mortality for women was associated with low levels of cardiorespiratory fitness (RR = 5.35); however, there was no association between the two based on self-reported physical inactivity (Blair, Kohl, & Barlow, 1993). Other evidence suggests that increases in physical activity result in improved psychosocial status, functional status, and physical fitness (Minor & J. D. Brown, 1993).

Physical activity provides protection against osteoporosis, a major cause of morbidity and mortality of older women (NIH, 1985), by increasing peak bone mass at maturity, maintaining bone mass during the third and fourth decades, and by retarding the loss of bone mass in the fifth decade of life (Kohrt, Snead, Slatopolsky, & Birge, 1995; Sinaki & Offord, 1988). Some evidence suggests that resistance exercise, as compared to endurance activities, may result in greater gains in bone mass, and for postmenopausal women, greater gain in bone density occurs when exercise is combined with estrogen replacement therapy (Kohrt et al., 1995; USDHHS, 1996). Among the elderly, increased muscle strength and balance appears to reduce the potential for falls and maintain the independent living status of elderly women (Wolfson, Whipple, Derby, Judge, & King, 1996).

Evidence of associations between inactivity and other diseases such as breast, ovarian, endometrial, and uterine cancers is both limited and inconsistent (USDHHS, 1996). Nonetheless, there is some evidence that physical activity during adolescence and early adulthood may be protective against breast cancer (Bernstein, Henderson, Hanisch, Sullivan-Halley, & Ross, 1994; Mittendorf et al., 1995). Moreover, regular moderate exercise limits symptoms and improves function for chronic conditions, such as osteoarthritis and rheumatoid arthritis (Allegrante, Kovar, MacKenzie, Peterson, & Gutin, 1993; Fisher, Kame, Rouse, & Pendergast, 1994).

Negative affects of physical activity on women's health, such as training-induced amenorrhea, excessive activity associated with eating disorders, and the need for adaptations in activity during pregnancy, are relevant for only a few girls and women (Dubbart, 1995). Because these conditions are not prevalent, they are best addressed in clinical settings rather than through public health interventions.

Prevalence of Physical Activity Patterns of Women

Despite the established positive health benefits of physical activity, 25% of U.S. adults have sedentary lifestyles (i.e., no leisure time physical activity) and an additional 33% are insufficiently active to realize health benefits or maintain cardiorespiratory fitness (USDHHS, 1996). In spite of the "fitness movement" and programs to increase activity levels during the last two decades, physical inactivity levels remain high among all women (i.e., 59%) and, more so among minority women (i.e., 65%; King, Jeffery, et al., 1995; CDC, 1995). Fifty percent of adults who initiate an exercise program are likely to drop out within 6 months (Dishman & Sallis, 1994). Unfortunately, with only minimal declines in the proportion of women who are sedentary, limited progress has been made toward the Year 2000 objectives of in-

creasing physical activity (Healthy people 2000, 1990; McGinnis & Lee, 1995).

Evidence indicates that inactivity levels increase with age, from 26% for women from age 18 to 34 as compared to 42% of women who are age 65 and older (Duelberg, 1992; Washburn, Kline, Lackland, & Wheeler, 1992). Physical inactivity is also associated with being overweight, having a history of being physically inactive, and smoking (Bild et al., 1993; Blair, Powell et al., 1993). In addition, smokers are more likely to drop out of exercise programs than nonsmokers (Dishman & Sallis, 1994).

Minority women are less likely than White women to engage in physical activity: only 29% of White women and 18% of African American women in the United States are physically active at a health enhancing level, according to data from the 1992 Behavioral Risk Factor Surveillance System (BRFS; CDC, 1995). A disproportionate number of minority women are also economically disadvantaged, have a lower level of education, and are overweight; each of those factors are independently related to low levels of physical activity (Caspersen & Merritt, 1995; Kanders et al., 1994). Thus, both African American and White women with less than a high school education were less likely to report regular activity (17%) than those women with a high school education (24%) and college graduates (34%). Women in the lowest income category were least likely to report physical activity (21%) as compared to women in the highest income category (35%).

Any discussion of patterns in women's physical activity must acknowledge that self-report measures used in national surveillance data may be less appropriate for women than men because they typically do not assess gendered activities such as housework, child and elder care, and occupational activity (Dubbart, 1995). In addition, some measures underestimate activity for those involved in multiple activities (Caspersen & Merritt, 1995).

Physical Activity Recommendations for Women

The substantial positive health benefits of physical activity have led the NIH consensus conference on physical activity (1995) to recommend that all Americans should engage in regular activity at a level appropriate to their ability. To this end, all children and adults should set and reach a goal of accumulating at least 30 minutes of moderate-intensity physical activity on most, preferably all days of the week. Those who currently meet these standards may derive additional health and fitness benefits by becoming more physically active or including more vigorous activity. Similarly, it has been shown that regular moderate intensity activity, such as walking and gardening, results in substantial health benefits (Pate et al., 1995; USDHHS, 1996).

Women can meet the daily goal of 30 minutes of moderate intensity exercise—enough to expend approximately 200 calories—by briskly walking 2 miles, bicycling 7 miles at a moderate pace (13 miles per hour), or swimming half-a-mile at a moderate pace (35 yards per minutes) (Cooper, 1982; Pate et al., 1995). Unfortunately, many women may find it difficult to set aside 30 minutes a day for exercise. For them, it is espe-

cially important to recognize that short bouts of activity lasting 8 to 10 minutes, such as walking up multiple flights of stairs, walking short distances, gardening, housework, and child care activities also have been shown to result in health benefits (Leon, Connett, Jacobs, & Rauramaa, 1987; Paffenbarger et al., 1986).

Compared with the health benefits, the risks of physical activity are low, so most women do not need medical consultation or pretesting prior to initiating a program of moderate-intensity physical activity (ACSM, 1995; USDHHS, 1996). A medical evaluation is suggested, however, for women over age 50 planning a vigorous program with known coronary heart disease (CHD) or who have multiple CHD risk factors. However, women who are currently not engaged in physical activity should gradually increase the time spent in a physical activity from an initial comfortable time period (e.g., 10 minutes) to the recommended time of 30 minutes. This may take 2 to 16 weeks, depending on the women's age, health, weight, and initial fitness level (ACSM, 1995; Cooper, 1982). Women with specific fitness goals beyond the health-related benefits of physical activity may need to obtain more specific recommendations, including the type of activities, level of intensity, frequency, duration, and information about strength and flexibility exercises (Pate et al., 1995).

Barriers and Facilitators to Physical Activity for Women

There is a dearth of research regarding the specific types of impediments that contribute to women's low participation in physical activity (Crawford, E. L. Jackson, & Godbey, 1991; B. H. Marcus, Dubbert, et al., 1995). However, the limited evidence suggests that barriers to physical activity differ by gender and among women, and vary by ethnic background, income level, and education (Dishman & Sallis, 1994).

Time is consistently the most frequently mentioned hindrance to initiating and sustaining a regular exercise program (Benedict, 1996; Johnson, Corrigan, Dubbert, & Gramling, 1990; Martin & Dubbert, 1982). Many women may not begin exercising or may drop out of physical activity programs if the time issue is not adequately addressed. It is not surprising, therefore, that having children is negatively associated with women's participation in vigorous exercise (Verhoef, Love, & Rose, 1992), and that women with children under age 5 are least likely to report exercise participation (B. H. Marcus, Pinto, Simkin, Audrain, & Taylor, 1994).

Social-psychological and structural factors intervene between intention and actual participation, and consequently are important considerations in developing a program to increase women's participation in physical activity (Dishman & Sallis, 1994; Jackson, Crawford, & Godbey, 1993; Kay & G. Jackson, 1991). Psychological dispositions such as social anxiety, self-consciousness, low will power, low self-efficacy, and perceived lack of coordination and fitness level can inhibit women's participation in physical activities, as can social factors such as a lack of companionship or a lack of role models (Benedict, 1996; Dishman & Sallis, 1994; Dubbert, 1995; Ebrahim & Rowland, 1996; B. H. Marcus, Dubbert et

al., 1995; NIH, 1995; USDHHS, 1996). Women's concern for safety and security are also important in their decision to participate in physical activities (Henderson, Stalnaker, & Taylor, 1988). Poor health is also a common barrier to consistent exercise for women (Kriska et al., 1986). When health-related conditions hinder women's physical activity, it is important that their physicians be knowledgeable and interested in promoting their participation in physical activity (Ebrahim & Rowland, 1996; U.S. Preventive Services, 1996).

Women also report numerous structural barriers to physical activity, including limited financial resources, inhospitable climate, scheduling difficulties, lack of opportunity to participate (and knowledge of such opportunity), transportation problems, and negative reference group attitudes about the appropriateness of certain activities (A. C. King et al., 1992). Available information concerning structural barriers that are specific to minority women (Bild et al., 1993; J. Datillo, A. M. Datillo, Samdahl, & Kleiber, 1994; Shaw, Bonen, & McCabe, 1991) suggest that among low income minority women, responsibilities for family care, lack of finances, body image/health problems, and housework are factors that inhibit their physical activity. Minority women also place less value on fitness and thinness, and report fewer opportunities for leisure activities as compared to White women (Mayo, 1992).

In contrast, factors that facilitate physical activity include inexpensiveness of the activity, greater "accessibility" (Bild et al., 1993) that includes a convenient location and flexibility in scheduling (Stephens, Jacobs, & White, 1985). Moreover, different factors are associated with initiation of a physical activity program compared to those that encourage long-term maintenance of the program (B. H. Marcus, Dubbert et al., 1995). Due to changes in life circumstances, women often have a greater number of lapses in regular activity programs compared to men during an equivalent time period (Dubbert, Stetson, & Corrigan, 1991; Marcus, Dubbert et al., 1995; USDHHS, 1996). As noted by A. C. King (1991), more information is needed to prevent the relapses typically occurring as women experience significant transitions: passage through puberty, attending college, becoming pregnant, raising children, going through menopause, and becoming involved in family caregiving.

In sum, many women must overcome barriers to engage in physical activity. Some of these barriers, such as perceived lack of coordination, may be related to gender stereotypes suggesting that strenuous activity is unfeminine. Other barriers—low self-efficacy, low will power—signify the important links between beliefs and behavior. However, many barriers reflect the contemporary reality of limited time, money, or adequate public space that is safe for physical activity. It is difficult to imagine how the many hindrances to physical activity can be overcome, without attention to the structural barriers imposed by policies and the environment.

Interventions to Increase Physical Activity

Most health behavior change programs related to physical activity are focused primarily on individual behavior change (Gottlieb & Green, 1987; Lewis et al., 1993). But successful

interventions require multiple strategies that are focused on contextual factors (structural, organizational, environmental, and public policy determinants) and individual behavior (Stokols, 1992; Winkleby, 1994). Unfortunately, it is difficult to identify the most effective programs for women because most exercise intervention studies have involved a limited number of participants, have been of short duration, and have validated participants' self-reported activity; moreover, gender differences in response to interventions are often not reported (Dubbert, 1995; A. C. King et al., 1992). Very few interventions have been specifically designed to increase women's, and more particularly minority and older women's, levels of physical activity (B. H. Marcus, Dubbert, King, & Pinto, 1995).

Individual Behavior Change Approaches. Individual strategies focus on psychological barriers to physical activity that they seek to eliminate through reinforcement, goal setting, self-monitoring, feedback, decision making, skills training to prevent relapse, incentives and contests, behavioral counseling, and prompts and reminders (A. C. King et al., 1992; B. H. Marcus et al., 1995; USDHHS, 1996). Intervention studies demonstrating significant changes have involved programs that were convenient (A. King, Taylor, Haskell, & Debusk, 1988; A. King, Haskell, Young, Oka, & Stefanick, 1995) and based on social learning theory (McAuley, Courneya, Rudolph, & Lox, 1994). New developments in tailored messaging allow messages promoting physical activity to be individually tailored to stage of change and self-identified barriers.

Interventions in Health Care Settings. The U.S. Preventive Services Task Force (1996) identified "physical activity counseling" in their list of recommended clinical preventive services. But there are barriers to physician recommendations regarding physical activity, including lack of time, limited reimbursement for such services, and physician's lack of confidence in counseling patients (A. C. King et al., 1992). The recently developed Physician Assessment and Counseling for Exercise Program (PACE) is a protocol developed by Sallis and his colleagues (CDC, 1992; Wooten et al., 1991). The training program developed as part of the PACE project was successful in preparing providers to counsel patients in 5 minutes or less about exercise (Long et al., 1996). The PACE program was found efficacious in a controlled intervention study involving 255 patients, 84% female, from 17 physician offices (Calfas et al., 1996). The intervention group received 3 to 5 minutes of physical activity counseling from the physician and a telephone call 2 weeks later. At follow-up, 52% of intervention patients adopted regular activity as compared to only 12% of the controls and of the patients who were already active, the intervention patients reported walking more than controls (Calfas et al., 1996).

Worksite Interventions. Some employees benefit from working for organizations that provide facilities, equipment, or favorable policies (e.g., flextime) to promote physical activity. The 1992 survey of U.S. worksites reported that

33% of worksites with from 50 to 99 employees and 47% of worksites with from 100 to 249 employees provide exercise facilities. This represents a significant increase in worksites offering programs during the past 10 years. However, these figures may overestimate employee access to exercise facilities or equipment and health promotion programs because the majority of U.S. employees (56%) work for companies with fewer than 99 employees.

In recently completed worksite trials, the primary focus of the interventions was on individual behavior change strategies (Abrams et al., 1994; Glasgow et al., 1995). Worksite physical activity programs usually involve less than 20% of the eligible employees (Crump, Earp, Kozma, & Hertz-Picciotto, 1996). These programs often do not attract the sedentary, blue-collar, less educated employees, however there are some exceptions when a program uses multiple communication methods, offers incentives to encourage participation, and ensures that the program activities are offered at convenient times for shift employees (Heirich, Foote, Erfurt, & Konopka, 1993; A. King, Carl, Birkel, & Haskell, 1988). Programs that encourage peer support or train lay health advisors may have great potential in manufacturing worksites (Heirich et al., 1993; Tessaro, 1996).

Community Interventions. Community-wide interventions concentrate on producing population change rather than individual change. The three large health behavior trials conducted in the United States during the 1980s—Minnesota Heart Health Program (Luepker et al., 1994), Pawtucket Heart Health Program (Carleton et al., 1995), and the Stanford Five-City Project (Farquhar et al., 1990)—all included a physical activity component. It is difficult to compare results across these studies because the outcome measures of physical activity varied. Unfortunately, the results of these community-based trials have been disappointing. However, many of the strategies and approaches used were actually individually oriented. The recent focus on environmental and policy level changes may increase the chances of realizing community level change in physical activity levels.

Summary Physical Activity and Women

In contrast to improved lifestyle habits, reduction in dietary fat and smoking and control of high blood pressure and cholesterol, levels of physical inactivity have not improved in the United States during the last 10 years. The strong relation between physical inactivity and chronic disease demands a strong public health approach that includes a combination of environment, organization, and public policy strategies (A. C. King et al., 1992). A social ecological approach seeks to change policies, physical structures, and social norms, as well as individual factors (e.g., behavior and attitudes), that have an impact on physical activity (McLeroy, Bibeau, Steckler, & Glanz, 1988; Stokols, 1992). Interventions targeted at public and organizational policies are the next generation of community-based interventions and such interventions may have a greater impact on community levels of health behaviors than individual change programs (Winkleby, 1994).

CANCER SCREENING

Recommendations for cancer screening vary across the age spectrum and depending on what organization issues the advice. Most medical organizations (see Table 31.1) recommend Pap tests and clinical breast exams for women in their 20s and 30s, mammograms either in the 40s or starting at age 50, and screening for colorectal cancer with fecal occult blood tests (FOBTs) and sigmoidoscopy at age 50. Data indicate that there is widespread, but not universal, adherence to Pap test guidelines, but most women are not being screened appropriately for breast and colorectal cancer. Moreover, rates are lower for low SES and older women. Screening for breast, cervical, and colorectal cancers is discussed briefly.

Current Status of Breast Cancer Screening in the United States

In 2000, more than 182,000 women were diagnosed with breast cancer and 40,800 women died of the disease (American Cancer Society, 2000). Numerous studies have shown that regular mammograms with or without clinical breast exams can reduce mortality by about 30% for women from age 50 to 69 (Fletcher, Black, Harris, Rimer, & Shapiro, 1993). However, there is considerable debate about the benefits of mammography for women in their 40s (Fletcher et al., 1993; Rimer, 1995a; Smart, Hendrick, Rutledge, & R. A. Smith, 1995).

The proportion of American women who are receiving regular mammograms has increased dramatically since 1987, when one third of women had ever had a mammogram, and only 17% had one in the preceding year (Dawson & Thompson, 1990). By 1990, nearly two thirds of women age 40 and older reported having had at least one mammogram, although only 31% were following guidelines (Morbidity Mortality Weekly Report, MMWR, 1990). From 1987 to 1992, the proportion of women who reported recent mammograms increased at least twofold for women in every age and racial/ethnic group. Screening remained lower for women over age 70 (Breen & Kessler, 1995). The proportion of women who are getting regular mammograms has increased dramatically since 1987. In 1992, based on the NHIS, about 35% of women over age 40 had ever been screened; 35% of women in their 40s, 42% of women in their 50s, 29% of women in their 60s, and 31% of women 70+ reported a recent mammogram.

In 1987, the NHIS showed that underusers were more likely to be less educated, reside outside of metropolitan areas, and to be members of a minority. By 1990, the racial gap had been reduced on a national level, although it was still significant in many regions of the United States, such as the South. Currently, the most relevant demographic factors for predicting mammography use are lower income status and lower levels of education (Breen & Kessler, 1994), which transcend the impact of race alone.

Barriers and Facilitators to Breast Cancer Screening

The characteristics of women who do not get regular mammograms are generally consistent from study to study and are sim-

TABLE 31.1
 Screening Guidelines for Breast, Colorectal, and Cervical Cancers for Selected Health Care Organizations

American Cancer Society	American College of Obstetrics and Gynecology	U.S. Preventative Health Services Task Force (72)	National Cancer Institute's Patient Data Query (PDQ) System	American College of Radiology	American College of Family Physicians
Breast Cancer Mammography and CBE yearly for women age 40 and older. CBE every three years ages 20-39; every year age 40 and older. Monthly BSE for all women age 20 and older.	Mammography should be performed every 1-2 years for women ages 40-49 and then annually thereafter.	Mammography every 1-2 years with or without CBE for women ages 50-69.	Mammography every 1-2 years for women age 40 and older. Women at higher risk should talk with their physicians re schedule.	Yearly mammographs for asymptomatic women age 40 and older. It is reasonable to institute screening mammography at an earlier age in women with high risk factors.	Counsel about potential risks and benefits of mammography and CBE for women ages 40-49. Offer mammography and CBE every 1-2 years for women ages 50-69.
Cervical Cancer Pap test and pelvic exam yearly for all women who are, or have been, sexually active or who have reached age 18. After 3 consecutive normal smears, Pap test less often at the discretion of physician.	Pap test and pelvic exam yearly for all women who are, or have been, sexually active or who have reached age 18. After 3 consecutive normal smears, Pap test less often at the discretion of physician.	Pap test every 1-3 years for all women who are sexually active and/or who have a cervix. No evidence to support an upper limit, but age 65 can be defended in women with a history of normal and regular Pap tests.	Evidence strongly suggests a decrease in mortality for regular screening with Pap tests in women who are sexually active or who have reached age 18. The upper limit at which such screening ceases to be effective is unknown.	N/A	Offer Pap test at least every 3 years for women who have ever had sex and have a cervix.
Colorectal Cancer One of the following schedules for men and women age 50 and over; FOBT yearly and sigmoidoscopy every 5 years; colonoscopy every 10 years; double-contrast barium enema every 5-10 years (DRE at time of screening except for FOBT). Those with high risk for colorectal cancer should begin screening earlier and/or more frequently.	After the age of 50 years, a DRE should accompany the pelvic examination and an annual FOBT should be performed; sigmoidoscopy should be performed every 3-5 years.	FOBT and/or sigmoidoscopy yearly at age 50 and older. There is insufficient evidence to determine which screening method is preferable or whether the combination produces greater benefit than either one alone.	FOBT either annually or biennially using rehydrated or nonrehydrated stool specimens in people ages 50-80 decreases mortality for colorectal cancer. Regular screening by sigmoidoscopy in people over age 50 may decrease mortality from colorectal cancer. There is insufficient evidence to determine the optimal interval for such screening.	N/A	Screen for colorectal cancer annually with FOBT, sigmoidoscopy, colonoscopy, or barium enema in adults age 50 and older.

Note. CBE, clinical breast examination; BSE, breast self-examination; DRE, digital rectal examination; FOBT, fecal occult blood test. Adapted from "Cancer Screening" by B. K. Rimer, J. M. Schildkraut, and Robert Hiatt in V. T. Devita, S. Hellman, and S. A. Rosenberg (Eds.). *Cancer: Principles and Practice of Oncology*, Philadelphia: Lippincott-Raven. Copyright 1997. Adapted by permission.

ilar to those for Pap tests (Rimer, 1994). The most important barrier is the lack of a recommendation by a woman's physician (Burg, Lane, & Polednak, 1990; Coleman & Feuer, 1992; Fox, Murata, & Stein, 1991; Rimer, Keintz, Keller, Engstrom, & Rosan, 1989; Siegler, Feaganes, & Rimer, 1995). Women who are older, African American, or Hispanic are less likely than middle-aged White women to report receiving such a recommendation. Other factors contributing to women's nonparticipation in mammography, according to their self-report, are an absence of breast problems or the belief that mammograms are unnecessary in the absence of symptoms.

Other barriers to mammography exist, but they account for much less of the variance in explaining the behavior. These barriers, which may be important for individual women or subgroups of women, include anxiety about the possibility of finding a problem and concern about radiation and pain (e.g., Fullerton, Kritz-Silverstein, Sadler, & Barrett-Connor, 1996). Pain, in fact, may be more of a problem than previously indicated (Kornguth, Keefe, & Conaway, 1996). These concerns may be important for individual women or subgroups of women. For example, African American and Hispanic women seem to be more concerned about pain and report more anxiety about the mammography experience. There is some evidence that older African American women are more fatalistic about cancer in general (Rimer, Ross, Cristinzio, & E. King, 1992), and unmarried women are less likely to have mammograms (Calle, Flanders, Thun, & Martin, 1993).

Access and environmental barriers also may inhibit mammography use. A study conducted in a health maintenance organization (HMO; McBride et al., 1993) found that nonparticipants had more difficulty getting to the facility, would have to travel farther, and were more likely to rate the facility as inconvenient. Women without health insurance are less likely to participate in mammography or Pap testing (Breen & Kessler, 1994). Women in managed care organizations are more likely to get mammograms and Pap tests (Collins & Simon, 1996).

However, studies show that even when the cost barrier is removed, other important psychological barriers remain (Rimer et al., 1989). If these barriers are not addressed, women still may not pursue regular mammograms. Although not a major barrier, cost has been reported as a barrier for some (e.g., women age 50 to 59 or Hispanic women; Fox et al., 1991).

Women are more likely to get mammograms when advised by their physicians (Dawson & Thompson, 1990; Rimer et al., 1989), when they know the recommended screening interval for their age, and when they are aware of the relation between age and breast cancer screening (Champion, 1991; Slenker & Grant, 1989). There also is evidence that women with more social ties are more likely to have mammograms (E. King et al., 1993). Having had a recent CBE also is related to having mammograms (Lane, Caplan, & Grimson, 1996). Finally, Fullerton et al. (1996) showed that regular mammography users were more likely to use estrogen, have a history of reproductive cancer, and rate their health as excellent.

In one of the few analyses to examine the relation of personality variables to mammography, Siegler et al. (1995) showed that among women in their 40s who were part of the UNC

Alumnae Study, conscientiousness, extroversion, assertiveness, and low depression predicted mammography use.

Cervical Cancer Screening

In 2000, cervical cancer was diagnosed in 12,800 women, and 4,600 died of the disease (American Cancer Society, 2000). U.S. mortality from cervical cancer has not declined since the 1970s (Devssa, Young, Brinton, & Fraumeni, 1989; Eddy, 1990). This is unfortunate because deaths from cervical cancer are nearly 100% preventable. The Pap test is a widely accepted screening test to prevent mortality for cervical cancer. Although there never has been a randomized clinical trial (RCT) to evaluate the Pap test, and precise estimates of sensitivity and specificity are not known (Wong & Feussner, 1993b), cervical cancer is considered almost totally avoidable through regular Pap tests. The only real controversy about Pap test screening centers on the upper age for screening.

According to the 1987 NHIS, the percentages of women who reported never having had a Pap test were approximately 11% of women overall, 10% of White women, 11.9% of African American women, and 24.7% of Hispanic women. The proportion of women who reported having had a Pap test remained stable from 1987 to 1992 overall, but it increased slightly for Hispanic women and remained low for women over age 70 (Breen & Kessler, 1995). The 1992 NHIS data show that from 89% to 95% of women from age 18 to 69 report ever having had a Pap test, but the number is a bit lower (82%) for women age 70+. In addition, anywhere from 43% to 76% of women report having had a Pap test in the past year.

Barriers and Facilitators to Cervical Cancer Screening

Many of the barriers and facilitators to Pap tests are similar to those for breast cancer screening. Older women and women past childbearing age may not recognize that Pap tests are still necessary (Caplan, Wells, & Haynes, 1992), and some women and physicians believe that women who are not sexually active do not need Pap tests (Wilcox & Mosher, 1993). Most women who have not had Pap tests have had contact with the health care system, indicating that, as for mammography, the failure of women to receive Pap tests reflects a missed clinical opportunity (Harlan, Bernstein, & Kessler, 1991).

Knowledge and beliefs about cervical cancer screening vary by age and ethnicity. For example, Hispanic women are less likely to be aware of Pap tests and therefore may require education about the need for Pap tests. Most studies show a relation between a belief in the benefits of Pap tests and regular screenings (Rimer, 1995a). Women who are embarrassed about getting a Pap test and those who say they are too busy also are less likely to be screened (Cockburn, White, Hirst, & Hill, 1992). Women who do not participate in screening are more likely to cite procrastination or a belief that the test is unnecessary as reasons for not being screened (Harlan et al., 1991). As with mammography, women who do not get other preventive services are less likely to have Pap tests (Rimer,

1992, 1995a). Minority women seem to be more embarrassed than White women about getting Pap tests (Calle et al., 1993). Older Hispanic women are especially at risk for underusing both mammography and Pap testing. Some studies show that women who are more knowledgeable about Pap tests, including the recommended screening interval, are more likely to be tested (Howard, 1987).

Interventions to Increase Screening Adherence

More studies have been conducted to test interventions of increased screening for breast cancer than for other cancers. The literature shows that the best approach to screening is to use multiple interventions directed at patients, physicians, the health care system and, if possible, the community. Multistrategy interventions generally are more effective, although single approaches have been successful in some cases (Rimer, 1994). For example, a nurse practitioner in a hospital clinic was given the responsibility for identifying older, poor, African American women who were due for mammograms and then approaching them (Mandelblatt et al., 1993). This intervention resulted in a significant increase in the proportion of these women who received mammograms. Similarly, public health nurses and community health workers were used to increase cervical cancer screening among poor women in Chicago (Ansell, Lacey, Whitman, Chen, & Phillips, 1994). In another case, a video was created that highlighted a woman's internal attributions about her personal responsibility for getting mammograms (Rothman, 1992), which according to self-reports increased use of mammography.

In one study, women in an independent practice association model HMO were invited to participate in breast cancer screening (Rimer, Ross, Balshem, & Engstrom, 1993). Nonadherent women were sent reminders, which doubled adherence rates. For women who remained adherent, telephone counseling tripled the chances that woman would get a mammogram. During a brief counseling session that averaged 5 minutes, the counselor's goal was to identify and overcome a woman's personal barriers to mammography (A. C. King et al., 1994). These strategies have been tested in other settings with similar results (e.g. Davis et al., 1997), although in many other settings the effect of reminders has been more modest.

Costanza et al. (1992) conducted patient education in a community health center, and Fletcher et al. (1993) implemented a community-wide media campaign. Lane, Polednak, and Burg (1989) used community health education strategies, including a game (Burg et al., 1990). These studies also included free or low cost mammograms as part of the intervention package. Similar community-based approaches have been used to increase cervical cancer screening (Dignan, Michielutte, Wells, & Bahnson, 1994). This approach was effective among high risk women. Thus, these programs included strategies that were parent directed, physician directed, system directed, and sometimes community based.

Although less research has been conducted in cervical cancer screening compared with breast cancer screening, many of the same approaches appear to be effective. Outreach strategies led by community health workers can increase use of

cervical cancer screening, and in reach interventions within community health centers also can be effective (Ansell et al., 1994; Lacey et al., 1993). Because most U.S. women are getting regular Pap tests, mass media approaches may not be effective or appropriate. Clinic-based approaches hold promise. Attempts to streamline the process of appointments and waiting time contribute to improved adherence (Harris, O'Malley, Fletcher, & Knight, 1990), and invitations from providers also increase cervical cancer screening (Creighton & Evans, 1992). The combination of health education and the immediate offer of a Pap test increased screening in one study (Cockburn, 1990).

Thus, as with breast cancer screening, the most effective behavior change investigations use a mix of intervention strategies directed at physicians, patients, and in some cases, the community (Costanza et al., 1992; Fletcher et al., 1993; Lane et al., 1989; Rimer et al., 1993; Vellozzi, Romans, & Rothenberg, 1996).

COLORECTAL CANCER SCREENING

Colorectal cancer is one of the leading causes of mortality in the Western world (Solomon & McLeod, 1993). In 1996, 66,800 U.S. women were diagnosed with colorectal cancer and 28,500 died from the disease. Five percent of Americans reaching age 50 will develop this disease by age 80; 2.5% will die from it (Wong & Feussner, 1993a). Well-established risk factors for colorectal cancer include familial polyposis syndromes, Crohn's disease, ulcerative colitis, age, family history, previous history of cancer (endometrial, ovarian, or breast), and Ashkenazi Jewish lineage (Oldenski & Flareau, 1992).

The long natural history of colorectal cancer makes it a good candidate for screening. And in recent years, studies have shown the efficacy of both fecal occult blood tests (FOBT) and sigmoidoscopy in reducing mortality from colorectal cancer (Ahlquist et al., 1993; Ransohoff & Lang, 1993; Selby, 1993; Selby, Friedman, Quesenberry, & Weiss, 1992). Recently, the U.S. Preventive Services Task Force (1996) upgraded its evidence for colorectal cancer with FOBTs and sigmoidoscopy, periodicity unspecified, and other organizations recommend more frequent screening (see Table 31.1). Colorectal cancer screening is especially important for women; women often think they are at lower risk than men for this disease. Yet, according to the 1992 NHIS, only 15% of women had a recent fecal occult blood test and 5% had a recent sigmoidoscopy.

Barriers to Colorectal Cancer Screening

Far less is known about adherence to colorectal cancer screening than to screening for breast and cervical cancer, and even less is known about barriers for women. There do appear to be barriers that are related to perceptions and concerns about the tests. The tests are seen as painful, embarrassing, and inconvenient. Many people do not know that colorectal cancer screening is needed (Myers et al., 1990). As with other cancer screening tests, people are more likely to be screened if their physician advises them to do so (Myers et al., 1991;

Myers, Balslem, Wolf, Ross, & Millner, 1993). There is some evidence that women may be less likely to be screened than men. For example, Borum (1996) found that 39% of female patients in a university clinic had an FOBT as compared to 59% of male patients. Efforts need to be made to encourage physicians to increase their use of CRC screening.

Blalock, DeVellis, Afifi, and Sandler (1990) and Hunter et al. (1990) also found that personal experience with cancers of relatives or friends increases participation in screening by FOBT and sigmoidoscopy. In addition, increasing age, not smoking, and higher education levels in populations who believe that cancer is curable are likely to be associated with greater participation in colorectal screening activities (Myers et al., 1990).

Interventions to Promote Colorectal Cancer Screening

There have been no reported studies designed to increase colorectal cancer screening among women specifically, and few have been developed for men and women. Those few interventions tested to date suggest that the same approaches that have been successful for enhancing breast and cervical cancer screening are likely to be effective for colorectal cancer. These include such techniques as reminder letters, postcards, and telephone calls (Thompson, Michnich, Gray, Friedlander, & Gilson, 1986; Myers et al., 1991). Because physicians have not yet accepted colorectal cancer screening, physician education is essential. There is a real need to extend what is known about screening for women's cancers to colorectal cancer. In view of the fact that perhaps one third or more of colon cancer deaths could be avoided by regular screening, the need for intervention research is urgent.

CONCLUSIONS

Over the past decade, significant progress has been made in understanding women's health and particularly health promotion. Significant progress has been made in identifying barriers to participation in screening for breast and cervical cancer, and successful interventions have been developed. Major challenges for the future are to increase screening for these cancers among the women who have not yet been reached, including some ethnic minorities and women with low levels of education. In addition, almost nothing is known about women's barriers to colorectal screening or how to overcome them.

As the previous sections have demonstrated, too few women are exercising, and far too many are overweight. Far too little is known about how to prevent smoking among girls or how to help women stop smoking. Gender-appropriate interventions are needed that fit into women's increasingly busy lifestyles. Time-intensive, centralized interventions are not likely to be the answer for most women; brief programs and tailored methods that can be delivered by telephone or mail should be investigated further. Special attention in program design and evaluation should be paid to those groups of

women who are most likely to be out of step with health promotion recommendations. These include minority women, poor women, and those with less education. Instrumental help in reducing access barriers may be needed.

Finally, there should be more attention to the efficacy of multiple risk factor or, at least, phased risk factor reduction programs. Health promotion behaviors do not exist in isolation, and it is important to determine whether and how health promotion synergy can be achieved by focusing on more than one risk factor. Similarly, both the benefits and risks of behaviors and interventions need to be considered not just for a single disease, such as cancer, but for cancer and heart disease, for example. As women live longer, health promotion behaviors are a critical part of not just living but living well.

Male Partner Violence: Relevance to Health Care Providers

Mary P. Koss

Maia Ingram
University of Arizona

Sara L. Pepper
Region 2 Consortium, Idaho

Since the 1970s, researchers and advocacy groups have documented the extent of partner violence, as well as the health and medical consequences of violence in women's lives. As a result, violence by male intimates is now recognized as one of the most prevalent and serious threats to the health of women. Despite gains in awareness and knowledge of the risk and outcomes of abuse, however, victims of partner violence have remained largely unrecognized in medical care settings. Yet, as efforts aimed at primary and secondary prevention of illness and injuries, as well as cost containment, become central to health care, partner violence is ever more clearly an issue of medical concern. To underscore the relevance of the problem to health care practitioners, this chapter reviews empirical evidence regarding both the prevalence and the impact of partner violence within the medical care system. The review covers three principal areas. First, the most frequent portals of entry, the consequences and medical presentations associated with abuse, and the disproportionately high rate of medical care utilization by victims are reviewed. Second, the rate and consequences of failure to identify and appropriately treat and refer victims in the medical setting are described. Third, the potential role of health care providers in the detection and referral of victims, as well as personal and systematic barriers to these actions are presented. The chapter concludes with a critique of the existing

methodologies in the field and suggests avenues of future study to address the many gaps in existing knowledge.

TERMINOLOGY

Although the term *domestic violence* is often used to describe abusive adult relationships, the present discussion adopts the expression *male partner violence* to denote violence against women by male intimates. This alternative term reflects a need to clearly define the predominant pattern in violent relationships, as well as those most likely to result in physical harm. Although large scale studies have reported that men and women are about equally likely to be physically aggressive toward an intimate partner at least once (Straus & Gelles, 1990; Straus, Gelles, & Steinmetz, 1980), further analysis reveals that both the frequency and severity of assaults by men against female intimates are much greater than assaults perpetrated by women against male partners (R. A. Berk, S. F. Berk, Loseke, & Rauma, 1983; Brush, 1990; Bureau of Justice Statistics, 1994; M. P. Koss, Goodman, et al., 1994; Makepeace, 1989). Women are much more likely to be injured in assaults by a male intimate than are men by a female partner (R. A. Berk et. al., 1983; Brush, 1990; Bureau of Justice Statistics, 1995; Makepeace,

1989; Stets & Straus, 1990). Likewise, women are four times more likely to be stalked in their lifetime than men (8.2% vs. 2.3%; Tjaden & Thoennes, 1998b). Men are also more likely to kill an intimate partner than are women (Browne & Williams, 1989, 1993; Bureau of Justice Statistics, 1994; Campbell, 1992; Mercy & Saltzman, 1989).

In addition, the intention of violence perpetrated by male and female partners is found to differ. From interviews with 232 men and 67 women arrested for domestic violence under a mandatory arrest law, Hamberger, Lohr, and Bonge (1994) found that reasons for women's violence sorted into categories of retribution (i.e., "payback") and self-defense, whereas the intentions of violence perpetrated by men sorted into categories such as domination and punishment. Issues of ownership and control are also found to be primary factors involved in the lethal outcomes of men's violence against female partners (Campbell, 1992). An analysis of all homicides involving intimate partners during a 5-year time period in Dayton, Ohio, revealed that the largest category of male motive for murder of a female partner was jealousy, followed by those labeled "male dominance issues," such as one in which the woman refused to get the perpetrator more wine, and those in which the woman resisted the murderer's sexual advances. In contrast, in approximately 85% of female homicides of a male partner, the woman had a history of being battered by that man, and the murder was precipitated by his threatening with a weapon or actually striking the woman (Campbell, 1992).

The term *partner violence* is also descriptive of the assailants women most typically face. Women are at a greater risk of assault, including rape and homicide, by a current or former husband or boyfriend than they are by a casual acquaintance or stranger (Browne & Williams, 1989, 1993; Campbell, 1992; Finkelhor & Yllo, 1985; Frieze, 1983; Russell, 1982). Assault by male intimates is more likely to be severe—involving punching, kicking, choking, and threats or use of a weapon—and to result in more severe injuries, than are assaults by others (Browne, 1993). In addition, the term highlights the fact that violence against women often occurs within relationships that are not, or are no longer, formal marriages. Women receiving treatment for battering-related injuries or health problems are more likely to be single, separated, or divorced than are nonbattered women (Berrios & Grady, 1991; Elliott & M. M. Johnson, 1995; Stark et al., 1981). Furthermore, violence in dating and courtship relationships is increasingly recognized as a significant problem (Browne & Williams, 1993; Makepeace, 1989).

Finally, use of the term male partner violence serves a practical purpose. It limits the focus of the present review to violence within adult relationships; the significant problems of childhood victimization and its sequelae are not specifically addressed here. Violence within same-sex couples is similarly not covered in this chapter (but see Kanuha, 1990; Lobel, 1986; Renzetti, 1992). Additional practical considerations limit the scope of the chapter to the consequences of abuse on the physical health of women. For discussion of psychiatric sequelae, see M. P. Koss, Goodman et al. (1994).

FORMAL DEFINITION OF PARTNER VIOLENCE

Male partner violence is generally broadly defined to be inclusive of the various types of behaviors that are used to coerce, control, and demean women. From an international perspective, the United Nations recognizes violence against women as "any act of gender-based violence that results in, or is likely to result in, physical, sexual, or psychological harm or suffering to women, including threats of such acts, coercion, or arbitrary deprivations of liberty, whether occurring in public or private life" (Economic and Social Council, 1992, p. 5). Specifically included in this definition are marital rape, sexual harassment, and threats or intimidation. Although discussion of the global health impact of violence against women is beyond the scope of this chapter, it is important to note that researchers and health care providers worldwide are singling out partner violence as a major public health threat to women. For a comprehensive review of the health burden of violence against women throughout the world, see Heise, Raikes, Watts, and Zwi (1994), Heise, Ellsberg, and Gottmoeller (1999), and M. P. Koss, Heise, and N. F. Russo (1994).

As defined by the American Medical Association, partner violence "is characterized as a pattern of coercive behaviors that may include repeated battering and injury, psychological abuse, sexual assault, progressive social isolation, deprivation, and intimidation. These behaviors are perpetrated by someone who is or was involved in an intimate relationship with the victim" (AMA, 1992, p. 40). The violence within an abusive relationship is characterized as a recurrent experience in which a woman is placed in physical danger or controlled by the threat or use of force. Included in the definition of physical abuse are pushing, slapping, punching, kicking, choking; assault with a weapon; tying down or restraining; leaving the woman in a dangerous place; and refusing to help when the woman is sick or injured. Partner violence may also involve emotional or psychological abuse, including physical and social isolation; extreme jealousy and possessiveness; deprivation, degradation, and humiliation; intimidation and threats of harm; intense criticizing, insulting, belittling, and ridiculing; and driving fast and recklessly to frighten the woman. Sexual abuse is also often part of violent relationships, and may include forced sexual acts or sexual degradation, such as trying to make her perform sexual acts against her will; hurting her during sex or assaulting her genitals, including use of objects intravaginally, orally, or anally; pursuing sex when she is not fully conscious or is afraid to say no; and coercing her to have sex without protection against pregnancy or sexually transmitted diseases (AMA, 1992).

In referring to the patterns of abusive relationships so defined, the AMA uses the terms *partner violence* and *domestic violence* interchangeably. For the reasons already cited, however, the term *male partner violence* is preferable. It more adequately conveys the broad range and classes of acts that define abusive relationships. Domestic violence more typically connotes battery, obscuring the other manifestations of abuse included in the definition. This use of the term *domestic*

violence appears to put blinders on what researchers study. As this review reveals, other forms of abuse—such as isolation, psychological abuse, and threats—have been little studied or written about by the medical community. Empirical data is thus largely limited to the impact of physical and sexual violence on women's health and medical care utilization.

GENERAL PREVALENCE AND PATTERNS

Physical Assault

Limited surveillance techniques and widely acknowledged underreporting make reliable estimates of the prevalence of partner violence difficult. No nationwide system exists to collect and update data specifically on violence within intimate relationships, and no consistent procedures are employed for identification of victims. The National Crime Victimization Survey (NCVS), an annual general survey of crime, provides estimates that 572,000 women annually are victims of violent crimes by intimate partners, giving a rate of 5 per 1,000 population (Bureau of Justice Statistics, 1994). These estimates, however, are heavily criticized on the basis of serious methodological flaws in the data collection methods and questioning regarding intimate violence used in the NCVS (Browne, 1993; M. P. Koss, Goodman et al., 1994; Stark & Flitcraft, 1988). These statistics fall far below the range of generally accepted estimates based on large scale surveys of violence within couples. The National Family Violence Surveys, based on probability samples and telephone data collection, have estimated that each year nearly 2 million women, or more than 3 out of every 100, are severely physically assaulted by a male partner (Straus & Gelles, 1990; Straus et al., 1980). In a randomized telephone survey of 6,000 households, nearly one in eight husbands reported using physical aggression against their wives during the preceding 12 months (Straus & Gelles, 1990). A study of dating or courtship violence, conducted with women students at colleges and universities nationwide, found that 32% had experienced at least some degree of physical aggression in these types of relationships (White & M. P. Koss, 1991). The national estimates based on telephone surveys are likely to be conservative due to the exclusion of nonhouseholds from the sample frames. This omission means that several living situations are missed where women may be at high risk for violence, including prisons, psychiatric hospitals, the military, and colleges. Additionally, the method misses the homeless, those too poor to own a telephone, and women whose partners control their ability to freely receive calls. Overall, based on review of these data, experts have concluded that a true estimate would lie somewhere between 3 and 4 million women (8%–10%) annually, and between 21% and 34% of women in their lifetime, are victims of male partner violence (Browne & Williams, 1993; Stark & Flitcraft, 1988).

Demographically, studies of prevalence consistently find that younger women are at greater risk of abuse than are older (Gin, Rucker, Frayne, Cygan, & Hubbell, 1991; Grisso et al., 1991; McLeer & Anwar, 1989; Parker, McFarlane, & Soeken, 1994; Stark et al., 1981). In a study of women pre-

senting for injuries at an urban emergency department, McLeer and Anwar (1989) found that 42% of injuries in the 18- to 20-year-old age group were due to battering, compared to 35% in the 21- to 30-year-old age group, and 26% in the 31- to 40-year-old age group. Battering caused 18% of injuries among women age 61 and older. This pattern is also seen among women presenting for prenatal care, with teenagers and women in their early 20s more likely to be abused during pregnancy than are older women (Helton, McFarlane, & Anderson, 1987; Parker et al., 1994). Researchers have documented differences in rates of partner violence among ethnic groups, but suggest that these are confounded with social class, indicated by income, unemployment, and education (Lockhart, 1991). For example, the rates of partner violence are higher for low income Black women (144/1,000) than for higher income Black women (58/1,000; Hampton & Gelles, 1994). Russo, Denious, Keita, and Koss (1997) reported similar results among the 439 Black women who participated in the Commonwealth Fund's national survey on women's health. The problem of male partner violence is found across all socioeconomic groups (Elliott & M. M. P. Johnson, 1995; Gin et al., 1991; Heise et al., 1994; McFarlane, Parker, Soeken, & Bullock, 1992; Stark & Flitcraft, 1988). Review of the data reveals that although low income women report higher rates of current partner violence (11%) than do middle income women (10%) or higher income women (8%), the difference in rates is fairly small (Stark & Flitcraft, 1988). In another aspect of the pattern, some evidence suggests that violence within a relationship may escalate over time. Of women killed by a male partner, 64% had been previously physically abused by that man (Campbell, 1992).

Marital Rape

Between 10% and 14% of women are raped and sexually assaulted within the context of marriage or cohabitation, applying the legal definitions (Finkelhor & Yllo, 1985; Frieze, 1983; Russell, 1982). Women who are victims of physical abuse are especially vulnerable to sexual abuse, with estimates of prevalence from various studies ranging between 26% and 52% of physically abused women also being raped by their husband or partner (Campbell, 1989; Finkelhor & Yllo, 1985; Frieze, 1983; Hanneke, Shields, & McCall, 1986; Russell, 1982; Shields & Hanneke, 1983). Marital rape in the absence of other forms of physical violence is rare (Campbell, 1989; Elliott & M. M. P. Johnson, 1995; Hanneke et al., 1986). Men who are both physically and sexually abusive are consistently found to perpetrate the most violent and severe assaults on their partner, with the majority of victims being repeatedly assaulted during the course of the relationship (Campbell, 1989; Finkelhor & Yllo, 1985; Frieze, 1983; Shields & Hanneke, 1983). Women who are victims of both physical and sexual violence are also at greater risk for abuse during pregnancy, as well as at greater risk of homicide (Campbell, 1989; Frieze, 1983). The occurrence of sexual assault in marriage is associated with greater trauma and more severe depression and low self-esteem than is found among victims of physical abuse alone (Campbell, 1989; Frieze, 1983).

Psychological Abuse

Limited data are available on the prevalence and impact of stalking and emotional or psychological abuse on health and health care utilization. Such nonphysical forms of control and character assassination may be more difficult to measure and relate to outcomes, as well as less apparent. Several attempts have been made to address the issue, however (Canadian Centre for Justice Statistics, 1994; Elliott & M. M. P. Johnson, 1995; O'Campo, Gielen, Faden, & Kass, 1994; Talley, Fett, Zinsmeister, & Melton, 1994; Tjaden & Thoennes, 1998b). The National Violence Against Women Survey collected data via telephone from 16,000 women nationally (Tjaden & Thoennes, 1998a). Results revealed that 8.1% of U.S. women have been stalked in their lifetime. Of these incidents, 60% involved current or ex-boyfriends, spouses, cohabiting partners, or dates. Just 21% of the stalking behavior was initiated before the relationship ended. The remainder occurred both before and after (36%), or just after the relationship ended (43%). The Canadian Centre for Justice Statistics' National Survey on Violence Against Women used five questions to measure prevalence of emotional abuse of women by male partners in that country, including questions on jealousy, limiting her contact with family or friends, belittling and insulting her, preventing access to family income, and insisting on knowing her whereabouts at all times. Approximately one third of ever-married women reported that their current or previous partner was emotionally abusive in at least one of the five ways. In the majority of cases, emotional abuse was concomitant with physical or sexual abuse; only 18% of women who reported no physical violence by a partner reported experiencing emotional abuse (Canadian Center for Justice Statistics, 1994). A U.S. population-based study found similar results (Talley et al., 1994). Talley and colleagues found that only 14% of reported emotional and verbal abuse occurred in the absence of either sexual or physical abuse.

Elliott and M. M. P. Johnson (1995) described the complex relation between the types of partner violence experienced by women patients seen in a primary care setting. In this sample, all women who were physically abused also reported experiencing emotional abuse in that relationship. Descriptions of the excessive control over emotional and social behavior that typified emotional abuse in this sample included being followed, made to feel guilty when she wanted to go out with friends, taking away or disabling her car, and constant threats of assault. Two thirds of the women who reported any type of partner violence experienced all categories of abuse used in the study, including severe battery and use of weapons (Elliott & M. M. P. Johnson, 1995).

PREVALENCE OF PARTNER VIOLENCE IN MEDICAL CARE SETTINGS

The American Medical Association recommends screening for partner violence in all portals of entry into the medical care system (AMA, 1992). For women, the most common entries are emergency, obstetric, and primary care services. The prevalence of victims in these settings, and the presentations

most commonly associated as outcomes of abuse, are discussed in the material that follows.

Emergency Care

The overall prevalence of intimate partner abuse identified in surveys of 3,455 patients in 11 community emergency rooms was 14.4% for past year physical or sexual abuse (Dearwater et al., 1998). The lifetime prevalence of emotional or physical abuse was 36.8% (Dearwater et al., 1998). Approximately one in eight women patients, or more than one in four emergency department visits by women are related to assault by a male partner (Abbot, R. Johnson, Koziol-McLain, & Lowenstein, 1995; McLeer & Anwar, 1989; Stark et al., 1981). Male partner violence is the largest single cause of injury to women requiring emergency medical treatment, accounting for up to one half of all injuries to women seen there (Stark et al., 1981). Further results of the study by Stark and colleagues (1981) show that the pattern of injuries sustained in beatings can generally distinguish victims of violence from accident victims. Physically abused women compared to those involved in accidents are more likely to have injuries to multiple parts of the body, as well as more likely to have injuries to the face, head, neck, throat, breast, chest, or abdomen. Accidental injuries are likely to involve the extremities, particularly the elbow, knee, or hip area. The types of injuries seen also differ, with battered women likely to have abrasions and contusions, or pains for which no physiologic cause can be discovered. Accidental injuries are more likely to involve sprains or strains. Fractures, dislocations, and lacerations occur with about equal frequency to abused and nonabused women.

In a study of 218 women who had presented to an emergency department with injuries resulting from partner violence, Berrios and Grady (1991) found that as a result of the abusive episode, many women required significant medical intervention and testing. Forty-one percent of the women interviewed required radiographic studies, 25% required stitches or casting, and 27% received medications. Eleven percent had suffered loss of consciousness, and 5% had a permanent impairment, such as disfigurement, hearing loss, or visual impairment. Victims frequently had lacerations (39%), musculoskeletal injuries (25%), or internal injuries (13%), and many suffered choking or strangulation (23%). Twenty-eight percent of the sample had been admitted to the hospital, and 13% underwent major surgical intervention. In one third of all cases, a weapon had been used. Ten percent of the victims were pregnant at the time of the assault (Berrios & Grady, 1991).

Sexual assault victims often present with injuries from battery, as well as with genital injuries ranging from vulvar contusions to major vaginal tears (Geist, 1988). One third of rapes include anal or oral penetration in addition to vaginal contact, with anorectal injuries likely (Geist, 1988). In emergency department-based studies, nearly one third of rape victims had documented histories of battering; 58% of rape victims over age 30 were battered (Stark et al., 1981). The pattern of partner violence was very rarely identified as the context of rape, however.

One of the most troublesome aspects of the problem, the recurrent and perhaps escalating nature of partner violence, can clearly be seen in emergency care utilization (Berrios & Grady, 1991; Grisso et al., 1991; Stark et al., 1981). Nearly one in five abused women has presented for medical treatment of trauma more than 11 times; another 23% has been treated 6 to 10 times previously for injuries from abuse (Stark & Flitcraft, 1988). In a study of the incidence of injuries in women of Philadelphia, Grisso and colleagues (1991) found that the majority of women presenting for emergency care two or more times during the study year had been victims of violence. Of the women repeaters whose first injury was due to violence, nearly half of subsequent injuries were also due to violence (Grisso et al., 1991). Women positively identified as victims of partner violence had, on average, seven treatment episodes in the emergency service, compared with 4.89 for those identified as having a probable history of partner violence, 3.94 for women with histories suggestive of abuse, and 1.96 for nonbattered women (Stark et al., 1981). A medical response that appropriately identifies and treats victims of violence and addresses safety from continuing abuse is clearly needed.

Prenatal Care

Since young women in their most active childbearing years are among those at highest risk for abuse, the experience and outcomes of violence during pregnancy deserve special attention. The effect of the pregnancy on the risk of assault apparently differs across relationships. In a sample of 290 pregnant women, Helton and colleagues (1987) found that 15% reported physical battering by their current male partner prior to the present pregnancy, and 8% reported battering during the present pregnancy. Another 4% had been threatened with physical assault before and/or during the pregnancy. Of the women battered while pregnant, 88% had been abused before the pregnancy; one third of whom reported that battering increased since they were pregnant. One third of the women battered during pregnancy had sought medical care for injuries sustained in the attack. The most frequent sites of abuse were the head and face, the breasts, and the back and buttocks (Helton et al., 1987). Stewart (1995) also reported findings on the prevalence of abuse from a survey of 548 pregnant women. In this sample, 10% were physically abused by their partner prior to becoming pregnant, and 7% reported abuse during the current pregnancy. Nearly two thirds of those battered during pregnancy reported that the abuse increased during this time. Two thirds of those abused during pregnancy received medical treatment for the abuse (Stewart, 1995).

In a study of 691 Black, Hispanic, and White pregnant women in public prenatal care clinics in Houston and Baltimore, 17% reported physical or sexual abuse during the current pregnancy (McFarlane et al., 1992). Sixty percent of abused women in this sample reported two or more violent episodes, with White women experiencing the most frequent and severe assaults. These researchers also found that abuse is related to timing of entry into prenatal care. Compared to nonabused women in this sample, abused women were twice as likely to begin prenatal care in the third trimester (21% vs.

11%; McFarlane et al., 1992). In a comparison of the prevalence of abuse during pregnancy among 1,203 poor teenage and adult women, teenagers were found to have significantly higher rates of physical and sexual abuse (20.6%) than were adults in this sample (14.2%; Parker et al., 1994). Compared with teenagers, however, adult women experienced more severe physical and emotional abuse, and were more likely to be abused within an ongoing relationship with a significant partner. This study found no difference in timing of entry into prenatal care between teenage and adult women overall, but did find a significant association between abuse and late (third trimester) entry into prenatal care (Parker et al., 1994).

Women who experience violence during pregnancy are at increased risk for giving birth to premature as well as full-term low birth weight infants (Bullock & McFarlane, 1989; Parker et al., 1994; Satin, Hemsell, Stone, Theriot, & Wendel, 1991). This difference is especially pronounced among women giving birth at private hospitals, where 17.5% of infants born to battered women were of low birth weight (< 5 lb., 8 oz), compared to 4.2% of births to nonabused women (Bullock & McFarlane, 1989). Overall, of both public and private hospital births in this sample, twice as many low birth weight infants were born to battered women (12.5%) as were born to nonbattered women (6.6%). Compared with nonpregnant victims, sexual assault during pregnancy has been found to be associated with less severe genital and nongenital trauma, yet a high rate of preterm (16%) and low birth weight (24%) births (Satin et al., 1991).

Parker and colleagues (1994) also found physical or sexual abuse during pregnancy to be significantly associated with low birth weight. In addition, abuse was associated with the risk factors and maternal complications of low weight gain, infections, anemia, smoking, and alcohol or drug usage (Parker et al., 1994). Amaro, Fried, Cabral, and Zuckerman (1990), in a study of the relation between partner violence during pregnancy and drug use, found that victims as compared to nonvictims were more likely to be White, born in the United States, single, and to be on Medicaid. The two groups were similar in educational attainment, age, employment, and parity. On psychosocial measures, victims were more likely than nonvictims to report a history of depression, attempted suicide, and lack of support during their pregnancy. Women abused during pregnancy were at greater risk than those nonabused to be heavy users of alcohol and illicit drugs (Amaro et al., 1990). Thus abuse may itself be a risk factor for pregnancy complications, as well as contribute to other known risks, compounding the effect.

Primary Care

The health and medical impacts of violence against women extend well beyond the immediate risk of injuries and the need for emergency services. In fact, a majority of medical visits related to abuse take place in primary care offices (Stark et al., 1981; Stark & Flitcraft, 1988). At least one incident of criminal victimization, including noncontact crimes such as break-in, attempted robbery, and purse snatching, is a common experience among women primary care patients, affect-

ing as many as 57% (M. P. Koss, Woodruff, & P. G. Koss, 1991). In this sample, 21.3% had experienced completed rape since age 14. Through further analysis, M. P. Koss and associates (M. P. Koss, P. G. Koss, & Woodruff, 1991; M. P. Koss, Woodruff, & P. G. Koss, 1991) revealed that victims of severe physical crimes such as rape and assault are especially likely to use medical care services up to 2 years following the attack. In a clinic-based study, Walsh and Broadhead (1992) found 48% of female patients at a combined family practice and university student health center reported having some type of contact sexual victimization in their lifetime; 25% of the patients in this setting reported experiences of rape or attempted rape. Women of all ages with a history of past or current partner abuse are found to be disproportionately represented among women receiving a variety of services in primary care settings. A study of the prevalence of partner violence among women patients in a midwestern family practice clinic found that 38% reported experiencing physical abuse (defined to include sexual abuse) by a partner during their lifetimes, and 12% reported current physical abuse (Elliott & M. M. P. Johnson, 1995). In a study conducted across three university-affiliated internal medicine clinics, 34% of women in the ethnically diverse sample had ever experienced partner violence, and 17% were currently victims of violence from a cohabiting male partner (Gin et al., 1991).

Elliott and M. M. P. Johnson (1995) compared the reasons for the medical appointments of women patients in a family practice clinic, and found group differences between women with no history of physical abuse, those with a past history, and those currently living in a physically abusive relationship. Of the women reporting no history of partner abuse, over half (52%) stated the purpose of their visit as routine health maintenance, such as a physical exam. Of those who had past experience with an abusive partner, 38% were being seen for routine examinations and 62% had specific complaints. Of the women reporting current physical abuse, none had appointments for routine exams; all visits were related to a specific complaint such as neck stiffness, the need to refill a prescription for antidepressant medication, a rash, migraine headaches, and an injured arm (Elliott & M. M. P. Johnson, 1995).

A history of sexual and physical abuse is associated with a variety of physical health complaints. Many studies on the physical health consequences of abuse have focused on childhood abuse and later medical problems in adult women (see Fry, 1993; E. A. Walker et al., 1992). Studies that address the health consequences of victimization by violence in adulthood generally include in their sample women with any history of abuse and so too include those abused as children (Drossman et al., 1990; Rapkin, Kames, Darke, Stamper, & Naliboff, 1990; Reiter, Shakerin, Gambone, & Milburn, 1991; E. A. Walker, A. N. Gelfand, M. D. Gelfand, M. P. Koss, & Katon, 1995; E. A. Walker, Katon, Roy-Byrne, Jemelka, & J. Russo, 1993; Walling et al., 1994). It is therefore difficult to separate the effects of these childhood and adulthood abuse experiences. The health problems most studied in relation to abuse are chronic conditions, most commonly pelvic pain and gastrointestinal disorders.

Chronic Pelvic Pain. Chronic pelvic pain, generally defined as noncyclic pelvic pain of greater than 6 months duration, accounts for approximately 10% of all gynecological visits, and is listed as the indication for up to 34% of diagnostic laparoscopies (Reiter, 1990; Reiter & Gambone, 1990). It is the third most frequent indication for hysterectomy, accounting for approximately 12% or 78,000 such surgeries annually (Lee, Dicker, Rubin, & Ory, 1984; Reiter et al., 1991). It is considered a frustrating syndrome to treat for both the patient and her physician, because in approximately 35% of cases no intrapelvic pathology is evident, diminishing hope for a medical cure (Reiter, 1990).

Research on correlates of chronic pelvic pain indicates that between 53% and 64% of patients referred to a specialty clinic for this condition have a history of physical and/or sexual abuse (Rapkin et al., 1990; Reiter & Gambone, 1990; Toomey, Hernandez, Gittleman, & Hulka, 1993; Walling et al., 1994). Rapkin and colleagues (1990) found a high prevalence of childhood abuse (52%) among a sample of chronic pelvic pain patients, whereas abuse during adulthood (since the 18th birthday) was reported by 16%. In this sample, physical abuse was more predictive of chronic pelvic pain than was sexual abuse. A similar study (Walling et al., 1994) distinguished between any sexual abuse (i.e., forced or coerced fondling through clothing, touching, kissing) and major sexual abuse (i.e., penetration or other direct contact with unclothed genitals). Using these criteria, in this sample 36% of 64 chronic pelvic pain patients experienced major sexual abuse before age 15, and 33% had experienced such abuse since their 15th birthday; some women had experienced both. Rates for "any" sexual abuse were even higher. In addition, 39% reported physical abuse before age 15, and 36% since that time (Walling et al., 1994). It should be noted that sexual abuse in these samples, as in the general population, generally was found to be concomitant with physical abuse.

Reiter and colleagues (1991) reported that rates of abuse are higher among chronic pelvic pain patients with no identifiable somatic abnormality than among patients with probable somatic pelvic pain. Of 52 women with "nonsomatic" pelvic pain, 67% had experienced sexual abuse or trauma before age 20, compared with 28% of 47 women with identified "somatic" pelvic pain reporting such abuse. The study by Rapkin and associates (1990) looked at women with chronic pelvic pain and found a significant difference in the proportions of those with and without identified pelvic pathology who had experienced physical abuse in adulthood. None of the 19 chronic pelvic pain patients with identified pathology had been victims of physical abuse as an adult, compared to 27% of 11 women with no identified pathology.

An abuse history also appears to be associated with other physical symptoms. Two studies of chronic pelvic pain each used two comparison groups: one of pain-free gynecology patients, and one of female chronic headache patients. The data suggest a general association between abuse and chronic pain, as well as a specific association between major sexual abuse and chronic pelvic pain (Rapkin et al., 1990; Walling et al., 1994). Women evaluated for chronic pelvic pain who have a positive history of abuse also report significantly more

physical and psychological symptoms unrelated to pelvic pain than do women who have not been abused (Reiter et al., 1991; Reiter & Gambone, 1990; Toomey et al., 1993).

Gastrointestinal Disorders. Among the most common additional complaints of chronic pelvic pain patients are those consistent with gastrointestinal disorders, most particularly irritable bowel syndrome (IBS). Considerable overlap has been reported in diagnoses of the two disorders, with as many as 79% of chronic pelvic pain patients also meeting criteria for probable irritable bowel syndrome (Hogston, 1987; E. A. Walker et al., 1991). Both organically based and functional gastrointestinal disorders have also been researched for association with abuse history in women (Drossman et al., 1990; Talley et al., 1994; E. A. Walker et al., 1993, 1995). Functional gastrointestinal disorders, including IBS, nonulcer dyspepsia, and chronic abdominal pain make up about 35% of gastrointestinal disorder diagnoses, and occur more frequently in women (Drossman et al., 1990). These disorders have no known pathogenesis or established treatment, and are the most common chronic gastrointestinal conditions seen in primary care, as well as the most common reason for referral to gastroenterologists (Drossman et al., 1990; Talley et al., 1994).

In various clinical samples, between 44% and 59% of all female gastroenterology patients report a history of sexual abuse, and between 32% and 48% of female patients have experienced severe sexual trauma (Drossman et al., 1990, Walker et al., 1993, 1995). Thirty-six percent of 206 female patients in a study by Drossman and associates (1990) reported physical and/or sexual abuse since age 14. In this study, women with functional gastrointestinal disorders were more likely than those with organic disorders to report a history of severe sexual abuse and frequent physical abuse. However, another study of women gastroenterology patients with and without histories of severe sexual trauma found no significant difference between the two groups in terms of diagnostic category (functional or organic disorder; E. A. Walker et al., 1995). These authors found that a history of severe sexual trauma was significantly associated with physical abuse as an adult, however. Victims of severe sexual trauma also suffered from significantly more lifetime psychiatric disorders, and more medically unexplained physical symptoms, both including and excluding gastrointestinal symptoms, than women patients without a history of sexual trauma (E. A. Walker et al., 1995).

Other Chronic Pain. Other chronic pain, particularly chronic headache, is also found to be associated with physical and sexual abuse in women (Domino & Haber, 1987; Haber & Roos, 1985). Some evidence suggests that chronic headache may be a syndrome especially related to experience with male partner violence in adulthood. Of women referred to a pain center for chronic headaches unresponsive to headache medication regimens, 61% had experienced prior physical abuse, 11% had been sexually abused, and 28% had experienced both physical and sexual abuse (Domino &

Haber, 1987). The abuse reported occurred primarily after age 20, with an average duration of abuse of approximately 8 years. Headache onset in all cases followed initiation of the abuse. A major difference in headache etiology was found between abused and nonabused women, with 75% of abused women developing headache pain after age 20, as compared to 86% of nonabused women developing headache problems before age 20.

Several studies have demonstrated that medical utilization increases following victimization experiences (Golding, 1994; Golding, Stein, Siegel, Burnam, & Sorenson, 1988; Kimerling & Calhoun, 1994; M. P. Koss, P. G. Koss, & Woodruff, 1991; Liebschutz, Mulvey, & Samet, 1997). One related factor may be that women who have experienced contact or noncontact crime rate their health significantly less well than women who have not been victimized (Kimerling & Calhoun, 1994; M. P. Koss, Woodruff, & P. G. Koss, 1991; M. P. Koss, P. G. Koss, & Woodruff, 1990). M. P. Koss, P. G. Koss, and Woodruff (1991) found that those women who had experienced severe crimes such as rape or repeated physical assault had the greatest number of health complaints and symptoms of emotional distress. In addition, this study found a positive linear relation between the level of victimization and both the mean number of outpatient visits in the year of the crime (index year), and the mean outpatient expenses during that time, as recorded in medical records. Medical record review indicated that medical care utilization of victims surpassed that of nonvictims only following the victimization. Whereas nonvictims' utilization in the index year increased only 2% over a 2-year baseline period, assault victims' physician visits increased 31% and those by rape victims increased 56% during the same time period. The rate of utilization among victims remained significantly higher than that of nonvictims in the last year of the study, 2 years following the crime. Kimerling and Calhoun (1994), controlling for all routine medical visits such as annual physicals and gynecological exams, as well as initial emergency room and other medical visits due to injuries sustained in the attack, found similar increased utilization with victims of sexual assault in a self-report study of medical usage.

Victims of abuse suffering from pelvic pain or gastrointestinal disorders appear to have higher rates of medical utilization than their nonabused counterparts (Schei, 1990; Talley et al., 1994). A study of pelvic pain conducted in Norway found that 48% of 63 women living in an abusive relationship within the past year had a history of pelvic pain, as compared to 21% of 114 women in a comparison group never abused by a male partner. The abused women were significantly more likely to have seen a physician for the condition (26%) than were the nonabused women (9%) (Schei, 1990). A population-based study with 30- to 49-year-old residents of a midwestern county, surveying gastrointestinal symptoms and self-reported abuse, found a similar result (Talley et al., 1994). There were significant associations between symptoms of functional gastrointestinal disorders and physical, sexual, and psychological abuse in childhood and adulthood. Fifty-two percent of abused subjects reported abuse as both children and adults. Of all respondents classified as having

IBS, 60% had seen a physician for their symptoms at some time in the past. Among respondents with gastrointestinal symptoms, significantly more visits were made to physicians by those patients who had experienced any abuse, those who had been abused in adulthood and childhood, by those with any history of sexual abuse, and by those with a history of frequent emotional or verbal abuse, as compared to nonabused respondents (Talley et al., 1994).

Increased health care utilization is not a unique attribute of women with a history of abuse, but rather is found among those people experiencing psychological distress and stressful life events in general (Katon, Ries, & Kleinman, 1984). Neither are the symptoms of those with psychosocial factors such as anxiety, stress, depression, and lack of social support necessarily more associated with functional, or "nonsomatic," disorders than with organic or medically explained disorders (Smith et al., 1990; E. A. Walker et al., 1995; Whitehead, Bosmajian, Zonderman, Costa, & Schuster, 1988). For example, Smith and associates (1990) found that psychosocial factors could not distinguish between patients with irritable bowel syndrome and those for whom an organic disease was found to explain the symptoms. Both groups of patients, however, had significantly more psychosocial difficulties than did a comparison group of patients with no gastrointestinal disorder. It was concluded that psychosocial criteria were determinants of health care seeking for the entire study group (Smith et al., 1990). Such somatization is regarded as highly prevalent in primary care. In a review, Katon et al. (1984) estimated that between 25% and 75% of primary care visits are primarily related to psychosocial distress, but that patients most often present with somatic complaints. As many as 60% of primary care patients present recurrently with physical symptoms that are related to psychosocial distress, a pattern that has been found to decrease significantly when the patient is referred to short-term psychotherapy (Katon et al., 1984).

Consistent with these findings, victims of partner violence experience higher levels of psychological distress than nonvictims (McCauley et al., 1995; Gelles & Harrop, 1989), yet somatic complaints are most often the problems bringing abused women into contact with the health care system. Victims are more likely to seek medical care than they are to use mental health services, social services, victim assistance, legal aid, or counseling from clergy (Kimerling & Calhoun, 1994; M. P. Koss, P. G. Koss, & Woodruff, 1991). Physicians and other health care practitioners are thus exceptionally well positioned to identify victims and to provide an opportunity to consider treatment options. Perhaps partially accounting for increased medical utilization is the finding that victimized women are more likely to engage in health risk and self-injurious behaviors such as smoking, alcohol use, and failure to use seatbelts (M. P. Koss, P. G. Koss, & Woodruff, 1991). Women with a history of abuse are also at a higher risk for exhibiting eating disorders than nonabused women (Root & Fallon, 1988). In addition, risk of suicide is increased among victims of partner violence compared with nonvictims (Amaro et al., 1990; Berrios & Grady, 1991; Stark et al., 1981).

IMPLICATIONS FOR MEDICAL CARE

The medical community has begun to recognize both the impact of partner violence and the role that health care providers can play in detecting and referring patients who have been physically abused. In 1992, the American Medical Association issued guidelines on the diagnosis and treatment of domestic violence, and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) began requiring that all accredited hospitals implement protocols in their treatment facilities for identifying, treating, and referring victims of abuse (AMA, 1992). The AMA Council on Ethical and Judicial Affairs has written that the principles of beneficence and nonmaleficence that guide medical practice require physicians to do more than treat only the injuries and symptoms of abuse (Council on Ethical and Judicial Affairs, 1992). These calls for involvement in the issue are prompted both by growing awareness of the health and financial costs associated with violence, and evidence for the appropriateness of screening for abuse due to the high likelihood that physicians and other practitioners will encounter victims in their practices (Council on Scientific Affairs, 1992). Despite these recommendations, the medical community has been reluctant to recognize its obligation in partner violence intervention. The majority of women favor routine physician inquiry about physical and sexual abuse and believe that physicians can be helpful (Friedman, Samet, Roberts, Hudlin, & Hans, 1992), but physicians in every medical setting neglect screening for partner violence among their patients. In fact, women report that among the services to which they turn for help in ending violence in their lives, such as the police, social service/counseling, lawyers, clergy, women's shelters, women's groups and district attorneys, medical professionals are least likely to be very or somewhat effective (Bowker & Maurer, 1987). Failure to identify victims as abused may lead to continued medical utilization for physical complaints, inappropriate diagnoses, and may contribute to her staying in a potentially life threatening situation.

Victims' Experience in the Medical Care System

The medical community is in a critical position to intervene in partner violence. Not only are victims of partner violence highly likely to present themselves to some type of health care setting, it may also be one of the only types of services with which they come in contact. Isolation characterizes the life of a woman experiencing partner violence. A violent partner attempts to minimize the contact that his victim has with outside organizations that he believes may jeopardize his control over her (Sasseti, 1993; L. Walker, 1979, 1984). Violent incidents may precipitate contact with law enforcement, but the likelihood that the victim will reach out for help in these high stress situations is slim. Experience with the criminal justice system has taught many women that the police can only hold her abuser for a limited period of time, and on release she will be unprotected. She is under extreme pressure to make decisions, and believes that the law cannot protect her (Bouza, 1991).

A victim of partner abuse can, however, justify trips to the doctor for routine examinations, prenatal care, or treatment of conditions that are not recognized as an outcome of the abuse. Medical attention following a violent explosion may also be necessary, although women often wait several days before presenting to a physician for fear that the abuse will be detected. Of 74 women surveyed in a woman's shelter in Michigan, over half revealed that they did not seek care immediately after an attack (Campbell, Pliska, Taylor, & Sheridan, 1994). A woman's abuser may refuse to allow his victim to seek medical treatment for fear of being detected, however it may become apparent in the following days that she must seek attention. At this point, the woman is calmer and more likely to have entered a stage of reconciliation with her abuser (L. Walker, 1984). Unless she is asked, she may prefer to mask the source of her injuries.

Lack of Detection

Emergency Departments. Emergency departments have been recognized as a portal of entry for victims of partner violence, but physicians in this setting have consistently failed to routinely screen their patients. Stark, Flitcraft, and Frazier (1979) conducted a retrospective study to determine the incidence of partner violence among women presenting in an emergency department during a 2-month period by evaluating medical records for evidence of abuse. Although physicians had identified less than 3% of the 481 female patients as victims of violence, the full medical histories revealed that at least 10% of the patients could positively be identified as victims and another 15% had case histories strongly indicative of abuse (Stark, Flitcraft, & Frazier, 1979). In a more recent study of 47 women (12% of total sample) who indicated on an anonymous survey that their present trip to the emergency department could be related to abuse by a current partner, only 4 were asked about partner violence by emergency department professionals (Abbot, R. Johnson, Koziol-McLain, & Lowenstein, 1995).

To better understand how clinicians respond to partner violence, Kurz (1987) conducted a participant observation study of health care providers in four emergency departments in Philadelphia. The staff in three departments had been informed of the study and referral cards were made available to them, but no additional information was given about partner violence. In the fourth setting, a formal documentation system was set up and one staff member actively educated herself on the characteristics of partner violence. Of the patients that met the observers' established criteria for suggested violence, 40% of cases in the first three departments received no response from medical staff, 49% received acknowledgment and a hotline number but staff involvement was brief and routine, and 11% received a positive response in which staff viewed the case as legitimate and deserving of time and attention, noted partner violence on the record, and spoke with the woman about safety issues. Women who were characterized as "true victims" were more likely to receive a positive response than those who were

viewed as "troublesome," "evasive," or appeared under the influence of drugs or alcohol. These women were more often diagnosed as suffering from depression or substance abuse. Under the conditions of the fourth emergency department, 32% of cases still received no response and 21% only a partial response, however 47% received a positive response, due primarily to the efforts of eight of the staff members who saw intervention as part of their job. Reasons given for lack of response were similar to those found in the other three sites (Kurz, 1987).

Education is a key factor in facilitating the screening process, and has only recently begun to be incorporated into formal medical training (Baker, 1995). Of the California emergency departments responding to a survey, only 23% of the physician directors confirmed that their emergency department had conducted an educational session on the issue of spousal abuse (Morbidity & Mortality Weekly Report, 1992). This is unfortunate because even without protocol, education exerts a positive influence on the likelihood that a physician will suspect abuse (Tilden et al., 1994).

Having a formal protocol in place for the treatment of partner violence has a positive impact on the rate of screening in emergency departments. For example, McLeer, Anwar, Herman, and Macquiling (1989) conducted a retrospective study in the years before and after the establishment of protocol formalizing policies and procedures to identify victims of partner abuse in an emergency department in Philadelphia. Rates of identification jumped from 5.6% to 30.0% with the implementation of protocol. When the same emergency department was studied 10 years later to determine if screening continued in the absence of a protocol, identification had again fallen to 7.6%, despite little demographic alteration in the population seeking care at the hospital. This dramatic change was interpreted as employee turnover and due to new staff who had not been included in the training on partner abuse and who did not prioritize its identification (McLeer et al., 1989). A recent Morbidity and Mortality Weekly Report survey to assess the progress of emergency departments in California toward the year 2000 objectives found that as few as 29% had established written policies and procedures regarding suspected victims of partner abuse. Although 93% reported having referral lists, only 9% of those submitted were comprehensive, including information on domestic violence services, mental health and community agencies, criminal justice system agencies, social services agencies, and legal assistance agencies (Morbidity & Mortality Weekly Report, 1993).

Nevertheless, establishing protocol does not ensure that the recommended practices regarding victims of violence will be followed. Emergency department physicians neglect to fully carry out policies and procedures when administering rape examinations to victims of sexual assault. The National Victim Center reported that 60% of victims receiving examinations were never advised about pregnancy testing or how to prevent a pregnancy, 73% were not given information about testing for exposure to HIV/AIDS, and 34% were not given information about testing for exposure to sexually transmitted diseases (National Victim Center, 1992).

An underlying issue that must be addressed is that with or without protocol, physicians generally underestimate the likelihood that their patients are victims. A recent survey of emergency departments in Massachusetts revealed that half of the respondents estimated that 2% or less of their patients were victims of partner violence (Isaac & Sanchez, 1994). Compared with an established rate of from 20% to 30% (Flitcraft, 1990; Morbidity & Mortality Weekly Report, 1993), this appraisal seems improbable. It is more likely that a large percentage of victims go undetected and unaided.

Primary Care. Although primary care providers are more likely than emergency department physicians to attend victims of partner violence for a variety of presenting health issues, formal policies and procedures have been even slower to appear in primary care settings. Just as in emergency departments, without protocol physicians are extremely unlikely to question their patients about possible abuse. Moreover, many are unaware of the true prevalence of partner violence. A mail survey was sent to 221 health care providers asking about their attitudes toward partner violence among their patients. The majority of physicians believed that abuse was infrequent (Tilden et al., 1994). Of 164 female patients surveyed in both a private and public health care site, only 7% were ever asked about physical abuse, and just 6% were asked about sexual abuse (Friedman et al., 1992). There is evidence that protocol for screening for violence would be effective. Inclusion of a question regarding partner violence on a self-administered health history form resulted in 11.6% of women responding affirmatively as compared to 0% identified among the group not given the question (Freund, Bak, & Blackhall, 1996).

Prenatal Care. It has been established that pregnant women are at risk for partner violence (Gielen, O'Campo, Faden, Kass & Xue, 1994; Hamberger, Saunders & Hovey, 1992; Helton, 1989; Helton et al., 1987; Hillard, 1985; Morbidity & Mortality Weekly Report, 1994). Routine prenatal care, however, is limited to the assessment of risk factors such as hypertension, diabetes, and nutritional inadequacies that may predict pregnancy complications or poor birth outcomes. Although the American College of OB/GYN has recommended that routine screening for partner violence be included on the list of risk factors because it places women in immediate danger (American College of Obstetrics and Gynecology, 1989), screening in prenatal clinics is rare. Survey of 374 pregnant women seeking care at a community health care clinic during a 2-month period revealed that 23.7% of the respondents affirmed that they had experienced physical assault in the past year, but only 1.7% had been asked by their physician if they were a victim of abuse (Hamberger et al., 1992). The Helton et al. (1987) study of 290 women attending public and private prenatal clinics identified 8% as experiencing violence during their current pregnancy, none of whom had been assessed for partner violence by their physician (Helton et al., 1987).

Misdiagnosis

Failing to probe for the underlying cause of injuries or unexplainable somatic problems not only sends a woman back into a dangerous situation where she may suffer more serious injury, it also initiates an ongoing cycle of contacts with medical and mental health providers with increasingly severe sequelae for the patient (Council on Scientific Affairs, 1992). Treatment of chronic pelvic pain, a common presenting complaint among victims of partner violence, can be perplexing for the physician who cannot find an etiology for the pain, and is therefore unable to make a diagnosis. Hysterectomies are often recommended in the absence of a definitive etiology, in spite of significant morbidity and occasional mortality accompanying the operation and the frequent lack of desired therapeutic outcomes (Gambone & Reiter, 1990). A study of 152 chronic pelvic pain patients found that 30% had undergone a previous hysterectomy, only to experience a recurrence of the pain after the surgery (Slocumb, 1990).

Physicians looking for the physical etiology of a disease may become frustrated and decide that their patient's condition is mentally based. Physicians who fail to find an organic cause of the woman's complaints of headache, bowel disorders, muscle pains, or painful intercourse tend to label her as "somatizing," "hysterical," or as a "well-known patient with multiple vague complaints." Medical records confirm that 1 in 4 female victims of partner violence are diagnosed using pseudopsychiatric labels, as compared to 1 in 50 nonvictims (Stark et al., 1979). The likely response of the physician is to prescribe medication for the "somatizing" woman with the aim of calming her down and satisfying her need for some type of medical response to her problem. Nearly 1 in 4 victims receives a prescription for tranquilizers, as compared to 1 in 10 nonvictims (Stark et al., 1979).

Primary care physicians' use of labels to classify the physical complaints of victims of partner violence is based on misapplication of the terms *psychosomatic* and *somatization disorder* as defined by the psychiatric profession. Those patients suffering from somatization disorder are defined by the *Diagnostic and Statistical Manual of Mental Disorders* (3rd, rev. ed., *DSM-III-R*) as having a lifetime history of physical complaints and current experience of multiple (13 or more) somatic symptoms. Numerous medical problems manifested in victims of partner violence present with symptoms similar to those with somatization disorder, such as the psychological components of anxiety, which is often expressed in abdominal pain, the vegetative symptoms of depression, and panic disorder (Smith, 1990). In the case of violence victims, however, these are in direct response to a life context that is producing the condition. "Psychosomatic" is often misused to refer to a somatic dysfunction for which psychological factors are believed to play a causal role, however the term actually refers to the inseparability and interdependence of psychosocial and biologic aspects of humankind, of which the immediate social context of the patient is an integral part (Lipowski, 1984). Proper clinical management cannot be achieved without correct diagnosis. If the complaint finally is

found lacking medical explanation, screening for factors such as partner abuse is even more strongly indicated.

Retraumatization

A woman caught in a cycle of partner violence is in constant battle to control her situation and minimize the damage to herself and her family. She is the daily target of accusations that she is the cause of the problems in the relationship, and although she may suspect that this is another facet of her partner's abuse, her isolation makes this difficult to confirm. Because a slip on her part may lead to severe outcomes, she must carefully choose ways to reach out for help that will not put herself and her children at more danger. Lack of response to her efforts may drive her further into desperation and the belief that she is alone in a situation for which there is no escape. An outside perspective may view a woman's behavior as "helpless," however this is a misinterpretation of a victim's struggle for survival.

A victim of partner abuse may risk asking for a physician for help in resolving a violent predicament (Martins, Holzapfel, & Baker, 1992). But, rather than openly exposing herself and her situation, she is more likely to give strong clues to her physician that she is experiencing abuse (Warshaw, 1992). Affirmation that she is not responsible for the violence and information about options available to her may be all a woman requires in order to begin the process of ending the abuse. When the physician misses her underlying pleas for help, the woman's fears that she is without social support are verified.

Women seeking assistance from their physician by presenting with unexplainable complaints often find that it is their batterers who receive affirmation. Victims of male partner violence are frequently labeled with substance abuse problems or mental disturbances in order to explain the failure to identify a medical explanation for the illness (Flitcraft, 1993; Kurz, 1987; Stark et al., 1981). In this manner, the physician-patient relationship actually replicates the subjugation and name calling that a victim is currently experiencing with her partner. This results in an increased sense of despair and helplessness that may contribute to the sequelae she is already experiencing due to the violence (Warshaw, 1992). Medical labeling occurs at the height of a woman's vulnerability, encouraging her perception that her abusive relationship is the symptom of her own dependency and helplessness, and the impression that she, and not her partner, is sick. This intensifies her sense of confusion about the situation, as well as heightening fears that she cannot escape this dangerous relationship (Stark et al., 1979).

Physician Involvement in Patient Care

Many explanations have been offered to account for the low rate of victim identification among health care providers. Burge (1989) argued that the biomedical framework does not consider partner violence to be a health problem, and therefore physicians do not feel responsible for dealing with the is-

sue. Candib (1990) pointed out that recognizing male partner violence against women is a challenge for the family physician who holds fundamental assumptions about the importance of the nuclear family for the health of all its members. Kurz (1987) suggested that among partner violence victims presenting in an emergency department, only those who appear to be "true victims," thus evoking the sympathy of the health care provider, will be identified. The fact that identification of victims is low across all types of medical care settings regardless of protocol indicates that screening will not take place unless physicians consider it part of their role as health care providers. Attitudes toward screening, however, constitute only one of the many impediments to victim identification.

Systemic Barriers. Physicians encounter myriad obstacles to diagnosing the existence of partner violence, from the type of training they receive to the systematic pressures of the medical setting. The biomedical framework in which physicians are trained does not prepare them to consider the social context in which the patient lives, but rather defines her problem in a physical, diagnostic category that can be cured and prevented from recurring. By looking at only physical body parts, physicians are actually reconstructing a false history, because they neglect to recognize the possibility that the real danger to her well-being comes not from the illness or injury that they are treating, but from returning to a situation of escalating violence (Warshaw, 1992).

Biomedical training also requires that physicians evaluate what is directly presented to them, including the immediate symptoms, the medical history of the patient, and the relevant physiological data. They are expected to fit this information into diagnostic categories that are linked to various treatments. This single process does not allow the physician to consider the social causes of the symptoms or factors that cannot be controlled by a medical solution (Stark et al., 1979).

The medical record provides evidence of the manner in which the woman's perspective is devalued in the patient-physician exchange. Inherent in the words "complaints of" is the assertion that the woman's symptoms are not indicative of a real problem. By focusing on the physical character of these symptoms exclusive of the woman's life experience, she is further diminished, and the real etiology behind her "complaint" is obscured (Warshaw, 1993). The needs of the patient reaching out for assistance and the physician attempting to diagnose her are subsumed by the more powerful medical community.

Personal Barriers. Physicians, as well as patients, are operating within larger social contexts, and the implications of partner violence have resonance in their lives far beyond the point that the patient departs from their office. Just as in society as a whole, it is much more comfortable to underestimate the existence of this type of violence, which is frightening and incomprehensible. Depending on education and personal experience, a physician may undergo a range of emotional responses

from believing that the woman must be doing something to provoke such violence to being extremely frustrated that any one would choose to stay in such a situation.

Attitudes Toward Women. Evidence of the sexism experienced by women in the medical field is well established. Women entering medical school are extremely likely to undergo an incident of gender-based discrimination or sexual harassment from supervisors and men of higher professional status during their years of study (Cotton, 1992; Grant, 1988; Komaromy, Bindman, Haber, & Sande, 1993), contributing to an overall hostile learning and work experience (Komaromy et al., 1993). Women also endure more subtle forms of discrimination from their supervisors, such as the questioning of their physical stamina and emotional stability, and being addressed in disparaging terms in front of colleagues (Grant, 1988). Although perhaps better able to control their environment as professionals, women physicians suffer discrimination in the form of lower salaries, regardless of their years spent in practice (Council on Ethical and Judicial Affairs, 1994).

Gender-based discrimination has recently been emerging as a concern facing the medical profession, however the slow pace of the community to confront the issue is further evidence of the entrenched state of the problem. It is inevitable that such attitudes be transferred to the care of female patients. Evidence suggests that gender bias plays an inappropriate role in clinical decision making. Physicians are more likely to attribute women's health complaints to emotional causes, and to characterize women's concerns about their health as overanxious (Council on Ethical and Judicial Affairs, 1994).

Societal beliefs also influence physician treatment of victims of male partner violence. Health care providers with more liberal attitudes are less likely to blame victims for the violence (Rose & Saunders, 1986), and victims are more likely to receive empathetic treatment from female practitioners (Rose & Saunders, 1986; Saunders & Kindy, 1993; Tilden et al., 1994).

Personal Fears. Sugg and Inui (1992) employed an ethnographic interview technique to discover barriers to partner violence screening, and determined several dominant themes among the 38 physicians interviewed. The responses, characterized by the analogy of opening Pandora's box, were broken down into several categories. In all, 38% expressed fears that seeing a patient as a victim was "too close for comfort," indicating that physician identification with their patients may preclude them from considering intimate violence in their differential diagnosis, especially when patients are from similar, typically White, middle-class backgrounds. A second category was "fear of offending" (55%), originating in the physician's discomfort with areas that are culturally defined as private. By overwhelming response the physicians faulted "the tyranny of the time schedule" for failing to screen, and voiced frustration with the expectations on the physician to address all of these problems. Finally, a major concern was that physicians felt "powerless" (50%) in their

capacity to help a woman who disclosed an abusive relationship (Sugg & Inui, 1992).

Warshaw (1989) suggested that issues put forth by physicians, such as lack of time, are really masking feelings of being professionally overwhelmed. Because the expectation of health care providers is that they find out what is wrong and solve the problem, they find it difficult to enter areas that are unfamiliar and do not have a prescribed response. Personal bias may also impede physicians who feel their own personal safety at risk when someone whom they perceive as similar to themselves is also a victim of partner abuse (Warshaw, 1989).

To explore the constraints of the biomedical framework on partner violence intervention, Warshaw and Poirier (1991) reconstructed a videotaped interview between a physician and his patient who was suffering from extremely high blood pressure for which the etiology was unclear. The forms of treatment provided to the patient had all been unsuccessful. The physician was clearly frustrated as he limited himself to searching for an organic cause of his patient's condition. He finally broke out of the biomedical structure of the patient-physician interaction in order to inquire into the social context of her life and understand the larger and abusive context in which she lived for the past 25 years. Warshaw and Poirier argued that although the medical model may provide distance from disturbing realities by confining itself to objectivity, it also limits the physicians' ability to understand the etiology of the disease they are treating (Warshaw & Poirier, 1991).

CONCLUSIONS

The studies reviewed here document the extent of male partner violence, and in particular the prevalence of victims in the medical care system. Injuries resulting from partner violence are recognized as a major threat to the lives of women presenting in emergency departments. Although data confirming direct links between violence and health outcomes in primary and prenatal care is sparse, the high rate of medical utilization among victims as compared to nonvictims points to an association, if not a causal relation. Health care institutions have begun to respond to the problem by recommending policies and procedures with regard to identifying and treating victims, however this effort has not yet been adapted on an individual level, nor has the effect of this approach been evaluated. It is clear that more and better research is necessary in order to understand the full impact of violence on the health of women, and to reach appropriate conclusions about how best to treat the problem within the medical community.

Methodological Problems

Violence is a multifaceted phenomenon, and is manifested not only physically, but also psychologically and sexually. Studies to date reflect the attempts of investigators to understand the impact of different forms of violence on victims. However, the process is complicated by the complexity of the problem, as evidenced in the lack of consistent definitions across studies, difficulties around measuring health out-

comes, and a lack of analysis of the multivariate nature of factors that may influence or compound the effects of violence.

The most widely used tool to define and measure violence between partners is the Conflict Tactics Scale (CTS), which assesses overall violence during the past year as well as incidents of severe violence. This scale has been criticized as a measurement of male partner abuse because it fails to reflect the inequality inherent in an abusive relationship and does not take into account issues of power and control. For example, women may consider threats to take the children more threatening than actual incidence of violence. Recent studies have utilized instruments that include elements of psychological abuse in their analysis, but as yet a more sensitive and reliable alternative has not been developed to replace the CTS. Such an instrument is necessary to provide a consistent measure of the occurrence of violence between partners.

A problem similarly exists with the lack of a standardized screening instrument to identify victims of partner violence in the medical setting. Studies and protocols employ varying definitions of any abuse, severe abuse, childhood versus adulthood abuse, and partner violence, for example. Estimates of prevalence and assessment of outcomes of abuse are made difficult by the use of inconsistent terminology. The development, testing, and use of a common screening tool could facilitate data collection, as well as more appropriate identification and referral of victims.

The health outcomes of partner violence are also difficult to measure due to the lack of routine documentation in medical charts. Currently, investigators must rely on self-report of partner violence and the recorded frequency of care. As long as health care providers fail to consider and document the relation between violence and the manifestations of illness in their patients, no reliable record will exist. Recommendations to establish protocol for screening victims need to be operationalized across medical settings in order to adequately assess the effects of partner violence on the health of women and improve treatment.

A related issue concerns the need to more clearly define and research symptoms associated with violence in order to establish etiology. For instance, it has been shown that patients suffering from either functional or organic gastrointestinal disorders are relatively likely to have a history of abuse, yet the pathogenesis has not been elucidated. In addition, the high overlap of chronic pelvic pain and gastrointestinal symptoms suggests perhaps a similarity in the experience of these disorders that needs further investigation.

A third problem with current research on partner violence is the lack of a methodological approach to deal with the interaction between different forms of violence and the resulting impact on health. There currently exist two bodies of literature addressing violence toward women, one focusing on physical aggression and the other on sexual assault. Often, however, these two forms of violence are part of the same phenomenon. Yet the health outcomes associated with rape may be overlooked for partner violence victims because the abuse is continuous and the assailant is not a stranger. Multivariate methodologies are needed to study the interactional nature of

physical and sexual abuse, rather than continuing to view them in isolation.

A multivariate perspective is needed, too, in order to understand the relations and effects of other factors that may co-occur with partner violence. The interactions and cumulative effects of poverty, childhood experiences, witnessing violence, drug and alcohol misuse, and other social factors on health outcomes are unknown. The pathways of the various associations—for example, between alcohol misuse and gastrointestinal disorders, alcohol misuse and partner violence, and partner violence and gastrointestinal disorders—could be made clearer with multivariate approaches.

Finally, the majority of the research regarding the health impacts of male partner violence continues to be informed primarily by the medical model. Analysis focuses on the individual and fails to see the social context in which violence takes place. This process tends to dehumanize and decontextualize women, and obscures social factors that compound the health effects of violence and play a large role in their emotional and physical responses to the situation. Future research must include a gender analysis that legitimizes these responses to better elucidate the most appropriate form of treatment for the problem by the medical community.

Gaps in Knowledge

This chapter has suggested that in failing to diagnose the existence of partner violence in the lives of their patients, health care providers may actually be contributing to its maintenance. In order to better inform health care providers on the effects of violence among their patients and suggest approaches to treatment, several aspects of violence and its interaction with other social factors are recommended as a focus for further research. A prerequisite is the formation of a nationwide data collection system that will more accurately measure incidence and prevalence. The system should also help to develop and promote the use of consistent definitions of psychological, physical, and sexual violence against both children and adults. Breakdowns in terms of age, ethnicity, and socioeconomic status and the relation of these factors to forms and outcomes of violence will also provide valuable information.

Anthropological study of the meaning of violence among different groups within the general population is a second area for research. Too little empirical research examines the extent and nature of partner violence from a cultural context (for exceptions see Chester et al., 1994; Chrestman, Polacca, & Koss, 1999; Lefley, Scott, Llabre, & Hicks, 1993, 1997; Ramos, Koss, & Russo, 1999; Russo, Denious, Keita, & Koss, 1997). Hampton and Gelles (1994) suggested three reasons for the neglect of women of color in partner violence research. First, small sample sizes make it difficult to generalize findings to the minority population. Small sample sizes also hinder intragroup analyses of ethnic groups by further breaking them down based on established predictors of violence such as unemployment and education. Second are concerns that research findings will exacerbate already existing perceptions that violence is more prevalent within minority ethnic groups. Third

is a general lack of interest in the impact of partner violence on women of color. Furthermore, existing research investigating ethnic differences suffers from methodological complications. Crenshaw (1993) pointed out that research measures are developed and validated in majority populations and they tend to ignore the social and cultural context of other ethnic groups. Current instrumentation reflects uniformity assumptions about family organization, lifestyle, place of residence, and beliefs about what is acceptable conduct within a relationship. Specifically, partner violence screening questions may assume a nuclear family when extended families are the norm in many cultures, may be written from a paternalistic family model that ill-suits matrilineal and matrilocal kin structure that is prevalent among American Indians as well as other groups, and are biased toward urban lifestyles, failing to consider that denying telephone or transportation may be frequent and serious forms of intimidation in rural areas.

Current instrumentation reflects the assumption that beliefs about what is acceptable conduct within a relationship and what constitutes violence are the same across cultural groups. Questions may emphasize behaviors that are less important within some cultures, while failing to elucidate others that could cause more damage to the physical and emotional safety of women. Research on the definitions of violence in different groups is necessary in order to develop an instrument that competently measures violence, as well as providing health care providers with cross-cultural information on the best ways to screen for victimization among their patients.

More descriptive research is also needed on women's experience in the medical system. As the chronic pelvic pain and irritable bowel syndrome literature is beginning to suggest, some women may be shunted through the system and treated according to the diagnosis they receive, while in fact their symptoms may overlap both, and may be related to an undisclosed history of abuse. The problem of inappropriate prescribing of tranquilizers and sedatives to victims of partner violence is another area in need of further research.

As in the case of physical violence and sexual assault, there is currently little understanding of how other factors may interact with partner abuse to result in the high utilization of health services. Current studies on health outcomes of victimization generally include women with any history of abuse thus failing to partial effects among cumulative violence a woman may have faced across her life span. A second area of investigation must be directed toward isolating the effect of partner violence, as well as attempting to identify and assess other components accompanying the abuse, such as substance abuse, poverty, and childhood experience that may either interact with partner violence or work in isolation to produce health effects.

A final area of research involves the provision of more information on the potential effects of screening in order to base recommendations regarding victim identification on reasonable conclusions. Although patient screening is currently being encouraged in all health care settings, there has been no evaluation of whether identification improves treatment or actually assists the victims in some way. Negative outcomes

must also be assessed, such as the possible threat to confidentiality by institutions that may discriminate against the victim. It is also necessary to examine the impact of forcing physicians to screen while their attitudes regarding women and partner violence remain the same. If physicians do not agree with the underlying causes and effects of partner violence, then they may be less likely to make the referrals proposed by the protocol.

The research community has begun to respond to the need for more research in the area of women's health. However, the overwhelming impact of violence on the lives and health of women outlined here is not reflected in the allocation of resources. The research community must begin to make violence against women a priority in order to adequately address a major health concern of women and provide the medical community with an appropriate response.

Confronting Fertility Problems: Current Research and Future Challenges

Lauri A. Pasch
University of California, San Francisco

The great majority of young adults intend to become parents at some point in their lives (Jacobson & Heaton, 1991). Couples who desire to have children usually assume that pregnancy will occur naturally over a period of months of not using contraceptive methods. For at least 8% of married couples in the United States in which the woman is of childbearing age, this period of anticipating pregnancy passes without success (Abma, Chandra, Mosher, Peterson, & Piccinino, 1997). For many of these couples, the life goal of having biologically related children is at least temporarily out of reach. Infertility is not a discrete event, but instead an unfolding process. The recognition that pregnancy is not occurring is often followed by attempts to increase the likelihood of pregnancy. Some couples decide to seek the assistance of a physician. If medical intervention is pursued, a protracted period of medical tests and treatment follows, with or without success. Eventually, unsuccessful couples consider other options, including adoption, surrogacy, or remaining without children. Some couples never seek medical treatment, perhaps as a result of financial, moral, cultural, or religious reasons. These couples may pursue other options to having children aside from biological parenthood, may continue to attempt conception by traditional methods, may seek nonmedical assistance (e.g., from religious leaders or alternative medicine providers), or may conclude that having children is simply not meant to be for them. Whatever the circumstances, each step in the process has the potential to be emotionally devastating.

This chapter provides an introduction to psychological issues associated with infertility and its treatment. Over the past two decades, there has been an explosion of technology avail-

able to treat infertility and a concomitant growth in public demand to use these so-called high tech treatments. These developments have made infertility and its treatment a topic of considerable public interest and concern. Unfortunately, medical advances are occurring faster than their individual, family, and societal implications can be anticipated or understood. Many misunderstandings and myths persist in popular culture about infertility and its treatment. This chapter presents what is currently known and what further information is needed.

The first section presents background information on infertility and introduces the complexity of the issues couples face. The second section examines the empirical literature pertaining to how fertility problems affect individuals and couples and discusses risk and protective factors for psychological adjustment. The third section focuses on psychological consequences of the use of assisted reproductive technologies when they are and are not successful. The fourth section turns to the question of how infertility can be prevented, which is a new area of interest for psychologists. Unfortunately, current knowledge in these areas is limited by the almost exclusive focus in research on White individuals of middle to upper socioeconomic status who seek medical treatment for their fertility problems. It is possible that the findings would be very different if the literature were more representative of all individuals facing infertility. The final section delineates challenges for future work that cut across the specific topic areas.

BACKGROUND

Infertility is medically defined as the inability of a couple to conceive after 12 months of sexual intercourse without con-

trapection (Office of Technology Assessment, OTA, 1988). Impaired fecundity is a broader concept affecting substantially more couples, and includes difficulty or danger carrying a baby to term, as well as problems in conception. The medical definition of infertility is used to screen couples for fertility treatment, and is different from the more permanent condition of sterility. Indeed, estimates suggest that 50% of couples meeting the medical definition for infertile who seek medical treatment will eventually be successful in bearing a child, either through medical intervention or simply with the passage of time (OTA, 1988).

Media reports have suggested that there is an infertility epidemic in the United States. Unfortunately, there are few reliable sources of information regarding rates of infertility. However, the best source currently available, the National Survey of Family Growth (NSFG), has not found an overall increase in rates of infertility in recent years, although there have been increases among certain subpopulations (Mosher & Bachrach, 1996). Mosher and Bachrach (1996) concluded that the widespread perception of an "epidemic" of infertility is probably due to a combination of the aging of the "baby boom" cohort who often delayed childbearing and thus have faced difficulty conceiving, and the dramatic increase in high tech treatments for infertility and the resulting demand for infertility services. The NSFG found that of the 60.2 million women of reproductive age, 9.3 million had sought medical services related to fertility problems (Abma et al., 1997).

The last two decades have seen major advances in scientific understanding of the causes of infertility. These advances have improved understanding of the role of psychological factors. For example, two decades ago, it was commonly believed that psychological problems, particularly of the woman, were to blame for a significant number of cases of infertility (OTA, 1988). Now a biological explanation (i.e., hormonal problems, blockage in the fallopian tubes, low sperm count or sperm abnormalities) can be found for most cases of infertility. Psychogenesis models have been largely refuted by research (OTA, 1988). When psychological distress does occur in infertile couples it is now thought to be a result of the stress of infertility or its treatment, as opposed to a cause of the fertility problem itself. Nevertheless, remnants of psychogenesis models persist in popular culture. The common but usually unhelpful suggestion "Relax and you'll get pregnant" is an example of the lingering belief that a woman's psychological status is to blame for her fertility problem. These messages are painful for many infertile women, and may lead them to retreat from their social networks (Abbey, Andrews, & Halman, 1991).

The lack of evidence that psychological problems cause infertility does not mean that psychological issues never play a role. For example, there is now concern that the stress of infertility treatment itself may reduce the likelihood of success. For example, Boivin and Takefman (1995) found that women who reported more daily stress during an in vitro fertilization (IVF) cycle were less likely to become pregnant in that cycle than their less stressed counterparts. What is not clear from this or other similar studies is whether stress had a causal role in determining the success of treatment or if patients who had

lower chance of success for medical reasons were simply more stressed before and during the process, knowing that they would probably have disappointing results. Clearly, the influence of stress on treatment success is an area in need of further inquiry because results would possibly suggest a need for radical changes in treatment practices.

Advances in scientific understanding of the causes of infertility have also led to a shift to thinking of infertility as a couple's issue not solely a women's issue. Fertility problems were previously attributed the woman, but the biological cause is now thought to be equally likely due to male factors as female factors, or due to joint problems (OTA, 1988). Therefore, from a medical point of view, infertility is now thought to characterize the couple who is attempting pregnancy, even though only one member of the couple may have the biological problem. From a psychological point of view, infertility is truly a couple's issue, not an individual issue, because regardless of which member of the couple has the biological problem, both partners are unable to achieve their goal of having children.

Even though infertility is a couples' issue, it remains a significant women's health issue as well. There is evidence that infertile women see having children as more important than men do, are more affected emotionally by the experience of infertility, and play a more central role in seeking treatment and making treatment decisions (see Berg, Wilson, & Weingartner, 1991; Leiblum, Kemmann, & Lane, 1987). The vast majority of treatments are aimed at the woman. Thus, women bear more of the physical and emotional costs of infertility treatment. They also suffer more of the stigma associated with the patient role than their partners and are at greater risk of being exploited by technological advances that do not take into account the potential impact on the individuals involved.

The last two decades have seen an explosion of advances in medical technologies aimed at increasing infertile couples' chances of pregnancy. The most publicized of the advances is IVF. IVF is a technique in which drugs are used to stimulate the maturation of oocytes, mature oocytes are removed from the ovary using ultrasound-guided aspiration, fertilization is attempted in the laboratory using the man's sperm, and the resulting embryos are transferred into the uterus. Other similar but less commonly used techniques include gamete intrafallopian transfer (GIFT) and zygote intrafallopian transfer (ZIFT). These treatments are collectively termed *assisted reproductive technologies* (ARTs). First used successfully in 1978, ARTs have evolved from being a cutting edge technology used by a small number of patients to a relatively mainstream procedure (Society for Assisted Reproductive Technology/American Society of Reproductive Medicine, 1998).

New infertility treatment options become available each year. For example, an important development in 1991 was a procedure called intracytoplasmic sperm injection. This procedure is used for couples with moderate to severe male factor infertility. A single sperm is chosen and injected into the egg to achieve fertilization. Another popular choice is the use of donor oocytes, which offers older couples the opportunity to experience pregnancy and to have a child who is genetically related to the father. The use of donor oocytes has increased

most significant barrier to conception with advanced maternal age is deterioration of the older woman's oocytes as opposed to uterine factors (Sauer, Paulson, & Lobo, 1992). Oocytes from a younger donor are stimulated using drugs, retrieved from her ovary, fertilized in the laboratory with the recipient's partner's sperm, and then transferred to the recipient's uterus. The use of donor oocytes (and donor sperm, which has been available for many years) brings many challenges for couples, including how to choose a donor, and whether and what to tell the child and others about the child's genetic heritage.

Infertility treatment decisions are often made under conditions of extreme stress and vulnerability. Couples usually consider these high tech techniques after months or years of trying other, less invasive approaches. When many couples face these decisions, they feel they have no time to waste, because the chances of success fall as the woman ages (SART/ASRM, 1998). Treatment decision making also occurs within the broader context of the couple's life, which may involve securing jobs, reaching educational goals, changing careers, managing work stress, relocating, dealing with family problems, dealing with other medical problems, and so forth. Fertility problems can create barriers in this broader context. For example, individuals may put off changing jobs or going back to school to maintain their medical insurance. Couples may wait to relocate or buy a home until the children are born, and so forth.

THE PSYCHOLOGICAL IMPACT OF INFERTILITY

Psychological Reactions to Infertility

There is no doubt that infertility is deeply distressing for many people. Indeed, Freeman et al. (1987) found that half of their sample of women described infertility as the most upsetting experience of their lives. However, there is significant controversy in the literature regarding the extent of psychological distress among individuals who experience fertility problems. The clinical and anecdotal literature suggests that infertility almost invariably sparks a life crisis. However, methodologically rigorous quantitative research has generally not upheld this view (see Dunkel-Schetter & Lobel, 1991; Stanton & Danoff-Burg, 1995). Quantitative studies have compared the psychological adjustment of individuals experiencing fertility problems assessed using standard measures to either normative data for the general population or to a population of fertile individuals (i.e., Connolly, Edelman, Cooke, & Robson, 1992). Overall, these studies have found that although the experience of infertility is emotionally upsetting and disruptive for many people, the majority do not experience clinically significant emotional reactions, loss of self-esteem, or adverse marital or sexual consequences.

What accounts for the discrepancy between clinical/anecdotal reports and quantitative research? A number of explanations have been offered including: lack of sensitivity of the

global measures used in quantitative research, desire on the part of research participants to appear more healthy so that they will be considered good candidates for infertility treatment, and overgeneralization of the problems experienced by a small number of patients who seek mental health treatment to the infertility population in general (Dunkel-Schetter & Lobel, 1991). There is probably some truth to each of these explanations. However, as Dunkel-Schetter and Lobel (1991) concluded, perhaps the most compelling reason for the discrepancy is that there is substantial variability between individuals in their response to the infertility. No one set of responses characterize most people who experience infertility.

Infertility from a Stress and Coping Framework

In light of these findings, Stanton and Dunkel-Schetter (1991) proposed that psychological reactions to infertility be conceptualized using a stress and coping framework (i.e., Lazarus & Folkman, 1984). The use of this well-established theoretical model represents a major advance, in light of the atheoretical nature of most previous research on infertility. In this framework, psychological adjustment in response to stressful life events is thought to be a function of characteristics of the situation the individual is facing, cognitive appraisal, and coping resources (including social support). This framework is useful because it helps researchers to go beyond simply describing the psychological status of infertile couples or comparing them to other couples. Furthermore, the stress and coping framework is not based on the idea that infertility necessarily represents an emotional crisis for all individuals, which is an assumption of much of previous work. Instead, the framework points to factors that might impede or facilitate psychological adjustment. An overview of recent research organized using a stress and coping framework is presented next.

Characteristics of the Situation. The evaluation period prior to receiving a diagnosis is associated with particularly high levels of distress (Berg & Wilson, 1991; Connolly et al., 1992) and the longer this period lasts without progress, the more distress individuals experience (Connolly, Edelman, & Cooke, 1987). There is also evidence that the greater the number of tests and treatment procedures attempted and the more money invested, the more distress individuals experience (Abbey, Halman, & Andrews, 1992).

The type of diagnosis (i.e., male factor, female factor, unexplained, or combined causes) may lead to differential levels of distress. Several studies have addressed this question but have shown conflicting results (see Connolly et al., 1992; Nachtigall, Becker, & Wozny, 1992). One finding that has emerged is that regardless of the type of diagnosis, women have been found to take more responsibility and blame for the couple's infertility (McEwan, Costello, & Taylor, 1987; Tennen, Affleck, & Mendola, 1991). This has been attributed to a desire to protect their husbands from stigma and may add to the psychological burden women experience (Stanton & Danoff-Burg, 1995).

Whether a couple is facing primary infertility, meaning they have no children, or secondary infertility, meaning they are experiencing difficulty having another child, may also lead to differential levels of distress. Leiblum et al. (1987) reported that initial childlessness was a significant predictor of depressive symptoms among women. Newton, Hearn, and Yuzpe (1990) reported that initial childlessness predicted anxiety but not depression for women, and for men, initial childlessness did not predict either depression or anxiety. Litt, Tennen, Affleck, and Klock (1992) did not find that childlessness was related to adjustment.

Individual Appraisal. There are a number of potentially important domains of cognitive appraisal regarding infertility, including meaning of the fertility problem with regard to threat to important life goals, causal attributions for the fertility problem, and perceived control over having a child. Each of these has received some attention in research, but most have used small sample sizes and/or mixed samples in terms of timing within the treatment trajectory, or nonstandardized measures, thus limiting their impact. Extent of threat to life goals has been studied in patients using ARTs but not among general infertile populations. For example, Newton, Hearn, Yuzpe, and Houle (1992) reported that women who thought having children was necessary for their gender role fulfillment were more depressed and anxious following ART failure than those who did not endorse such views. Causal attributions were examined in several studies showing that those who believed they were responsible for their fertility problem were more distressed (Morrow, Thoreson, & Penney, 1995; Stanton, 1991; Tennen et al., 1991). Regarding perceived control over an individual's ability to have a child, termed *infertility-specific control*, two studies have found that higher perceived control was adaptive (Campbell, Dunkel-Schetter, & Peplau, 1991; Tennen et al., 1991), whereas others have found no relation (Abbey & Halman, 1995), perhaps owing to differences in the nature of the samples studied with respect to the treatment trajectory.

Coping Resources. A number of studies have addressed the relation between coping and adjustment. Escape-avoidance coping (e.g., "I hoped a miracle would happen") appears to be associated with more distress (Band, Edelman, Avery, & Brinsden, 1998; Morrow et al., 1995; Stanton, Tennen, Affleck, & Mendola, 1992). Finding positive aspects of infertility or using positive reappraisal as a coping strategy (e.g., "I focused on other fulfilling things I can do outside of parenting") and seeking support (e.g., "I talk to someone about my feelings") appear to be associated with less distress (Stanton, 1991).

These coping studies used cross-sectional designs with couples who were at various points in their treatment trajectory. An important unanswered question is whether particular coping strategies are more effective at different points in the treatment trajectory. Also, it is unclear from these studies whether these coping strategies play a role in determining the level of distress or are used as a result of the level of distress (i.e., those in great distress may feel they need to use es-

cape-avoidance strategies to reduce distress). These two possibilities have different implications for intervention.

Social Environment. Support from one's spouse and good quality of the relationship with one's spouse appear to be associated with more positive adjustment to infertility (e.g., Connolly et al., 1992). The protective effects of relationships with family and friends are not well-understood because fear of insensitive remarks sometimes leads individuals with fertility problems to avoid discussing their problem with others (Abbey et al., 1991).

Conclusions Regarding Literature Using a Stress and Coping Framework

Research using a stress and coping framework to understand adjustment to infertility represents a major advance over previous work that was mainly descriptive, but it is clearly in its early stages. Although some potential risk and protective factors have been identified, the research is limited by the use of nonstandardized measures, small sample sizes, poor sampling methods, and the lack of longitudinal designs.

Research to date has also been limited by the individual nature of traditional stress and coping models. These models do not fully appreciate the dyadic context in which medical problems occur. Attention to the dyadic context is particularly important when studying infertility, which is even more of a "couples issue" than many other medical problems. Other medical problems clearly affect both partners, but basically characterize only the afflicted partner. A departure from the traditional individually based stress and coping framework is evident in a few studies that examine how the appraisal, coping, and adjustment of one partner may be related to the psychological adjustment of the other and how differences between partners in appraisal and coping may impact communication and the overall impact of the fertility problem on the relationship and each partner's adjustment. Stanton, Tennen, Affleck, and Mendola (1992) studied couples who were seeking treatment for infertility and found that the only variable of one partner that was related to the other's adjustment was coping through seeking support. As wives sought more support, their husbands reported less distress. Levin, Goldman, Sher, and Theodos (1997) found that husbands, but not wives, were more distressed to the extent that both partners were high in the use of emotional-oriented coping.

Pasch, Dunkel-Schetter, and Christensen (1995) developed a dyad-oriented conceptual model of individual and relationship adjustment in response to infertility. The model proposes that spouses make individual appraisals of the meaning and threat posed by the fertility problem and that each spouse has a tendency toward the use of certain coping strategies. Each spouse's appraisal and coping then impacts the couple's ability to communicate with each other regarding the fertility problem. Specifically, it was proposed that differences between partners in their appraisal and coping with infertility would increase the likelihood of communication problems. To study communication, partners were asked to participate in a communication task in which they discussed

an aspect of their fertility problem that was a source of tension in their relationship (e.g., deciding which treatments to try). Briefly, it was found that destructive communication was more common in couples in which partners differed in their commitment to having children, and in their use of several coping strategies. For example, to the extent that husbands used distancing as a coping strategy to a greater degree than their wives did, communication was more destructive. Couples with more destructive communication reported more negative effects of the fertility problem on their marriage, and more adjustment problems. Although further testing is needed, this model can be applied to understanding the effects of other health problems that couples face and is intended to yield a more complete understanding of how stress and coping processes occur within the marital context.

PSYCHOLOGICAL CONSEQUENCES OF ART USE

Although ARTs offer the possibility of pregnancy and child-birth for infertile couples, there is little doubt that the use of ARTs is highly stressful and has the potential to lead to significant negative psychological consequences, particularly when they fail. The potential for negative psychological consequences of using these treatments is a major concern (see Leiblum, 1997).

Despite recent advances in the success of ARTs, the vast majority of ART attempts do not lead to achievement of the valued goal of a baby. Based on data from 1995 attempts, 18.2% of ART cycles lead to the birth of infants, 26% of ART cycles were incomplete, and 56% ended in complete cycles but negative pregnancy tests. Furthermore, at least 18% of ART pregnancies did not go to term and at least 3% ended in serious delivery or neonatal complications or death (SART/ASRM, 1998).

The potential for negative psychological consequences of ARTs is heightened by several critical changes that have occurred over the past 5 years. ARTs have evolved from being a cutting-edge technology used by a small number of patients to a relatively mainstream procedure (SART/ASRM, 1998). The routinization and spread of ART services has had the effect that patients no longer receive intensive individualized care, and may no longer feel like pioneers in trying the new technology. Negative psychological effects of failure may intensify as couples no longer experience the positive emotions that can be associated with being one of the few patients who have access to the latest technology (Milne, 1987) and as the individualized care and special attention given to patients using new technology is reduced.

In addition, patients are making multiple ART attempts in the face of repeated failure. When IVF first became available, it was common for patients to try it as a "last chance effort." Now patients are often told that they should expect to make multiple ART attempts to achieve pregnancy. Although making multiple attempts increases the overall likelihood of pregnancy, recent data suggest that from 40% to 60% of couples

will still not be successful in achieving a pregnancy following six cycles (Alsaili et al., 1995). The negative psychological impact of repeated failed attempts may be substantially greater and more debilitating than those associated with one failed attempt. Also, the recommendation that couples make multiple attempts may also increase couples' difficulty in knowing when to stop treatment and may make it even more difficult, as time elapses, to explore other options (i.e., adoption; Leiblum, 1997).

The following section discusses the current research literature on the psychological consequences of ART failure and on factors associated with psychological adjustment to ART failure.

Research on Psychological Consequences of ART Failure

Although much concern has been voiced about how patients react to failed ART, strong research evidence is sparse. However, the few studies that used standard measures suggest that during the period from initial assessment for treatment to a few weeks after receiving negative pregnancy test results, the prevalence of mild to moderate depression increases substantially (Newton et al., 1990; Reading, Chang, & Kerin, 1989). Although women tend to be at higher risk for negative reactions to failure than are men, studies that have included men reveal they also experience increases in depression following failure (Newton et al., 1990).

Very few follow-up studies have addressed the longer term effects of ART failure. The evidence that has appeared on psychological effects beyond the few weeks following negative pregnancy test results is generally based on very small sample sizes, use of nonstandardized measures, and/or retrospective accounts. For example, Baram, Tourtelot, Muechler, and Huang (1988) studied 32 women and 14 men who, on average, had made their last IVF attempt 1.5 years prior to the study. A significant number of respondents (66% of the women, 40% of the men) reported depression following IVF failure, many noting multiple episodes, with an overall decrease in depressive symptoms over time. However, the number reporting on time periods over 6 months is far too small to allow conclusions to be drawn, and nonstandard measures of depression were used. Because prospective, longitudinal studies have not been conducted, there is very little information about the duration of depressive symptoms.

The psychological effects of repeated ART failures have received even less research attention. However, the few studies that do exist, albeit with significant research design limitations, suggest increasing negative effects with increasing numbers of failures. Thiering, Beaurepaire, Jones, Saunders, and Tennant (1993) compared cross-sectionally 113 first-time IVF patients (1 month prior to their first cycle) with 217 patients who had had one or more previous IVF attempts (on the first day of the subsequent cycle) and found that 25% of repeat patients met standard criteria for clinically elevated depression, whereas rates for first-time patients (15%) were similar to community norms (12%).

Research on Factors Associated With Psychological Adjustment to ART Failure

Mental health professionals who conduct pretreatment assessments with ART patients are in the position of needing to identify patients who might have significant adjustment problems. However, currently little is known about what predicts poor psychological outcomes in response to ART failure.

One important issue from both a theoretical and applied perspective is the role of pre-ART expectations regarding treatment success in determining distress in the event of failure. Several studies have shown that ART patients tend to overestimate their chances of success and believe they have control over whether they will become pregnant (Leiblum et al., 1987). There is controversy over the function of these unrealistically positive expectations in determining psychological outcomes in the event of failure. Concern has been raised that patients who have unrealistic expectations may experience severe distress in the event of failure (Callan & Hennessey, 1988). However, this concern has not been tested empirically. Collins, Freeman, Boxer, and Tureck (1992) found that women who made high estimates of the likelihood of success anticipated less distress in the event of failure, but the researchers did not investigate whether they actually were more distressed. Regarding optimism as a general trait, Litt et al. (1992) found that women who were high in trait optimism were less distressed postfailure than their more pessimistic counterparts, even after controlling for pre-ART distress. The finding that positive expectations are related to less distress is consistent with other psychological research. Specifically, cognitive adaptation theory (S. E. Taylor & Brown, 1988) suggests that unrealistically positive expectations and exaggerated perceptions of control (termed *positive illusions*), instead of being indicators of poor functioning, are actually adaptive reactions to threatening life events in many circumstances. Numerous studies of adjustment to health threats have supported this proposition (Leedham, Meyerowitz, Muirhead, & First, 1995). What is unclear is what happens when patients' expectations are clearly not met, as in the case of a failed ART attempt. Some have argued that in situations like ART in which patients have little control, positive illusions may be damaging (Tennen & Affleck, 1987). Others have argued that when positive illusions are disconfirmed, individuals are able to rethink the situation so that they can continue to see it in a positive light (e.g., S. E. Taylor & Armor, 1996). This theoretical puzzle remains unresolved. Based on cognitive adaptation theory, positive illusions in ART patients may actually prove to be a reasonable and adaptive stress management technique, given the intense demands of treatment, and would not be expected to lead to undue distress in the event of failure.

From a clinical practice point of view, the findings with respect to positive expectations will have important implications concerning how to prepare patients for treatment. The need for patients to have a clear understanding of the likelihood of success is critical because of the invasive nature of treatment, the high financial cost, the low likelihood of success, and the intense value patients place on achieving the

goal of pregnancy. However, concern that patients' unrealistic expectations may lead to serious distress in the event of treatment failure has led some members of the field of reproductive medicine to conclude that patient expectations must be monitored throughout the process and patients must be repeatedly reminded of the low success rates, the risk for multiple births, and so forth (e.g., Callan & Hennessey, 1988). Although the need for informed consent at the time of the decision to embark on ART is clear, without evidence that later interventions would have the desired effect of reducing post-ART distress, it is premature to intervene with patient expectations once a decision to elect to use ART is made. If unrealistically positive expectations are actually a sign of adaptive coping, it may not be beneficial to undermine those expectations.

Prospective longitudinal research is needed that identifies factors present prior to ART that render a person or couple vulnerable to distress following failure. This research would be able to solve puzzles, such as the role of positive expectations in determining postfailure distress. More generally, it would provide an empirical basis to guide assessment protocols and supportive interventions.

Conclusions Regarding Psychological Consequences of ART Failure

Although there has been much concern about the psychological effects of ART treatment, the research literature contains more gaps than answers. The psychological effects of ART failure, and the effects of repeated failures are not yet known. Furthermore, most research has not addressed the entire range of possible ART failure experiences (i.e., patients who are not even able to complete a cycle, patients who experience miscarriages). The psychological effects of ART miscarriages may be substantial given that patients experience the happiness of receiving a positive pregnancy test after the stressful treatment experience only to find that the fetus did not survive. Ultimately, their sense of loss and concomitant distress may be greater than if they had not become pregnant.

Only a few of the studies are prospective and longitudinal (see Downey & McKinney, 1990). The few longitudinal studies that have been conducted have either used very small sample sizes, had poor sampling methods, or used nonstandardized measures. In the absence of prospective, longitudinal research, little is known about the psychological consequences of the possible paths couples take and of outcomes they encounter. Very little research has placed the experience of ART failure in the broader context of possible outcomes that infertile couples might experience (i.e., having a child through ART, choosing not to use ART, or adopting a child). Even patients who have success with ARTs may experience psychological distress. Such distress could be associated with having multiple gestations, preterm delivery, residual stress from previous failures, or simply having a new baby. There may also be psychological consequences of the decision not to try ARTs, as individuals may find themselves regretting the decision not to try everything possible. New advances in technology may intensify this problem, as individu-

als may feel obligated to revisit their decision as hopes for success are renewed. In order to facilitate informed decision making and policy, there is a clear need to identify the relative consequences of different choices and outcomes.

Finally, despite the importance of identifying those patients at highest risk for poor adjustment, very little research has investigated factors associated with adjustment to ART failure.

Research on Psychological Adjustment Among Families Created by ARTs

There has been initial concern about the psychological functioning of families created by ARTs. These concerns have included unrealistic expectations for the child, overprotectiveness, maternal depression, marital difficulties, and so forth (e.g., see McMahon, Ungerer, Beaupaire, Tennant, & Saunders, 1995). In the last several years, a number of studies have begun to evaluate whether parents, children, and families created by the use of ARTs differ from other families on a number of indicators of psychological adjustment. For example, Golombok, Cook, Bish, and Murray (1995) compared four types of families (IVF families, donor insemination families, families with a naturally conceived child, and adoptive families) with a child between age 4 and 8 on a host of standardized measures of family functioning and found relatively few differences, with the exception of quality of parenting, which was found to be superior in IVF and donor insemination families.

Although the sample sizes have been limited and sampling methods for control families need to be improved, thus far the existing studies suggest that early concerns were not warranted. In fact most differences favor assisted conception families, perhaps due to the fact that these children are always wanted and the parents tend to be older than the average parent and perhaps more prepared for becoming parents. However, research on ART families is clearly just beginning. Suggestions for advancing this area of research are discussed later.

PREVENTION OF INFERTILITY

Infertility prevention efforts could help some women and men to avoid the many psychological, social, economic, and health consequences associated with infertility. Infertility prevention is an important new area in need of psychological research. However, prevention of infertility is inherently complex. Although there are several known controllable and therefore preventable causes of infertility, many causes of infertility are not well-understood (e.g., abnormal sperm count), and some are not currently known to be amenable to prevention (e.g., endometriosis; OTA, 1998). Additionally, there are many potential causes of infertility that are difficult to avoid (e.g., environmental toxins). Thus for many couples who experience infertility, there was nothing known that could have been done to prevent it.

Emphasizing the idea that infertility can be prevented could send the destructive message that individuals are to

blame if they do encounter fertility problems. There is evidence that women already tend to blame themselves for infertility, even in the case of male factor infertility. Therefore, a fine line must be walked between providing information about those aspects of infertility that are controllable, and inappropriately suggesting that those who experience infertility are to blame for it.

Two of the most prevalent preventable causes of infertility, sexually transmitted diseases and delayed childbearing, are discussed next.

Sexually Transmitted Diseases

One preventable cause of infertility is sexually transmitted diseases (STDs), primarily gonorrhea and chlamydia. Pelvic infections (i.e., pelvic inflammatory disease, PID), which are caused by STDs, cause blocked or scarred fallopian tubes. Tubal abnormalities caused by STDs account for at least 15% of infertility cases in the United States (Eng & Butler, 1997). The risk of infertility increases with the number of times a person has chlamydia or gonorrhea, the duration and severity of infection, and the time between infection and treatment. STD-related infertility is fully preventable if the STD infection is diagnosed and treated promptly. One of the major challenges in preventing infertility due to STDs is that the original STD infection is often asymptomatic, and thus undetected for many years. The resulting fertility problem may be discovered many years after acquiring the infection.

Adolescent and young adult women are at greatest risk for experiencing damage to their reproductive potential as a result of STDs. Women are at greater risk than men because STDs spread from men to women more easily than from women to men; STDs are more likely to be asymptomatic in women, and thus remain undetected, resulting in delayed treatment or no treatment; and STDs pose serious threats to women's reproductive capability, as well as cause potential harm to unborn children and breastfed infants, whereas STDs rarely cause harm to male reproductive organs (Eng & Butler, 1997). Adolescents and young adults are at risk because STDs are so common among their age group, they are more likely to have multiple partners, and given the same level of exposure, adolescent women may be biologically more susceptible to cervical infections than older women (Cates, 1990). Although it is well-known that adolescence is a particularly risky period for unwanted pregnancy, it is less well-known that adolescence is a reproductive life stage with potentially dire consequences for later reproductive life stages.

Currently there is very little knowledge of what adolescents and young adults know and believe about STDs other than HIV, and the extent to which health professionals convey this information to their patients. A study of African American adolescents at high risk for acquiring STDs showed that over 80% of boys and girls reported that having children was important to them, but that most thought it was best to postpone having children until their twenties or thirties (Levin, Pasch, Millstein, & Ellen, 1999). However, many were lacking in critical information that would assist them in protecting their reproductive po-

tential for the future. The majority of adolescents thought that fertility problems were not preventable. More than one third did not know that STDs can be asymptomatic. Over half of the adolescents did not know that chlamydia, gonorrhea, and PID cause fertility problems, with boys having significantly less knowledge than girls. Importantly, among sexually active adolescents, those who knew that particular STDs cause infertility were more likely to have had an STD check-up in the last 6 months when they did not have symptoms than those who were not aware of the relationship.

These results and future research on what adolescents believe about STDs and infertility may have implications for improving existing STD prevention programs. Emphasizing to adolescents that screening and treatment of STDs can help them to protect their fertility may be an effective motivator because having children in the future is salient for most adolescents. Also, focusing on protecting a person's ability to achieve the valued goal of having children is more positive than traditional STD prevention messages, which emphasize abstinence and avoidance of disease and unwanted pregnancy. Future research is needed to address how to frame messages regarding protecting fertility, particularly those directed at young men, because the potential risk to their own reproductive potential is relatively low. In one STD prevention program targeting high risk adolescents, messages have been developed aimed at encouraging young men to seek STD screening in order to protect the reproductive potential of their current and future partners and their community in general (Ellen, McCright, & Davis, 1998).

The need for effective STD prevention programs is particularly great in light of recent dramatic increases in rates of chlamydia, particularly among ethnic minority adolescents (Centers for Disease Control and Prevention, 1996). Why ethnic minority adolescents tend to be more likely to contract STDs is not well-understood, but several reasons have been suggested, including lower socioeconomic resources, poor access to health care, and geographic location (CDC, 1996). Based on current STD rates, ethnic minority women will begin to constitute a greater proportion of the infertile population in the years to come, often without the financial resources needed to take advantage of high tech treatments.

Delayed Childbearing

Because a woman's reproductive life span is biologically circumscribed, delaying childbearing increases the likelihood of infertility. Fertility decreases somewhat after age 30, with a sharp drop around age 35, and falls substantially after age 40 (Speroff, Glass, & Kase, 1994). The longer a woman waits to attempt conception, the greater the likelihood that she will encounter difficulty becoming pregnant. With women's changing roles in society, delaying having a first child to the 30s and 40s has become increasingly common. Often women who have pursued careers and postponed starting a family are very disappointed to learn that the option of becoming a parent by traditional methods is no longer available to them.

Should women who want to have children be encouraged to do so when they are younger? This is a difficult question

because, on the one hand, the optimal timing of reproduction can only be determined by the individuals involved and occurs in the context of sociocultural, developmental, and economic considerations. Also, emphasizing the importance of not waiting too long to have biologically related children assumes the primacy of biological parenthood, when for many people adoption or other ways to resolve infertility may be acceptable (see Revenson, 1997). Additionally, it is important to note that broad societal problems play an important role in leading women to delay childbearing (i.e., inadequate parental leave policies and childcare options; see Maranto, 1995). Nevertheless, young women may benefit from more complete information regarding the relation between age and fertility and from encouragement to consider formulating a life plan that allows adequate time for reaching reproductive goals—whatever those goals may be.

Future medical advances will likely change the meaning and implications of the "biological clock." As described earlier, recent evidence has revealed that it is the poor quality of older women's oocytes that causes them to be unable to conceive (Sauer et al., 1992). Advances in scientific understanding of oocyte microbiology suggest that in the next few decades, young women will have the option of freezing their oocytes to preserve their chances of biological motherhood later (Porcu et al., 1997). However, limits in the availability and costs of this technology will likely make it an option for a relatively small number of women, at least in the foreseeable future.

Conclusions Regarding Prevention of Infertility

Because of the social, personal, and economic costs of infertility, there is a need for research geared toward the development of infertility prevention programs targeting young men and women. The goal of these programs would be to facilitate young men and women in achieving their personal reproductive goals, both in terms of protecting their fertility from STDs and making reproductive choices that take into account the relation between age and fertility. Formative research is necessary because at present, little is known about the attitudes and beliefs underlying these behaviors. Established behavioral health decision-making models can be used to guide research and interventions in this domain.

For example, the Theory of Planned Behavior (TPB; Ajzen, 1985) can be applied to the behavior of delaying childbearing. The TPB has been previously applied successfully to decisions about contraceptive use in addition to a variety of other health behaviors (i.e., Adler, Kegeles, & Irwin, 1990). Briefly, the TPB contends that an individual's behavior is a function of his or her behavioral intention to perform that behavior. Behavioral intentions, in turn, are thought to be influenced by how favorable the individual is toward the behavior (attitude), and the perceived social pressure from significant others with respect to the behavior (subjective norm). Attitudes, in turn, are a function of the individual's beliefs concerning the likelihood that the behavior will be accompanied by certain outcomes, weighted by the evaluation of each outcome (how good or bad it would be if it were to occur). In this case, a woman may believe that delaying childbearing will

have the positive consequences of allowing her to achieve career advances, increase financial status, and reach a sense of emotional maturity. She may also believe that it may have the negative consequence of increasing the likelihood that she would never be able to have children, but feel that the likelihood of that outcome is small relative to the likelihood of the positive outcomes she expects. The subjective norm is a function of the perception of whether significant others (in this case, perhaps the partner, doctor, friends, boss) think the individual should perform the behavior, weighted by motivation to comply with these wishes. The TPB also takes into account that not all behaviors are under the individual's control, and thus actual and perceived control are thought to influence behavioral intentions and the translation of intentions into behavior. In the case of delaying childbearing, a woman may not have the intention to delay childbearing, but may not have a suitable partner, or may encounter health problems that limit her ability to attempt conception. Additionally, sociocultural influences can be examined within the TPB framework as factors influencing both attitudes and subjective norms regarding childbearing. By concentrating on the rational and predictable nature of behavior, the use of the TPB or other established decision-making theories can identify important target areas and specific messages for educational and behavior change efforts that focus on the key considerations determining intention and behavior.

Finally, a note of caution is appropriate regarding the dissemination of information about infertility prevention. It is important that individuals be informed of the controllable causes of infertility because this knowledge will allow them, along with their partners, to make informed decisions and attempt to achieve their future reproductive goals. However, educational efforts must be framed carefully so as not to suggest that infertile individuals are to blame if they do encounter fertility problems. Women are the most likely victims of such destructive messages, because infertility has historically been attributed to them.

FUTURE CHALLENGES

Although the empirical base on psychological aspects of infertility is growing, it is evident that many questions remain. This section delineates several key challenges for future research that cut across specific content areas.

Attention to Nonrepresented Groups

Available research on psychological aspects of infertility is not representative of the general population of infertile individuals in the United States. There are several factors that reduce the generalizability of the findings. First, most research has been conducted on White women or couples. As described earlier, it is estimated that ethnic minority women, specifically African American women, will begin to constitute a greater proportion of the infertile population in the years to come, because they are contracting STDs at high rates. At this point almost nothing is known about the psycho-

logical meaning of infertility or its treatment for these populations. There is evidence from other areas of reproductive health research of racial and ethnic differences in preferences for the use of medical intervention (i.e., prenatal diagnostic testing; see Kupperman, Gates, & Washington, 1996). Understanding how cultural or ethnic issues may impact what it means to be unable to have biologically related children, decisions regarding whether and how to seek medical treatment, and the acceptability of various resolutions of infertility (i.e., adoption, living without children, assisted reproductive technologies) are important avenues for future research. Such research may provide medical professionals with information that could improve access to and comfort with medical treatment for the individuals of various cultural and ethnic groups.

Second, individuals from lower socioeconomic groups are underrepresented in research. An individual's ability to make use of infertility treatments is highly dependent on their financial resources, because most medical insurance does not cover infertility-related services. Because individuals from lower socioeconomic groups have not been participants in research, nothing is known about the psychological consequences of wanting to use fertility treatment and not being able to for economic reasons. Additionally, among those patients who do use infertility services, individuals from lower socioeconomic groups are far more likely to experience financial stress and strain. Couples may take out loans, take second mortgages on their homes, or put off taking vacations or making large purchases in order to pay for fertility treatment. Little is known about how this financial strain may impact couples. If treatment is successful, then couples may be left with residual financial problems as they enter the transition to parenthood. If they are not successful, then they may experience serious regret at having expended their life savings and still not have a baby.

Third, the majority of research has studied individuals who are seeking infertility treatment and mostly from infertility specialists. As a result, there is little information about the experience of couples with fertility problems who do not seek treatment at all, or those who terminate treatment. What factors do couples consider when deciding whether or not to pursue treatment? How does the relative value placed on having biologically related children determine whether and how long couples seek medical treatment? What barriers exist with regard to access to treatment?

Fourth, although there has been recent attention to the issues lesbian couples and single women face (see Jacob, 1997; Chan, Raboy, & Patterson, 1998), they have also been largely neglected. Although not facing infertility as medically defined, these women can face additional barriers in pursuing their reproductive goals within a sociopolitical system that questions their rights to procreate at all, and particularly to use reproductive technologies (see Golombok & Tasker, 1994).

All of the aforementioned problems concerning the representativeness of the current research literature stem from the sampling methods employed. Most research participants have been recruited through infertility specialists at the time when they were in the process of treatment, or shortly thereafter. Although the ease of this approach renders it an obvious

first step in understanding the experience of infertile individuals, many infertile individuals never see an infertility specialist. It is now necessary to go further with sampling methods to include the broader array of possible paths. A number of methodologies can be used to address this goal. For example, large national surveys similar to the National Survey of Family Growth could include detailed investigation of when and why individuals sought or did not seek treatment. Another strategy would be to recruit research participants at earlier points in the treatment trajectory, such as from family practitioners or obstetrics and gynecology practices. Additionally, it will be important to conduct prospective studies that follow participants as they consider various options and experience various outcomes. Only in this way can we understand the natural history of the experience of infertility and its treatment, and those factors that predict who will experience significant adjustment problems. Increasing the representativeness of research will not only provide information about currently unstudied groups, it will also broaden understanding of the sociocultural construction of the importance of biological parenthood, the meaning of infertility, and various modes of resolution of it.

Incorporation of Theory and Knowledge From Psychology

As described, most research on psychological aspects of infertility has been atheoretical. The move toward the use of stress and coping models represents an important advance. However, there is a wealth of knowledge and theory within psychology that can be brought to bear on understanding infertility aside from theories of psychological adjustment.

For example, as discussed earlier, there has been concern about the psychological functioning of families conceived through ARTs. Early research has focused on the question of whether ART families are more poorly adjusted overall than other families. This focus on pathology may have developed because of remnants of the belief that infertile individuals are psychologically deficient in some way. Research should now move beyond comparing these families to others to tackle important challenges these families face. For example, one question that is beginning to be addressed is whether, what, and when to tell ART children about their origin. This question is particularly important with respect to children conceived through donor gametes, because these children not only are conceived using reproductive technology but also do not have genetic ties with one or both of their parents. Regarding the question of whether to tell the child, there is significant research on the effects of family secrets on children that can be usefully applied (e.g., Imber-Black, 1993). Regarding the questions of when and how to tell the child, there is basic research on children's cognitive development that might help in judging what types of information about their origin children can understand at particular ages (e.g., Springer, 1996). There are also many lessons to be learned from the literature on the psychology of adoption (e.g., Brodzinsky & Schechter, 1990). Making use of broad theory and knowledge will pre-

vent research and clinicians working in the area of infertility from having to "reinvent the wheel" each time a new issue must be faced. In addition, there is the potential to advance the scope of the theory itself.

Attention to Applied Problems

In addition to incorporating theory, attention should be directed to addressing applied problems. Practicing psychologists and other mental health professionals working in the field of reproductive medicine are now faced with many challenges. They conduct pre-ART assessments with couples. These assessments often have multiple purposes, including identification of patients in need of additional support services during the ART process and sometimes to identify patients they think would not be good candidates for treatment for psychological reasons. They conduct assessments of potential oocyte donors to determine if they understand and are psychologically prepared for being a donor. They offer supportive interventions to patients who experience significant distress.

As the knowledge base advances, there is a need for development of research-based assessment, prevention, and intervention protocols for use with infertility patients (Adler, Keyes, & Robertson, 1991; Pasch & Dunkel-Schetter, 1997). Although there is widespread belief in the importance of psychological interventions, current procedures are based on an extremely limited empirical foundation. For example, research identifying the risk and protective factors present prior to ART that predict which individuals are likely to be in need of additional support would provide a much-needed empirical basis for pre-ART assessments. By identifying the factors associated with adjustment to ART failure, mental health professionals would be able to target psychological services to those patients at highest risk and thus prevent the development of serious negative outcomes.

Attention to the Constantly Changing Face of Infertility Treatment

The future is sure to bring many more technological developments, raising even more complex ethical, legal, and moral dilemmas. New treatments will continue to come into popular use before the psychological community can consider their potential risks to emotional adjustment and family development. Current treatments will become medically obsolete before their impact is fully understood. Because infertility treatment is a constantly moving target, psychologists who work in this area must remain abreast of new developments and employ the tools of the field to investigate and intervene as appropriate to assist patients, the medical community, and the community at large in understanding the psychological impact of these developments.

Patient Adherence to Treatment Regimen

Jacqueline Dunbar-Jacob

Elizabeth Schlenk
University of Pittsburgh

There is little doubt that a major contributor to health care costs is the failure of patients to adhere satisfactorily to treatment regimen. Indeed, the costs of nonadherence to pharmaceutical therapies alone has been estimated to exceed \$100 billion a year (Grahl, 1994). The costs of nonadherence to other forms of treatment (e.g., diet, exercise, smoking cessation, and dialysis) have not been estimated, but given their contribution to disease management, they yield costs over and above those due to poor adherence to prescribed medication.

A portion of the costs of poor adherence lies in the necessity to further treat the complications or progression of varied diseases. For example, the person with hypertension who adheres poorly to treatment may progress to a stroke; the person with diabetes who adheres poorly may progress to limb loss, blindness, and/or cardiovascular disease. Both instances may lead to the necessity for rehabilitation and caretaking services as well as additional forms of treatment. Even in life threatening conditions, poor adherence has been observed. For example, poor adherence to treatment accounts for 25% of graft failures in organ transplantation (Rovelli et al., 1989). Even small deviations from the prescribed regimen can have significant clinical implications for the transplant patient. Indeed, poor adherence to treatment has been linked to unnecessary complications, as well as to disease progression in multiple diseases (Dunbar-Jacob & Schlenk, 1996).

More recently, poor adherence has been linked to the development of treatment-resistant organisms in infectious disease. The increase in tuberculosis in the past decade has been linked in part to variable adherence and/or to early cessation of antituberculosis medications (Bloom & Murray, 1992;

Gibbons, 1992; Nolan, Aitken, Elarth, Anderson, & Miller, 1986). Similarly, poor adherence to antibiotic therapies has been associated with treatment resistance among children with otitis media (DeLalla, 1998) and has been suspected in a portion of disease-resistant staphylococcal and streptococcal infections (Schwarzmann, 1998). Most recently, there are indications that even slight deviations from prescribed antiretroviral medications may lead to the development of drug resistant strains of the HIV virus (Vanhove, Schapiro, Winters, Merigan, & Blaschke, 1996). Unfortunately, these drug resistant viruses are themselves transmissible.

The problems of poor adherence are also found in other conditions. For example, in primary prevention immunization rates are less than optimal in both the pediatric and geriatric groups. The failure to immunize leads to excess cases of such conditions as measles in childhood (Mason, 1992) and pneumonia among the elderly (Nichol, Margolis, Wuorenma, & VonSternberg, 1994). Poor adherence has also been a significant problem in rehabilitation where performance of therapeutic exercise looks similar to efforts to follow drug regimen (Dunbar-Jacob, 1998).

DEFINITIONS OF ADHERENCE

One factor that influences the degree of poor adherence found in research and clinical populations is the definition of adherence that is selected. Adherence can be defined in at least two general ways. The first is through the pattern of adherence problem expressed by the patient. The second is by the quantitative assessment that is made.

Patterns of Adherence

There are at least six behavior patterns that constitute problematic adherence. These consist of failure to adopt the regimen, early stoppage of treatment, reduction in levels of treatment, over treatment, variability in the conduct of the regimen, and dosage interval errors.

Adoption of the treatment regimen is the first step in adherence. Yet the problem of adoption is fairly significant. There are some data to suggest that as many as 20% of persons fail to fill medication prescriptions (Burns, Sneddon, Lovell, McLean, & B. J. Martin, 1992). The proportion of persons who simply fail to start dietary or exercise regimens has been less well studied but is estimated to be significant. These individuals are rarely described in studies of adherence.

For those who initiate treatment, there is the problem of early stoppage. These persons are often referred to as dropouts or as nonadherers. There is considerable variation in the proportion who drop out of treatment, with the lowest rates seen in clinical trials and the highest in exercise regimen. Indeed, 50% of persons who initiate exercise programs for cardiac rehabilitation are found to terminate early (Oldridge, 1984, 1988). In the clinical trials arena, the rates of dropout are estimated to average between 5% and 25% (Dunbar & Knoke, 1986). One of the difficulties in defining dropping out of treatment is that some portion of these persons may drop back in to treatment at a later point in time or with a different care provider.

For those individuals who stay in treatment, several patterns may be found. First among those is alterations in treatment dosing. This may include both reductions in the dose or in increases in the dose that has been prescribed. For example, the patient may reduce or increase the dose of medication that is taken or the number of exercise regimens performed per week. Underdosing may occur, for example, in response to side effects, to spacing out inadequate quantities of medication, or to a belief that a lower dose is preferable. Overdosing occurs in at least two ways. Patients may miss medication and "double up" to achieve the requisite number of doses. Or individuals may decide that extra doses are called for to combat symptoms. In either case, the risks of overdosing and of untoward side effects are high. Our research has found these patterns in patients with rheumatoid arthritis and for those with hyperlipidemia, symptomatic and asymptomatic disorders, respectively, as well as among posttransplant patients. Both patterns may be found within the same individual.

The second pattern found among those who stay in treatment is variability in adherence. This pattern may be the most common form of adherence problem found. In this instance, the individual follows medication, dietary, and/or exercise regimen to varying degrees over time. Typically, the regimen may be missed at episodic intervals. Whole days or specific doses may be missed for varying intervals. When the regimen is missed for a period of several days and then resumed seemingly spontaneously, the period is referred to as a "regimen holiday" (Urquhart & Chevalley, 1988).

The third type of problem found among those who stay in treatment is that of dosing interval errors. This pattern is par-

ticularly the case for medication taking, but also may be seen with exercise regimen. In the case of medication taking, individuals may consume doses too close together or too far apart. For example, asthma patients have been found to consume puffs of inhaled medication too close together to support efficacy (Berg, Dunbar-Jacob, & Rohay, 1995). Similarly, patients with rheumatoid arthritis have been found to take doses as close as 2 hours apart as well as more than 36 hours apart (Dunbar-Jacob et al., 1992).

There are, therefore, numerous patterns of poor adherence or nonadherence. Typically, these have been treated as equivalent in studies of adherence with the term *adherence* defined as the total dosage consumed divided by the total prescribed over some period of time. This obscures the nature of the adherence problem. Thus, the first consideration in defining poor adherence is the specification of the type of adherence problem or problems that are of interest.

Quantitative Assessment of Adherence

Another approach to defining poor adherence relates to the level of data used. The proportion of the prescribed regimen that is carried out can be examined. This yields a percentage adherence score. For a group, then, the average (mean or median) adherence is reported. Related to this, and often not clearly specified in the literature, is a report of the proportion of persons who meet some adherence criterion, that is, defining a group's adherence by the proportion of persons who achieve or fail to achieve some preestablished level of adherence. The convention has been 80% for most investigations since the landmark study of adherence to antihypertensive medications by Haynes et al. (1976). Although logic would suggest that the level of adherence set would be related to the level necessary to achieve therapeutic benefit, little data are available on the relation between level of adherence and achievement of clinical benefit. Other methods of defining adherence include a determination of the proportion of persons who have attained clinical benefit, a desired outcome of good adherence, but not the equivalent; the clinical judgment of level of adherence; and the level of attainment of performance of multiple components of a treatment regimen. Each of these definitions influences the rate of adherence reported.

MAGNITUDE OF THE PROBLEM

The problem of poor adherence to treatment regimen has a significant impact on the outcomes of care and subsequently on health care costs. Nonadherence to health care regimens is a prevalent problem that cuts across disorders, treatment regimens, ages, gender, and ethnic and socioeconomic groups (Burke & Dunbar-Jacob, 1995; Dunbar-Jacob, Burke, & Puczynski, 1995). There is some indication that persons with life threatening conditions may adhere somewhat better than others. But in these conditions (e.g., cancer, AIDS, and transplantation), there is a burgeoning body of evidence to suggest that even modest deviations have significant clinical impact (DeGeest, 1996). Additionally, there is some evidence that persons participating in clinical trials may also have better ad-

herence (Schron et al., 1995). Even in these situations, adherence is far from perfect.

Nonadherence varies over the course of treatment with steeper declines in adherence noted earlier in treatment. For example, from 16% to 50% of patients with hypertension discontinue their medication within the first 12 months (Flack, Novikov, & Ferrario, 1996; Jones, Gorkin, Lian, Staffa, & Fletcher, 1995) and 50% of patients in cardiac rehabilitation programs drop out in the first 12 months (Oldridge, 1984). Over the long run, adherence continues to decrease but at a less marked rate than observed at the outset of treatment. For example, in the Lipid Research Clinic-Coronary Primary Prevention Trial (LRC-CPPT), reductions in dietary fat and cholesterol began to show reversals at 12 months that continued over the 7-year clinical trial (Lipid Research Clinics Program, 1984a, 1984b). Thus, interventions to promote adherence need to focus on initial adherence as well as maintenance of adherence.

Medication Adherence

Studies have shown that from 20% to 80% of persons do not adhere to medication prescriptions to the extent of gaining therapeutic benefit (Dunbar-Jacob et al., 1995). Among persons with chronic disorders, from 50% to 90% do not adhere to medication prescriptions (Cramer, Scheyer, & Mattson, 1990). Medication nonadherence rates vary depending on the method and time of measurement. A review of antihypertensive medication adherence found that adherence by self-report was 75%, whereas adherence by pill count was 52% (Dunbar-Jacob, Dwyer, & Dunning, 1991). Dunbar-Jacob, Burke et al. (1996) compared self-report, pill count, and electronic monitors in subjects taking a lipid-lowering drug and found poor correspondence among the measures with self-report by 7-day recall at 97%, pill count at 94%, and electronic monitors at 84%. Using electronic monitors in subjects with epilepsy, Cramer et al. (1990) reported mean adherence rates of 88% during the 5 days before the clinic visit, 86% during the 5 days after the clinic visit, and only 67% during a 5-day period 1 month later. Thus, electronic monitors seem to provide a more accurate measure of medication adherence compared to self-report and pill counts, and medication adherence appears to decline between clinic visits.

Dietary Adherence

Dietary recommendations often accompany medication prescriptions for chronic disorder regimens, for example hypertension, diabetes, and hyperlipidemia. Modifying long-standing dietary habits and maintaining newly established eating plans can be difficult. Adherence with low fat, low cholesterol diets ranges from 13% to 76% (Glanz, 1979), whereas long-term adherence with weight reducing diets is less than 50%, with few persons maintaining the weight loss (Glanz, 1979).

Exercise Adherence

Exercise adherence is a problem across healthy and chronic disorder populations with 50% dropping out of exercise during the first 3 to 6 months and a leveling off of the dropout rate between 55% and 75% by 1 year (Carmody, Senner, Malinow, & Matarazzo, 1980). An exercise regimen can be time consuming, inconvenient, and expensive, all of which are barriers to exercise adherence. For persons managing chronic disorders, additional exercise barriers exist, such as fatigue and pain. For example, in fibromyalgia, exercise nonadherence was high at 44%. Reasons reported for missing exercise included finding time when facing changes in routine (85.2%) and presence of fibromyalgia symptoms, such as fatigue and pain (44.4%; Schlenk, Okifuji, Dunbar-Jacob, & Turk, 1996).

In 1996, the U.S. surgeon general released a report on physical activity and health that recommended 30 minutes or more of moderate-intensity physical activity on all, or most, days of the week (U.S. Department of Health and Human Services, 1996). This physical activity can be accumulated during the course of the day (Pate et al., 1995). Despite this recommendation, over 60% of U.S. adults are not regularly active and 25% of U.S. adults are not active at all. Only 22% of U.S. adults engage in sustained physical activity of any intensity five times weekly for 30 minutes (U.S. Department of Health and Human Services, 1996).

PREDICTORS OF POOR ADHERENCE

In general, the literature over the past three decades has examined poor adherence as a solitary construct. Most predictors that have been identified have accounted for small proportions of variance in adherence and further have not been consistently supported in studies. Perhaps the most consistent predictors have included self-efficacy, initial adherence, complexity of the regimen, and disruptive schedules (e.g., Dunbar-Jacob, 1998; Dunbar-Jacob, Schlenk, Burke, & Matthews, 1998). Numerous other factors have been identified, but have not been consistently related to adherence across studies. These factors include age, social support, mood, income, system of care, clinician-patient communication, and beliefs (e.g., Dunbar-Jacob, Schlenk et al., 1998).

Predictor studies and intervention studies typically have not discriminated between the various patterns of poor adherence. Nor have the predictor studies distinguished between varying models of adherence. Yet poor adherence can take multiple forms. Thus, it makes intuitive sense that predictors and interventions might vary between these forms. There are a number of dimensions that would appear to separate adherence behaviors into independent categories or models, with the probability of identifying differing predictor variables and differing effectiveness in interventions. Two of these important dimensions include whether poor compliance is intentional or unintentional and whether it is a lack of capability. Unfortunately, the research on predictors of adherence has not separated out those factors that may predict a decision to not adhere versus unintentional nonadherence episodes versus a lack of capability to adhere.

Much of the literature on adherence treats adherence problems as intentional decisions or a failure of motivation on the part of patients. Thus, patients may make decisions based on numerous factors. One of these important factors is beliefs. These may be beliefs about treatment, about capability to carry out treatment, or about the effectiveness of treatment. Several theories have addressed adherence from this perspective, including Self-Efficacy Theory (Bandura, 1997), Health Belief Model (Janz & Becker, 1984; Rosenstock, 1974), Theory of Reasoned Action/Theory of Planned Behavior (Ajzen, 1991; M. Fishbein & Ajzen, 1975), and the Common Sense Model of Illness (Leventhal, Meyer, & Nerenz, 1980). A second factor, which relates to an intentional decision model of adherence, is the evaluation of the burden of adherence. In this case, factors such as the personal costs associated with care, the stigma that may be encountered from having treatment witnessed, the impact on quality of life, and the effort associated with managing treatment all may influence the decision to follow treatment.

An examination of the patient reports of poor adherence reveals that the most commonly reported reason is forgetting (Dunbar-Jacob, 1997). Research (Morell, Park, Kidder, & M. Martin, 1997) suggests that busy and/or disruptive schedules may also contribute to poor adherence. Forgetting and disruption would be related to nonintentional nonadherence episodes. Research has suggested that it is not unusual for patients to report intending to take a dose of medication but something interrupted them (a phone call, a visitor, etc.) and then they became distracted and forgot to return to the medication when the distraction ended. Similarly, patients who report business travel or vacations where daily schedules are disrupted also report higher missed doses of treatment (Dunbar-Jacob, 1997; Schlenk et al., 1996). Although such reports are offered by patients, there has been little systematic research in this area.

A third model of poor adherence addresses whether or not the patient has the capability to carry out the regimen. A variety of factors are at play here. These factors include whether the patient has adequate knowledge to carry out the treatment, whether the skills are present, and whether the patient has the cognitive and/or physical capability to engage in the treatment. Few studies have examined these factors. Studies identifying the proportion of poor adherence that was related to lack of adequate knowledge were conducted in the mid-1970s (e.g., Boyd, Covington, Stanaszek, & Coussons, 1974) but have not been examined more recently. Studies examining cognitive or physical capability have also been limited. Park, Willis, Morrow, Diehl, and Gaines (1994) suggested that those dimensions tapped by standard neuropsychological tests have not been associated with adherence. But much work remains to be done in this dimension.

In addition to the failure to examine determinants of or predictors of adherence from the perspective of either patterns of adherence or models of poor adherence, multiple methods of measurement of adherence have been used in these studies. As becomes evident later, different measures of adherence classify different persons as adherent or nonadherent. It is likely, therefore, that predictor variables will behave differ-

ently in different studies. Research supports this notion, suggesting that different measurement methods lead to different predictor variables in the same population on the same regimen (Dunbar-Jacob, Sereika, Rohay, Burke, & Kwoh, 1995).

MEASURES OF ADHERENCE

An examination of the research on adherence shows that multiple methods of assessment are used. These include such strategies as self-report (interview or questionnaire or daily diaries), clinician reports, pill counts, biological indicators, clinical outcome, and electronic event monitoring. Each yields somewhat different information about the patient's behavior with regard to their regimen as well as different reports of adherence. Thus, the selection of a strategy to measure adherence requires careful attention to the limitations of each method and ideally requires a well-specified definition of adherence. There is no gold standard for assessment of adherence (Cramer, Mattson, Prevey, Scheyer, & Ouellette, 1989), although electronic event monitors provide the most complete and timely data on adherence (Dunbar-Jacob, Sereika, Rohay, & Burke, 1998). Measures, in general, should provide accurate, relevant, specific, objective data that is economically feasible, practical, and easy to administer (Westfall, 1986).

One of the major differences between measurement methods is the difference in reported adherence that may be obtained between them, even when the same regimen in the same person is assessed. The variation in reported adherence by different measurement methods was first reported by Mattson and Friedman (1984) based on data from the Aspirin Myocardial Infarction Study. In this study, subjects were randomly assigned to aspirin or to placebo. Adherence was measured by pill count, platelet aggregation, and salicylate levels. Adherence ranged from 81% to 97% in the drug group and from 78% to 97% in the placebo group depending on the strategy examined, with adherence highest for the behavioral (pill count) method. These variations are likely dependent on characteristics of the measures. Salicylate levels would be fairly short lived and would reflect adherence just prior to the clinic visit. Work by a number of investigators indicates that adherence is at its peak just before and just after a clinic visit (Cramer et al., 1989; Kass, Meltzer, Gordon, Cooper, & Goldberg, 1986; Norell, 1981). Thus, the salicylate levels would reflect adherence just prior to the visit. Platelet aggregation would have a longer impact but would not provide information on the degree of adherence over time. Individual variations in drug metabolism and other related biological factors would impact on the level of platelet aggregation identified. The pill count, while estimating the amount of medication consumed over the measurement period, would also be affected by the willingness of the subjects to return all unused medication as well as their memory to do so.

Similar differences in adherence by measurement method have been reported by others (e.g., Burke et al., 1992; Dunbar, Dunning, Dwyer, Burke, & Snetselaar, 1991; Dunbar-Jacob, Burke et al., 1996; Dunbar-Jacob, Burke, Rohay, Sereika, & Muldoon, 1997; Hyman et al., 1982; Norell, 1981; Petitti, Friedman, & Kahn, 1981; Rand & Wise, 1994; Rudd, Ahmed,

Zachary, Barton, & Bonduelle, 1990; Wilson & Endres, 1986). Typically, self-report measures overestimate adherence when compared with other measures. This is not unexpected as the self-report measures, excluding daily diaries, rely on memory and willingness to report. Given the difficulties in remembering recurring behaviors, the tendency is to rely on recent events as indicators of longer term events. Coupled with peak adherence at the time of assessment at a clinic visit, this basis for estimation of adherence would lead to a personal overrating of longer term adherence behaviors. The diaries are more accurate than interviews or questionnaires, but also are limited by the willingness of the patient to record daily and accurately. Work suggests that group averages may approximate those seen with electronic monitoring, but sensitivity to poor adherence is low (Dunbar-Jacob, Sereika, & Burke, 1998).

The electronic measures tend to report the lowest levels of adherence. These methods record onto microprocessor chips the exact time and date that an event occurred. For a fuller discussion, see Dunbar-Jacob, Sereika, Rohay, and Burke (1998). Thus, patterns of poor adherence can be identified. Monitors are available for medication taking, exercise, and for cued diary entries. The major limitation is sensitivity to actual regimen conduct. Experience with electronic monitoring of medication taking over as much as a 12-month period suggests that the effort to manipulate the monitor at the prescribed time day after day without taking medication is an unlikely expenditure. Deception with the monitor may be estimated with the addition of relevant biological assays.

No matter the method of assessment, however, the distribution of adherence data for medication consumption and for appointment keeping appears to assume a J-curve, which is robust and resistant to transformation (Dunbar-Jacob, Sereika, Rohay, & Probstfield, 1994). Thus, the analysis of adherence data does not lend itself to traditional parametric approaches. Less information is available on the distribution of adherence data for exercise or for diet. Information on these distributions would be valuable.

IMPACT ON CLINICAL OUTCOME

Adherence is a mediator of clinical outcome. However, there is a paucity of knowledge about the amount of adherence to a prescribed treatment that is required to produce a desired clinical outcome. Only a few studies have investigated the amount of medication adherence required to produce a desired clinical outcome (DeGeest, 1996; Haynes et al., 1976). No studies have investigated the amount of adherence to behavioral treatment required for a desired clinical outcome.

The relations between the three adherence behaviors of medication taking, following a therapeutic diet, and following an exercise program and clinical outcomes are discussed. The clinical outcomes reported in the literature include relapse, sign and symptom relief, health status, hospitalization, morbidity, and mortality.

Medication Adherence and Clinical Outcomes

Most of the research on the relation between adherence and clinical outcomes has been conducted in the area of pharmacological treatment. Better medication adherence was related to prevention of relapse in tuberculosis (Dupon & Raynaud, 1992), epilepsy (Cramer et al., 1989; Reynolds, 1987), childhood leukemia (Klopovich & Trueworthy, 1985), schizophrenia (Leff et al., 1989; Mantonakis, Jemos, Christodoulou, & Lykouras, 1982), and alcoholism (Fawcett et al., 1984, 1987; Pisani, Fawcett, Clark, & McQuire, 1993). Interestingly, adherence to antibiotics for otitis media was not related to decreased reoccurrence based on urinary assay (Reed, Lutz, Zazove, & Ratcliffe, 1984). Perhaps adequate antibiotic was taken to fend off repeat infection.

Better medication adherence was related to sign and symptom relief in hypertension (Fletcher, Deliakis, Schoch, & Shapiro, 1979; Haynes, Gibson, D. W. Taylor, Bernholz, & Sackett, 1982; McKenny, Munroe, & Wright, 1992), peptic esophageal stenosis (Starlinger, Appel, Schemper, & Schiessel, 1985), chronic bronchitis (Dompeling et al., 1992), schizophrenia (Verghese et al., 1989), manic depression (Connelly, Davenport, & Nurnberger, 1982), and chronic pain (Berndt, Maier, & Schutz, 1993). Medication adherence was not related to symptom relief in asthma (Dompeling et al., 1992) or open angle glaucoma (Granstrom, 1985).

Better medication adherence was related to some dimensions of health status in a few studies. In hypertension, medication adherence was related to clinical health status and perceived health status but not functional status (B. Given, C. W. Given, & Simoni, 1979). In rheumatoid arthritis, self-reported medication adherence was not related to health status or functional status (Taal, Rasker, Seydel, & Weigman, 1993) but was related to reduced pain (Dunbar-Jacob, Kwok et al., 1996). Because self-report tends to overestimate medication adherence, measurement errors may have obscured the relation between adherence and health status.

Medication nonadherence was related to higher rates of hospitalization in hypertension (Maronde et al., 1989), manic depression (Connelly et al., 1982), schizophrenia (Gaebel & Pietzcker, 1985), and alcoholism (Fawcett et al., 1987). Medication nonadherence was related to morbidity across acute and chronic disorders as well as preventive regimens. Adherence to antibiotics was related to resolution of acute urinary tract infections in the elderly (Cheung et al., 1988). In chronic bronchitis, medication nonadherence was related to poorer pulmonary function test results (Dompeling et al., 1992). In psychiatric disorders, such as depression in the elderly (Cole, 1985) and manic depression (Connelly et al., 1982), medication nonadherence was related to a worse clinical course. Medication nonadherence among renal transplant recipients resulted in return to dialysis (Kalil, Heim-Duthoy, & Kasiske, 1992), renal insufficiency during pregnancy (O'Donnell et al., 1985), and organ rejection (Rovelli et al., 1989; Schweizer et al., 1990). Similarly, heart transplant recipients who had minor departures in immunosuppressive medications showed organ re-

jection and other adverse occurrences (DeGeest, 1996). Nonadherence to medications taken for preventive purposes was related to higher morbidity as well. Nonadherence to antihypertensive medications was related to an increase risk for coronary heart disease (Psaty, Koepsell, Wagner, LoGerfo, & Inui, 1990). Similarly, nonadherence to preventive medications for tuberculosis (Nolan et al., 1986) and malaria (Wetsteyn & deGeus, 1993) was related to higher occurrence of these respective disorders.

Medication nonadherence was related to mortality in patients with epilepsy (Lip & Brodie, 1992), asthma (Robertson, Rubinfeld, & Bowes, 1992), and organ transplantation (Lanza, Cooper, Boyd, & Barnard, 1984; Schweizer et al., 1990). Similarly, medication adherence was related to survival among patients with hematologic malignancies (Richardson, Shelton, Krailo, & Levine, 1990).

In summary, nonadherence to prescribed medication has been associated with poorer clinical outcomes across a wide variety of disorders. The costs of nonadherence are high in terms of patient health, health care utilization, and even mortality.

Dietary Adherence and Clinical Outcomes

Nonadherence to low fat diets was related to mortality (R. B. Singh, Niaz, Ghosh, R. Singh, & Rastogi, 1993; Swank & Dugan, 1990) and cardiac events (R. B. Singh et al., 1993). Nonadherence to diabetic diets was related to diabetic ketoacidosis (Mulrow, Bailey, Sonksen, & Slavin, 1987; White, Kolman, Wexler, Polin, & Winter, 1984) and hospitalizations and emergent visits (H. A. Fishbein, 1985; White et al., 1984) but not to measures of diabetic control, such as weight and glycosylated hemoglobin (Mulrow et al., 1987). Given that multiple factors influence diabetic control in conjunction with medication adherence, it may be difficult to impact these specific clinical measures.

Exercise Adherence and Clinical Outcomes

Nonadherence to prescribed exercise in postsurgical patients was related to lower range of motion, joint extension, and functional status, and higher relapse (Hawkins, 1989; Hawkins & Switlyk, 1993; Rives, Gelberman, Smith, & Carney, 1992). In older women, adherence to group exercise improved change in sway (Lichtenstein, Shields, Shiavi, & Burger, 1989). In summary, exercise adherence improves clinical outcomes, in particular sign and symptom relief and prevention of relapse.

INTERVENTIONS TO PROMOTE ADHERENCE

Interventions to promote adherence across medication, dietary, and exercise regimens have tended to focus on behavioral strategies or education plus behavioral strategies. Whereas most of these interventions have been modestly successful in promoting adherence, few have been tested in ran-

domized, controlled clinical trials. The strategies that have been shown to be successful in improving adherence include some combination of self-monitoring, counseling, stimulus control or cueing, positive reinforcement, self-efficacy enhancement, and social support enhancement.

Self-monitoring of blood pressure and/or medication taking (Edmonds et al., 1985; Haynes et al., 1976; Logan, Milne, Achber, Campbell, & Haynes, 1979) and exercise (Atkins, Kaplan, Timms, Reinsch, & Lofback, 1984; King, C. B. Taylor, Haskell, & DeBusk, 1988; Rogers et al., 1987) improved regimen adherence. Counseling promoted adherence with medication taking (Bailey et al., 1990; Colcher & Bass, 1972; Peterson, McLean, & Millingen, 1984), dietary management in large clinical trials (Dolecek et al., 1986; Glueck, Gordon, Nelson, Davis, & Tyroler, 1986; Simkin-Silverman et al., 1995), and exercise (Belisle, Roskies, & Levesque, 1987; King & Frederiksen, 1984; King et al., 1988). Stimulus control or cueing improved adherence to medication taking (Haynes et al., 1976; Logan et al., 1979) and exercise (Atkins et al., 1984; Keefe & Blumenthal, 1980). Positive reinforcement promoted adherence to medications (Bailey et al., 1990; Haynes et al., 1976; Logan et al., 1979) and exercise (Atkins et al., 1984; Keefe & Blumenthal, 1980). Self-efficacy enhancement is a newer strategy based on social cognitive theory (Bandura, 1997) that has been used successfully to promote dietary adherence (McCann, Follette, Driver, Brief, & Knopp, 1988). Social support enhancement promoted adherence to medication taking (J. P. Kirscht, J. L. Kirscht, & Rosenstock, 1981; Morisky et al., 1983) and dietary prescriptions (Barnard, Scherwitz, & Ornish, 1992; Bovbjerg et al., 1995).

In summary, these studies suggest that regimen adherence can be improved by behavioral interventions that are frequently complex. Future efforts should be focused on the development and testing of new treatments addressing specific patterns of poor adherence.

CONCLUSIONS

Adherence to a treatment regimen poses a significant problem in medical care both in terms of the patient's clinical status as well as financial burden. Efforts to intervene have been limited. Thus, there is minimal information that can be relied on with confidence in efforts to improve adherence within either a clinical or research setting. Clearly there is a need for randomized, controlled studies evaluating interventions.

In the research that has been carried out, limitations have existed due to the measurement and to the definitions of adherence that have been used. Each measure yields somewhat differing information about adherence. Differences in the rates of adherence and in the sensitivity to poor adherence exist leading to variations in reports of adherence among populations as well as within populations where more than one measure is used. These variations in sensitivity to poor adherence may lead to differences in the identification of predictors or determinants of adherence. Indeed, these variations may be contributing to the lack of consistency in the identification of adherence determinants.

The research that has been carried out has also tended to ignore the various patterns of adherence that may occur. These patterns range from failing to participate in the regimen altogether, to variability in regimen conduct, to timing errors, all of which can contribute to variations in clinical outcome. To move the understanding of adherence behaviors forward, the research needs to become more specific about the definition of adherence, its pattern, and the type of adherence problem being addressed. The use of electronic monitors and potentially diaries in the assessment of adherence will allow these subclassifications of poor adherence to be better identified and characterized.

As the clinical outcomes associated with poor adherence have become more salient and the costs have impact on a cost-conscious health care system, the interest in adherence has increased. The newer measurement technologies permit a more refined and specific assessment of adherence problems and patterns, which is contributing toward a finer understanding of this significant problem in health care. The limited studies detailing the problems of adherence, the paucity of intervention studies, as well as the variability created by the coarser view of adherence that has characterized research in the field all point to the need for further focused research in this difficult problem affecting all aspects of health care.

Rehabilitation

Robert G. Frank
University of Florida

Rehabilitation “is defined as the development of a person to the fullest physical, psychological, social, vocational, avocational, and educational potential consistent with his or her physiological or anatomical impairment and environmental limitations. Realistic goals are determined by the person and those concerned with the patient’s care. Thus, one is working to obtain optimal function, despite residual disability, even if the impairment is caused by a pathological process, it cannot be reversed, even with the best of modern medical treatment” (DeLisa, Martin, & Currie, 1988, p. 3).

Rehabilitation is a broad, interdisciplinary field, composed of “health care teams.” Rehabilitation teams utilize either a multidisciplinary or an interdisciplinary approach. In the *multidisciplinary approach*, individuals from a variety of disciplines work in parallel to improve an individual’s function. In contrast, *interdisciplinary teams* use a coordinated, integrated approach to treatment with a common focus on outcomes. Intrinsic to both approaches, however, is an inherent emphasis on restoring individuals to their highest level of function in multiple realms. As noted in the previous definition, psychological functions are an important rehabilitation outcome. Psychological factors have a significant influence in all domains involved in rehabilitation: physical, social, vocational, avocational, and educational. Psychologists are well accepted as a integral member of rehabilitation teams.

Over the last two decades, rehabilitation has been one of the fastest growing areas of the health care industry (Frank, Gluck, & Buckelew, 1990). The growth in rehabilitation has been fueled by a number of factors. Recent advances in medical management have led to higher survival rates for accident victims. Although survivors of traumatic injuries benefit from technological advances, many are left with residual disability requiring treatment (Frank et al., 1990). Second, the “graying of

America” has led to an increase in individuals who suffer from chronic conditions, many requiring rehabilitation. Chronic conditions engender significant health care costs. In the Medicare program, for example, 10% of the beneficiaries account for 70% of medical expenditures (Hoffman, Rice, & Sung, 1995). Individuals with limitations in activities due to chronic conditions account for only 17% of the population, but 47% of the medical expenditures. As many as 100 million Americans had chronic conditions in 1995, and per capita costs for these individuals are three times higher than individuals without chronic health care costs (Hoffman et al., 1995).

THE DEVELOPMENT OF REHABILITATION

Rehabilitation’s growth has been tied to armed conflicts that have produced large numbers of disabled individuals. After World War I, improvements in battlefield management led to an increased number of veterans with residual disabilities. During World War II, dramatic improvements in battlefield management, and accompanying residual disability, led to the development of a medical specialty in the area of rehabilitation. The term *physiatrist*, originally used in 1938 to describe a physician specializing in rehabilitation, gained prominence. Until World War II, rehabilitation consisted of enabling individuals to ambulate to perform low energy activities. During World War II, Howard A. Rusk, a prominent early physiatrist, demonstrated that aggressive rehabilitation, including early ambulation after surgery, diverse recreational activities of varying intensity, and psychologically supported programs produced better outcomes (Frank et al., 1990).

Medicare is the primary payment source for rehabilitation programs. Almost half of all rehabilitation care is funded by Medicare and a quarter of all rehabilitation outpatient stays

(Frank et al., 1990). Changes in Medicare payment policy have enormous implications for rehabilitation and the post-acute care segment as these services were the fastest growing component of Medicare during the 1990s (MedPac, 1998).

In 1983, Congress amended the Social Security Act (PubL. No. 98-21) to create a prospective payment system for 467 diagnoses (or DRGs). Under this Prospective Payment System (PPS), a hospital was paid a fixed, determined amount for each diagnostic group. Free-standing rehabilitation units, psychiatric and pediatric units, and separate inpatient rehabilitation hospitals were exempted from the implementation of PPS. Rehabilitation's exemption from prospective payment led to a boom in rehabilitation hospitals and units. New models of care developed as a function of the change in payment methodologies. With the advent of prospective payment, care was divided into an acute and post-acute phase. Hospitals were rewarded for minimizing the acute treatment and moving patients rapidly to the rehabilitation or post-acute program, where payment limitations were less restrictive (Frank et al., 1990).

Exemption of rehabilitation from the prospective payment system led to an explosion in the number of post-acute care providers and the availability of services. The incentives to transfer patients from the acute to the post-acute environment led health care systems to develop methods of transferring much sicker patients to the post-acute environment. Financial incentives from Medicare that the payment policy created by the exemption from prospective payment for rehabilitation and post-acute services contributed to this surge of growth in rehabilitation. Within the post-acute environment, differentiation among providers emerged. Lower cost skilled nursing facilities (SNFs) began to compete with rehabilitation units and hospitals. The trend toward moving sicker patients to less intensive care settings extended to skilled nursing facilities. Patients that previously had been treated only in rehabilitation units were transferred to SNFs with no apparent decrement in the quality of their care. The growth in SNFs put substantial pressure on rehabilitation facilities. According to the language of the prospective payment exemption, rehabilitation facilities are limited to 10 specific conditions, most of which are musculoskeletal and neurological (MedPac, 1998).

In 1997, in the Balanced Budget Act, Congress modified the exemption from prospective payment. By expanding the definition of transfers, the breadth of the exemption from DRGs has narrowed substantially. Now, post-acute stays are more integrated into the payment for acute stays. This modification is creating another round of evolution in the post-acute sector. The benefit of transferring patients to post-acute stays has been reduced, and hospitals will no longer be incentivized to transfer to post-acute stays (MedPac, 1998).

Changes in payment methodology, as well as overall changes in health care delivery systems, portend rapid, continued evolution of rehabilitation, as well as other health care delivery models. Historically, changes in payment methodology for clinical interventions in rehabilitation have preceded periods of rapid evolution in clinical delivery systems.

Within rehabilitation, there has been increased recognition of the parallels between primary care delivery models and the

comprehensive care provided to individuals with disability in rehabilitation settings. Because disabling conditions also have pervasive effects across a spectrum of health needs, rehabilitation providers often provide comprehensive care to the individual with disability. Although technically a tertiary service, rehabilitation defies traditional classification. In contrast to traditional tertiary care providers, rehabilitation providers often focus across multiple organ systems addressing comprehensive health issues providing continuous care. This model of care, labeled the "cardinal symptom" approach, recognizes that a disabling condition can become the focus of health care. A disability may affect so many aspects of individuals' health care, that their health care is essentially defined by the condition. The consequences of a disability (e.g., spinal cord injury, MS, or brain injury) may interact pervasively to require that a typical tertiary care provider, such as a rehabilitation specialist, becomes the manager of all health care, much like a primary care clinician (Frank, 1997, 1999). In the "cardinal symptom" model, the rehabilitation provider uses primary care clinicians as consultants. This stands in contrast to the typical model in which the primary care clinician uses specialists as consultants.

Although psychologists have been integrated into rehabilitation care since the inception of the field, recognition of models of care (such as the cardinal symptom approach) creates unique opportunities for psychologists. Psychologists' skills readily exploit "cardinal symptom" management. Many psychologists working in rehabilitation settings provide continuous, comprehensive psychological services to their patients. In addition, psychologists often coordinate care and assure continuity of services from other providers. As psychologists' work with individuals attempting to reintegrate into their communities after experiencing a disabling condition, psychological factors often interact with medical outcomes and community limitations. As health care delivery systems evolve, alternative models of primary care (e.g., the cardinal symptom approach, in which specialists manage most aspects of care) using primary care providers as consultants will be more common. Psychologists working with individuals regarding adjustment to chronic symptoms will often coordinate other aspects of care. Undoubtedly, future psychologists practicing in rehabilitation settings will see substantial opportunities to coordinate care as cardinal symptom managers.

THE CONTEXT OF REHABILITATION

Three concepts—impairment, disability, and handicap—are critical to understanding rehabilitation. *Impairment* includes any loss or abnormality of psychological, physiological, or anatomical structure or function. Impairment is deviation from the norm that may be temporary or permanent. It may affect only one domain such as psychological, physiological, anatomical structure or function, or all areas. Impairment may reflect the active, ongoing activity of a pathological state or may be the consequence of a disease.

Disability is "in the context of health experience, a disability is any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner within the range

considered normal for the human being" (World Health Organization, 1980, p. 28). Whereas functional limitations derive from impairment, the synergistic effects of impairment on the person or body as a whole constitute disability. Disability relates to the integrated activities an individual would normally address. A disability is an aspect of an individual rather than a description of the person. For example, an individual has a disability in contrast to being disabled.

In contrast to impairment and disability, *handicap* refers to the individuals' perception and assessment of their abilities. An individual is handicapped relative to the activities of others. The values and attitudes of nonhandicapped individuals play a central role in defining the concept of "handicapped." Disadvantage from handicap develops as a result of an individual being unable to perform with expected norms (World Health Organization, 1980).

PSYCHOLOGICAL FUNCTIONING

A significant concern in rehabilitation is the adjustment of the individual to the change in functions. Whether the change begins after an acute injury with rapid onset or the change is a more gradual decline associated with the slow onset of a chronic condition, psychological adjustment is critical to the outcome. As noted in the World Health Organization's definitions of disability and impairment, the psychological perception, both in terms of the individual sustaining the disabling event and from the perception of the individual evaluating the person with a disability, is critical. In evaluating psychological response or coping with disability, two primary concerns are tantamount. First, what was the individual's psychological functioning prior to the onset of the disabling event? Second, after the onset of the disabling event, what psychological skills does the individual have to cope with the event?

Initial interest in psychological response to catastrophic injury increased after World War II when individuals began routinely surviving spinal cord injury (SCI). Adjustment to such a catastrophic change in life was of significant psychological interest. An array of models were posited to describe the psychological changes associated with SCI. Most frequent were variants of stage models in which individuals evolved through a series of fixed stages of psychological reactions to the SCI (Frank et al., 1987). Stage models were generally derived from psychoanalytic theory. All stage models, regardless of the unique variations, posited a "depressive" phase. The depression was viewed as therapeutic in aiding recovery. Indeed, in many early writings, it was common for authors to dogmatically assert the absence of a depressive phase as pathological. Implicit to most early models of adjustment—derived almost universally from adjustment to spinal cord injury—was the requirement that the injuring event was the most salient distinguishing feature and was viewed as a predictor of the individual's behavior (Elliott & Frank, 1996). Individual factors, personality, and coping were all viewed as less predictive of outcome than the occurrence and onset of the disabling event (e.g., SCI). Only in the last decade has this approach been viewed as inadequate (Elliott & Frank, 1996).

Research on spinal cord injury can serve as a template to understanding adjustment to both acute and chronic catastrophic injury or illness. Although there are many holes in the empirical literature, there is now adequate evidence to show that disorders associated with disability should be viewed as similar to other psychological disorders. Evaluation should include careful review of psychological, biological, and social factors. Each leg of this triangle represents a critical and interactive vector with the other two legs. Of particular importance in the arena of rehabilitation are biological factors. In many conditions treated in rehabilitation, profound alterations of the biology of the individual occur. For example, in SCI, there is reason to believe that the adrenal-cortical function is altered by injury. Frank, Kashani, Wonderlich, Lising, and Visot (1985) found a high rate of false positives among nondepressed individuals challenged in a dexamethanone suppression test. Such findings demonstrate the complexities of understanding the contribution of biological factors to psychological functioning and impairment after catastrophic injury or illness.

DEVELOPMENTAL FACTORS IN REHABILITATION

Within the realm of psychological response to injury or illness, there is a paucity of theory and empirical data. Clearly, development in late adolescence and early adulthood is critically important in understanding psychological response to catastrophic injury as, most often, catastrophic injury occurs during late adolescence. Younger adults show more pervasive psychopathology in response to catastrophic injury, such as SCI (Frank, Elliott, Buckelew, & Haut, 1988) or amputation (Frank et al., 1984), than older adults. Other psychological factors, such as locus of control, have been shown to have significant predictive value in determining psychological adjustment to catastrophic injury or illness. For example, Frank and Elliott (1989) found individuals who had higher internal attributions of control were less depressed than patients who attributed control to chance or health personnel. In contrast, Bulman and Wortman (1977) found that patients in rehabilitation who blame themselves for their injury were rated by nursing staff as coping more effectively, although this interpretation has been criticized (Frank et al., 1987).

PSYCHOLOGICAL FACTORS IN REHABILITATION

The majority of empirical and theoretical work on adjustment to catastrophic injury or illness has focused on psychopathological responses. A plethora of studies has examined depression as well as a few other responses (e.g., anxiety or adjustment disorders). Few studies have focused on what has sometimes been labeled the "positive emotions," such as hope or courage. Indeed, even within the realm of psychopathological responses, little is known of the discreet symptoms constituting mood disorders. Hopelessness is a frequently cited symptom of depression, yet little is known of the

course of hopelessness after catastrophic injury or of the factors that mitigate the emotion. There is some evidence that cognitive affective symptoms such as dysphoric mood, acknowledgment of guilt, and suicide ideation are the most efficient predictors of the development of a major depressive disorder (Frank, Chaney, Clay, & Kay, 1991). Dysphoria appears to be a core symptom in the development of depression following chronic illness or catastrophic injury (Frank et al., 1992).

Cognitive factors are significant in predicting outcome to catastrophic injury or chronic illness. It appears individuals with greater personal psychological resources who have demonstrated better adjustment before injury or illness are less likely to display depressive or other psychopathological behaviors after the incident. Although there is little direct evidence for this hypothesis, there is significant indirect support (Elliott & Frank, 1996). Elliott and colleagues found that effective skills in problem solving and greater confidence in problem solving were significantly associated with lower scores of self-import depression among individuals with spinal cord injury. In other work, Elliott, Witty, Herrick, and Hoffman (1991) found that higher levels of hope and goal-directed energy are associated with less distress, regardless of time since injury onset. Social and cognitive characteristics (e.g., problem solving, hope, and locus of control) play significant roles in mediating the outcome of adjustment to catastrophic injury or illness (Elliott & Frank, 1996).

INTERPERSONAL ASPECTS OF ADJUSTMENT

Interpersonal dynamics also mediate adjustment to catastrophic illness or injury. Overall, psychopathological responses to catastrophic injury are overdiagnosed by staff in rehabilitation settings (Frank et al., 1987). The skill of rehabilitation staff in diagnosing depression varies considerably across disciplines (Caplan, 1983; Frank et al., 1987). Although rehabilitation staff overdiagnose depression, the presence of depressive symptoms also alters the interpersonal dynamic.

In a series of studies, Frank and colleagues (1987) demonstrated that individuals with catastrophic injury may receive more ingenuine feedback and support than depressed, noninjured persons. Consequently, many individuals with catastrophic injury or chronic illness may receive more complex, less clear responses from individuals around them. In addition, rehabilitation staff have been found to have more hostile and anxious feelings after listening to individuals with disabling conditions present as depressed. The stigma of disabling conditions pressures individuals with disabilities to monitor their demeanor and to maintain an optimistic and positive attitude. The manifestation of dysphoria or depression results in more punitive responses to the behavior of the individual with disability (Frank et al., 1987).

The role of families in the adjustment of individuals with disability is significant (Frank, 1994). The interaction between family function and the recovery of an individual with catastrophic injury or chronic illness is poorly understood. It is now clear that families with enhanced problem-solving and behavioral coping strategies are more facilitative to effective

adjustment (Leach, Frank, Bouman, & Farmer, 1994). Assessment of family functioning and its contribution to individual outcome is complex. The domains of both the parent and child must be individually assessed, and the interaction of these relationships also must be reviewed (Frank et al., 1998).

Disease status may be independent of psychological perceptions and skills. Comprehensive assessment of individual adjustment to catastrophic injury or illness is now recognized as a multidimensional process. Individuals appear to adapt according to psychological skills and attributes, personality factors, biological factors, and environmental responses. Within these multiple domains, common adaptation models can be articulated. In contrast to historic approaches that have attempted to define adjustment according to the impeding event (e.g., spinal cord injury, traumatic brain injury, rheumatoid arthritis), more recent approaches evaluate individual attributes, environmental factors, and the biology of the illness yielding cohorts presenting of common psychological responses. Frank and colleagues (1998) showed how common trajectories of adaptation to chronic illness can be developed that classify individuals and their families. Critical to this approach is recognition that individuals and their families change continuously; factors such as the disabling condition, individual and family development, and psychological and environmental factors all modify the response.

THE SOCIAL PSYCHOLOGY OF DISABILITY

Research on attitudes of individuals toward persons with disabilities is more than half a century old. Nondisabled persons tend to hold an unfavorable attitude toward persons with disability, although some authors have suggested that societal opinion is more ambivalent than prejudicial (Dunn, in press). Individuals without disability often intentionally ignore people with disabilities to suppress emotional reactions. This creates an environment of rejection and isolation for individuals with a disability. Most often, the "just world" hypothesis (Lerner, 1980) has been invoked to describe the attitude of individuals without disability toward those with disability. The "just world" theory holds that people believe good things should happen to good people and bad things, such as disability, happen to bad individuals. To maintain this view, nondisabled people must devalue or castigate individuals with disability. Not all views of individuals with disability are negative in content. Individuals with disability can be viewed as coping with their impairment in an ennobling or otherwise outstanding manner. Such attitudes place undue emphasis on the disability, ignoring the individual's abilities (Yuker, 1994). Typically in social interactions, the disability becomes a pervasive characteristic of the individuals with little attention paid to their other attributes or abilities.

Individuals with disability can establish positive interactions by reducing the discomfort of the able-bodied individual. When individuals with disability recognize their disability, assertively request assistance, or express interest in other people and common topics, or display adaptive emotional adjustment to the disability, they are more accepted by individuals without disability (Dunn, in press).

Recently, increasing attention has been paid to the construct of reality negotiation as a useful organizing principle respecting the multiple perspectives applicable in rehabilitation (Dunn, in press). Reality negotiation occurs when individuals rely on cognitive strategies to promote favorable beliefs about the self and situations that threaten self-esteem and well-being (Elliott et al., 1991). Reality negotiation utilizes an array of important constructs that appear to have relevance to rehabilitation, including positive illusions (Taylor & Brown, 1988), dispositional optimism (Scheier, Carver, & Bridges, 1994), attributional style (Peterson, Maier, & Seligman, 1993), control (Heckhausen & Schultz, 1995), locus of control (Leftcourt & Davidson-Katz, 1991), and hope (Snyder, 1994). In practice, it is difficult to empirically evaluate the person-environment interaction when considering adjustment or reactions to disability (Dunn, in press).

DESCRIPTION OF REHABILITATION INTERVENTIONS

Rehabilitation has applications to a staggering array of health conditions. Most often, attention has been directed to acquired conditions that limit function. As noted earlier, spinal cord injury has been an area of interest for all disciplines involved in rehabilitation. More recently, as survival after traumatic brain injury has increased, much attention has been directed to that field. Although SCI piqued interest in the psychology of adjustment to catastrophic injury, the first catastrophic injury with a high survival rate was amputation. In the following section, each of these conditions is reviewed to provide perspective on rehabilitation psychology. Spinal cord injury is examined in greatest detail. The rehabilitation treatment issues elaborated here have relevance to all rehabilitation treatment. Congenital conditions or disabling conditions of childhood are not discussed.

Spinal Cord Injury

Treatment of spinal cord injury (SCI) has defined the development of rehabilitation psychology. Although rehabilitation psychology is much broader than this single condition, the work of rehabilitation psychologists in virtually every aspect of the treatment of individuals with SCI has defined the broader context of rehabilitation psychology. In SCI, the psychological treatment needs of the individual and family change through out the individual's life span. Although adjustment to disability is often the initial issue motivating referral to a psychologist, psychological treatments associated with SCI are diverse. Treatments may range from behavioral approaches to managing bladder dysfunction, to family or marital therapy, consultation with treating professionals regarding sadness arising from repeated exposure to profound loss, to psychological issues the individuals with injury encounter related to their disability.

The prevalence of spinal cord injury in the United States is about 906/1,000,000, yielding 230,000 living individuals with SCI in 1992 (Richards, Kewman, & Pierce, in press). More than half of all injuries occur in individuals from age 16

to 30, with men making up almost 80% of all spinal cord injury cases (Richards et al., in press).

Damage to the spinal cord may result in a complete or incomplete lesion. An incomplete lesion results in some sparing of neurologic function in the spinal cord. Complete lesions sever all function of the cord. Neurologic level refers to the lowest level of the spinal cord with intact sensory and/or motor function (although motor and sensory functions may have different neurological levels and may affect the sides of the body differently). Paraplegia results from loss of function in the thoracic, lumbar, or sacral portions of the spinal cord; arm and hand function are intact. Tetraplegia results from injury to the cervical portion of the spinal cord; arm and hand function are impaired.

Spinal cord injury creates a number of unique and vexing problems both in daily function and psychological adjustment. Substance abuse, related to both alcohol and drugs, is common among individuals with spinal cord injury. Substance abuse is frequently a factor in the injury. Many spinal cord rehabilitation programs address substance abuse. Sexuality can be profoundly impaired by spinal cord injury. Depending on the level of neurological deficit, males can experience impairment of "psychogenic erections" (i.e., erections solely triggered by mental or nontactile stimulation). Patients with complete upper motor neuron lesions are likely to have reflex erections (i.e., automatic erections typically stimulated by contact that can occur in the absence of arousal). These erections cannot reach adequate tumescence to allow sexual intercourse. Ejaculation in psychogenic erections are unlikely in this group.

In men with complete lower motor neuron lesions, about one in four is able to have a psychogenic erection and is less likely to have reflex erections. About one in five of these individuals is able to ejaculate. Even in those individuals able to ejaculate, fertility often is problematic, because sperm counts tend to be low (Richards et al., in press). Women with SCI are capable of achieving orgasm. A substantial portion of women post-SCI may be able to be taught manipulation techniques that could improve sexual response and experience. Hormonal and menstrual cycles in women are altered after spinal cord injury, and appropriate birth control counseling should be emphasized. The absence of stimulation often leads many women to the erroneous belief that they are not able to get pregnant.

Spinal cord injury is associated with a number of secondary complications that are preventable and costly. Psychological interventions have pertinence to the behavioral factors involved in the development of these complications. Two of the most common disabling, and costly, secondary complications are pressure ulcers and urinary tract infections. The occurrence of each of these secondary complications can be lessened if the individual with SCI utilizes effective and routine self-care methods.

Pressure ulcers result from restriction of blood flow to the skin that depletes available oxygen resulting in degeneration of tissue, lack of sensory input, and impaired mobility. The skin is sensitive to even moderate, persistent pressure. Atrophy, repetitive trauma, scarring, and/or secondary bacterial infection, shearing force, and reduced transcutaneous oxygen

tension are major etiologic factors. Sites most prone to the development of pressure ulcers are bony prominence such as the sacrum, ischium, heels, ankles, and trochanter.

Pressure ulcers are one of the most common debilitating secondary complications of SCI, and severity of pressure ulcers varies. Treatments range from bed rest, or "down time," to surgery. Enormous cost is associated with surgical intervention. More than a decade ago, surgical intervention for a pressure ulcer cost more than \$60,000 per case (Stover, Whiteneck, & DeLisa, 1995). Over time, most individuals with SCI will develop pressure ulcers.

Coping with spinal cord injury requires exacting self-care. Skin pressure must be relieved at least every 30 minutes, fluid consumption must be monitored, skin must be inspected daily, and a balanced diet must be maintained. A person's ability and motivation to follow this complex regimen can be affected by poor psychological adjustment to injury or the presence of overshadowing psychopathology or substance abuse. In addition, depressed individuals may be prone to self-neglect. Untreated or improperly treated pressure ulcers will not heal and tend to be potentially life threatening.

The incidence of renal failure secondary to recurrent urinary tract infections (UTI) in persons with physical disability has decreased markedly. Despite this decrease, UTI remains a common event after spinal cord injury, because a complex regimen is required to manage bladder function. The bladder must be managed to establish and maintain unrestricted urine flow from the kidneys and to maintain urine sterility and bladder continence, thereby preserving renal function. Neurologic damage that affects control of the bladder coupled with the need for catheters to facilitate emptying result in impairment of normal anatomic and physiological defense mechanisms responsible for eliminating bacteria and maintaining urine sterility. In the neurogenic bladder, stagnant residual urine allows bacteria to accumulate leading to bladder infections.

Psychological variables, personal hygiene, and the ability to understand and implement the treatment regimen are all prerequisites for effective management of bladder dysfunction associated with SCI. Similarly, the prevention of pressure ulcers requires a complex self-care regimen. Management of bladder dysfunction and prevention of pressure ulcers following spinal cord injury are two vivid examples of the high need for self-care following spinal cord injury. A number of psychological parameters interact with these treatment regimens altering health outcomes. Failure to follow these treatment regimens can result in serious medical complications, high cost hospitalizations, and impaired health for the individual with SCI. Although routine education regarding self-care and prevention often is provided by other professionals, rehabilitation psychologists have an important role in the educational process, scientific understanding of the behavioral aspects, and the treatment of poor regimen compliance. Relatively little attention has been directed to these important areas within the rehabilitation psychology literature and in the clinical literature. The opportunity to impact these important self-treatment skills through telemedicine interventions, better definition of risk

factors, and better assessment of cognitive and behavioral skills required for effective self-care and the role of primary care giving is needed.

Psychological interventions with individuals who sustain SCI have been fairly common. Interestingly, although there has been a strong interest among psychologists in spinal cord injury, many of the individuals who sustain spinal cord injuries are not introspective individuals (Rohe & Krause, 1993). Consequently, a number of models of intervention have been developed for spinal cord rehabilitation units. Often, psychologists work with physicians and other staff to indirectly treat the individual. Psychological services can be packaged as part of the rehabilitation treatment. Routine referral to the psychology service can destigmatize the process and reduce resistance (Richards et al., in press). Increasingly, there has been an emphasis on educational approaches to psychological treatment. Group sessions are common, and information regarding areas such as coping, stress management, common psychological changes, and physiological changes after spinal cord injury are presented in a didactic model with discussion. Introduction of family members into treatment groups allows treatment of broader systems. An important aspect of these groups is the management of interpersonal reactions to spinal cord injury. Spinal cord injury is a stigmatizing condition that can result in excessive reactions from individuals lacking experience with persons with disabilities (Frank & Elliott, 1987). Individuals with spinal cord injury face strong pulls for cheerful and optimistic demeanor. The manifestation of depression or other aberrant psychological states results in rejection and alienation (Frank & Elliott, 1987). In addition, rehabilitation settings can demand "appropriate" psychological responses to injury such as grieving and depression. Individuals who fail to exhibit these responses may be pressured to respond according to more appropriate "norms" (Frank & Elliott, 1987).

Treatment of caregivers and families can be a critical part of rehabilitation after SCI. Caregiving requirements for persons with SCI can range dramatically. Individuals with high level tetraplegia can be entirely dependent, whereas low level paraplegics can be essentially independent. The adjustment of the individual with SCI has been studied frequently, but much less is known of the reaction of caregivers to SCI. It is known that individuals with SCI demand increases in emotional and physical duties of care providers, especially in the first year postinjury (Shewchuk, Richards, & Elliott, 1998). Also, it is known that, over time, SCI creates significant deterioration in functioning of families with a member with SCI (McGowan & Roth, 1986).

Elements of social support have been found to be associated with adjustments following spinal cord injury. Relationships that provide a sense of attachment and intimacy have been associated positively with more satisfying spare time activity (Elliott & Shewchuk, 1995). Physical symptoms and anxiety have been shown to be highly interdependent in a study of caregivers and individuals with spinal cord injuries. Anxiety was found to be a salient predictor of the initial levels of and rate of change in physical symptoms of the caregivers. Physical symptoms in younger patients received significantly predictive initial levels of anxiety. Physical symptoms and

positive affect predicted initial levels of depressive behavior among caregivers. Expressive social support predicted the rate of change and anxiety in depressive behavior over time (Shewchuk et al., 1998). Finds such as this underscore the need for longitudinal assessment of family and dynamics after spinal cord injury.

Caregiver problem-solving ability is pertinent to the outcomes of the individual with spinal cord injury. In a recent study, depressive behavior at admission was significantly predictive of acceptance of disability at discharge. Caregiver tendencies to impulsively and carelessly problem solve are associated with lower acceptance of feelings at discharge. Moreover, caregiver impulsiveness/carelessness in problem-solving style was significantly predictive of pressure ulcer diagnosis at follow-up (Elliott, 1998). Overall, this finding suggests that caregiver problem-solving styles are associated with health outcomes following disability. Rehabilitation efforts need to be directed to the caregiver as well as to the individual with the disability during rehabilitation and following return to the community.

Traumatic Brain Injury

Over the last two decades, traumatic brain injury (TBI) has become one of the primary diagnostic entities treated in medical rehabilitation facilities. Traumatic brain injury comprises about 10% of the inpatient rehabilitation unit population. Overall, the incidence of TBIs is estimated to be 102.1/100,000 in the United States (Rosenthal & Ricker, in press). The pattern of behavioral cognitive and psychosocial disabilities resulting from TBI provides many opportunities for psychological interventions.

Damage to the brain from external mechanical forces, such as occurs in TBI, can result in a broad array of sequelae. Initial neurobehavioral response to injury typically is classified by the Glasgow Coma Scale (Teasdale & Jennette, 1974). The Glasgow Coma Scale assesses the patient's behavior response within the domains of eye movement, motor functions, and vocalization. The total score ranges from 3 to 15 with lower scores representing increased depth of unconsciousness. Scores of 8 or lower typically are considered severe brain injuries, whereas scores between 9 and 12 are classified as moderate injuries. The Glasgow is an excellent crude indicator of likely outcome, but it is far from a perfect predictor.

A traumatic brain injury generally is classified as a closed or open injury. A *closed brain injury* occurs when the brain, which is bathed with cerebral spinal fluid, is rapidly reaccelerated and then decelerated (most commonly in a motor vehicle accident or fall). Mechanical forces are applied to the brain in the acceleration and deceleration that produce shearing and tearing effects. The anterior aspects of the skull can become contused against the bony prominence as the brain is accelerated and decelerated. The posterior aspects of the brain meet the relatively smooth rear casing of the skull; consequently, contusions to the frontal areas of the brain, including the frontal lobes and temporal lobes, are common following TBI. Acceleration and deceleration injuries are accompanied by shearing and torquing effects as the brain ro-

tates within the skull creating excessive pressure on the ascending and descending pathways. This widespread disruption of axonal tracks typically is referred to as diffuse axonal injury (DAI; Rosenthal & Ricker, in press). Diffuse axonal injury is a primary source of post-brain injury impairment, however, biochemical cascades occurring days to hours following the injury also are a significant factor in the residual impairment.

Open, or penetrating, injuries share many of the same characteristics as closed head injuries. In addition, a penetrating injury of the skull casing results in direct tissue destruction in the area of impact. Resulting mechanical changes in the brain may produce many of the same effects noted in an acceleration/deceleration injury.

Edema is a common secondary complication of most severe brain injuries and occurs when there is an increase of water concentration within the cells or between the cells or both. Edema leads to increased inner cranial pressure that may create further cerebral impairment. Following a traumatic brain injury there is an increase of the catecholamines, norepinephrine and epinephrine. This cascade of catecholamines can result in changes in glucose, cortisone, and thyroid hormones. Rosenthal and Ricker (in press) provided a more comprehensive description of biological factors associated with brain injury.

Predicting the specific deficits of TBI is difficult. Commonly, deficits in arousal, attention, memory, capacity for new learning, ability to initiate behavior, maintaining and organizing goal-directed behavior, self-awareness, language and communication, visual spatial, efficiency, agitation, aggression, decision in habitation, and oppression are observed. An individual may present one, all, or a combination of these symptoms.

Psychologists play an important role in the assessment and treatment of TBI. While an individual is on the acute (neurosurgery or medicine unit) unit, psychologists frequently are involved in assessing their recovery and gross domains of function. In addition, psychologists may work with hospital staff to develop behaviorally based treatment programs to manage difficult behaviors such as agitation, disinhibition, or aggression. Often, psychologists work with the family members of the injured individuals regarding their responses to the injury, helping family to understand the changed cognitive status of their loved ones.

Once injured individuals are transferred to the rehabilitation unit, the psychologist may become more involved in the management of their care. While continuing, in a more comprehensive manner, many of the activities in the acute unit, the psychologist also will begin more complex evaluations of the individual's cognitive and emotional functioning. This often includes a neuropsychological assessment focusing on the domains of intellectual functioning, cognitive functioning, memory, and problem solving. Although batteries utilized for this assessment vary according to practitioner preferences, a common emphasis in all batteries is the evaluation of stable cognitive skills, as well as more "fluid" areas that are more frequently affected by injury. In addition, continued involvement in behavior management is common for psychologists

treating individuals with TBI. Often, behavior management programs are paired with psychopharmacological interventions designed to help modulate problem behaviors such as disinhibition or agitation. Psychologists must be knowledgeable about psychopharmacological interventions for these disorders and their effects on both the normal and impaired brain. Sensitivity to the power of the psychopharmacological effects is critical to the design of carefully titrated behavioral programs, which produce a joint treatment package that is most effective. Continued education of patients and their family regarding the issues they will face in recovery is critical to successful outcomes. Invariably, severe or moderate brain injury produces some sequelae that the individual and family must find ways to manage. Awareness of these disabilities and the ability to address these problems are critical to good outcome.

One of the more controversial areas of rehabilitation within TBI is the use of "cognitive rehabilitation." Cognitive rehabilitation emphasizes cognitive retraining to ameliorate deficits produced by injury. There are two general approaches to cognitive retraining: compensatory and restorative. The compensatory models are more congruent with general rehabilitation approaches, but place a much higher emphasis on cognitive intervention. Rosenthal and Ricker (in press) provided a more detailed description of these views. Whereas there is some promise for both types of rehabilitation, little empirical study has validated these approaches. It is likely that some specific skills, such as visual scanning, attention and concentration, and spatial organization are impacted by cognitive treatment. Such improvements are difficult to evaluate due to the lack of untreated controlled studies and difficulty developing sensitive measurement devices.

Following the rehabilitation phase, individuals are likely to return to their community for the *post-acute* phase of treatment. Post-acute refers to any treatment after rehabilitation hospitalization and may range from treatment in a sub-acute, high intensity skilled nursing facility, to treatment in the community and day treatment programs (Malec & Ponsford, in press). Many issues involved in post-acute rehabilitation are similar to those described in cognitive retraining. In addition to addressing basic cognitive deficits, post-acute programs emphasize community reintegration, the management of deficits, and the response of individuals in the communities to these deficits. Frequent emphasis is placed on the use of orthoses, or compensatory devices that can improve outcome (e.g., memory notebooks).

Like other community-based rehabilitation efforts, post-acute rehabilitation typically is managed with a transdisciplinary team. These teams are more focused on individual community integration than many other rehabilitation programs. In some countries such as Australia, there has been extensive development of community-based post-acute programs. Although such programs flourished briefly in the United States, lack of funding curtailed these programs. Post-acute programs serve individuals with a profound range of defects, ranging from gross memory and planning and motivation defects to minor levels of physical impairment. Some individuals return to work, and others are challenged by having

any social activity. Moreover, the pattern of defects often is unique. The absence of a consistent outcome measure for describing post-acute outcome studies has clouded understanding of the efficacy of these programs. Generally, community integration programs appear to increase the number of individuals who can live independently in the community, but few individuals are totally independent and most continue to require some support. Community integration programs may need to provide rehabilitation interventions long after the onset of injury, perhaps for the entire life of the injured individual.

Amputation

Fifty years ago, the first study of adjusting to "misfortune among war veterans with amputations" marked the beginning of psychology's involvement in rehabilitation (Rybarczyk, Szymanski, & Nicholas, in press). Despite the early interest of psychologists in amputation, there have been relatively few studies of the psychological changes associated with this catastrophic limb loss.

The most common type of amputation is the removal of a lower extremity (90%). Men are more likely to have amputations than women, and the majority of amputations (75%) are performed in individuals over age 65 (Rybarczyk et al., in press). Many individuals undergoing amputations have complex medical conditions leading to death for from 40% to 60% of lower extremity amputees within 2 years of the procedure. Individuals with amputation are at high risk for a second amputation in the contra-lateral leg. The common causes of amputation are vascular disease and infection, trauma, tumors, congenital deformities, or abnormalities. The majority of amputations results from vascular disease. In addition to the medical challenges associated with amputation, there are common psychological changes. As many as 62% of amputees experience dysphoria, 33% experience anxiety, 53% experience crying spells, and 47% experience insomnia (Shukla, Sahu, Tripathi, & Gupta, 1982). The incidence of depression ranges from 21% to 35% (Kashani, Frank, Kashani, Wonderlich, & Reid, 1983).

Despite these common emotional reactions, amputation can induce a wide spectrum of psychological responses. Responses range from viewing the amputation as a great personal tragedy to a "new lease on life" (Rybarczyk et al., in press). Careful assessment of psychological reactions, as well as medical comorbidities, is essential. Although conventional wisdom suggests individuals improve as a function of time from the point of amputation, there is little research to support this idea. There is little research to support systematic stages of reaction to catastrophic injury, and amputation is no exception.

Pain in the amputated limb, referred to as phantom limb pain, is a common experience after amputation, affecting from 60% to 90% of individuals (Rybarczyk et al., in press). Phantom limb pain can be continuous or episodic and most frequently is experienced shortly after surgery. About half the individuals experiencing amputation note a decrease in phantom limb pain, and the remainder experience no relief or an exacerbation of pain. The ideology of phantom limb pain is poorly understood, but appears to be higher in individuals

who had amputation secondary to blood clots and in those who experienced more preamputation pain and pain in the stump following amputation.

Disability following amputation is believed to be greater for below-the-knee amputations than above-the-knee amputations. Little empirical data has been found to substantiate this belief.

CONCLUSIONS

The continuum of care for health conditions can be grossly divided into acute conditions and chronic conditions. Chronic conditions that require continuous intervention for the same medical problems include rehabilitation services. Rehabilitation is defined as goal oriented interventions designed to develop individuals to their fullest physical, psychological, social, vocational, and educational potential. Psychologists have significant opportunities in each of these domains. In addition, the evolving "post-acute" sector of care that focuses on the integration of an individual into the community following the disabling conditions offers many role opportunities for psychologist.

Rehabilitation requires a broad range of psychological skills ranging from the treatment of more common psychopathological disorders to health psychology intervention to family and marital treatment. System issues are of critical importance in rehabilitation. Both the treating milieu, including the reactions of the rehabilitation staff, the family, and the individual are critical in determining the outcome. Psychologists working in rehabilitation must be knowledgeable of systems interventions and proficient in understanding both the social psychology and the clinical psychology of disability. Increasingly, psychologists in rehabilitation are designing interventions that collate interventions at the individual, family, and community level. At the same time, these interventions also are often sensitive to the diminishment of health resources and to maintaining the individual at the highest level of individual function. Rehabilitation and the chronic sector of care offer an important paradigm for the delivery of psychological services as the number of individuals with disabilities increases in the United States. Delivery systems such as the "cardinal symptom approach" that focus on the most disabling health concerns offer psychologists opportunities to create primary care delivery roles in which they provide continuous, comprehensive, coordinated service to individuals. Although this model may defy traditional definitions of primary care, as health care delivery systems evolve to meet the needs of consumers, traditional definitions will fall by the wayside.

Community Intervention

David G. Altman

The Wake Forest University School of Medicine

Robert M. Goodman

Tulane University School of Public Health and Tropical Medicine

This chapter reviews community interventions to promote health and prevent disease. Community interventions typically emanate from a health promotion perspective, with health promotion defined as education, organizational, economic, environmental, and advocacy efforts that foster healthful behaviors and settings. The goals of community interventions can be quite diverse, ranging from decreasing morbidity or mortality, to increasing the practice of a healthy behavior, to securing passage of health policies. Community interventions typically employ an array of programmatic approaches. These include those steeped in informational, behavioral, organizational, community development, environmental, and policy perspectives. A distinction is sometimes made between community interventions (i.e., interventions that attempt to achieve small but widespread changes) and interventions in communities (i.e., interventions that seek large changes among targeted groups; Green & Kreuter, 1991). Issues surrounding both types of intervention are covered.

Because most community interventions employ a wide array of intervention approaches, from those focused on changing individual behavior to those that target policies that facilitate or impede individual behavior, the line between community interventions and individual interventions is drawn artificially. Instead, community interventions are viewed as a set of approaches that utilize a vast array of change strategies. As noted throughout this chapter, however, a community intervention does have features that distinguish it from interventions that only target individuals or small groups.

There is a long history of community intervention in the field of public health (Rosen, 1993). Contemporary approaches to community health promotion can be traced to the late 1800s (Minkler, 1990; Nyswander, 1967). Over the years, community interventionists have drawn on a variety of theoretical perspectives to guide community intervention, including those from psychology (Farquhar, Fortmann, Wood, & Haskell, 1983; Iscoe & Harris, 1984; Levine, Toro, & Perkins, 1993; Maccoby & Altman, 1988; Shea & Basch, 1990), health education, community development (Bracht & Kingsbury, 1990; Kinne, Thompson, Chrisman, & Hanley, 1989), social ecology (Binder, Stokols, & Catalano, 1975; Stokols, 1992), and policy (Bennis, Benne, & Chin, 1969; Elder, Schmid, Dower, & Hedlund, 1993; Freudenberg, 1984–1985; McAlister, 1991; McKnight, 1987; Milio, 1981; Sarason, 1983; Steckler, 1989).

Although public health professionals have utilized community interventions for many years, psychology has played a less prominent role in recent years, although the theoretical underpinnings of health education and health promotion were articulated by Lewin (1951; field theory) and Rosenstock (1974; Health Belief Model), to name two. As noted throughout this chapter, however, the knowledge, skills, and perspectives of modern-day psychology, especially community psychology, have great potential for contributing to this domain of work (Iscoe, 1982; Revenson & Schiaffino, 2000; Winett, King, & D. G. Altman, 1989).

The following case illustration of a partnership approach serves as an example of community interventions that are in-

formed by many of the concepts in this chapter, particularly social ecology, which is defined after the illustration.

BRIEF CASE STUDY: COMMUNITY-BASED SUBSTANCE ABUSE PREVENTION

The use of alcohol, tobacco, and other drugs (ATOD) by young people remains a substantial threat to the nation's health, and the age of initial ATOD use appears to be dropping (Department of Health and Human Services, 1991; Duran, Escobedo, & Heath, 1995). In the early 1990s, the

Centers for Substance Abuse Prevention (CSAP) responded to the continuing threat to the nation's young by funding approximately 250 community partnerships, each for 5 years, with the goal of reducing the adverse health consequences that ATOD use can cause (Davis, 1991).

Figure 36.1 is a model of a CSAP partnership (Butterfoss, Goodman, & Wandersman, 1993). The model shows a formative stage for the partnership during which the agency that is granted the funding (lead agency) convenes an ad hoc committee of local community leaders. The ad hoc committee nominates influential citizens to serve on committees repre-

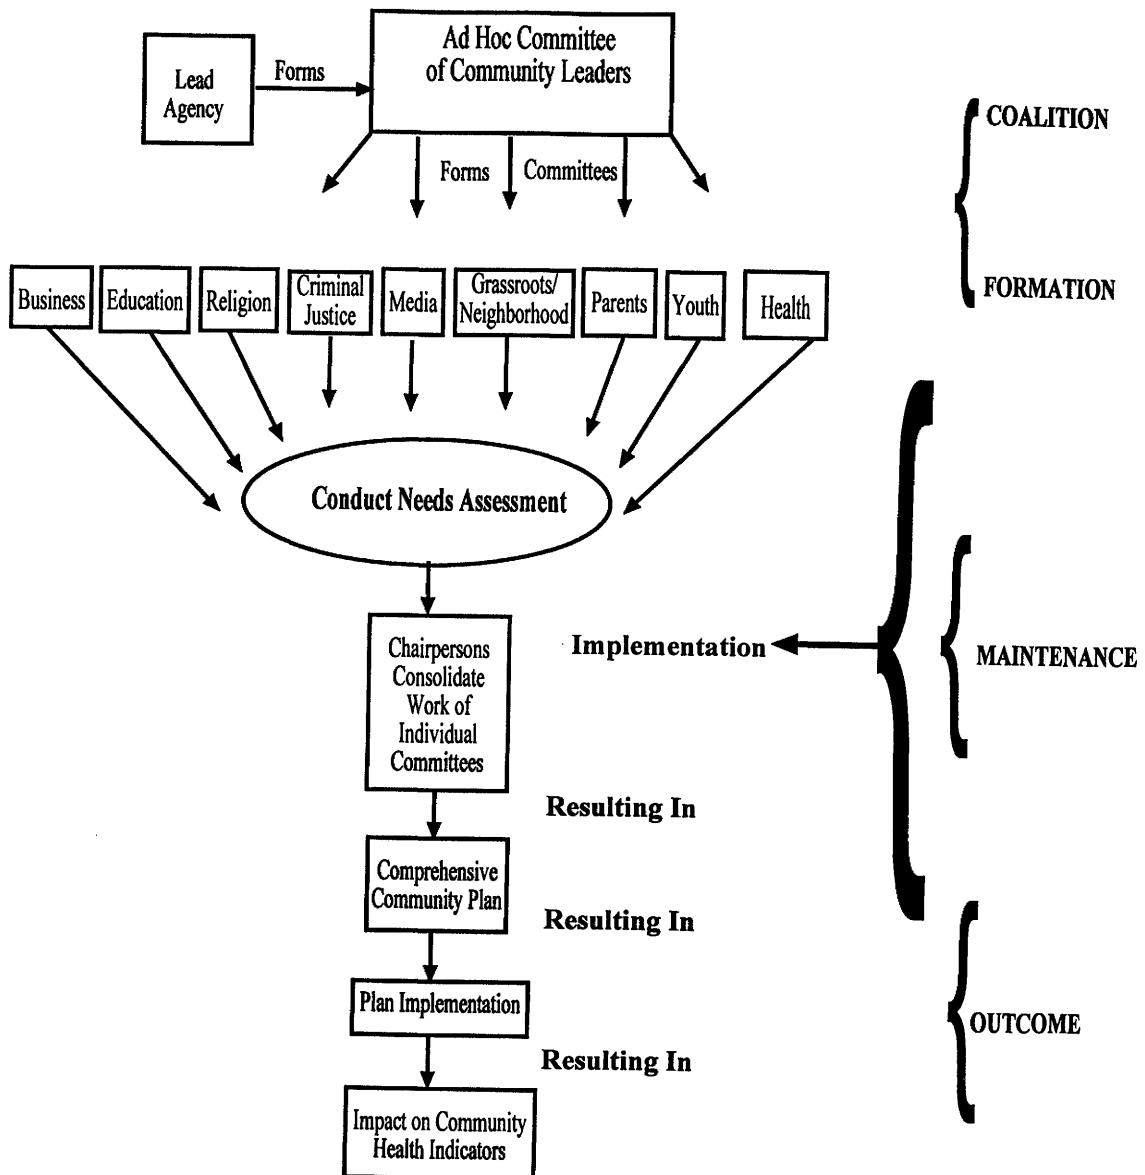

FIG. 36.1. A model for a community coalition to address alcohol, tobacco, and other drug abuse.

senting important sectors of the community. Once the committees are formed, the members are provided with background information of the seriousness of ATOD use among youth, and possible strategies for use reduction and prevention. The proposed strategies are directed at individual influences, such as degree of coping skills, self-esteem, and communication skills; family influences, such as family cohesiveness, parental modeling, and parenting skills; and community influences, such as the presence of supportive resources, sound economic conditions, and limited availability of potentially harmful substances.

Prior to deciding on which combination of strategies to adopt, each committee gathers information regarding ATOD use in its community, thus assessing the level of the problem locally. The availability of local resources to address ATOD use also is ascertained. Based on this assessment, the committees integrate their findings and develop a community-wide plan for addressing youth ATOD use. The plan consists of the selected strategies to be implemented, time lines for implementation, agencies and individuals designated to carry out the strategies, sources and amounts of funding for the effort, and the types of positive health outcomes anticipated if the strategies are effectively implemented. During implementation, the lead agency and highly committed volunteers from the community assure that the committees and their planned activities are monitored and maintained. The partnership uses professional evaluators to assess whether the desired outcomes result.

The example serves to illustrate a complex community intervention. It is characterized by active participation of multiple community sectors and constituencies. An advantage in working with such a pluralistic group is that members bring different talents and resources into play, thus facilitating the implementation of health promotion strategies that are applied simultaneously to influence individual youth, their family, the surrounding neighborhoods, the organizations that serve them, and local policy that influences community life. The use of multiple strategies that are directed at the "social fabric" of communities derives from a social ecological perspective.

THE SOCIAL ECOLOGY PERSPECTIVE FOR COMMUNITY INTERVENTION

The approach to community intervention discussed here is influenced by ecological and systems theories as well as by epidemiology. Disciplines concerned with the overall health of communities, such as community psychology and public health, are experiencing a shift in emphasis from social psychology to social ecology (Trickett, 1987, 1996). The traditional approach to community health development is grounded largely in social psychology where successes often are calibrated as changes in the risk producing behaviors of individuals (Hawkins & Catalano, 1992; McLeroy, Bibeau, Steckler, & Glanz, 1988; Steckler et al., 1995) or in the context of stages of change (DiClemente & Prochaska, 1985; Prochaska & DiClemente, 1983, 1984; Prochaska, Velicer, DiClemente, Guadagnoli, & Rossi, 1990). The "Just Say No" campaign championed by Nancy Reagan in the 1980s is one example of such a strategy. In contrast, the example in Fig.

36.1 focuses on community factors such as peer pressure, family home life, availability of unhealthy substances, and advertising that often make just saying no quite difficult.

Another prominent example in the 1970s and 1980s derives from several large scale community studies funded by the National Institutes of Health that extended from social psychology models. These included the Stanford Five-Community Project, the Minnesota Heart Health Project, and the Pawtucket Heart Health Project (Carleton, Lasater, Assaf, Feldman & McKinlay, 1995; Farquhar et al., 1983, 1990; Luepker et al., 1994). These projects used a combination of strategies directed at different segments of communities (often referred to as channels). The project evaluations were directed largely at behaviorally based outcomes such as weight reduction, modification of food buying habits and other diet-related risk behaviors, reduction in blood pressure, cholesterol, pulse rate, smoking, and coronary heart disease and mortality risk (Mittelmark, Hunt, Heath, & Schmid, 1993). Although reductions in risk-associated behaviors are essential outcomes of community interventions, these individual changes are influenced by, and often depend on, larger level social changes, or alterations in the social ecology of communities (Stokols, 1992; Winett, 1995).

From an ecological perspective, the potential to change individual risk behavior is considered within the social and cultural context in which it occurs. Interventions that are informed by this perspective are directed largely at social factors, such as community norms and the structure of community services, including their comprehensiveness, coordination, and linkages, in addition to individual motivations and attitudes. As others noted (Thompson & Kinne, 1990):

The increasing focus on "community" in health promotion is due, at least in part, to growing recognition that behavior is greatly influenced by the environment in which people live. Proponents of community approaches to behavioral change recognize that local values, norms, and behavior patterns have a significant effect on shaping an individual's attitudes and behaviors. (p. 45)

In the Fig. 36.1 example, the use of key community influentials on committees, such as school principals, police chiefs, juvenile court justices, and editors of papers is directed at influencing local norms and consequently behavior. For instance, involving juvenile justices in the coalitions may influence the approaches to sentencing youth drug offenders to assure family involvement, mandatory drug counseling, and school attendance.

Ecological and systems theories view behavior as a function of the surrounding context. Articulation of an ecological approach has been provided by others writing in diverse disciplines (Binder et al., 1975; Bronfenbrenner, 1977; Kelly, 1966, 1968, 1988; McLeroy et al., 1988; Mills & Kelly, 1972; Moos, 1979; Rappaport, 1977; Revenson, 1990; Stokols, 1992, 1996; Trickett, Kelly, & Todd, 1972; Vincent & Trickett, 1983). At its most basic level, ecological theory posits that individuals and settings are mutually influential, this influence occurs in subsystems at multiple levels of analysis, and influence changes over

time and settings. Central to this chapter are the implications of taking a social ecological perspective in the design and implementation of health promotion interventions. Thus, an interventionist committed to the ecological model would not typically take a reductionism approach. Rather, they would search for, as in the case of the ATOD partnership, points of leverage at multiple levels of analysis in the sociocultural context relevant to the topic at hand, and would use multiple approaches to achieving change.

Rapaport (1977) wrote an eloquent statement on the implications for interventionists adopting an ecological model:

Interventions should be based on an understanding of local conditions and on a longitudinal assessment of the organization in the community; they should focus on anticipating effects of the intervention on all the members of a setting and use a wide variety of strategies and tactics for creating change. ... Accountability requires this orientation which focuses on a local situation and is concerned with its future side effects rather than short-term data analysis. ... Given the opportunity to develop and use its own resources a community will adapt to its environment, and often the job of community development will require interventionists to assist in the location and development of such resources. (p. 156)

From a social ecology perspective, individual change is understood within the social and cultural context in which it is to occur; the interventions that are suggested as efficacious, therefore, are more often directed at the social fabric rather than at individual motivations and attitudes. Mittelmark and colleagues (1993), for instance, suggested that the most effective NHLBI projects targeted a higher level of analysis: contests in work settings for producing weight reduction; church-based programs to reduce diet-related risk behaviors; school-based programs directed at smoking control, body fatness and food preferences; media programs that influence risk-related behaviors. Other evidence suggests that for comprehensive community strategies to be maximally effecting in reducing risk, sufficient resources are essential, especially the time allotted for interventions, the number of staff, and the level of staff expertise (Goodman, Steckler, Hoover, & Schwartz, 1993; Goodman, Wheeler, & Lee, 1995).

There are four overarching principles that best characterize an ecological systems approach, and each is described briefly here. The ecological purist may well object to the broad categories of the ecological paradigm used here. The discussion resorts to "lumping," rather than "splitting," in order to simplify the connection between the core components of an ecological approach and principles of health promotion strategy.

ECOLOGICAL PRINCIPLE 1: MULTIPLE LEVELS, COMPLEXITY, NEGATIVE ENTROPY

Multiple levels of analysis are perhaps the single most identifiable feature of an ecological approach. Levels have been defined differently by people, but in essence they relate to

personal, interpersonal, organizational, and societal dimensions (see Fig. 36.1). An ecological model also assumes that these different levels relate to each other in a complex and embedded array of relations. Negative entropy is a concept taken from systems theory and thermodynamics and refers to the idea that systems have a tendency to strive for energy and complexity and away from simplicity. Certainly, community partnerships illustrate this complexity. As previously noted, the development of a community plan requires coordination across multisectorial committees. The plan strategies require integration of complementary approaches—for instance, school-based drug prevention education may be linked to policies restricting teachers and other school employees from smoking on school grounds; these strategies may be linked to the vigilant enforcement policies restricting the placement of vending machines selling tobacco that youth may access, or store sales of liquor to minors. Such strategies are not only complex, but also require a degree of energy and commitment that exceeds a "Just Say No" strategy.

ECOLOGICAL PRINCIPLE 2: INTERDEPENDENCE, HOLISM, CONTEXT

The combined strategies noted in the previous paragraph suggest holism as a second ecological principle. *Holism* refers to the idea that phenomena are more than the sum of their parts. Intervening on one part of a multilevel system, for example, will both affect other parts of the system and the system as a whole. Thus, the properties of interdependence and reciprocity suggest that to intervene on one aspect of a system, it is advisable to evaluate how other components in the system, and the system as a whole, might change as a result. Drawing attention to the context in which intervention occurs and the interrelations between levels within context, is one of the most important contributions that an ecological orientation makes to health promotion intervention. The CSAP partnership committees are one illustration of the interrelationship among levels. Effective committee operations were crucial to the organization of the partnership, because the committees conducted community needs assessments, formulated community plans, and spearheaded plan implementation. The success of the partnership was predicated on building a strong organizational infrastructure through a committee system. The formation of the infrastructure depended on good working relationships among committee members and staff. Thus, reinforcing good interpersonal interactions among committee members assured positive group functioning and increased the likelihood that the committees produced and implemented a workable community plan.

ECOLOGICAL PRINCIPLE 3: DYNAMIC EQUILIBRIUM, CYCLING OF RESOURCES

The principle of resource cycling orients the interventionist to the fact that systems are rich in resources that change over time. These resources are available to be marshaled by interventionists for the benefit of the people and environments in a

setting. Dynamic equilibrium refers to systems and relations within systems being in motion, energetic, changing, and productive. In contrast to a static view of a context, a dynamic view focuses on the acquisition and utilization of resources by system components. The partnership approach demonstrates both dynamic equilibrium and cycling of resources that are in evidence when the partnership makes an effective transition across the stages of formation, implementation, maintenance, and outcomes (see Fig. 36.1). Each stage requires a different configuration of resources (e.g., implementation requires expertise in needs assessment and community interventions, or programmatic resources; maintenance requires ongoing commitments to funding and staffing, or political influence with funding organizations).

ECOLOGICAL PRINCIPLE 4: ADAPTATION, EQUIFINALITY, SUCCESSION

Underlying adaptation are the concepts of change and coping. Thus, adaptation refers to the components in systems, and the systems themselves, being in a constant stage of influence, flux, accommodation, and change. Equifinality is a concept taken from systems theory and refers to the idea that there are many paths to a final state. Succession refers to the notion that over time, forms of life change in a regular sequence. In addition, an ecological approach is oriented toward studying naturally occurring phenomena and contributing to improving or maintaining the functioning of biopsychosocial systems.

Ecological theory is guided by the principle that the whole is more than the sum of its parts and thus behavior and environment are viewed as interdependent rather than independent (Wicker, 1979). Furthermore, an ecological perspective considers different levels of analysis like the layers of an onion, each system nested within another with each system constrained both by the system it surrounds and the system that surrounds it (Wicker, 1979). Few studies of health behavior specify the sequence or causal linkages by which individuals influence, and are influenced by, the larger social context (D. G. Altman, 1986; Winett et al., 1989).

The ultimate goal of most health interventions, regardless of the level of analysis, is to improve the health status of individuals as individuals, not systems or environments, experience illness and health. In the case of a community intervention to reduce tobacco use, for example, the focus of macrolevel interventions (e.g., increasing the tax on cigarettes) may also influence the actions that individuals take (e.g., not purchasing cigarettes). Similarly, a goal of many microlevel interventions (e.g., teaching worksite employees how to quit smoking) may influence actions taken at higher levels of analysis (e.g., implementation of a worksite smoking policy). There are interactional and synergistic connections among levels of analysis. The means by which individuals are reached and influenced, however, can vary as a function of the level at which one intervenes. In more cases than not, there is a reciprocity of influence between levels of analysis (Winett et al., 1989). Furthermore, Green (1986) noted that individuals and systems are not "mutually exclusive or opposite ends of a political or theoretical continuum" (p. 29). Focusing on one level has concomi-

tant costs and benefits. Curtailing and eventually eliminating smoking in the workplace may require changes in organizational policies that are mutually agreeable to management and labor, implementation of coworker support programs, and availability of cessation programs for individuals attempting to quit smoking.

OTHER THEORETICAL PERSPECTIVES ON COMMUNITY INTERVENTION

Although the use of ecological theory in community intervention has been advocated, the reality is that a variety of other theoretical and conceptual perspectives have guided many community intervention campaigns conducted to date (McAlister, 1991). These include the health belief model (Rosenstock, 1974), communication-persuasion model (McGuire, 1981), diffusion theory (E. M. Rogers, 1983), social cognitive theory (Bandura, 1986, 1997), the theory of reasoned action (Ajzen & Fishbein, 1980), and community development (Bracht et al., 1994; Bracht & Kingsbury, 1990; Bracht & Tsouros, 1990; Lefebvre, Lasater, Carleton, & Peterson, 1987).

The Stanford Three Community (TCS) and the Five City Projects (FCP), for example, used hybrids of these theoretical perspectives (Farquhar et al., 1983, 1990; Maccoby & D. G. Altman, 1988) as did many other large interventions (Puska, 1984; Shea & Basch, 1990) (Lefebvre et al., 1987). There have been several useful reviews (Bloom, 1996; Shea & Basch, 1990) of the theoretical perspectives underlying community intervention and primary prevention and thus this topic is only summarized here.

Social Cognitive Theory

Social cognitive theory has been a key approach guiding the development of many community health promotion interventions (Farquhar et al., 1983; Flora & Cassidy, 1990; Winett et al., 1989). There is a substantial empirical database of research on social cognitive theory (Bandura, 1986, 1997) and it is utilized in whole or part by many researchers and practitioners involved in community intervention work. Key variables in social cognitive theory include self-efficacy, outcome expectancies, and perceived incentive value. Self-efficacy refers to people's belief about how capable they are to perform a specific behavior (Bandura, 1986, 1997). Self-efficacy has been identified as one of the cornerstones of a person's willingness to participate in community change (Zimmerman & Rappaport, 1988). Self-efficacy plays a role in promoting the induction, generalization, and maintenance of a new behavior. Outcome expectancy refers to a person's belief that a behavior will result in a specific outcome (Bandura, 1986, 1997). It is unlikely that a person will expend time and effort to bring about a change if it is perceived that the change will not have the intended effect. Perceived incentive value refers to the relative importance placed on a possible outcome (Bandura, 1986, 1997). In general, people are more likely to engage in a behavior if they consider the behavior to be important (i.e., valuable).

Social Marketing

Social marketing has grown in popularity in recent years (Kotler & Roberto, 1989; Novelli, 1990) and now is incorporated at some level in most community health promotion programs. In addition, the substantial track record of the field of marketing, from which social marketing draws heavily, provides further justification for its inclusion. Social marketing approaches are utilized widely in health promotion and these approaches are built on the large knowledge base of more general business marketing. Social marketing is the extension of marketing principles to social and health issues (Kotler & Roberto, 1989; Novelli, 1990; Wallack, Dorfman, Jernigan, & Themba, 1993). Kotler and Roberto defined it as "a social-change management technology involving the design, implementation, and control of programs aimed at increasing the acceptability of a social idea or practice" (p. 24). The marketing context—comprised of product, price, promotion, position, and place—forms the overarching organizing structure for a marketing approach. The adoption of a social marketing approach requires the interventionist to study and attend carefully to the context (marketplace) and the needs of the target population (consumer) so that tailored interventions are designed and delivered. Social marketing is based on two general assumptions: (a) Programs/messages should be designed on the basis of the perceived needs and expectation of consumers, and (b) successful programs are those that achieve a successful exchange between message sender and receiver (Kotler & Roberto, 1989; Novelli, 1990).

Community Development

Community development (or community organization) refers to the study of or intervention around the natural organization of persons and institutions in community systems. A key goal of community development is the stimulation and coalescing of community resources and expertise (Bracht & Kingsbury, 1990). Bracht and Kingsbury defined community organization as "a planned process to activate a community to use its own social structures and any available resources (internal or external) to accomplish community goals, decided primarily by community representatives and consistent with local values" (p. 67). Comprehensive planning and community diagnosis/analysis, a key dimension of many public health intervention models, is a prerequisite to successful community intervention (Farquhar et al., 1990; Haglund & Tillgren, 1988; Winett, 1995; Winett et al., 1989). There are three critical dimensions at the core of successful community development: multisectoral inclusion, organizational linkages, and enabling and support.

Multisectoral inclusion refers to the involvement and subsequent active participation of diverse community members and organizational constituencies in planning, implementing, and evaluating community health programs (Chavis & Newbrough, 1986; Chavis & Wandersman, 1990; Wandersman, Chavis, & Stucky, 1983). There is a substantial literature documenting the importance of inclusion and participation in determining a program's success and long-term

viability (Bracht & Tsouros, 1990; Goodman, Burdine, Meehan, & McLeroy, 1993). Coalitions have become popular vehicles for enhancing community inclusion and participation. More empirical research needs to be conducted on inclusion strategies and tactics. In particular, it is important to understand better how coalitions operate, how they maintain their viability, how best to utilize local human and material resources, and the processes through which they improve the impact of community interventions.

The Pawtucket Heart Health Program (PHHP) was guided by community development underpinnings through its emphasis on recruiting and developing a strong lay leadership program and associated community networks at both individual and organizational levels (Carleton et al., 1995; Lefebvre et al., 1987; Lefebvre, Lasater, Assaf, & Carleton, 1988). This network consists of recipients of intervention as well as agents of communication about CVD prevention. PHHP was also guided by aspects of social cognitive theory in that attention was directed at increasing self-efficacy of individuals (see earlier discussion) and collective efficacy (i.e., group beliefs that networks or organizational can lower CVD risk status in the community; Lefebvre et al., 1988).

Organizational linkages refer to communication, coordination, and collaboration among multiple community sectors. Community groups that promote open and honest communication, have formal and informal mechanisms for exchanging information regularly, and agree on a common purpose have the essential building blocks for mounting a successful community health program. Coordination refers to interorganizational planning, objective setting, and health services delivery. By definition, comprehensive community health programs require diverse community organizations and constituencies to coordinate efforts. Significant barriers to coordination include territoriality, competition, ineffective communication, and lack of resources. Collaboration is the most complex function faced by community groups because it requires multiple constituencies to work for jointly determined goals and objectives.

A community's ability to determine its own "health" is the core principle underlying enabling and support. An *enabling approach* will change the typical hierarchical relationship between researchers (giving direction) and community groups (taking direction). A theoretical perspective that overlaps with enabling and support function of community development is empowerment and thus this is reviewed next.

Empowerment

There is a small but growing literature on empowerment, as is evidenced by publication of an entire issue of the *American Journal of Community Psychology* on this subject in 1992. The empowerment literature examines the processes and effects of individual, organizational, and community empowerment, with *empowerment* defined as efforts at these multiple levels of analysis to exert control and gain mastery over salient issues. Empowerment can also be defined by the absence or low levels of normlessness, powerlessness, social isolation, and helplessness (Chapman, 1994; Wallerstein, 1992;

Zimmerman, 1990b; Zimmerman, Israel, Schulz & Checkoway, 1992). Wallerstein (1992) considered empowerment as “a social action process that promotes participation of people, organizations, and communities towards the goals of increased individual and community control, political efficacy, improved quality of community life, and social justice” (p. 198). Participation, control, and critical awareness are essential aspects of empowerment. At the individual level of analysis, these factors include a belief in people’s ability to exert control, their involvement in decision making, and their understanding of causal agents. At the organizational level of analysis these factors refer to settings that provide individuals with opportunities to exert control and to organizational effectiveness in service delivery and the policy process. At the community level of analysis, these factors refer to the contexts in which organizations and individuals interact to enhance community living and to insure that their communities address local needs and concerns.

According to Zimmerman (in press), “Empowerment theory connects individual well-being with the larger social and political environment, and suggests that people need opportunities to become active in community decision-making in order to improve their sense of empowerment” (p. 31). Empowering communities provide opportunities for individuals and groups in the community to exert control and influence (i.e., shape the community agenda, participate in community decision making, have access to community resources). Empowered communities can be characterized as providing community members with opportunities to participate actively in the community by addressing community problems and utilizing community resources.

There are several key concepts underlying empowerment theory: environmental awareness, control, participation, and community connectedness. Environmental awareness includes understanding the factors that impede or facilitate goal attainment, as well as strategies to overcome barriers through resource utilization. It also includes an understanding of the causal agents underlying a problem or issue (Zimmerman, 1990a; Zimmerman et al., 1992). Perceived and real control is perhaps the core construct underlying empowerment. The importance of encouraging broad participation has generated consensus in health promotion networks (Green, 1986). Green (1986) pointed out that “the principle holds that the practice of health education depends for its success on involving people in defining their own needs, setting their own priorities, controlling their own solutions, and evaluating their own progress” (pp. 211–212). Perspectives complementary to empowerment (i.e., those that focus on power, choice, self-determination, control over destiny) are found in theories or constructs such as powerlessness, learned helplessness, competent community, health locus of control, and self-efficacy (Bandura, 1986; Iscoe, 1974; Seligman, 1975; Zimmerman, 1990b).

There are four general categories of empowering competencies in community interventions: diagnosing, organizing, issue framing, and taking action (hereafter referred to as the “Just DO IT” framework): *Diagnosing* is the ability to understand the root causes of a problem or issue at multiple levels of

analysis and to identify the barriers to and facilitators of alternative solutions. This competency requires a commitment to diligent investigation, reconnaissance, and detailed issue analysis. *Organizing* is the ability to work with various community constituencies on an issue of mutual interest, to resolve interpersonal conflicts, work as part of a team, and put the agenda of the group ahead of any personal agenda. *Issue framing* presents an issue in such a way that it generates interest, concern, and desire to take action among targeted constituencies. *Taking action* is the ability to determine which action(s) are appropriate to the issue and situation at hand (i.e., the costs and benefits) and the skill in implementing the action(s) effectively.

Mass Media

It is unlikely that a large scale community intervention can be successful without mass media involvement (Flora & Cassidy, 1990; Green & McAlister, 1984). Although the media can affect awareness, interest (or motivation), trial attempts (or experimentation), and adoption of behavior (Green & McAlister, 1984), there is strong evidence that media approaches alone are more likely to influence cognitive factors such as awareness and motivation than health-related behavior. The media are important in setting the public agenda about health issues (i.e., what people think about, how issues are framed). Thus, the media can create and reinforce public awareness about an issue, contribute to its salience, serve as a cue to action, and reinforce action that is taken. Media campaigns have the advantage that they can effectively reach opinion leaders. In turn, opinion leaders who adopt innovations into their own lives can promote broader adoption among others whom they influence through modeling and persuasion.

Effective media campaigns have used multiple and diverse channels and formats (Farquhar et al., 1990; Flora & Farquhar, 1988). For television, this includes free speech messages, public service announcements, paid advertisements, editorials, news stories, news series, public affairs programs, talk shows, magazine programs, live remote broadcasts, specials produced by a station, acquisitions aired by a station, and community calendars. For newspaper, this includes paid advertisements, letters to the editor, editorials, guest opinions, spot news coverage, multipart news coverage, feature stories (in news, business, sports, lifestyle, feature columns), and community calendars. For radio, this includes live copy public service announcements, preproduced public service announcements, paid editorials, news stories, news series, talk shows, call-in tips, live remote broadcasts, and community calendars. Less utilized channels are also important. These include the internet, cable television, neighborhood newspapers, organizational newsletters, trade magazines, videos in medical offices and other settings, films at community events, direct mail, billboards, grocery bag advertising, monthly bill inserts, paycheck inserts, placemats, telephone book advertisements, bumper stickers, public transit advertisements, and sponsorship of community events. Soliciting cosponsorship and funding of interventions from

local community organizations is a media strategy that utilizes principles of community development.

The Stanford Five City Project (FCP), and its predecessor, the Three Community Study (TCS), are widely recognized as models for the effective use of media in community intervention (Farquhar et al., 1983, 1990; Flora & Farquhar, 1988; Maccoby & D. G. Altman, 1988), although the Stanford studies also were heavily influenced by community development, diffusion of innovations, and social cognitive theories. The Stanford projects employed media professionals, both academic and frontline, to shape the message content and channels through which to best reach the community. A social marketing perspective (Kotler & Roberto, 1989; Novelli, 1990) guided their efforts. A diverse array of heart healthy messages were delivered continuously through mass media, social networks (e.g., physicians, teachers, parks and recreation staff), lifepath points (e.g., grocery stores, restaurants, banks, libraries), worksites, schools, and households (Flora & Farquhar, 1988).

INTERVENTION STRATEGIES

An often asked question is, "What approaches to community intervention work?" Whereas on the surface, this is a legitimate question, it may be the wrong question. Thus, before this chapter attempts to answer this question, an important caveat should be stated. As others have noted, it may be more instructive to analyze how interventions work (in what settings, at what times, and with whom) than to address whether an intervention does or does not work (D. G. Altman, 1986; Hornik, 1980). Because interventions "work" differently in different contexts, knowing whether an intervention worked in one place is of marginal value. Instead, addressing the mechanisms underlying the outcomes achieved is the most important information to obtain. This perspective is consistent with the ecological roots reviewed previously.

That said, some conclusions are offered from the literature. First, the best individual-level interventions are not very effective. A cynical, if not honest, response to the question about what works is, "not enough." A cursory evaluation of published studies on the efficacy of interventions as diverse as tobacco use, body weight, nutrition, practice of unsafe sexual behaviors, injury-prone behavior, use of sunscreen, medication-taking, environmental protection, and so on, leads to the conclusion that not enough is known about preventing disease and promoting health. Indeed, the best interventions achieve changes in a small proportion of the target population, many of whom were motivated to make a change in the first place. Furthermore, many changes achieved in the short term are not sustained over the medium and long term. Because there is publication bias favoring interventions with positive effects, it can be assumed that taken together, the true effectiveness of all interventions in a particular health area is lower than published studies.

With that as a backdrop, it is suggested that community interventions with the following characteristics are likely to achieve desired changes more times than not:

Utilize data-based planning and feedback systems (epidemiological, public opinion, strategic) as the driving force behind the development and refinement of interventions.

Involve the target population in some aspects of intervention planning, implementation, and evaluation.

Develop clearly articulated, highly focused, agreed-on goals and objectives and stick to them, all the while maintaining flexibility at the tactical (programmatic) level.

Emphasize passive prevention approaches whenever possible so that people are protected automatically rather than having to engage in an active behavior.

Change the social norms around which individual behavior occurs.

Target the root causes of problems, especially those at the sociocultural environment.

Consider community intervention strategies that take into account the resources available (i.e., ends being adjusted to the means). Taking on too much given the available resources, a tradition for health educators, is a recipe for failure.

Consider the timing and location of intervention in design and implementation.

As noted by Green and McAlister, large scale intervention, compared to targeted intervention, typically requires more planning and coordination and attention to the diffusion of innovations (Green & McAlister, 1984). Both types of intervention, however, are enhanced by the active participation of individuals and organizations affected by the issue addressed (Green & McAlister, 1984). A predominant theme in community intervention is the need for comprehensive intervention at multiple levels in the community (Cheadle et al., 1993; Elder et al., 1993; Mittelmark et al., 1993; Stokols, 1992, 1996). More recently, this discussion has expanded to include policy approaches to intervention, both within the community and from outside the community.

LEVEL OF INTERVENTION

Health problems or issues can be defined in numerous ways and the way an issue is defined has a direct bearing on the type of intervention (Winett, 1995; Winett et al., 1989). In the case of dietary behavior, for example, the problem of people eating a diet too high in fat can be attributed to the behavior of individuals who eat too much fat, to restaurants or food producers who do not provide healthy options for consumers, to advertisers who mislead consumers about the healthfulness of their products, and to agricultural or economic policy that affects the profitability of growing or manufacturing certain foods. In theory, a community intervention to reduce dietary fat intake would ideally approach the problem comprehensively by targeting the multiple influences on dietary behavior. Similarly, the causes of gun violence can be considered from multiple

perspectives. Ownership of firearms can be framed as a constitutional right of self-protection or as the primary cause of a public health epidemic. The well-known sound bite, "guns don't kill people, people kill people," illustrates how the definition of an issue can influence subsequent interventions. Available interventions for reducing gun violence include passage of laws requiring a waiting period for gun ownership and/or the possession of a gun permit, gun owner education programs, laws limiting the type of guns and ammunition allowed to be purchased, grassroots action (e.g., "take back our streets" marches) to convey community norms, and family education to encourage safe use and storage of weapons.

Green asserted that the community level of analysis should be the "center of gravity" for health promotion (Green & Kreuter, 1990):

Governments can formulate policies, provide leadership, allocate funding, and generate data for health promotion. ... Individuals can govern their own behavior and control the determinants of their own health up to a point. ... But the decisions on priorities and strategies for social change affecting the more complicated lifestyle issues can best be made collectively as close to the homes and workplaces of those affected as possible. (p. 322)

Although, in practice, health promotion is implemented through multiple levels (from the individual through policy), the community level is key to building a comprehensive strategy to promote health and prevent disease among the population at-large.

In simple terms, then, a community approach can be distinguished from a clinical or individual approach by the outlook taken to disease etiology and prevention (Rose, 1992). For example, community health psychologists, reflecting on heart disease in their community, might ask, "Why do so many people in my community have premature heart attacks?" In contrast, clinical psychologists practicing in the community might ask, "Why did this patient have a heart attack?" As Rose noted, these two perspectives, although complementary from the larger perspective of heart disease prevention and treatment, actually focus on different aspects of disease etiology and prevention. The public health, or community, approach is concerned primarily with incidence rates (i.e., new cases of a disease or health condition) and prevalence rates (i.e., total number of cases of a disease or health condition) and in methods to change the behavior and environments that contribute to disease incidence and prevalence. The clinical approach is concerned primarily with disease etiology among individuals and targeted methods to reduce risk or treat disease among these individuals. According to Rose (1992), "The individual strategy is a rescue operation for individuals in need, whereas the population strategy is a radical attempt to deal with the underlying causes" (p. 312). Thus, the importance of community intervention is often based on the assumption that greater improvement in health can be obtained by small changes in the behaviors (or environments) of large numbers of people than by large changes among a small number of people at high risk (Altman, 1995a).

The Policy Level Approach to Intervention

The implementation of policy is a key area where intervention strategies can have a dramatic effect on community health. In the 1990s, there has been increased attention to the linking community intervention with health policy (E. R. Brown, 1991; Brownson, Koffman, Novotny, Hughes, & Eriksen, 1995; Glanz et al., 1995; King et al., 1995; Schmid, Pratt, & Howze, 1995; Schwartz, Goodman, & Steckler, 1995; Steckler, Dawson, Goodman, & Epstein, 1987). In fact, scholars in health education rarely wrote about policy approaches until the late 1970s and early 1980s (Mico, 1978; Milio, 1981; Steckler & Dawson, 1982; Steckler et al., 1987) and there is even less attention to this topic in the health psychology literature. Historically, many of the advances in public health had at the roots policy change (Schmid et al., 1995). Notable successes include policies around food preparation, sanitation, waste disposal, refrigeration, sewage treatment, and water purification (Rosen, 1993). In health psychology, policy approaches have not been central to the field, although a small, but increasing, number of psychologists are encouraging the field to expand along these lines (Ewart, 1991; Leviton, 1996; Winett, 1995; Winett et al., 1989).

Policies can be oriented to active prevention (i.e., policies that require individuals to take action in order to be protected) or passive prevention (i.e., policies that protect individuals without the individual engaging in a health protective behavior). In the case of interventions to reduce motor vehicle fatalities, for example, active strategies might include driver education around safe driving habits or seatbelt education programs. Passive strategies—including engineering roads to be safer (e.g., quality of surfacing, signs, curves, etc.), providing airbags in all automobiles, installing automatic seatbelt restraints, enforcing DWI laws through roadside checks and increased police funding, and designing cars better able to withstand impact—contributed to the 50% reduction per mile driven over the last 25 years (Schmid et al., 1995).

From the perspective of dietary behavior to prevent CVD, the tradition of intervention is to persuade individuals to change their eating habits. Indeed, at first glance, eating is the epitome of individual behavior. Although interventions directed at individual behavior are certainly worthwhile, Glanz and colleagues (1995) articulated a series of policy interventions that would complement an individual focus. Nutrition-related policy interventions might include regulations requiring labeling of food products and point-of-purchase advertising to facilitate informed consumer choice, expanding the accessibility of healthy food products to make it easier for individuals interested in purchasing healthy food products to readily obtain these products, requiring that institutional providers of food (e.g., schools, nursing homes, hospitals) make healthy food items accessible, educational policies that ensure that health professionals (particularly physicians and nurses) have adequate training in nutrition, and policies that provide monetary incentives for food producers and consumers to purchase healthy food choices (e.g., through taxation, price supports, coupons, tax incentives).

Along similar lines, King and colleagues (1995) presented a range of policy and environmental intervention options to promote physical activity, a behavior with strong relations to a variety of acute and chronic mental and physical health conditions. These included restricting downtown city districts to foot or bicycle traffic only, zoning parking lots to facilitate both convenience and physical activity, designing buildings that make stairs safe and readily accessible for routine use, and building communities that allow for walking and biking between residential, school, and commercial areas. There also are legislative and regulatory mechanisms to promote physical activity (King et al., 1995), including: reduce liability costs for physical activity centers through better certification, equipment/facilities, and training; develop zoning regulations that protect open spaces and areas for exercise (e.g., bike or walking paths, greenways, par courses), provide tax incentives for nonmechanized consumer products or recreational products that require physical activity; establish incentive systems for walk/bike-to-work/shop programs; require enhanced physical education curriculum in schools; and encourage workplaces to facilitate opportunities for physical activity through flex time, on-site facilities, or discounts with off-site facilities.

Public opinion surveys find broad-based support for public policies to promote health and prevent disease (Jeffery et al., 1990). Some people, however, make the mistake that such data and health policy are highly associated. Indeed, advocacy is often more important than the "facts" in garnering support for and ultimately influencing health policy (D. G. Altman, Balcazar, Fawcett, Seekins, & Young, 1994; Chapman, 1994; Wallack et al., 1993). Data are usually necessary for health policy change, but they are not usually sufficient. Furthermore, the person(s) who disseminates the data is often as important as the data.

Thus, community interventions are popular because they have the potential to improve health above and beyond what can be achieved by individual approaches alone. Indeed, part of the rationale underlying the efficacy of community intervention is the belief that changing the community at-large is a more cost-effective means to achieving societal health goals than reaching individuals one person at a time. Also, community interventions have the potential advantage of delivering beneficial programs both to those who explicitly desire assistance as well as to those who could benefit from intervention but who do not know if they could benefit or who do not have access through more traditional service delivery mechanisms.

RESULTS OF KEY COMMUNITY INTERVENTION TRIALS

Community interventions have been employed in a variety of substantive areas, although those targeting cardiovascular disease prevention and substance abuse have been widely recognized as model programs (Cardiovascular Disease Plan Steering Committee, 1994; Elder et al., 1993; Farquhar et al., 1990; Haglund & Tillgren, 1988; Maccoby & D. G. Altman, 1988; Puska et al., 1985; Shea & Basch, 1990). Wagennar, Murray, Wolfson, Forster, and Finnegan (1994) tested a com-

munity activation model to reduce underage drinking, a problem that is so widespread that 64% of high school seniors report alcohol consumption within the last 30 days (L. D. Johnston, O'Malley, & Bachman, 1991). T. Rogers, Feighery, Tenacati, Butler, and Weiner (1995) described community mobilization and media strategies in California to counteract the influence of \$6.03 billion tobacco companies spent nationally on product marketing.

The emphasis on cardiovascular disease (CVD) is in part due to the fact that CVD is the leading cause of death in the United States, causing over 720,000 deaths in 1990 and that many risk factors are behavioral in origin (McGinnis, 1994). Many risk factors for heart disease (e.g., tobacco, nutrition, obesity, physical activity, hypertension) are associated with the second and third causes of death, cancer (over 550,000 deaths each year) and cerebrovascular diseases (over 144,000 deaths). Other preventable causes of death among the top 10 include unintentional injuries (over 92,000 deaths), chronic lung disease (over 86,000 deaths), diabetes (over 47,000 deaths), and AIDS (over 25,000 deaths; McGinnis, 1994). On the cost side, the proportion of the Gross National Product spent on health care has increased from 6% in 1960 to over 14% today. Some of costs are associated with preventable, premature disease. For example, a typical coronary artery bypass graft costs over \$30,000 and typical treatment for lung cancer costs about \$29,000 (Department of Health and Human Services, 1991). Thus, to improve the health of the population, individuals must be encouraged to practice healthier behaviors, design environments that facilitate the practice of these behaviors, and pass/enforce public policies that reinforce healthy choices. Community interventions represent a key approach to achieving these goals.

Results from large community intervention trials to promote health and prevent disease have been mixed (Susser, 1995). In light of earlier comments about the importance of understanding the contextual underpinnings of how programs work, however, these trials have generated important data that will be instrumental in helping guide future community interventions. In addition, the fact that policy approaches to health promotion are relatively new tools in the armamentarium of interventions, the large community intervention trials described here did not generally employ policy as primary intervention strategies and tactics. If these programs were begun in the current era of health promotion/disease prevention, it is likely that policy intervention would take central stage (Brownson et al., 1995; Glanz et al., 1995; King et al., 1995; Schwartz et al., 1995; Speers & Schmid, 1995). A few key community intervention trials are reviewed later.

The Community Trial for Smoking Cessation (COMMIT), a 4-year study in 22 communities in the United States and Canada (11 treatment communities, 11 comparison communities), found small, but significant, treatment effects in cohort analyses for light-to-moderate smokers but no treatment effects for heavy smokers (the COMMIT Research Group, 1995a, 1995b; Fisher, 1995). No treatment effects were found in cross-sectional analyses on overall smoking prevalence (The COMMIT Research Group, 1995b). Although the effects among light-to-moderate in the cohort analysis were

small from a clinical cessation perspective (quit rates were .306 in treatment and .275 in comparison communities), taken across the 11 treatment communities, the results had public health significance: Three thousand more smokers in treatment communities compared to comparison communities quit smoking.

Similarly, results on adult cigarette smoking in the six community Minnesota Heart Health Program (MHHP) found short-term effects favoring treatment communities but long-term effects were limited to women in the cross-sectional (vs. longitudinal) sample (Lando et al., 1995). Although MHHP interventions were comprehensive (e.g., cessation contests, classes, self-help materials, telephone counseling, home correspondence courses), little attention was given to policy or environmental tobacco interventions.

Another large CVD community-based risk reduction study, the Pawtucket Heart Health Program (PHHP), was evaluated in two communities over a 8.5-year period (Carleton et al., 1995). The effects found were similar to those found in the MHHP already described. That is, with the exception of inconsistent treatment effects for body mass index and overall CVD risk, there were no effects attributable to the intervention (Carleton et al., 1995).

In contrast, CVD risk factor findings from the Stanford Five-City Project (FCP) and in its predecessor, the Stanford Three Community Study, generally reveal treatment effects favoring treatment (Farquhar et al., 1983, 1990; Maccoby & D. G. Altman, 1988; Meyer, Nash, McAlister, Maccoby, & Farquhar, 1980). The treatment was multifaceted, including mass media, extensive community organization, health professional delivered services, school- and worksite-based intervention, and environmental supports. Over a 5-year period of intervention in the FCP, analyses revealed effects favoring treatment communities for CVD knowledge, smoking, and blood pressure, with smaller changes in pulse rate and cholesterol level (Farquhar et al., 1990). All-cause mortality risk reduction also favored treatment communities at the majority of timepoints for both longitudinal and cross-sectional analyses. Excluding research costs, Farquhar et al. estimated that it cost about \$4 per capita to deliver the intervention each year.

Likewise, 10-year findings from the North Karelia Project in Finland found that CHD mortality reductions were 22% in the treatment community, 12% in the comparison community, and 11% in Finland as a whole (excluding the treatment community; Puska, Nissinen, Salonen, & Toumilehto, 1983; Puska et al., 1985). In contrast, CVD risk factor findings from the MHHP were not as promising (Luepker et al., 1994). In essence, although MHHP treatment communities showed declines in relevant risk factors, these declines were just as evident in comparison communities (i.e., the intervention did no better than the secular trend). Because there is evidence that the specific interventions employed in the MHHP were effective, the investigators concluded that failure to find treatment effects was probably due to inadequate penetration in the community such that the proportion of the population exposed to intervention was sufficient to exceed the secular trend (Luepker et al., 1994). Luepker et al. concluded, "What we now recognize is that it is far easier to change the risk pro-

files of the people who participate in those programs than to engage a large enough fraction of the community to change risk profiles of the entire community" (p. 1392).

The Stanford team articulated this difficulty in a different way (Fortmann et al., 1995). They noted that each year in the FCP, each adult in treatment communities was exposed to about 100 educational messages, delivered over 5 hours. Of these 5 educational hours, about 1 hour was from radio and television. In contrast, the average American is exposed each year to 35,000 advertisements (or 292 hours of advertising). Clearly, community health programs will always be underresourced with respect to the effects of broader secular influence.

In addition to the daunting amount of advertising that health promotion programs must overcome, the programs themselves are underresourced. The Stanford, Pawtucket, and Minnesota studies had annual budgets that exceed what many community organizations have available. In addition, the research studies were conducted by highly trained professionals and community leaders. In order to test community approaches with more modest means, the U.S. Centers for Disease Control and Prevention funded a series of studies focused on reducing cardiovascular disease. One of these community mobilization efforts, which received \$2.2 million over 5 years and operated through a state and local health department, produced mixed results, having a favorable intervention effect on cholesterol and smoking but not on other risk factors for cardiovascular disease. In addition, the project influenced levels of community awareness of risk and fostered greater cooperation among community health agencies (Goodman et al., 1995). The Planned Approach to Community Health (PATCH), a community mobilization initiative also funded by CDC, is an even more modest effort that provides communities with \$5,000 per year on average, and with most work being implemented by volunteers. PATCH reports modest, but in some cases, promising results especially in mobilizing community members (Buckner, Miner, Dreuter, & Wilson, 1992; Goodman, Steckler, Hoover, & Schwartz, 1993).

Taken together, the results of these large trials leave room for optimism and pessimism. On the one hand, there is little question that broad-based community interventions can be implemented in diverse communities with fidelity and effectiveness. Whether these interventions can penetrate broadly and deeply enough to produce community-wide change above and beyond secular trends is less certain. In addition, there is little evidence that specific interventions, or even types of interventions, are essential to success. Rather, because there are complex interactions between community characteristics and the health problems targeted, a "one-size-fits-all" orientation to intervention is certain to be problematic.

THE PROCESS OF INTERVENTION

This chapter does not provide an exhaustive discussion on the logistics of designing and implementing a community intervention. Other publications make this contribution (Bracht et al., 1994; Bracht & Kingsbury, 1990; M. Johnston, 1988;

Mittelmark et al., 1993; Wallack & Wallerstein, 1986). Rather, an overview is provided that helps to define community intervention among other interventions that promote health and prevent disease. The overview that follows discusses processes by which interventionists enter communities, develop community relationships, evaluate outcomes, and sustain programs.

Gaining Community Entree

Community health promotion may best be understood as a staged, sequential, and developmental process that begins with the skillful entree into a community, including the diagnosis of community structures, needs, capacities, and history. Kahn (1970), a pioneer of modern approaches to community entree based on labor organizing experiences in the South, maintained that community organizing is a technique and discipline—and not a mystique. This maxim sets a tone for community entree as an intervention strategy that is planned and well-orchestrated. The first step in the entree process is discerning who has political power and social influence, and what relations different sectors of the community have with sources of local influence. The CSAP partnership (see Fig. 36.1) used multisectorial committees, in part, in recognition that each committee represented community “stakeholders” of power and influence. R. B. Warren and D. I. Warren (1977), who focused on neighborhood development, provided a list of elements to consider prior to entree, including defining the boundaries of the neighborhood, identifying businesses, homes, and areas for recreation, and cultivating key informants to get a sense of the local history and current issues of importance. Such explorations prior to active involvement in communities enable the expert to choose appropriate tactics in making contact with community gatekeepers. Well-developed approaches with gatekeepers can legitimize the community health promotion specialist’s entree into the community. Eng and Blanchard (1991) provided a step-by-step approach to community diagnosis, using environmental health as a case study, and described how health promotion initiatives can be derailed when the experts’ initial contacts were with individuals who did not hold widespread credibility in a rural Southern community. As a result, subsequent efforts to gain entree into the community were not successful. This provides a cautionary tale illustrating the importance of an accurate diagnosis of community structure and especially gatekeepers.

In community health promotion, needs assessment is a frequently used approach to facilitate entree (Green & Kreuter, 1991). Usually, the assessment combines data collection methods to determine the needs most important to both target populations and funding agencies. For example, the CSAP needs assessment (see Fig. 36.1) combined demographic information about the number of youth in the community, with social indexes including the number of youth suspended from school or arrested due to illegal substance use, survey methods that identified levels of community awareness and concern regarding youth ATOD use, group interviews to gain a richer and deeper understanding of community concerns, and resource inventories of services available.

The Planned Approach to Community Health (PATCH), developed at the Centers for Disease Control and Prevention, also typifies this technique (U.S. Department of Health and Human Services, 1995). Overall, the PATCH approach consists of five phases: mobilizing the community, collecting and organizing data, choosing health priorities, developing a comprehensive intervention plan, and evaluating the intervention. Phase I mobilization involves compiling demographic profiles and other information regarding the makeup of the community. Phase 2 is a needs assessment that consists of mortality and morbidity indicators, coupled with perceptions of need from community leaders. These types of data form the basis for prioritizing and addressing the needs expressed in the assessment. Because needs will differ across these groups and across different methods of data collection, integrating perspectives is critical (McKillip, 1987) and convergent analysis is an often-used technique for this purpose. Convergent analysis is the sequencing of data produced by each method to assure that community groups and funders have a logically presented and full picture of the data on which to base planning decisions. McKillip (1987) provided a rich and distinct approach to gathering and integrating needs assessment data.

Reliance on needs assessment may be insufficient in mobilizing communities to participate effectively. For instance, in a critique of the PATCH approach, Goodman and colleagues (1993) noted that assessments based on health status and needs perceived by the community do not identify the capacities present in communities to effectively address needs. As a result, PATCH projects may accurately reflect need, but may not suggest what community assets are present to implement community health promotion strategies effectively. Marti-Costa and Serrano-Garcia (1983) echoed critiques of needs that are based primarily on health status indicators and community leader perceptions, noting that such assessments rarely involve grassroots community members and thus do not contribute to developing community capacity. In reaction to this criticism, recent approaches to entree include the mapping of community capacities. For instance, Kretzmann and McKnight (1993) provided inventories for mapping the capacities of individuals that includes skills, levels of community interests, and involvement in community activities. They also provided maps of associations that may be present in neighborhoods that can offer opportunities for residents to meet.

Cultivating Citizen Participation

An important result of skillful entree is the health promotion specialist’s cultivation of trust among community constituencies who are most concerned and/or affected by a presenting health issue. Webster’s dictionary defines trust as the “total confidence in the integrity, ability, and good character of another.” The definition suggests that trust engenders the absence of perceived harm. The entree process, if well-organized and based on an accurate understanding of community dynamics, enables the community health promotion specialist to be sensitive to community concerns and to approach

community members in a way that produces trust. Often, the health promotion specialist will have to overcome citizen reservations in order to gain their support.

In the CSAP partnership, the formation of committees was often hampered by competition or "turf" guarding among organization members. Organizations within a community may compete for the same resources and this may limit cooperation. The ability for organizations to put aside such fears for the greater community good that concerted action can bring is often facilitated by an individual who is trusted by all parties. The specialist tries to cultivate participation among various community constituencies through an organized recruitment approach that is calculated to raise awareness of the importance of the health promotion initiative, and to instill a concern for the issue. Most importantly, participation is likely to result when concern is internalized and community members feel a personal responsibility to participate (Parham, Goodman, Steckler, Schmid, & Koch, 1993).

Goodman, D. W. Smith, Dawson, and Steckler (1991) identified five phases for recruiting participants in complex health promotion initiatives that consist of establishing legitimacy for the community development effort and credibility of the community health promotion specialist; anticipating questions from community members regarding the nature of that effort; overcoming initial skepticism and resistance that members have about becoming involved; addressing community questions about the logistics involved in participating; and convincing the community of the benefits to be derived. Several studies indicate that strategies directed at increasing perceived benefits and reducing attendant costs tend to sustain participation (Wandersman & Alderman, 1993; Wandersman, Florin, Friedmann, & Meier, 1987). Perceived high costs can also result in the untimely termination of community health programs (Goodman & Steckler, 1987–1988), whereas perceived benefits can increase the likelihood that programs are sustained (Bracht et al., 1994; Goodman & Steckler, 1989a, 1989b; Prestby, Wandersman, Florin, Rich, & Chavis, 1990). Frequently, cited benefits and incentives include those that achieve the organization's goals that are perceived as important and enhance group identity and status (Knoke & Woods, 1981; Rich, Edelstein, Hallman, & Wandersman, 1995; Wandersman et al., 1987).

Planning and Implementing Community Initiatives

To foster effective participation, health promotion specialists facilitate the participants' abilities to plan, organize, and implement effective community actions. Thus, aiding community groups in planning initiatives is an important intervention in community health promotion. Butterfoss and colleagues (Butterfoss, Goodman, Wandersman, Valois, & Chinman, 1996) described the evolution of a Plan Quality Index developed for the partnerships in Fig. 36.1 that, at first, was used by professional evaluators to rate the adequacy of the plans. Because community groups objected to such ratings, the index was transformed into a narrative that provided the community with guidance for making the plan more effective and for effectively implementing it. Such interventions are important, as the

level of community participation does not seem to correlate with the plan quality or degree to which the plan is implemented (Butterfoss, Goodman, & Wandersman, 1996).

Empowerment As Means and End in Community Health Promotion

Citizen initiatives in community health promotion often entail influencing governmental, health, social, and welfare organizations to be responsive to community concerns. Consequently, the health promotion specialist may facilitate the development of community power. Empowerment is "a process by which individuals, communities and organizations gain mastery over their lives" (Rappaport, 1984). Citizen participation can be empowering (McMillan, Florin, Stevenson, Kerman, & Mitchell, 1995) and, for many communities, empowerment can be an end in itself (Rich et al., 1995). But, once empowered, communities may seek to influence the types of services and policies that affect the community (Zimmerman, 1995). Interventions that promote empowerment among participants have been reported as effective in improving birth outcomes for homeless women (Ovrebø, Ryan, Jackson, & Hutchinson, 1994), influencing governmental policy (Wang & Burris, 1994), producing modest (and mixed) results in increasing community competence (Eng & Parker, 1994), and increasing awareness and concern of the adverse consequences of excessive drinking among Native American teenagers (Wallerstein & Bernstein, 1988).

Community Coalitions, Mediating Social Structures, and Other Strategic Alliances

For community members to become empowered, their participation in a larger organized effort often is necessary (Speer & Hughey, 1995). A community coalition exemplifies the "empowering" process, because coalition members pool their individual resources to develop a critical mass in leveraging community change (C. Brown, 1984; Butterfoss et al., 1993). The CSAP partnership depicted in Fig. 36.1 is an example of a coalition that can empower citizen action. McMillan and colleagues (1995) demonstrated that such coalitions are empowering of members when they perceive that important benefits result from participating, that the group climate is supportive of members, that the group is highly committed to the work, and that the group has a strong identification with its community. McMillan et al. suggested that group interventions be directed at these variables. Guides to coalitions are beginning to proliferate and thus the health promotion specialist may be assisted by checklists and worksheets for coalition development (C. Brown, 1984; Kaye, 1990).

Community coalitions, like the CSAP partnership, may be classified as "mediating social structures," or "institutions standing between the individual in his private life and the large institutions of public life" (Berger & Neuhaus, 1977). McLeroy and colleagues (1988) noted that mediating structures are important components of a community and, besides community coalitions, include family, informal social networks, churches, voluntary associations, and neighborhoods.

Several studies illustrate the effectiveness of mediating structures as points of intervention. For instance, the strategic use of mediating structures (individuals or organizations) proved effective for enlisting participation and increasing social support (Eng & Young, 1992), and in connecting community residents to health programs. Lay health advisors can increase access to health services among disenfranchised groups like migrant workers (Watkins et al., 1994), among pregnant women who are poor, rural, and isolated (Goodman, 1992), and between local health agencies and churches in African American communities (Eng & Hatch, 1991). Other studies describe how linking agents influence the process of support for the institutionalization of health promotion programs in organizations (Goodman & Steckler, 1989a, 1989b; Penha-Walton & Pichert, 1993). The partnership depicted in Fig. 36.1 served as a mediating structure by linking committees representing parents and youth with important institutions like the police. Such linkages facilitated community-wide campaigns like the CSAP "Red Ribbon" campaign, where youth in cooperation with the police place red ribbons on highway overpasses to reinforce awareness to not drink and drive and police work with youth to see whether stores would sell alcohol or tobacco to minors.

Coalitions are one type of strategic alliance that may be nurtured by the community health promotion specialist. Others include networks, consortia, leadership councils, and citizen panels (Bracht & Gleason, 1990). Regardless of its form, strategic alliances generally share certain characteristics. Typically, they work well when members gain access to new information, ideas, materials, and other resources; when duplication of services and competition is minimized and consensus decision making is maximized; when the potential for each member to maximize power and influence is achieved; and when responsibility for addressing complex or controversial issues is shared across member organizations. Strategic alliances are forestalled when members' resources are diverted unduly to the alliance, when the alliance focuses on issues that are not of core concern to members, or when the alliance delays in taking action due to a slow and cumbersome process for reaching consensus (Alter & Hage, 1993; Butterfoss et al., 1993).

Because strategic alliances are hard to cultivate and maintain, technical assistance can be contoured to facilitate ongoing development among member groups (Florin, Mitchell, & Stevenson, 1993). For example, Gray (1989) outlined three stages of the collaborative process: problem setting for developing a common definition of the problem, identification of stakeholders, and a commitment to collaborate; direction setting for setting the agenda, exploring options, establishing ground rules, organizing subgroups, and reaching agreement; and implementation for building external support, establishing structures to sustain collective activities, and monitoring the agreement. Others propose a three-stage model of network development as a continuum from informal to formal linkages (Alter & Hage, 1993). The three stages include exchange or obligational networks composed of loosely linked organizations devoted to resource exchange with few joint activities and that are maintained by individuals who coordinate and integrate tasks across organizations; action or promo-

tional networks of organizations that share and pool resources to accomplish concerted action, but whose interorganizational activities tend to be peripheral to member organizations' goals; and systemic networks of organizations that have formal links that are long term to abet the joint production of goods or services.

The literature on voluntary community-based organizations and the institutionalization of community health promotion programs identify organizational characteristics and operations that are indicators of organizational competency (Goodman, McLeroy, Steckler & Hoyle, 1993; Goodman & Steckler, 1987-1988, 1989a, 1989b; Goodman, Wandersman, Chinman, Imm, & Morrissey, 1996). Among the organizational characteristics and operations that are likely to play a role are: formalization of rules and procedures for managing the coalition; well-established internal communication patterns; a variety of leadership roles; ability to access and exchange resources; procedures for conflict resolution; active recruitment and training of members who are representative of community agencies and constituencies; and participatory decision making. Keeping coalition members participating actively benefits from provision of incentives. Viable coalitions do a better job of accessing resources external to the organization. Finally, coalitions that evaluate their mission, goals, objectives, and activities regularly are more efficacious than coalitions that are not privy to such self-evaluation data. Organizations that achieve high levels of each of these processes and outcomes are more likely to create a favorable organizational climate, such as greater group cohesiveness, which in turn has been shown to be related to greater satisfaction, participation, and performance (Florin & Wandersman, 1990). Likewise, there is a body of research illustrating that citizen participation in the research and intervention process not only has the potential to improve the quality of life for communities and individuals but it can also increase the quality of data collected by researchers.

EVALUATION OF COMMUNITY INTERVENTIONS

There is a substantial literature on evaluating community intervention (D. G. Altman, 1986; Blackburn et al., 1983; Blake et al., 1987; Carleton et al., 1995; Cowen, 1978; Fawcett et al., 1995; Goodman & Steckler, 1989a; Group, 1995; Jackson, Altman, Howard-Pitney, & Farquhar, 1989; Kelly, 1988; Levine et al., 1993; Luepker et al., 1994; Pirie, 1990; Wandersman et al., 1983; Winkelstein & Marmot, 1981). A systematic review of this literature is beyond the scope of this chapter, although there is reasonably strong evidence that interventions in community settings can be effective in changing individual health behavior and environmental supports that promote health. Most of these interventions employ multilevel intervention approaches, but it is not possible to disentangle the effects of the different approaches.

Evaluations of large scale community intervention trials face several key evaluation challenges (Fortmann et al., 1995). Validity threats include compensatory rivalry of comparison communities, compensatory equalization of treatments, re-

sentful demoralization of comparison communities, between-city variation on baseline risk factors even after census matching, and diffusion or imitation of treatment in comparison communities. Also, there are several critical choices about the design that need to be considered. These include whether to evaluate specific effects of individual interventions, synergistic effects of entire interventions, or effects of complementary interventions. In recent years, evaluators of community interventions have developed highly refined systems of process monitoring (Fawcett et al., 1995; Goodman et al., 1996).

With respect to monitoring and evaluation of community health promotion initiatives, it is often the case that community groups do not have the expertise and financial resources to monitor progress and results. Consequently, community development experts have begun to develop monitoring and evaluation systems that can be implemented in collaboration with nonprofessionals. A goal of such evaluations is the transfer of expertise to the community members to build capacity and to empower community groups to implement self-monitoring and evaluation of community health promotion initiatives. Approaches that establish partnerships with community members and build monitoring and evaluation skills may be viewed as a type of capacity building intervention. Recent notable examples of such approaches to promote physical and mental health include Prevention Plus III (Linney & Wandersman, 1991, 1996), a four-step approach to identifying program goals, processes, outcomes, and impacts applicable to most community-based programs, and FORECAST (Formative Evaluation, Consultation, and Systems Technique), a technique that is used to help community groups monitor the development of community initiatives and make systemic adjustments to assure that the initiative evolve according to plan (Goodman & Wandersman, 1994). Fawcett et al. (1994) and Francisco, Paine, and Fawcett (1993) developed a complementary system that uses "Tracking of Actions" logs to monitor the vital community processes that may indicate whether the community is on track in producing desirable community changes. The log data are graphed cumulatively from month to month so that trends in effort can be assessed over time; community groups use the graph to fine tune the community intervention.

Both longitudinal (cohort) and cross-sectional (independent) surveys have been utilized as core outcome evaluation data collection tools. Cohort designs have the advantage that they allow for controlling baseline levels, studying stable population groups, analyzing change processes, increased statistical power, and studying changes based on intervention exposure and individual covariates. Disadvantages of cohort designs include out-migration, selective dropout, and testing effects. In contrast, the advantages of cross-sectional designs are that data are collected from a representative of entire community and data are not affected by drop-outs or by prior participation. Disadvantages of cross-sectional designs include lower statistical power, midstudy in-migration and thus reduced intervention exposure, expense and greater difficulty in accounting for individual characteristics.

In reviewing the community-based literature as a whole, Fortmann et al. (1995) concluded that "health education in

various forms, as well as social policies and economic conditions, causes risk factor changes. The most important questions now address how communities change and how interventions can be designed to enhance most effectively these changes in healthful directions" (p. 582).

RESEARCHER AND COMMUNITY RELATIONSHIPS

At the root of community intervention is the relation between interveners and communities. There is a long history of strained relations, different priorities, and poor communication between communities and interventionists (D. G. Altman, 1995b; Wandersman et al., 1983). Some of the key issues that affect the relation between researchers and communities working on health, as well as other topics, revolve around the following themes (D. G. Altman, 1995b): (a) ownership and control; (b) research versus service delivery; (c) time orientation; (d) ensuring program integrity; (e) overcoming the status quo; (f) gaining broad-based support; (g) reliance on experts and being an expert; (h) funding priorities versus community priorities; and (i) competition for existing resources. Ideally, researchers and community representatives who are engaged in collaborative projects to promote community health offer each other new ideas and perspectives in a mutually beneficial way. Historically, however, barriers have prevented researchers from carrying out their "public trust" with communities and a variety of "town-gown" tensions have become commonplace. This is unfortunate because researchers and communities have resources that are mutually beneficial (D. G. Altman, 1995b). Indeed, projects that include significant and meaningful citizen participation can create strong linkages between the community and interventionists and improve on the design and implementation of effective interventions (Chavis, Stucky, & Wandersman, 1983; Marentette & Kurji, 1988). Sustaining community health interventions (also referred to as institutionalization or incorporation) has presented itself to psychologists and policymakers with as yet little evidence that it is a high priority. Institutionalization is predicated on building community and organizational supports for programs (Goodman & Steckler, 1989b) and increasing community and practitioner competence in addressing community health issues (Eng & Young, 1992). Strategies (Steckler & Goodman, 1989) and measures (Goodman et al., 1993) for program institutionalization exist and community programs can benefit by building institutionalization into their planning and assessments.

Lewin (1951) coined the term "action research" to describe theoretically based research that made a difference in the real world. Many community interventions were implicitly influenced by an action research perspective. In the Minnesota Heart Health Program, for example, three quarters of the programs initiated by the researchers were continued by local community groups (Bracht & Gleason, 1990; Murray, 1986). In the Stanford Five City Project, allocation of resources to the communities, ongoing technical assistance and training, and encouragement of local community program de-

velopment, resulted in the community building a permanent infrastructure to support chronic disease prevention and the adoption by numerous community groups of specific programs and programmatic strategies initiated under the research grant (D. G. Altman, 1995b; Farquhar et al., 1990; Fortmann et al., 1995). Indeed, over half of the larger programs initiated by the Stanford group were maintained by community groups for at least a few years after the research program ended (Fortmann et al., 1995). Furthermore, the Stanford group alone has distributed over one million copies of educational materials used in the study to other researchers, educators, worksites, and other community-based organizations. In a community intervention to reduce CVD in a low socioeconomic status section of New York City, Shea and colleagues concluded that it is feasible to deliver a broad-based community intervention in a disadvantaged community. Programs originally developed in an academic health center can be transferred to a community-run organization, however, without ongoing resources, community organizations in poor communities are unlikely to be able to sustain programs (Shea, Basch, Wechsler & Lantigua, 1996).

The conflicts between researchers and communities can be understood from a dialectical perspective. A dialectic is partly defined by the opposition of two forces (Altman, Vinsel & Brown, 1981; Rappaport, 1977), although these forces are aspects of a unity with each force partly defining the other. For the researcher concerned with sustaining interventions, a dialectical tension exists between maintaining control over the interventions and allowing the community to assume control. Similarly, there are dialectical tensions for the community between the desire for autonomy and the community's dependence on researchers for their expertise and for taking action immediately versus waiting until evidence for intervention efficacy emerges. These dialectical tensions affect the extent to which interventions are sustained. Without recognizing and coping with these tensions, sustaining community interventions will be difficult to achieve.

We suggest that it is time once again for health psychology to confront the issue of how its research makes a difference to communities (Altman, 1995b). This issue has both practical and empirical ramifications. The practical ramifications relate to social relevance and utility of science. Scientists, however, must believe that participating in community interventions will also result in more valid empirical research and theory. In psychology, a number of distinguished scientists have commented on these relationships. Bevan (1970), for example, noted:

It is tragic that so many academicians—including many of us in psychology—whose fields of expertness give them a legitimate interest in the substance of such problems are so ignorant of what is going on in the real world beyond the campus gates. . . . Indeed, in the very least, such ignorance is a denial of the responsibilities of enlightened citizenship. (p. 445)

One of the problems that has prevented psychologists from being more active in community interventions is the age old

conflict between theory and action. Indeed, there are some psychologists with whom we have interacted who believe that community intervention is inconsistent with a psychological approach. Lewin (1951) commented on similar tensions some years ago:

Many psychologists working today in an applied field are keenly aware of the need for close cooperation between theoretical and applied psychology. This can be accomplished in psychology, as it has been accomplished in physics, if the theorist does not look toward applied problems with highbrow aversion or with a fear of social problems, and if the applied psychologist realizes that there is nothing so practical as a good theory. (p. 169)

A psychological perspective could bring value to community interventions and involvement in community interventions would bring value to psychologists. Thus, health psychologists have much to offer to community interventionists, but they must be willing to apply their knowledge and expertise in the community laboratory. Unfortunately, many psychology students and many psychology training programs do not view the community at-large as an appropriate setting for psychological intervention. As the next generation of psychologists is trained, they are well-advised to follow the advice of Miller (1969), a 20th-century leader in psychology:

Our responsibility is less to assume the role of experts and try to apply psychology ourselves than to give it away to the people who really need it—and that includes everyone. The practice of valid psychology by nonpsychologists will inevitably change people's conception of themselves and what they can do. When we have accomplished that, we will really have caused a psychological revolution. (p. 1071)

CONCLUSIONS

This chapter has reviewed the theoretical, conceptual, empirical, and logistical underpinnings of community intervention. As a strategy, the popularity of community intervention has grown substantially in recent decades. As others have noted (Thompson & Kinne, 1990): "The increasing focus on 'community' in health promotion is due, at least in part, to growing recognition that behavior is greatly influenced by the environment in which people live. Proponents of community approaches to behavioral change recognize that local values, norms, and behavior patterns have a significant effect on shaping an individual's attitudes and behaviors" (p. 45). The basis for social and community interventions extends from at least two lines of reasoning, one philosophical and one practical. On philosophical grounds, the principals of democracy are the ideological girders for social approaches to health education. Steckler and colleagues (1987) maintained that health education practice is founded on democracy as a political philosophy and citizen participation is *sine qua non* as a professional principle. This professional orientation extends from Nyswander (1967), who was most concerned with social par-

ticipation in an open society, and Steuart (Steuart & Kark, 1993), who maintained that "health education is rooted in the recognition that the culture of a community has a deep and abiding influence on its health ... [and] is socially oriented in its interpretations of the epidemiology of health and disease" (p. S-29). From the standpoint of democratic principles, the most effective health education strategy is one that raises the levels of awareness and concerns for groups at health risk and enables them to devise their own strategies to reduce risk, strategies that are valid culturally and contextually. On practical grounds, change in health behavior and status is more likely to occur when the social and cultural context is altered to support pro-health options.

Citizen Participation and Health: Toward a Psychology of Improving Health Through Individual, Organizational, and Community Involvement

Frances Butterfoss
Center for Pediatric Research

Abraham Wandersman
University of South Carolina

Robert M. Goodman
Tulane University School of Public Health and Tropical Medicine

Never doubt that a small, thoughtful group of committed citizens can change the world. Indeed, it is the only thing that ever has.

—Margaret Mead

How can citizen participation affect health? What can psychology contribute to this field? This chapter uses a case example of a community coalition to illustrate the powerful forces that shape citizen participation and how that participation can be mobilized to build a community's capacity and competence in achieving meaningful health outcomes. In this case, the Consortium for the Immunization of Norfolk's Children (CINCH) had the potential or capacity and developed the competence to engage in effective research, planning, action, and evaluation. Although immunization has been the cornerstone of traditional medical practices tracing back to the smallpox immunization paradigm, CINCH used a nontraditional citizen participation approach to improve childhood immunization rates. By encourag-

ing citizens to develop comprehensive and effective strategies that were carefully implemented, CINCH delivered results. Community volunteers and health and human service professionals from the public, private, and military sectors proved their competence by increasing childhood immunization rates 17% in Norfolk, Virginia. Using the case study, the chapter shows how psychological theories from personality, social, organizational, and community psychology can help advance the understanding and strategic use of community partnerships. Finally, it overviews major issues in participation at the individual, organizational, and community levels that focus on developing community capacity and competence to improve health outcomes.

CITIZEN PARTICIPATION

Citizen participation is defined as "a process in which individuals take part in decision making in the institutions, programs, and environments that affect them" (Heller, Price, Reinhartz, Riger, & Wandersman, 1984, p. 339; see Churchman, 1987, for definitions of participation in different disciplines). Participation offers the potential to make schools, neighborhoods, institutions, environments, and services responsive to individuals and families.

Citizen participation results in multiple benefits, including: (1) improved quality of the environment, program, or plan because the people who are involved in implementation or usage have special knowledge that contributes to quality; (2) increased feelings of control over the environment and development of programs, plans, or environments that better fit with people's needs and values; (3) increased feelings of helpfulness and responsibility; and (4) decreased feelings of alienation and anonymity (see Wandersman, 1979).

Citizen participation can take place at multiple levels: individual, organization, and community participation. For many years, the individual model of participation in the health field has been guided by an expert medical model exemplified by the doctor-patient relationship. In a provocative book *The Silent World of Doctor and Patient*, J. Katz (1984) described the patients' rights to decision making and centered his arguments around a concept of psychological autonomy and psychological capacities (e.g., reflection and choice) of the patient to decision making. Recently, medical education has developed techniques and trained physicians to provide patients with responsible choices in decision making.

Similar changes in health models are taking place at the community level. The medical model of public health is currently being complemented by citizen participation in making decisions about community health. According to social ecological models of health and health promotion (e.g., Stokols, Allen, & Bellingham, 1996), the health of individuals is inextricably linked to the health of communities. The Healthy Cities/Healthy Communities movement defines a healthy city or community as "one that is continually creating and improving those physical and social environments and strengthening those community resources which enable people to mutually support each other in performing all the functions of life and achieving their maximum potential" (Hancock & Duhl, 1986, in Hancock, 1993, p. 7). A major vehicle for developing a healthy community is a type of citizen participation organization called a *community coalition*.

COMMUNITY COALITIONS DEFINED

The development of partnerships of community agencies, institutions, and concerned citizens to combat chronic health conditions is gaining popularity as an intervention aimed at strengthening the social fabric. A community coalition is a particular partnership that is defined as "an organization of individuals representing diverse organizations, factions, or constituencies who agree to work together in order to achieve a common goal" (Feighery & Rogers, 1989, p. 1). These di-

verse interest groups "combine their human and material resources to effect a specific change the members are unable to bring about independently" (Brown, 1984, p. 3).

Currently, hundreds of millions of dollars are being invested in partnership development as a prevention and health promotion intervention. Examples include "Community Partnerships" funded by the Center for Substance Abuse Prevention (CSAP); "Fighting Back" substance abuse programs funded by the Robert Wood Johnson Foundation; SAFE KIDS partnerships to prevent childhood injuries, supported by Johnson and Johnson; COMMIT and ASSIST community tobacco control programs funded by the National Cancer Institute and the National Institutes of Health; PATCH cardiovascular health promotion program granted by the U.S. Centers for Disease Control and Prevention; and Native American health promotion efforts sponsored by the U.S. Office of Minority Health.

A coalition approach to improve childhood immunization rates is appropriate given that underimmunization is a multifaceted challenge to health that must be solved by involving and strengthening multiple levels and sectors of our communities (Bernier, 1994; McLeroy, Bibeau, Steckler & Glanz, 1988; Orenstein, Atkinson, Mason, & Bernier, 1991). Even though *Healthy People 2000* set national goals to fully immunize at least 90% of children by age 2, this goal is still unrealized (Public Health Service, 1991). Depending on the state of residence, from 13% to 37% of 2-year-old children in the United States remain underimmunized and the picture is worse in urban areas (Centers for Disease Control and Prevention, 1996; Zell, Dietz, Stevenson, Cochi, & Bruce, 1994). The measles epidemic of 1989-1991 and the resurgence of pertussis prompted the Centers for Disease Control and Prevention (CDC) to provide resources to develop and implement plans to reduce morbidity and to improve availability and access to childhood immunization services (Centers for Disease Control and Prevention, 1993; National Vaccine Advisory Committee, 1991). Coalitions were a vehicle to accomplish these aims.

Research indicates that coalitions follow predictable stages from formation to institutionalization (Butterfoss, Goodman, & Wandersman, 1993). Figure 37.1 illustrates the model used to evaluate several local community partnerships for alcohol, tobacco, and other drug (ATOD) abuse prevention funded by CSAP. This model of coalitions is applicable to other public health problems.

The formation stage occurs at the initiation of funding. The agency granted the funding (lead agency) convenes an ad hoc committee of local community leaders. The ad hoc committee nominates influential citizens to serve on committees representing health care, business, education, religion, criminal justice, neighborhood organizations, the media, and other sectors of the community. Training on prevention goals, issues, and tasks takes place. The implementation stage occurs as each of the committees conducts a needs assessment to determine the extent and nature of its constituents' concerns and resources in regard to alcohol, tobacco, and other drug abuse. The needs assessment consists of secondary data as well as written questionnaires, town meetings, and interviews that

are developed and conducted by the committees, with input from the staff and the evaluation team. Implementation continues, with committees using the results of the needs assessment to develop a community-wide intervention plan. The maintenance stage consists of the monitoring and upkeep of the committees and their planned activities. The outcome stage consists of the impacts that result from the deployment of community-wide strategies. The series of activities of community mobilization (needs assessment, planning, and implementation of programs and activities) are aimed at ameliorating the risk factors listed in Fig. 37.1 and therefore facilitating positive outcomes.

Table 37.1 uses the same model to show CINCH's development with its stages and time frames, as well as the competencies developed and tasks accomplished during each stage. The stages are sequential, but overlap of tasks occurs between stages. CINCH is a dynamic organization, and it recycled through tasks of formation, implementation, and maintenance

as new members were recruited and strategies were revised or added. Within each stage, the capabilities that were brought to the effort and the competencies that were developed are discussed. Using needs assessment, problem solving, and decision making, members planned, implemented, and evaluated strategies to educate parents and providers and improve service delivery.

THE CONSORTIUM FOR THE IMMUNIZATION OF NORFOLK'S CHILDREN (CINCH)

Background

In 1992, the National Immunization Program of the Centers for Disease Control and Prevention (CDC) established Norfolk as a site to demonstrate how a community coalition could

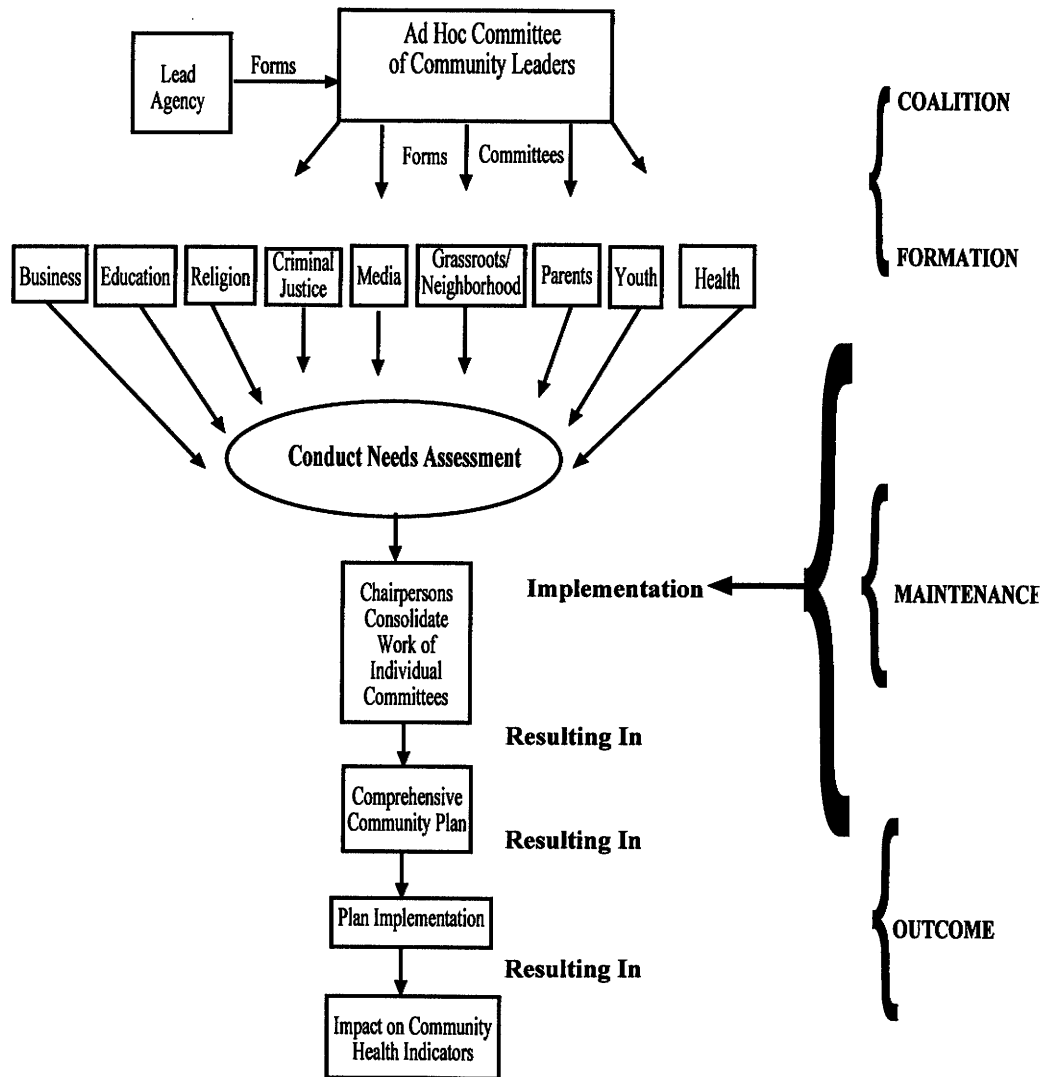

FIG. 37.1. Overview of the development of a community coalition.

TABLE 37.1
CINCH Development: Competencies Developed and Tasks Accomplished

Stage/Duration	Competency Developed	Tasks Accomplished
Formation (6 months)		Identify community problem Recruit members Create mission, rules, roles Collaborate Train on goals and issues
Implementation (12 months)	Skills Participation Leadership Community Values	Assess needs Collect, analyze, and feedback data Develop plan
Maintenance (12 months)	Resources Social Networks Critical Reflection	Initiate and monitor strategies Support and evaluate coalition group process
Outcome (> 12 months)	Sense of Community Power	Begin to accomplish goals Progress toward results or impacts from community-wide strategies

improve immunization rates for children under age 2. Norfolk was selected because of its low immunization rate, ethnic diversity, and mix of public, private, and military health care systems. The coalition was based in the Center for Pediatric Research, a joint program of Children's Hospital of The King's Daughters and Eastern Virginia Medical School.

Norfolk is located in eastern Virginia, or Tidewater, where many health indicators lag behind the state average by up to 10%. According to the 1990 census, Norfolk has a population of 261,229, a birth cohort of 5,561, and an ethnic distribution of 57% White, 39% African American, and 4% other groups. The median household income is below \$20,000, approximately 20% are enrolled in the Aid to Families of Dependent Children (AFDC) program, and 40% are enrolled in the Women, Infants, and Children (WIC) program. Children receive care from a combination of private, public, and military health services. Free immunizations are available to all children, regardless of family income, through five public health clinics, two hospital-based outpatient clinics, and three military sites. But, according to 1993 retrospective school-enterer data, only 46% of 2-year-olds were up to date on basic immunizations.

Year 1: Formation to Implementation

CINCH was founded in 1993. The coalition was built with consideration that it would have an inclusive membership and engage in comprehensive planning, action, and evaluation (Butterfoss et al., 1993; Kaye & Wolff, 1995). The staff helped members conceive CINCH as a competent organization—one that promoted excellence in regard to its participants, structures, and processes.

Careful consideration was given to recruiting and maintaining diverse representation from organizations that were committed to action. The staff recruited a core group of organizations who, in turn, recruited others to total 55 representatives from service organizations; academic, civic, and religious institutions; public, private, and military health care providers; and ordinary citizens. Members from various grassroots and professional organizations provided diversity according to age, occupation, ethnicity, and religion. This group of willing individuals had the capacity to mobilize for citizen action, and potential leaders stepped forward. The success of the coalition was closely related to the effectiveness of member participation and leadership.

Each member brought individual skills to the coalition and assessed the costs and benefits of participation in the overall effort. Each member also represented an organization that brought resources to the table. Members were relied on for skills, such as planning, teaching, mobilizing volunteers, and accessing the media. Member organizations contributed financially or in-kind to implement program strategies because grant funds were earmarked only for research.

To engage the membership, CINCH staff provided training about the effectiveness, efficacy, and importance of immunization, the vaccine schedule, current literature about barriers to immunization, and reasons why a coalition approach might be effective in dealing with underimmunization. Members did their part by infusing a sense of community and community values into the new coalition. They were willing to put aside differences in order to share responsibility for all of the community's children. Relying on new knowledge and core values, the coalition developed its mission which was to: (1) establish dialogue within the local community regarding immunization

of preschool children; (2) determine the causes of underutilization of health services and poor vaccine coverage among local preschool children; (3) form recommendations and mobilize the community to implement solutions to improve the health and immunization status of Norfolk's children; (4) evaluate the effectiveness of interventions and make revisions in strategies, as needed; and (5) share experiences and recommendations from the CINCH project with other communities. Again, this common mission and commitment to community improvement helped members overcome barriers that commonly stall new coalitions, such as lack of direction or turf battles and competition (Butterfoss, Goodman, & Wandersman, 1996; Kaye & Wolff, 1995).

Next, members focused on organizational structure and functioning. They developed written rules of operation, criteria for membership, and roles for members, leaders, and staff.

Staff provided administrative support to members by preparing draft documents, agendas, minutes, rosters, meeting reminders, and mailings. They helped leaders set agendas, run effective meetings, and plan strategies that promoted member retention. CINCH developed work groups with complementary missions, yet each work group focused on specific tasks and populations. Members elected chairs and vice-chairs for each group and for the coalition at large. Early successes included the development of a logo, slogan, and brochure for visibility and recruitment.

Throughout this stage, members developed skills that would later be combined into effective action. They learned to work toward a common purpose and to rely on each others' talents and resources. Members were valued for their contributions to the overall effort and not for their positions or the power of their organizations. Consequently, members excluded titles from nametags and discussions and used a "one vote per organization" rule for decision making. As previously competitive organizations learned the value of collaborating to accomplish tasks, the level of trust improved.

Year 2: Implementation

The implementation stage of CINCH focused on needs assessment, data collection, analysis and feedback, and plan development. First, the work groups assisted in a needs assessment to diagnose local causes of underimmunization. CINCH members participated in all phases of the needs assessment by planning or facilitating existing and primary data collection. Parent focus groups, patient exit interviews, and health care provider surveys were planned and conducted by work groups (Butterfoss, Morrow, et al., 1998; Houseman, Butterfoss, Morrow, & Rosenthal, 1997). A household survey established that underimmunization was found in all socioeconomic groups and among all types of health care services, with only 49% of children up to date on their immunizations by age 2 (Morrow et al., 1998). Staff were responsible for entering, analyzing, and presenting data to the coalition for feedback.

Based on the data, CINCH developed a 2-year strategic immunization plan that focused on parent and provider education and support for at-risk families, thereby increasing ac-

cess to immunizations and improving immunization delivery. Staff conducted workshops for work group members about the process of developing a quality action plan. Once trained, each work group used the data to identify a prioritized set of needs related to their target group (e.g., parents, providers). Then, goals, objectives, and strategies were developed to address each identified community need. The groups considered the strengths of their community and the resources they could draw on to implement various strategies. Linkages among appropriate community agencies were identified and evaluation of strategy effectiveness was planned.

After each group finalized its plan, coalition leaders coalesced the four individual plans into one overall plan that was presented at a community press conference. The intrinsic conflict and negotiation involved in this process cemented relationships among group leaders and strengthened internal support for the plan. The planning process resulted in the creation of a steering committee of leaders that met regularly to share coalition successes and challenges. Members also learned that planning is a continuous process and eventually concerned themselves with details such as developing strategy time lines, management plans, and budgets.

Year 3: Maintenance

The maintenance stage involved initiating new strategies and monitoring others. Work groups often collaborated on strategies and responsibilities overlapped between groups. Two work groups even merged to streamline their operations. Some activities were initiated and finished during the maintenance stage, and others were not achieved until the outcome stage. Each implemented strategy had a built-in evaluation component where members were taught to ask themselves whether the strategy was based on community need, was implemented as planned, and could be improved. Work group action plans were revised annually.

CDC funding restrictions prompted CINCH to develop community support for its activities and increased the likelihood of sustaining its efforts beyond the grant period. Private foundation funding enabled the coalition to hire an outreach coordinator, conduct a media campaign, and implement key strategies. In-kind contributions from CINCH members included the health department printing posters, flyers, and brochures; the medical school arranging satellite teleconferences; and community merchants contributing parent incentives.

During the maintenance stage of any coalition, membership and commitment may waiver with the realization that accomplishing goals takes time. To keep members involved, CINCH participated in health fairs, marches, and other visible community health efforts. Leaders were attuned to the need to retain members and maximize their participation. Attention was given to written reminders and phone calls about meetings and follow-up with members who missed meetings. Meetings were evaluated and members completed surveys to measure satisfaction and participation and to define areas for improvement. General membership meetings provided opportunities to cultivate and renew relationships and to celebrate incremental achievements.

Year 4: Outcome and Institutionalization

CINCH accomplished some of its more difficult strategies such as WIC linkage, physician practice assessment and feedback, hospital birth reminder systems, and legislative action during the outcome stage. Members not only had the ability to direct the course of community events, but wielded that power to influence some of the larger institutions such as hospitals and the state legislature. In 1996, members voted to broaden CINCH's geographic scope to include members from six other cities in the region and to expand its mission to address other child health issues in addition to immunization. The coalition also obtained funding to hire a coordinator and secretary. A new needs assessment work group identified, collected, and presented data related to regional child health problems. By this time, members could articulate what the greater community needed and valued. These values and data led CINCH to select perinatal health issues (infant mortality, low birth weight, lack of prenatal care) as its expanded mission under the name of the Consortium for *Infant and Child Health*.

CINCH has had an impact on the Norfolk community. The coalition effectively implemented 61 of 79 planned strategies (77%). Although any change in immunization levels for 2-year-olds cannot be attributed to CINCH alone, rates rose from 49% in 1993 to 66% in 1996 (Morrow et al., 1998). Higher rates were reported among hospital clinics and military providers.

CINCH's success has fostered new state contracts and federal grants that promote environmental change. The skills and experience gained from CINCH prompted a contractual agreement between CINCH's lead agency and the state health department to develop, manage, and evaluate a state immunization coalition, Project Immunize Virginia (PIV). PIV used CINCH as a model to bring together public and private partners to advocate for improved levels of immunization. Through PIV, CINCH members help other localities develop community partnerships to improve immunization rates for children. CINCH members and staff also provide technical assistance to other local partnership efforts that deal with drug and alcohol abuse, teen pregnancy, child abuse and neglect, and school health. CINCH collaborates with projects focused on case management, community policing, neighborhood improvement, and urban planning.

Under a grant from the Association of Teachers of Preventive Medicine, the Coalition Training Institute was established in Norfolk in 1995. The Institute models the CINCH process to train key health agency staff responsible for development and implementation of immunization coalitions in 88 state, territorial, and urban sites (Butterfoss, Webster, Morrow, & J. Rosenthal, 1998). CINCH members showcase what their coalition did to improve immunization rates and share lessons learned. By articulating these "lessons learned" in a way that could help others, members were empowered beyond original expectations.

Evaluation of CINCH was accomplished through member surveys, content analysis of minutes and evaluation of meetings (Butterfoss, Morrow, et al., 1998). Surveys showed that 86% of CINCH members were satisfied with the work of the

coalition, 70% stated they had great influence in decision making, 90% agreed that communication was productive and positive, and 93% were satisfied with the group environment. Ninety-four percent reported that staff were competent or highly competent and 75% reported that members were competent or highly competent. Finally, 97% agreed that the action plan reflected the needs assessment and would be effective, and 87% were certain that CINCH would improve immunization rates.

Average attendance over 130 meetings was 59%, which was considered acceptable by coalition research (Prestby & Wandersman, 1985). Content analysis of meetings showed that activities were balanced among tasks of member orientation, needs assessment, planning coalition structure and functions, information sharing, development of products or services, revision of coalition structures, and evaluation. Leaders and members also completed Meeting Effectiveness Inventories (MEIs) after all meetings to determine factors that contributed to success (Goodman & Wandersman, 1994). Out of a 5-point scale, with 1 being ineffective and 5 being highly effective, work group meetings were rated at 4.4 (88%) and general meetings at 4.6 (92%). After completing the MEI, leaders and staff debriefed about how to address barriers and promote meeting effectiveness. Recommendations focused on improving attendance, tardiness, agendas, participation, leadership, and grassroots representation.

In summary, during the outcome stage, CINCH members were empowered by their participation to change how immunizations were understood, accessed, and delivered to the target population; implemented an effective action plan; obtained funding; expanded by region and mission; and advocated for legislative change.

LESSONS LEARNED FROM COALITION PRACTICE AND RESEARCH

Coalitions have their share of difficulties, and they need resources to develop and time to build collaborative relationships. However, once coalitions are established, they may be able to create and sustain more effective strategies than traditional public health institutions can do alone. Several observations from the CINCH experience may be helpful for other health promotion coalition efforts.

First, CINCH's experience proved that whereas every member brought concern for children, not all had the skills needed to be effective. Through training and practice in leadership, meeting effectiveness, needs assessment, and planning, coalition members developed skills that improved their participation and could be generalized to other civic areas. Involving community members early in needs assessment and planning helps empower them to implement planned strategies (Kaye & Wolff, 1995; Butterfoss, Goodman, & Wandersman, 1996; Butterfoss, Morrow, et al., 1998). Involving citizens in solving real problems develops a competent community.

Second, CINCH made good use of its volunteers. Training, clear roles, and ongoing contact with participating institutions were essential for member retention. Member in-

volvement was bolstered by achievement of objectives and positive results. A clear vision of leadership and a commitment to a quality process kept members interested. Leaders were sensitive to member needs by allowing varying levels of participation during each coalition stage. They reduced burn-out and maximized resources by recognizing that some members are better planners, whereas others are better doers. CINCH also made good use of each member's linkage with others. Members constantly recruited others who represented the target population or who could provide resources. New recruits stimulated creativity and renewed effort among founding members.

Third, CINCH promoted partnerships with citizens and groups in neighboring cities. When personal agendas are put aside, resources may be effectively pooled. Work group members invited health department and hospital directors, as well as counterparts from professional and voluntary agencies in neighboring cities, to join them at the table. Communities often collaborate with other communities regarding issues such as water and land use or transportation, but collaborating to promote health and prevent disease is a newer concept. Experience proved that a regional health promotion partnership could build relationships for the future.

TOWARD A PSYCHOLOGY OF CITIZEN PARTICIPATION IN COMMUNITY COALITIONS: A MULTIPLE LEVEL APPROACH

At the individual, organizational and community level, there is both a *potential* for citizens to participate and *actual* citizen participation. This section organizes an understanding of participation, based on a framework described in Table 37.1.

The Individual Level of Participation

A major puzzle in the citizen participation literature is "If participation is such a good thing, why don't more people participate?" Despite the desirable outcomes proposed as consequences of participation and exemplified in actual coalitions like CINCH, relatively few people participate in government-initiated efforts, grassroots groups, or community partnerships (e.g., ISA Associates, 1994, Langton, 1978; Verba & Nie, 1972; R. Warren, 1963). The literature pertinent to individual characteristics and participation can be divided into demographic research and personality or social psychological research.

Demographic variables (e.g., age, race, and sex) have been used in political science, sociology, and psychological studies to predict participation, however, they tend to predict relatively little variance. Two studies that used multiple demographic variables to predict participation predicted 9% of the variance or less (Edwards & White, 1980; Vassar, 1978).

Personality and social psychological variables offer interesting opportunities to understanding and predicting participation. For example, many psychologists agree that a complex interaction exists between the characteristics of the

person and the environment that produces and sustains behavior. For this reason, an individual is likely to participate in only a few of the many organizations available. The organization(s) chosen are selected on the basis of the individual's own characteristics (e.g., needs, values, and personality) and the characteristics of the organization (e.g., purposes, efficacy, location).

Potential Levels of Participation. Mischel (1973, 1977) suggested five cognitive social learning variables as potentially useful in conceptualizing how personal qualities influence the impact of situations and how people generate distinct patterns of behavior in interaction with the conditions of their life. Florin and Wandersman (1984) operationalized the cognitive social learning variables to predict participation in community settings. The five cognitive social learning variables are now called skills, view of the situation, expectations, values, and personal standards (Wandersman, Florin, Chavis, Rich, & Prestby, 1985). The set of cognitive social learning variables was compared with a larger set of traditional demographic and personality trait variables for ability to discriminate members from nonmembers, and they accounted for more of the variance in participation.

Based on a review of the literature, Widmer (1984) concluded that many of the studies on why citizens participate say little about the motives and benefits of participation and focus instead on the characteristics of who participates. One approach to the issue of why people participate is represented by the political economy theory (e.g., Moe, 1980; Olson, 1965; Rich, 1980), which suggests that a social exchange takes place in organizations in which participants will invest their energy in the organization only if they expect to receive some benefits. This can be related to social exchange theory in psychology. (See Chinman & Wandersman, 1999, for a detailed review of costs, benefits, and incentives in community organizations).

Actual Levels of Participation. Wandersman, Florin, Friedmann, and Meier (1987) investigated the benefits and costs of participation in their cross-cultural study. They found two benefit (helping others and personal gains) and two cost factors (opportunity costs and organizational frustration). Absolute ratings suggested that both members and nonmembers agree that the greatest benefits are in making a contribution and helping others rather than in self-interest or personal gains. Regarding costs, nonmembers perceived more costs than members reported. In the CINCH coalition, only 9% of members reported costs and the top cost reported was the amount of time spent in consortium work. In fact, low costs of participation were associated with member satisfaction and commitment.

In the Block Booster Project (a study of 29 block associations), Prestby, Wandersman, Florin, Rich, and Chavis (1990) found that the most active participants reported receiving significantly more social/communal benefits and personal benefits than less active participants, with personal benefits best distinguishing the most active participants. They proposed that

personal benefits, such as learning new skills, are likely to be exclusive to the high level participants because they are contingent on participation. Regarding costs and participation, Prestby et al. found that the least active participants reported experiencing significantly more social and/or organizational costs than the active participants. In sum, social exchange and political economy theory were supported as the participation level and the amount and type of costs were significantly and negatively associated with level of participation.

Taken as a whole, the social psychological and cost/benefit results lend empirical support to Henig's (1982) three-step model of mobilization wherein individuals perceive a condition, evaluate it as important to their well-being, and calculate that something can be done about it. This points to the importance of understanding more fully the processes through which an individual engages in a decision to participate in a particular organization.

Researchers have compared the benefits of members at different activity levels. Prestby et al. (1990) asked leaders and members which benefits they received. In general, the most active members and leaders reported experiencing more total benefits and more personal and social/communal benefits than the less active members. In relation to costs, Prestby et al. found that the least active members experienced significantly more total costs and more social/organizational costs than members of all other activity levels. Participation in partnership committees was predicted by higher benefits and lower costs (Butterfoss, Goodman, & Wandersman, 1996). Chinman and Wandersman (1999) detailed results in this area.

The Organizational Level of Participation

Like any organization, a coalition needs resources, structure, activities, and accomplishments in order to survive. These are the essential elements of an open systems framework, so named because it is open to and interacts with the environment (D. Katz & Kahn 1978). The framework proposes that organizations can be seen as mechanisms for processing resources obtained from the environment into products that affect that environment. Using Katz and Kahn's work as a departure point, Prestby and Wandersman (1985) developed a framework of organizational viability suggesting that there are four components of organizational functioning: resource acquisition, maintenance subsystem (organizational structure), production subsystem (actions or activities), and external goal attainment (accomplishments). This section draws on an application of this framework to partnerships (Wandersman, Goodman, & Butterfoss, 1997).

Resource Acquisition. In reference to Table 37.1, potential at the organizational level is represented by resources brought to the organization by its members and those recruited from external sources. A partnership's membership is its primary asset. Several variables related to the members have been associated with organizational maintenance (Prestby & Wandersman 1985), including the size of the membership, depth of members' attachment to the mission,

and members' personal and political efficacy. As illustrated in CINCH, each member brings a different set of resources and skills to the partnership. The effective implementation and maintenance of a partnership require not only motivated and involved members, but also members with the skills or capacity to participate in a partnership and to gain legitimacy (Gray, 1985).

Partnerships also benefit by linking with external resources, especially those concerned with policy, planning, and services (Butterfoss et al., 1993). CINCH illustrated how external resources such as elected officials, government agencies, religious and civic groups, neighborhood and community development associations, and foundations were vital. In this and other coalitions, such resources provide expertise, meeting facilities, mailing lists, referrals, additional personnel for special projects, grant funding, loans or donations, equipment, supplies, and cosponsorship of events (Chavis, Florin, Rich, & Wandersman, 1987; Prestby & Wandersman, 1985).

Access to local communities is an important link for many partnerships (Roberts-DeGennaro, 1986), particularly those concerned with health promotion. Such partnerships often benefit by linking with individuals and organizations active in community affairs. For instance, Prestby and Wandersman's (1985) study of block associations demonstrated that those that endured tended to have strong linkages with local community organizers and with other neighborhood associations.

Partnership Structure and Functioning. The maintenance subsystem of the open systems framework involves organizational structure and functioning, which is the aspect of the partnership that obtains the resources and organizes the members. If partnerships are to be viable, they must be able to set goals, administer rewards, and mediate between members' individual needs and the task requirements of the organization. Examples of organizational structure and function include leadership, formalized rules, roles, and procedures, decision-making and problem resolution processes, and organizational climate.

Strong central leadership is an important ingredient in the implementation and maintenance of partnership activities (Butterfoss et al., 1993). Regardless of size, partnerships tend to have a few core leaders who dominate partnership activities such as the Steering Committee in CINCH (Roberts-DeGennaro, 1986). When these leaders are attentive to and supportive of individual member concerns and are competent in negotiation, garnering of resources, problem solving, and conflict resolution, the partnership tends to be more cohesive in reaching peripheral members and in maintaining partnership operations (Brown, 1984).

Formalization is the degree to which rules, roles, and procedures are precisely defined. Examples of formalization, used by coalitions like CINCH, include written memoranda of understanding, bylaws, policy, and procedures manuals; clearly defined roles; mission statements, goals, and objectives; and regular reorientation to the purposes, goals, roles, and procedures of collaboration (Butterfoss et al., 1993; Goodman & Steckler, 1989). Formalization often results in the routinization or persistent implementation of the partner-

ship's operations. The more routinized operations become, the more likely it is that they will be sustained (Goodman & Steckler, 1989).

The influence that participants have in making decisions is vital to a partnership. Prestby and Wandersman (1985) found that active block associations in the Neighborhood Participation Project were more likely to use a democratic decision-making process, whereas inactive associations used an autocratic or mixed democratic/autocratic process. The Block Booster project (Chavis et al., 1987) reported that active block association members felt they had a greater influence in deciding on the policies and actions of the group than did inactive block association members. Active block associations used consensus and formalized decision making procedures more often and were more decentralized than inactive block associations. In a 1993 CINCH survey, members reported either that they had a great degree of influence (74%) or some influence (26%) in determining policies and actions of the consortium.

Mizrahi and B. Rosenthal (1992) argued that conflict is an inherent characteristic of partnerships. It may arise between the partnership and its targets for social change or among partnership partners concerning issues such as leadership, goals, benefits, contributions, and representation. Mizrahi and Rosenthal identified four "dynamic tensions" that account for conflict in partnerships: (1) the mixed loyalties of members to their own organizations and to the partnership, (2) the autonomy a partnership requires and the accountability it has to its member organizations, (3) the lack of clarity about the partnership's purpose as either a means for specific change or a model for sustained interorganizational cooperation, and (4) the diversity of interests of its members. Eighty-two percent of CINCH members (1993 survey) reported that when conflict arose, they were able to resolve it effectively.

Organizational climate assesses members' perceptions of the "personality" of an organization. Moos (1986) assessed organizational climate on 10 subscales: cohesion, leader support, expression, independence, task orientation, self-discovery, anger and aggression, order and organization, leader control, and innovation. Giamartino and Wandersman (1983) used the Group Environment Scale to examine the relation of 10 social climate dimensions to member's satisfaction, enjoyment, and time involvement. Using aggregate data from 172 members of 17 block associations, they found that the average level of members' satisfaction and enjoyment was significantly related to three social climate dimensions. Members were more satisfied and enjoyed their involvement more in associations that were perceived to have higher levels of "team spirit" and comraderie among members (cohesiveness), have higher degrees of structure and formalization of activities (order and organization, and have leaders who actively directed the group and enforced rules (leader control). Importantly, no significant relations were found between any of the social climate dimensions and the average activity level of members in the organization (time spent on organizational activities in the previous 2 months). Butterfoss, Goodman, and Wandersman (1996) found that social climate characteristics (e.g., leader support,

leader control) were related to satisfaction with the work, participation in the partnership, and costs and benefits. Using a 12-item social climate scale (1993 CINCH survey), 96% of members reported a positive group climate that was significantly associated with satisfaction and commitment.

The Community Level of Participation

At the community level, partnerships function as an amalgam of individuals, organizations, and interest groups. They join together in common purpose, but retain primary allegiance to their individual pursuits and interests. Unlike capacity building at the organizational level where the focus is on intra-organizational issues (Goodman, Steckler, & Alciati, 1997), capacity building at the community level is primarily concerned with building interorganizational linkages and promoting harmony (Kegler, Steckler, McLeroy, & Malek, 1998). For partnerships to operate successfully at the community level, they must, for the common good, overcome the centrifugal forces that propel members to self-interest. Partnerships that successfully overcome individualistic or divisive tendencies may be considered competent in addressing community issues of common concern. To be competent, a community partnership must have certain capacities to operate effectively.

Capacity and competence can be distinguished as a potential versus an active state. Capacity reflects a community's potential for addressing pressing health issues, whereas competence signifies how well capacity is applied. Many of the elements that signify organizational effectiveness also are attributes of community capacity and competence. According to a recent symposium convened by the Division of Chronic Disease Control and Community Intervention of the CDC, capacity consists of at least the following characteristics: participation and leadership, skills, resources, social and interorganizational networks, sense of community, community power, community values, and critical reflection (Goodman et al., 1997). The competent community not only has capacity in each of these areas, but is also able to apply each with confidence.

Participation and Leadership. Participation and leadership are two important and related dimensions of community capacity. As previously noted, organizational effectiveness is enhanced by active citizen participation. Leaders encourage participation by mobilizing citizen action forming what Steuart (1985) called a "unit of solution." Participation is basic to capacity because involvement of individual community members in local events must occur if capacity is to develop. Competence, on the other hand, is characteristic of how effectively citizen action is employed. Similarly, capacity is reflected in the emergence of leaders who form the core group of a partnership. The leadership is responsible for assuring cohesion among partnership members. The literature suggests that competent leadership is a reflection of effective leadership and decision-making style (Knoke & Wood, 1981; Mayer & Blake, 1981; R. B. Warren & D. I. Warren, 1977).

Skills. One virtue of partnerships is that members bring different skills to the partnership that results in synergy among the partnership's constituents. The diverse skills that members bring are a reflection of capacity. The integrated application of skills reflects competence. As in CINCH, different members may have skills in planning community events, lobbying, and gaining media attention. But, unless community members are competent in combining these skills into effective action, the capabilities of members are not joined in a competent manner. In rendering a skill base into competent community action, partnership members must recognize the political arena in which the community must operate, coordinate member action, and assess how best to apply skills for maximum political effect.

Resources. Members of community partnerships also bring an assortment of complementary resources. These resources may be office and meeting space, equipment and supplies, property, money, knowledge, or skills and abilities. Such resources represent capacity for enhancing the partnership's operations. Competence is reflected in the application of the resources to effective community action. For instance, the CINCH partnership was interested in a community initiative to combat underimmunization. The resources necessary included a range of organizations that not only could provide in-kind support such as meeting space, but also could combine their resources in an effective manner. Often organizations must overcome turf issues for the actual coordination of effective community action. When resources are plentiful, but their coordination by a partnership is inadequate, then the community evidences capacity without competence.

Social and Interorganizational Networks. Having extensive social and interorganizational networks can enhance community capacity to address health concerns. In evaluating a community's social networks, structural characteristics, such as size or number of linkages can be considered to reflect a community's potential to act in concert. Network competence is demonstrated through the quality of interactions among network connections such as the frequency and intensity of contacts, and the benefits that members receive from their network ties, such as emotional or tangible support and access to social contacts (Israel, 1982). Without effective interaction, networks are like telephone lines that are connected nationwide (capacity), but produce many busy signals, line overloads, and static (competence). Therefore, competent partnership networks not only have capacity to extend to many organizations and individuals in a community, but also assure that the interactions are mutually supportive and synergistic. In fact, research demonstrates that the extent of regular contacts among community members can foster cooperation (Putnam, 1993).

Sense of Community. A strong sense of community—caring and sharing among the people in a community—enables collective action to address local concerns and produce desired changes (Iscoe, 1974; Newbrough & Chavis, 1986). A strong sense of community represents capacity.

When sense of community results in active relationships characterized by respect, generosity, and service to others, then community connectedness is competently used (McMillan & Chavis, 1986). Members of a competent community develop more than a sense of connection to community, but use community affiliation as a means of connecting with other community members to form active partnerships for community development. The ability to extend sense of community from one issue to another may also reflect on its competence. For example, a partnership like CINCH that forms to promote childhood immunizations may develop competent strategies to that end, but may or may not be competent in extending the partnership's activities to reduce infant mortality.

Community Power. When a strong sense of community develops, capacity exists and the community is predisposed to form partnerships around issues of shared concern. Where leaders and members are skillful in using resources, then community capacity is competently employed to increase its base of power and influence. Community power may be defined as the ability to create or resist change that matters to people who share common turf, interests, or experiences. Power is energy, and like energy may be potential (capacity) or actual (competence). A partnership by its nature forms a critical mass of members who together are able to influence change in ways that individual members alone cannot. Thus, the partnership represents potential power and has capacity to influence community direction. The way in which the partnership wields its power potential is a characteristic of competence. The term *win-lose relationships* characterizes power as limited and as a basis for control over others (Deutsch, 1973). By contrast, *win-win relationships* characterizes power as less limited and based on mutual respect, generosity, and service to others (Wallerstein, 1992). In the ideal, competent partnership action achieves win-win results. However, this is not always possible. For instance, if confronted by a turf battle with competing immunization service providers, win-lose relationships are a likely result. A partnership that can turn such confrontations into win-win situations—say, the ability to influence hospitals to collaborate in supporting a community-wide immunization awareness project—demonstrates competence in the wielding of power.

Community Values. Community capacity is not a value-free or objective term, but embodies expectations of norms, standards, and desired attributes. Community initiatives are embedded in the life and meaning of particular communities. Thus, a partnership that can articulate its core values develops capacity to act on what it believes. The way communities develop consensus about their values is an issue of competence. Community partnerships often reflect a range of values that exist in a community, creating the possibility of sharp conflicts on basic values that influence community health, such as the right of parents to home school their children and not immunize them. Diversity of values can enrich a community partnership, thus building its capacity. But diversity also may lead to conflict among the different cultural, ra-

cial, and social groups. The ability of community partnerships to reach a value consensus in implementing its initiatives is a sign of competence. This is especially critical in community coalitions, which have multiple points of view from which to draw an organizational base.

Critical Reflection. The ability of a community partnership to reach consensus around values is predicated on its capacity to engage in critical reflection, to reflect on the assumptions underlying community ideas and actions, and to contemplate alternative ways of thinking and living (Brookfield, 1987). Critical reflection includes the ability to reason logically and scrutinize arguments for ambiguity (Ennis, 1962). The ability to reason logically is a first step. The second is to put forth logical reflection so that community members gain an understanding of forces in their environment to enable them to act to promote both individual and social changes (Israel, Checkoway, Schulz, & Zimmerman, 1994; Wallerstein & Bernstein, 1994). The translation of reflection to reasoned action reflects the partnership's movement from the capacity to reflect to competently applying the lessons learned from introspection. A notable example of this process is *conscientization*, a term coined by Freire. People make the connections between themselves and the broader social context: when they reflect on their own roles in society, when they understand the history and conditions of a social problem, and when they believe they can participate in collective change (Freire, 1970). The ability, willingness, and belief in critical reflection represents a partnership's potential or capacity to act out of introspection. Capacity translates to competence when critical reflection is transformed into action based on insight. The involvement of CINCH members in training other coalition members at the Institute clearly illustrates that they have developed competency in critical reflection. By defining the challenges they faced in immunizing their children and developing innovative ways to address them, members transformed the way they related to health and human service institutions.

CONCLUSIONS

CINCH is a sustainable partnership that improved quality of life through education, advocacy, and empowerment. Throughout the project, members experienced the coalition as a unique opportunity for participation, organizational growth, and leadership. CINCH provided a positive group experience and exemplified the capacity of citizens and institutions to create dynamic, broad-based competent partnerships. This coalition model is generalizable to any locale where citizens seek to solve problems by drawing on their strengths. Promoting public health through coalitions is a community development approach that makes positive outcomes feasible.

The Effects of Physical Activity on Physical and Psychological Health

Orandum est sit ut mens sana in corpore sano
(Our prayer is for a healthy mind in a healthy body)
—Juvenal (60–130 AD)

The concept of a body–mind connection has survived since its origination with the early Greek philosophers. Although few people even today would disagree with the sentiments expressed in the aforementioned quotation, it is apparent that both physical and mental health in the United States are at suboptimal levels as physical effort becomes less and less a necessary requisite for everyday living. Today the majority of the U.S. population is essentially sedentary, reporting little or no exercise of even low to moderate intensity (Centers for Disease Control and Prevention, 1991). The links between such inactivity and the incidence of coronary heart disease (CHD), as well as other chronic disease states, have been well established with both epidemiological and clinical studies (Bouchard, Shephard, & Stephens, 1994; Bouchard, Shephard, Stephens, Sutton, & McPherson, 1990). Impaired psychological health is also a pandemic problem in the United States, with an estimated 8 to 20 million people (3%–8% of the population) suffering from an affective or depressive disorder (D. R. Brown, 1990; Hatfield & Landers, 1987). As many as 25% of the U.S. population suffer from mild to moderate depression, anxiety and/or other indicators

of emotional disorders (President’s Commission on Mental Health, 1978). These figures have been represented as “the tip of the iceberg,” because the majority of individuals with such conditions rarely seek treatment (D. R. Brown, 1990, p. 607). Additionally, more than 40% of the adult population are reported as experiencing adverse health effects from stress (U.S. Department of Health and Human Services, 1991).

The financial and social costs of such levels of physical and psychological ill health are now beginning to be addressed (Shephard, 1990) and are considerable, albeit complex and extremely difficult to quantify. Although no costs specifically attributed to physical inactivity have been published, Klarman (1964) estimated that the direct costs to the U.S. economy from all forms of cardiovascular disease in 1962 was \$3.1 billion, with a further sum of from \$3 to \$5 billion estimated for secondary costs such as loss of production, pain, and family distress. Considering that physical inactivity has been shown to be an independent risk factor for coronary heart disease (National Institutes of Health, 1995), and no more than 25% of the population meets the current physical activity–cardiovascular health recommendations (Haskell, 1995), a substantial portion

of the Klarman (1964) costs could logically be attributed to physical inactivity. In 1980 the cost of mental health care in the United States was estimated at between \$19.4 and \$24 billion (C. A. Taube & Barrett, 1986). A decade later, this figure had escalated to approximately \$148 billion per year with about half of these costs represented by nonsevere levels of mental/emotional disorders like depression and anxiety (National Advisory Mental Health Council, 1993).

The aerobics and running boom of the 1970s and 1980s brought the health benefits of exercise into high profile, and today an increasing amount of available scientific information has been accompanied by an ever-growing media focus on the desirability of physical activity and exercise from fitness and health perspectives. Despite this attention and the apparent public acceptance of the mental and physical benefits of exercise, only a relatively small percentage of the population is reported to be active on a regular basis (Caspersen & Merritt, 1992; Merritt & Caspersen, 1992; U.S. Department of Health and Human Services, 1991).

This chapter begins by reviewing the role of physical activity in a number of important physical and psychological health outcomes. The physical health outcomes discussed focus on cardiovascular disease morbidity and mortality, cardiovascular risk factors, and cancer. The psychological health outcomes discussed focus predominantly on depression, anxiety, and physiological "reactivity," that is, the psychobiological responses to acute and chronic stressful challenges. It also briefly reviews a number of putative mechanisms for such responses. Finally, it concludes with an overview of the rationale behind newly issued recommendations for physical activity and health, their implications for physical activity participation and adherence, and the unique challenges in terms of interpretation and implementation. Given the increasing concern for the high economic and health costs of physical inactivity, it is critical to examine how the more recent inclusive emphasis on diverse types of physical activity could be expected to affect the determinants of long-term physical activity participation, as well as the design of future clinical and community-level physical activity programs.

DEFINITION OF TERMS

With the increasing attention and investigation of its health benefits, there has been a gradual shifting of emphasis toward behaviorally oriented definitions of physical activity rather than defining such activity solely in terms of work performed or force produced (Knutsson, Lewenhaupt-Olsson, & Thorsen, 1973). This view of physical activity as a behavior has necessitated the development of new terms, or the revision of existing ones (Haskell, 1994b). This chapter focuses predominantly on the following behaviorally oriented terms.

Physical Activity

This is defined as any bodily movement produced by the contraction of skeletal muscle that increases energy expenditure above the basal level (Caspersen, Powell, & Christenson, 1985; Surgeon General's Report, 1996)

Exercise

Although the term *exercise* has been used synonymously with *physical activity*, it is more accurately categorized as a subset of physical activity, and defined as activity that is planned structured, repetitive, and purposeful with the objective of improving one or more aspects of physical fitness (Caspersen et al., 1985; Surgeon General's Report, 1996).

Fitness

This has been defined as a set of attributes (or "components") that people have or are able to achieve, relating to their ability to perform physical work (Caspersen et al., 1985). In behavioral terms, this can be defined as the ability to carry out daily tasks with vigor and alertness without undue fatigue, and with ample energy to enjoy leisure time pursuits and to meet unforeseen challenges. The components of fitness are considered to be cardiorespiratory endurance (often termed *aerobic fitness*), muscular strength, muscular endurance, muscular power, speed, flexibility, agility, balance, reaction time, and body composition. The definition of fitness has been further subdivided to differentiate those components considered to contribute more to health versus those considered to contribute more to skill or performance (Corbin & Lindsey, 1993).

Health-Related Fitness. This consists of cardiovascular fitness, muscular strength, muscular endurance, flexibility, and body composition.

Performance (or Skill) Related Fitness. This consists of speed, power, agility, balance, and reaction time.

Aerobic Fitness. This term is considered separately here because it is used in many studies as a measure of exercise capacity or exercise training. Aerobic fitness is defined by the body's capacity to take in, transport, and utilize oxygen, and is most accurately measured during a graded exercise test on a treadmill or stationary cycle. The amount of oxygen (O₂) a person's body uses ("takes up") is referred to as "oxygen uptake" and is commonly expressed as "VO₂" (volume of oxygen). The amount of oxygen able to be taken up by an individual at maximum effort (i.e., during a graded exercise test) is referred to as "maximum oxygen uptake" and is expressed as "VO_{2max}." This is generally accepted as the best measure of the functional limit of the cardiovascular system and is regarded as the gold standard index of cardiorespiratory fitness.

Psychological Health

This term, which has also been used synonymously with "mental health," has had a wide interpretation in the literature. Indeed, the diversity of definitions prompted one reviewer to note that psychological health was defined as "whatever an investigator has identified as being the psychological dependent measure in his/her investigation" (McAuley & Rudolph, 1995,

p. 69). The space limitations imposed by this chapter preclude a comprehensive coverage of such wide-ranging operational definitions. This review addresses the constructs most commonly investigated and focuses primarily on the amelioration of negative aspects of mental health such as depression, anxiety, and psychophysiological responses (i.e., stress reactivity).

PHYSICAL ACTIVITY AND PHYSICAL HEALTH

Physical Activity and All-Cause and Cause-Specific Mortality

Substantial data now exist demonstrating that higher levels of physical activity (Berlin & Colditz, 1990; Leon, Connett, Jacobs, & Rauramaa, 1987; Morris, Clayton, Everitt, Semmence, & Burgess, 1990; Paffenbarger, Hyde, Wing, & Hsieh, 1986; Powell, Thompson, Caspersen, & Ford, 1987; Shaper & Wannamethee, 1991) and endurance fitness (Blair et al., 1989; Ekelund et al., 1988; Sandvik et al., 1993) are significantly associated with reduced all-cause and selected cause-specific mortality rates, and with some increase in life expectancy (Paffenbarger et al., 1986; Pekkanen et al., 1987). Unfortunately, due to logistical constraints, no randomized clinical trial of adequate size or duration has been conducted to test the causality of this hypothesis, but the results of many observational studies are consistent with the interpretation that a more physically active lifestyle independently contributes to reduced mortality and increased longevity (Blair, Kohl, Gordon, & Paffenbarger, 1992; Powell et al., 1987).

It appears that if middle-aged men have been habitually active or become active, then they are more likely to reach old age than if they remain sedentary (Paffenbarger et al., 1993; Pekkanen et al., 1987). Men from age 35 to 39 who are assumed to have sedentary jobs, but who expend more than 2,000 kcal per week during leisure time (achievable with regular moderate intensity activity), have a life expectancy 2.51 years longer than similar men who expend less than 500 kcal per week (Paffenbarger et al., 1986). At age 55 to 59, this difference decreased to 2.02 years, and at age 65 to 69, there was a decrease to 1.35 years. Given that the average life expectancy of American men at age 65 was approximately 15.1 years in 1990 (National Center for Health Statistics, 1993), the more physically active man at age 65 would appear to have increased his life expectancy by approximately 9% over his sedentary counterpart. The data from Paffenbarger and colleagues are similar to those reported for Finnish men living in rural areas (Pekkanen et al., 1987). In that study, the adjusted gain in life expectancy for middle-aged men with high levels of physical activity was 2.1 years.

Other studies of men tend to support these results of increased longevity for more active persons together with significantly lower age-specific or age-adjusted all-cause mortality rates for more active versus sedentary men (Leon et al., 1987; Morris et al., 1990; Shaper & Wannamethee, 1991). The increased longevity attributed to a more physically active lifestyle is likely caused by the effect of physical activity on

reducing mortality due to coronary artery disease (Berlin & Colditz, 1990; Lakka et al., 1994; Powell, Thompson, Caspersen, & Ford, 1987) and Type II diabetes mellitus (Manson et al., 1992). Other possible contributors to a lower mortality rate, particularly in older physically active persons, include a reduced incidence of stroke (Wannamethee & Shaper, 1992), hypertension (Reaven, Barrett-Connor, & Edelstein, 1991) and some forms of cancers (Kohl, LaPorte, & Blair, 1988). Very few data are available on sufficiently large samples of women to address the issue of increased longevity as a result of increased physical activity or physical fitness, but the evidence shows lower all-cause and cause-specific mortality rates for more physically active and fit younger and older women and is consistent with data reported for men (Blair et al., 1989).

Physical Activity and Cardiovascular Disease

Studies examining the relation between physical activity and cardiovascular disease have been thoroughly reviewed (Powell et al., 1987). Consisting primarily of large epidemiological studies, this review carefully identified methodologically sound studies such as those that excluded people at baseline who could have been inactive due to the presence of subclinical disease. The review reported a consistent inverse association between physical activity and incidence of CHD, particularly in studies with stronger methodological designs. More recent reviews (Berlin & Colditz, 1990; Blair, 1994) have supported these findings and recent position statements (Fletcher et al., 1992; Pate et al., 1995) have stated that physical inactivity is now considered to be an independent risk factor for the development of cardiovascular disease.

The *physical activity–health paradigm*, with its emphasis on moderate physical activity levels, was developed principally from the qualitative examination of these large scale epidemiological studies (Haskell, 1994b; Pate et al., 1995). Although a quantitative examination of this literature has been published (Berlin & Colditz, 1990), the authors of this meta-analysis did not report relative risk statistics between sedentary and moderately active people, the comparison critical to the physical activity–health paradigm. The majority of these studies have demonstrated that highly active or fit people are at lower disease risk than sedentary or moderately active or fit people (Ekelund et al., 1988; Morris et al., 1990; Sandvik et al., 1993), whereas other studies have shown that highly active or fit people are at similar levels of risk to those who are moderately active or fit (Blair et al., 1989; Leon et al., 1987). However, across almost all the studies, those people who are at least moderately active are at lower risk for cardiovascular disease than people who are sedentary or inactive.

Coronary Heart Disease Morbidity

There are substantially more data linking physical activity or physical fitness to all-cause and CHD-related mortality than to the prevalence of morbidity due to most diseases in

younger or older persons. For example, in the past there has not been good documentation that a high level of physical activity reduces the incidence of nonfatal manifestations of CHD, including nonfatal myocardial infarction and angina pectoris. In several studies where higher levels of activity are associated with lower CHD mortality, there was no association between activity status and nonfatal manifestations of CHD (Morris, Heady, Raffle, Roberts, & Parks, 1953; Shapiro et al., 1969). Recently Lakka and colleagues (1994) reported an inverse relation between both level of physical activity and maximal oxygen uptake and acute myocardial infarction. Data are not reported separately for nonfatal and fatal events, probably because there were only 42 myocardial infarctions over 4.9 years of follow-up in 1,166 men free of CHD at baseline. The apparent difference in the association between physical activity and CHD mortality versus morbidity could be due to true biological differences in acquiring the disease as compared to dying from it, or to the known difficulty of collecting accurate morbidity data for many chronic diseases, including CHD, in population-based studies.

Data from secondary prevention or cardiac rehabilitation studies support the possibility that physical activity may be more associated with risk of dying from CHD than with nonfatal clinical manifestations. In a meta-analysis of the effects of exercise-based cardiac rehabilitation programs on cardiac morbidity and mortality, there was a 25% lower CHD mortality rate in the rehabilitation program participants but a somewhat (nonsignificant) higher prevalence of nonfatal myocardial infarction and angina pectoris (Oldridge, Guyatt, Fisher, & Rimm, 1988). Similar results evaluating a larger number of exercise-based rehabilitation programs were reported by O'Conner, Boving, and Yusuf (1989). Also, autopsy studies have observed no difference in the magnitude of coronary atherosclerosis in men who were classified as inactive or active by their major occupation, but there was less myocardial damage in the more active men (Morris & Crawford, 1958). Physical activity could reduce CHD mortality without affecting morbidity by favorably altering the "triggering event" for acute myocardial infarction or cardiac arrest. Recent data indicate that the primary triggering event for many myocardial infarctions is the acute rupture of atherosclerotic lesions and the rapid closure of the artery lumen due to platelet aggregation and cell proliferation (Fuster, L. Badimon, J. J. Badimon, & Chesebro, 1992). It could be that physical activity reduces either the risk of lesion rupture, platelet aggregation, or cell proliferation, thus reducing CHD mortality but not the development of atherosclerosis, which may be more related to the development of nonfatal clinical manifestations of myocardial ischemia.

Although the epidemiological evidence just reviewed is supportive of the importance of physical activity on CHD, the independent role of physical activity as a cardiovascular disease risk factor currently remains understudied in comparison to other CHD risk factors, such as hypertension or smoking. A timely issue in the area of physical activity (as well as for other risk factors) is the need for more studies examining populations other than White, middle-class males.

Physical Activity and Cardiovascular Disease Risk Factors

No randomized controlled studies of adequate methodological design have yet evaluated the effects of increasing physical activity or fitness on the primary prevention of cardiovascular disease (Haskell, 1995). However, a substantial amount of data reports positive effects on physical activity on the more intermediate endpoints of risk factors for cardiovascular disease.

Hypertension Hypertension has been identified as an independent risk factor for cardiovascular disease (Caspersen & Heath, 1993; Fries, 1976; Gordon, Sorlie, & Kannel, 1976; M. L. Pollock & Wilmore, 1990). Based on a considerable number of well controlled studies, the American College of Sports Medicine (ACSM) recently issued a position statement concerning the potential benefits of physical activity for primary prevention and treatment of hypertension (ACSM, 1993). Conclusions regarding the benefit of physical activity for primary prevention were based on evidence from both animal studies and large scale epidemiological studies, and generally supported the hypothesis that participation in endurance exercise training reduced risk of hypertension. For instance, the incidence of hypertension in male Harvard alumni who engaged in vigorous sports was 35% lower over a 6 to 10 year follow-up period as compared to inactive men (Paffenbarger et al., 1993). Similarly, the incidence of hypertension in physically fit men and women at the Cooper Institute for Aerobics Research in Dallas was 52% lower during a 4-year follow-up period as compared to unfit men and women (Blair, Goodyear, Gibbons, & Cooper, 1984).

Although it appears that vigorous physical activity is associated with lower incidence of hypertension, evidence that the types of activities espoused in the physical activity-health paradigm (i.e., moderate intensity physical activity) are associated with lower incidence is still evolving. Data from a large scale epidemiological study of University of Pennsylvania alumni demonstrated that although the incidence of hypertension was lower for individuals who had engaged in vigorous sports after college, the incidence was not lower for individuals who engaged in light to moderate activity after college (Paffenbarger, Jung, Leung, & Hyde, 1991). However, recent data from experimental studies using rats genetically predisposed to hypertension support the importance of moderate intensity exercise. Specifically, these studies demonstrated that animals trained at moderate intensity exercise had lower blood pressures than untrained animals (Tipton, 1991), whereas animals trained at vigorous intensity exercise had similar (and high) blood pressures relative to untrained animals (Tipton, Sebastian, Overton, Woodman, & Williams, 1983; Tomanek, Gisolfi, Bauer, & Palmer, 1988). In these studies, moderate intensity exercise training attenuated an age-related increase in blood pressure rather than actually reducing blood pressure below initial levels (Tipton, 1991). If these experimental results using rats predisposed to hypertension are found to generalize to humans, then the attenuation of an age-related increase in blood pres-

sure would still result in a lower incidence of hypertension. In support of this, a comprehensive review of the effects of endurance exercise training on blood pressure (Fagard & Tipton, 1994) found that hypertensive patients participating in endurance exercise training generally experienced a reduction in systolic and diastolic blood pressure of approximately 9 mm Hg. Borderline hypertensive patients and normotensive persons generally experienced a 6 mm Hg and 3 mm Hg reduction in systolic and diastolic pressures, respectively (Fagard & Tipton, 1994). This magnitude of blood pressure reduction in response to endurance exercise training has also been reported for men and women age 60 and older in some (Coconie et al., 1991; Hagberg, Montain, Martin, & Ehsani, 1989), although not all (Blumenthal, Siegel, & Appelbaum, 1991), randomized clinical trials.

Although the human and animal data are initially compelling, as with the literature examining physical activity and cardiovascular disease morbidity and mortality, more studies examining the primary prevention benefits of moderate as well as more vigorous physical activity for lowering blood pressure are needed with populations of women, ethnic groups other than non-Hispanic Whites, and a range of age groups.

Physical Activity and Other Chronic Diseases

Although the leading cause of death in the United States remains cardiovascular disease, age-adjusted death rates from CHD have been decreasing, whereas those of certain forms of cancer have been increasing (Lee, 1994). A growing literature suggests a strong inverse relation between physical activity and overall cancer mortality rates. However, because types of cancer (e.g., breast, colon) are thought to have different origins and biological mechanisms (Sternfield, 1992), site specific cancer in women and men is reviewed.

Breast Cancer. It has been reported that vigorous, or even moderate, physical training can interrupt the menstrual cycle and may inhibit carcinogenesis in the breast secondary to the reduction of cumulative exposure to estrogen and progesterone (Thune, Brenn, Lund, & Gaard, 1997). Research in this area has been equivocal, however, with studies reporting both positive (Frisch, Wyshak, Albright, Schiff, & Jones, 1985; Thune et al., 1997), negative (Dorgan et al., 1994), and no associations (Paffenbarger, Hyde, & Wing, 1987) between physical activity and cancer. Frisch et al. (1985) first reported a lower prevalence of breast cancer among former college athletes as compared to nonathletes in a cohort of more than 5,000 living alumni. Thune et al. (1997) reported that greater leisure time activity was associated with reduced risk of breast cancer after adjustment for age, body mass index, height, parity, and country of residence. In regularly exercising women, the risk was found to be lower in premenopausal and younger women, and with higher levels of occupational physical activity. In contrast to this, Paffenbarger, Hyde, and Wing (1987) did not find any association of breast cancer with participation in sports during early college years. Although a nonsignificant inverse trend for self-reported physical activity and postmenopausal breast cancer was reported

by Albanes and colleagues for participants of the First National Health and Nutrition Examination Survey (Albanes, Blair, & P. R. Taylor, 1989), this same study also reported a suggested increased risk of premenopausal breast cancer in more active women. This latter finding was also reported by Dorgan et al. in the Framingham Heart Study (Dorgan et al., 1994). The authors found an increasing gradient of risk for breast cancer with increasing physical activity. Gammon et al. recently conducted a critical review of the physical activity and breast cancer risk literature (Gammon, John, & Britton, 1998). Evaluating each study for coherence, validity, and bias, the authors reported that the majority of epidemiological studies suggested that higher occupational and leisure time physical activity may be associated with a reduced risk of breast cancer, with the latter reporting a range of from 12% to 60% reduction in risk. The data were not sufficient to establish any dose-response relations or any critical effects of frequency, intensity, or duration. However, most of the reported physical activity was at least of moderate intensity. To further elucidate the role of physical activity, future studies should focus on more prospective or retrospective cohort designs and utilize more reliable methods of physical activity assessment.

Colon Cancer. Consistent relations have also been found between levels of occupational physical activity and lower incidence of colon cancer (Sternfield, 1992). The few epidemiological studies that have examined recreational physical activity have primarily assessed only exercise-related behaviors (e.g., hiking, sports, etc.), making it difficult to determine whether the more inclusive types of activities currently recommended (i.e., diverse types of moderate intensity activities of daily living, household chores, etc.) are associated with a lower incidence of colon cancer. For instance, assessment tools used in such research have often included a one-item closed response question about the amount of exercise for recreation (Albanes et al., 1989) or the amount of time per day spent in more vigorous physical activities such as swimming, biking, or dancing (Wu, Paganini-Hill, Ross, & Henderson, 1987). One study that measured a full range of activities (e.g., stair climbing, city blocks walked, and active sports) demonstrated that Harvard alumni who engaged in moderate (1,000–2,500 kcals) and high (> 2,500 kcals) levels of activity at two timepoints after college were at lower risk for developing colon cancer (Lee, Paffenbarger, & Hsieh, 1991). Men who only engaged in those levels of activity at one timepoint were not at lower risk. Clearly, the development of appropriate physical activity assessment tools is a critical priority for future research across disease outcomes. Indeed, future tools will need to assess the types of moderate-intensity physical activities that are routine in many women's lives, such as child care and household tasks (King & Kiernan, 1997).

PHYSICAL ACTIVITY AND PSYCHOLOGICAL HEALTH

Psychological, or mental, health is a multifaceted condition made up of both positive and negative dimensions. However,

in a situation comparable to early views of health as simply the absence of disease, the majority of studies investigating the effects of physical activity on psychological function have generally represented mental health in terms of the absence, or reduction, of negative affect. This section reviews the existing literature on the role of physical activity in the prevention or reduction of negative affect (depression, anxiety, and physiologic reactivity).

Caplan (1964) operationalized the preventative aspects of physical activity as either (a) *primary prevention*: Can physical activity protect against the onset of mental health problems "by counteracting harmful circumstances before they have a chance to produce illness?" (Caplan, 1964, p. 23); (b) *secondary prevention*: Can physical activity improve or prevent the worsening of mild to moderate symptoms of mental health problems before they have a chance to turn into those requiring tertiary intervention?; and (c) *tertiary prevention*: Can physical activity serve as a treatment for already existing clinical mental health problems. The following sections briefly review the literature on these three aspects of prevention with regard specifically to depression and anxiety.

PHYSICAL ACTIVITY AND DEPRESSION

Clinical depression affects from 2% to 5% of the U.S. population per year (Kessler et al., 1994), and makes up approximately 6% to 8% of general medical practices (Katon & Schulberg, 1992). This situation, in conjunction with drug therapy that has been the treatment of choice for depressive symptoms, has significant financial implications for individual and national health care costs. Depressed individuals typically spend 1.5 times more on health care costs than nondepressed individuals and, if undergoing drug therapy, spend up to 3 times more on outpatient pharmacy costs than non-drug-treated individuals (Simon, VonKorff, & Barlow, 1995). There has been recent attention on exercise as an alternative therapy to more traditional drug treatments (Martinsen, 1990; Surgeon General's Report, 1996).

Primary Prevention

Epidemiological Studies. No longitudinal studies of adequate methodological design have yet been conducted to test the hypothesis that physical activity protects against the onset of depression, but associations between these two variables may be investigated by examining evidence from epidemiological studies. These consistently report that physical activity is associated with reduced symptoms of depression. Stephens (1988) carried out an extensive analysis of data from four large databases, two from the United States (i.e., the National Survey of Personal Health Practices and Consequences and the National Health and Nutrition Examination Survey) and two from Canada (i.e., the Canadian Health Survey and the Canadian Fitness Survey). Stephens found that physical activity was positively associated with general well-being, lower levels of anxiety and depression, and positive mood. This relation was particularly strong for women and persons over age 40. The results of the Stephens (1988) study were generally

consistent across all four populations and were considered to be very robust due to the diverse nature of the four study populations, the time over which such measures were taken (10 years), and the fact that four different measures of physical activity and six different mental health constructs were employed. Other epidemiological studies have reported similar reductions in depressive symptoms (J. D. Brown & Lawton, 1986; Camacho, Roberts, Lazarus, Kaplan, & R. D. Cohen, 1991; Farmer, Locke, Moscicki, Dannenberg, Larson, & Radloff, 1988; Fredrick, Frerichs, & Clark, 1988; Lobstein, Mosbacher, & Ismail, 1983; Paffenbarger, Lee, & Leung, 1994; Ross & Hayes, 1988; Stephens & Craig, 1990), although only two of these (Camacho et al., 1991; Farmer et al., 1988) are prospective in nature.

Farmer et al. (1988), using data from the National Health and Nutrition Examination Survey, found that baseline recreational activity was an independent predictor of depression at 8-year follow-up in White women, but not White men, who were not depressed at baseline. This relation persisted after adjustment for age, chronic conditions, education, employment, income, and length of follow-up. Similar results were found by Camacho et al. (1991) in a prospective study using data from the Alameda County Study. Among subjects who were not depressed at baseline, those who reported low physical activity levels at the 1974 follow-up were at significantly greater risk (OR = 4.32, 95% CI 3.17–5.62) for depressive symptoms than those who reported high physical activity (OR = 1). This relation changed little after adjustment for a number of covariates (i.e., physical health, socioeconomic status, life events, social support, and other health habits). The authors also found that increases in physical activity levels between baseline and 1974 significantly reduced the incidence of subsequent depressive symptoms in the 1983 follow-up, although this significance was not retained following adjustment for the covariates listed previously. The greatest change in adjusted odds ratio occurred when going from high to low activity. The prospective nature of these two latter studies provide somewhat stronger evidence for an activity–depression association than do the cross-sectional studies cited earlier.

Only one study could be found that investigated, a priori the preventative effects of physical activity on depression. In a longitudinal study, Gotestam and Stiles (1990) examined Norwegian soldiers exposed to a highly stressful life situation. Those who were actively engaged in sports were significantly less depressed 12 weeks after exposure to the stressful situation as compared to those who were inactive.

Secondary and Tertiary Prevention

Intervention Studies. Although exercise is generally believed to make you "feel good," the scientific evidence in support of a causal role for exercise remains somewhat speculative. Despite the fact that the mental health and exercise literature has been noted to be "voluminous" (Sime, 1987), it has been described by at least two major authorities as lacking in reliable, sound research methods (D. R. Brown, 1990; Morgan, 1994). A number of literature reviews on exercise and depression already exist in both narrative (Dunn & Dishman,

1991; Martinsen, 1990; Morgan, 1994; Raglin, 1990; C. B. Taylor, Sallis, & Needle, 1985) and meta-analysis (Kugler, Seelback, & Kruskemper, 1994; McDonald & Hodgdon, 1991; North, McCullagh, & Tran, 1990) formats. In general, the majority of these reviews found that exercise exerted a positive effect on depression in both clinical and nonclinical populations. The existing reviews on physical activity and depression have reiterated the methodological shortcomings of this particular body of literature. These have included the use of inadequate sample sizes; lack of random assignment to groups; an absence of placebo or control groups; and use of nonblinded methodological designs (D. R. Brown, 1990). Morgan (1994), in a comprehensive and explicit critique of methodological shortcomings in the physical activity and depression literature, called for scientists to pay much closer attention to design issues in order to avoid what he termed the "Garbage in Garbage out" syndrome (p. 861).

Although early studies of physical activity and depression focused almost exclusively on clinical populations (Morgan, 1969), the more recent literature has reported intervention studies investigating the preventative effects of physical activity not only in the clinically depressed, but in nonclinical symptomatic as well as healthy populations. The physical activity intervention has usually consisted of different forms of aerobic exercise, with a much smaller number utilizing anaerobic programs principally of strength training. The majority of such studies have been, with few exceptions (King, C. B. Taylor, & Haskell, 1993), of relatively short duration (6–12 weeks). These studies have generally reported positive results in groups with diagnosed clinical depression and those with depressive symptoms (D. R. Brown, 1990; Morgan, 1994; Tables 38.1 and 38.2). The principal self-report instrument used in such studies was the Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961). Healthy populations have been the least studied, and although early studies reported equivocal results, more recent studies have generally reported little or no effect of physical activity on depression or depressive symptoms (Table 38.3).

Time Series Studies. One of the earliest scientific studies to investigate the effects of physical activity on depression in noninstitutionalized healthy individuals was conducted by Morgan, Roberts, Brand, and Feinerman (1970). In this quasi-experimental study, 140 men from age 22 to 62 volunteered to participate in one of eight physical activity groups of running, swimming, cycling, or circuit training at an intensity of approximately 85% of predicted maximal heart rate for 2 to 3 days per week for 6 weeks. Depression was measured by the Zung Depression Scale (Zung, 1965). Mean baseline scores for all groups were within the normal range for this scale and were unchanged after the intervention. However, a subgroup of 11 of these exercisers scored above 53 on the Zung Depression Scale, indicating depressive symptoms of clinical significance (Zung, 1965). When the change scores of this subgroup were analyzed, a significant decrease in depression scores was revealed, and because these subjects were spread across all groups, this decrease appeared to be independent of mode or frequency of exercise. Although the

methodology of this study is open to criticism (no random selection or assignment to groups), it represented one of the first indications that physical activity could be effective in alleviating symptoms of mild to moderate depression, but had little effect in "normal" populations. Other early studies have used similar methodological designs in moderately and clinically depressed populations. Sime (1987) reported the positive effects of a multiple baseline time series design intervention in 15 subjects with moderately elevated scores on the Beck Depression Inventory at baseline ($M = 14.2 \pm 1.0$). Subjects were used as their own control during a graduated exercise program on a cycle ergometer conducted four times per week for 10 weeks. Significant reductions in BDI scores were found at both 6-month and 21-month follow-up. Doyne et al. (1983) also utilized a time series design in four female inpatients initially diagnosed with major depressive disorder according to the Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978) and the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978). Following a 6-week aerobic training program, significant decreases in depression, as measured by the Beck Depression Inventory and the Depressed Adjective Checklist (DACL; Lubin, 1965), were reported and maintained at 3-month follow-up.

Since that time, the use of comparative group designs has become the norm in investigating the effect of physical activity on depression. In view of the general agreement in the literature on the lack of methodological rigor of many of these studies (D. R. Brown, 1990; Morgan, 1994), the remainder of this section focuses on published studies with either a randomized or a randomized controlled design.

Randomized Studies Focusing on Aerobic Exercise.

Although the majority of reviews generally report positive effects of physical activity on depression, the number of randomized or randomized controlled trials reported in the literature is limited (Tables 38.1–38.4). Martinson, Medhus, and Sandvik (1985), in a randomized controlled trial of inpatients with major depressive disorder, randomly assigned subjects to an aerobic exercise or an occupational therapy group designated as "control." Significant postintervention differences were reported in depression scores between the aerobic exercise and occupational therapy groups. However, both groups were also reported as receiving psychotherapy during the intervention period, which calls into question the validity of the control group and somewhat blurs the independent effect of the aerobic exercise intervention. Greist, Klein, Eischens, Gurman, and Morgan (1979) randomly assigned 28 males and females diagnosed with Minor Depressive Disorder to one of three interventions (aerobic exercise, short-term psychotherapy, and long-term psychotherapy). All interventions were reported as reducing depression scores. No formal statistical analysis was presented in this study, and the randomization procedure was not strictly maintained throughout the intervention period, thus making interpretation of results difficult. Bosscher (1993) randomly assigned 24 women inpatients matched for depression scores to either a three times per week running group, or a usual care group. The authors reported significant reductions in depres-

sion scores for the running versus the usual care group. However, the usual care group consisted of mixed sports activities such as field hockey, soccer, volley ball, trampolining, and gymnastic activities—some of which also involved a major running component.

Randomized Studies Focusing on Anaerobic Exercise. The majority of studies investigating physical activity effects on depression have utilized aerobic exercise (D. R. Brown, 1990; Morgan, 1994; Surgeon General's Report, 1996) or aerobic fitness training (Folkins & Sime, 1981) as the physical activity intervention. However, the relatively few studies using nonaerobic physical activity, or comparing aerobic exercise to anaerobic exercise (Table 38.4), suggest that increases in aerobic fitness are not necessary to elicit such benefits (Doyle et al., 1987; Martinsen, Hoffart, & Solberg, 1989; Martinsen, Sandvik, & Kolbjornrud, 1989; Sexton, Maere, & Dahl, 1989; Stein & Motta, 1992). The strongest evidence to date on the beneficial effects of nonaerobic exercise was reported recently by Singh, Clements, and Fiaterone (1997). Thirty-two community living men and women subjects from age 60 to 84 and diagnosed with major or minor depressive disorder using *DSM-IV* criteria (American Psychiatric Association, 1994) were randomly allocated to either a progressive resistance training or an attention-control group. The progressive resistance group trained at 80% of a one repetition maximum (the maximum amount of weight they could lift in a single effort), three times per week for 10 weeks. The control group consisted of an interactive health education program of lectures and videos followed by discussion. Depression was measured by the Beck Depression Inventory and the Hamilton Rating Scale for Depression. Following the 10-week intervention program, depression was significantly reduced in the progressive resistance training group as compared to control. This is the first randomized controlled trial to directly compare the effects on depression of a high intensity resistance training program with a nonexercise control group.

Randomized Studies With Healthy Populations. The effect of physical activity interventions on depressive symptoms in healthy individuals who score in the normal range for depressive symptoms has also been little studied. Results from early studies were equivocal, reporting both positive effects (Berger & Owen, 1983; Blumenthal, Williams, Needles, & Wallace, 1982; Folkins, 1976) and no effect (Folkins, Lynch, & Gardner, 1972; McPherson, Paivio, Yuhasz, Rechnitzer, & Lefcoe, 1965; Morgan et al., 1970; Naughton, Bruhn, & Lategola, 1968) on depression. Such differences, however, could be attributed to the methodological shortcomings mentioned earlier (Morgan, 1994), because most of these studies employed a nonrandomized design, or lacked an appropriate control group. Recent studies in healthy populations using a randomized controlled design (Table 38.3) generally report no changes in depressive symptoms following physical activity interventions of up to 1 year.

Summary

Recent randomized and randomized, controlled clinical trials support the hypothesis that physical activity interventions of at least 8 weeks can significantly and beneficially impact depression in clinically depressed and nonclinical, symptomatic adult men and women. Longer duration and higher intensity interventions appear to be more effective than lower intensity shorter durations. The benefits of such interventions are not confined to aerobic exercise, but have also been reported for nonaerobic exercise such as high intensity running, moderate and high intensity resistance training, flexibility training, and yoga (Table 38.4). Although results of early studies investigating the effect of physical activity on depressive symptoms in healthy populations reported equivocal results, recent studies generally report that groups who score within the normal range of depression scores before a physical activity intervention will score within the normal range after intervention. Whereas the majority of reviews generally report beneficial effects of physical activity on depression, the relatively small number of randomized controlled studies published to date, and the methodological flaws present in a number of these, indicate that a causal effect of physical activity on depression, although tenable, still awaits more solid confirmatory evidence.

PHYSICAL ACTIVITY AND ANXIETY

Approximately 7.3% of the adult U.S. population suffers from an anxiety-related disorder necessitating treatment of some kind (Regier et al., 1988). High levels of stress-related emotions, including anxiety, are common even among otherwise healthy individuals (S. Cohen, Tyrell, & A. P. Smith, 1991). Anxiety is associated with a negative form of self-appraisal typified by worry, self-doubt, and apprehension (Landers & Petruzzello, 1994). Anxiety has been described by some authors (Franks, 1994, p. 3) as a form of "environmental stress" which usually arises when the physiological and psychological responses exceed the requirements of the new environment, although Landers (1998, p. 123) has stated that such a definition does not allow differentiation between healthy and unhealthy forms of stress. Anxiety is typically measured by questionnaire instruments that assess either *trait anxiety*, which is the general predisposition to respond with high levels of anxiety across many different situations, or *state anxiety*, which is the particular level of anxiety at a given moment. Although these two subcomponents of anxiety are often assessed separately (Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1983), they have been shown to possess a considerable amount of overlap (R. E. Smith, 1989).

Primary Prevention

Epidemiological Studies. As with the depression literature, no primary prevention studies have been conducted on physical activity and anxiety, although the epidemiological literature consistently reports associations between these two variables (Ross & Hayes, 1988; Stephens, 1988; Stephens & Craig, 1990). Stephens (1988), in a secondary

analysis of a large cross-sectional study of two Canadian surveys ($n = 23,791$ and $22,250$) and two U.S. surveys ($n = 3,025$ and $6,913$), reported that physical activity was associated with fewer symptoms of anxiety. Such associations, as with the depression data already reported, were strongest among women and persons age 40 or older. Ross and Hayes (1988), in a statewide telephone survey ($n = 401$), reported that adults who participated in regular exercise, sports, or other types of leisure time physical activity reported fewer symptoms of anxiety as compared to low active or inactive individuals. In contrast to the findings of Stephens (1988), these associations were similar across both age and gender.

Secondary and Tertiary Prevention

The literature reporting the effects of physical activity on anxiety is even more extensive than that of the physical activity and depression literature. Since the 1950s more than 50 reviews have been published on this topic (Gauvin & Spence, 1996). Although the great majority of these have been written in the form of a "narrative" review, in recent years this traditional format has increasingly been replaced by the "meta-analysis." This form of review enables results of different studies to be integrated (Glass, 1978) and expressed in a common unit—the "effect size" (calculated by subtracting the mean of the treatment group from the mean of the comparison group and dividing this difference by the pooled standard deviation). This allows results of studies to be combined, thus greatly increasing statistical power. In this approach a quantification of total results is also possible, providing a more objective estimate of the magnitude of an exercise treatment or intervention. Since 1991 six meta-analyses have been published in the area of exercise and anxiety (Calfas & W. C. Taylor, 1994; Kugler, Seelbach, & Kruskemper, 1994; Landers & Petruzzello, 1994; Long & van Stavel, 1995; McDonald & Hodgdon, 1991; Petruzzello, Landers, Hatfield, Kubitz, & Salazar, 1991), one of which focused exclusively on adolescents (Calfas & W. C. Taylor, 1994). In common with the depression literature, much of the research in the anxiety area has also been reported as applying relatively weak methodology that may confound the validity of the results (D. R. Brown, 1990; Gauvin & Spence, 1996), in particular that reported effects could be related to behavioral artifacts (Morgan, 1997; Raglin, 1997). Landers (1998), however, argued against this position stating that, because the effects of physical activity on anxiety reported in the meta-analytical studies are independent of both operational measures and scientific quality of study, the plausibility of this theory is severely limited.

Time Series Studies. In a similar fashion to the depression and physical activity literature, early studies on physical activity and anxiety also consisted of time series studies to investigate potential links between the two. Morgan (1986), reporting on a series of six early studies, investigated the effect of different formats of exercise on state anxiety in predominantly male groups of subjects. In the first of these studies, no anxiety-related effect was found in a group of healthy young adult men and women assigned to one of three conditions: rest, a 17-min-

ute mile at 0% treadmill grade, and a 17-minute mile at 5% treadmill grade. The authors suggested that light to moderate intensity exercise may not be sufficient to elicit any changes in state anxiety. It may also be that, in common with the depression literature, physical activity has no effect on anxiety in healthy persons who score within the normal range for state anxiety. No baseline levels of state anxiety are reported in this study. In the next two studies, the State-Trait Anxiety Inventory was administered before and after a 20- to 30-minute bout of vigorous aerobic exercise. Both studies reported significant decreases in post-exercise state anxiety. In Studies 4 and 5 in this series, adult men were asked to run and walk to exhaustion at 80% of their VO_{2max} on two separate days. State anxiety was reported as increasing during the first half of the exercise bouts, plateauing for the second half, and significantly decreasing as compared to baseline levels immediately following exercise. In the final study in this series, Bahrke and Morgan (1978) randomly assigned 75 adult males to either treadmill walking at 70% VO_{2max} , meditation using Benson's relaxation response (Benson, 1975) or quiet rest. All three groups reported a significant decrease in state anxiety and no differences were found between groups. This experiment led to the formulation of the "Time out" or "distraction" hypothesis of anxiety reduction, which is discussed in more detail later. Further support for this theory was implied in a later study (Raglin & Morgan, 1987) comparing the effects of exercise and quiet rest on the state anxiety of normotensive (Experiment 1) and pharmacologically controlled hypertensive males (Experiment 2) in two separate but linked studies. Blood pressure and state anxiety were assessed prior to and at intervals following the exercise intervention, which consisted of jogging, cycling, or a variety of sports activities. Both mode and intensity of exercise were self-selected in order to maximize ecological validity. Quiet rest consisted of a 40-minute session in a sound-proofed chamber. Blood pressure and anxiety levels were reduced in both experiments for both quiet rest and exercise, with no differences between groups. However, the authors noted qualitative differences in the pattern of response to the two interventions. The quiet rest condition led to a faster but smaller reduction in the postexercise systolic blood pressure as compared to the exercise condition. However, this effect lasted only 2 to 3 minutes following termination of the rest condition, whereas the blood pressure reductions following the exercise condition remained lower during an hourly assessment for 3 hours of follow-up.

Narrative and Meta-Analysis Reviews. Since the association between exercise and anxiety has been extensively addressed in a number of recent excellent and comprehensive reviews, this section presents an overview of these reviews and a summary and analysis of their reported results.

As indicated by results of recent randomized trials (Table 38.5), the narrative and meta-analytical reviews cited overwhelmingly conclude that physical activity and/or fitness is related to anxiety. For example, Landers and Petruzzella (1994) analyzed the results of 27 narrative reviews conducted between 1960 and 1991 and found that 81% of these studies concluded

that physical activity or fitness was related to anxiety reduction following exercise, and 19% found that most of the findings were supportive of an exercise-related reduction in anxiety. Not one of the narrative reviews concluded that there was no relationship. All six of the published meta-analyses reported positive anxiolytic effects of exercise with the magnitude of effect ranging from "small" to "moderate." This was consistent for trait and state anxiety as well as for age, gender, and the mental health status of subjects (Landers, 1998).

Although the majority of the narrative reviews conclude that exercise of higher intensities (70%–80% of VO_{2max}) is necessary to elicit anxiolytic effects, the meta-analytical reviews are not supportive of this claim. No consistent dose-response relationship has been found in these analyses; indeed, exercise at varying intensities and durations has been reported as producing similar significant reductions in anxiety following both acute and chronic exercise (Landers, 1998).

Summary

Exercise is generally reported as having a beneficial anxiolytic effect on subjects of all ages and mental health states. The greatest anxiolytic effects appear to result from aerobic rather than anaerobic exercise and when the length of the exercise training is more than 15 weeks. The law of initial values also appears to apply because subjects who have either lower levels of fitness, or higher levels of anxiety, appear to benefit the most from exercise programs. Exercise-induced reductions in anxiety appear to last between 4 to 6 hours postexercise, after which time anxiety returns to pre-exercise levels (Landers, 1997). More studies are needed to clarify dose-response relationships between intensity and duration of exercise. Current evidence is supportive of the claim that exercise, similar to other known anxiety reducing treatments such as relaxation training, has been consistently related to the relief of symptoms of anxiety.

STRESS REACTIVITY

Signs and symptoms of stress may manifest themselves through increased physiological (e.g. increased muscle tension; DeVreys, 1987), cardiovascular (Claytor, Cox, Howley, K. A. Lawler, & J. E. Lawler, 1988; Obrist, 1981), and/or biochemical (Sinyor, Schwartz, Peronnet, Brisson, & Seraganian, 1983) responses, as well as through changes in self-reported psychological stress states (Landers & Petruzzello, 1994; Morgan & Goldston, 1987; Spielberger et al., 1983). It has been pointed out by some authors that many of these physical and biochemical responses parallel those resulting from exercise (Obrist, 1981; Shulhan, Scher, & Furedy, 1986). This has led to a body of research investigating the interrelationships between physiological and psychological variables and how exercise and/or fitness may mediate such interactions. One related area of research has investigated the role of fitness in attenuating the physiological response ("reactivity") to psychosocial stressors of various kinds.

TABLE 38.5
Physical activity training effects on state and trait anxiety - Randomized studies

Author	Subjects	Diagnostic Tool	Assessment Tool	Intervention	Study Period	Result
Blumenthal et al. (1989) (RCT)	101 healthy M & F (Mean age 67 yrs)	SCL-90	STAI-S STAI-T	AE (3*wk) Yoga (2-3*wk) WLC	12 weeks	No change in ST-Anx or TR-Anx at 12 weeks or at 12- and 46-month follow-up

The reactivity literature is not extensive in comparison to that for anxiety or depression. For example, a recent meta-analysis in this area reported a total of 34 studies in a 10-year period between 1977 and 1987, only 20 of which were published articles. However, the reactivity and exercise literature is characterized by the use of a wide range and variety of psychosocial stressors and a wide range and variety of reactivity outcomes. The psychosocial stressors can be classified generally into five main categories: passive psychological stressors, such as watching a disturbing film; active psychological stressors, such as the Stroop test (Stroop, 1935) or a mental arithmetic or memory task; passive physical stressors, such as a cold pressor task; active physical stressors, such as exercise or grip strength testing; and various psychomotor tasks consisting of permutations of the first four categories (e.g., Stroop test combined with a physical response such as moving a lever). The reactivity outcomes reported have included cardiovascular (systolic blood pressure, diastolic blood pressure, and heart rate), biochemical (norepinephrine, epinephrine, endorphins), physiological (skin conductance, skin temperature, and electromyographic measures), and subjective (state and trait anxiety, mood) measures. These reactivity outcomes have been measured before, during, and after the administration of psychosocial stressors, resulting in a large number of possible permutations of dependent and independent variables. This, in combination with the lack of replication in the extant literature, makes comparisons across studies difficult. It is also probably true to say that most of the large number of reactivity responses are reported as being unaffected by exercise, although not uniformly so. This section focuses predominantly on cardiovascular and catecholamine outcomes, which are two of the most commonly reported measures in this area of research.

Cardiovascular and Catecholamine Reactivity

The "training effect" of exercise on cardiovascular and catecholamine parameters, and their concomitant benefits to physical health, are now well established (National Institutes of Health, 1995). In light of this and the cardiovascular and catecholamine responses to psychosocial stressors already mentioned, recent research has investigated whether cardiovascular fitness could also elicit a "psychological training effect," particularly because heightened cardiovascular and catecholamine reactivity to psychological stress has been linked with the development of cardiovascular disease processes (Beere, Glasgow, & Zarsins, 1984; Manuck, Kaplan, & Clarkson, 1983). Two questions follow: Is stress reactivity as measured by these two outcome variables attenuated in fit versus unfit persons? and, can the reactivity of unfit persons be attenuated following a program of regular fitness training?

Is Reactivity Attenuated in Fit Versus Unfit Persons?

Cross-sectional data on this question remain equivocal, with a number of studies reporting fitness-related effects but no effects on reactivity. Hull, Young, and Zeigler (1984), in a relatively complex study, investigated the reactivity of four

groups of subjects categorized with low, intermediate, high, and very high fitness according to their total time to voluntary exhaustion on a treadmill during a Bruce protocol. Cardiovascular reactivity was assessed during and after passive and active psychological stressors and passive and active physiological stressors. All stressors significantly increased cardiovascular responses, but there were no fitness-related differences in reactivity except for a lower diastolic blood pressure response to the viewing of the film and to the Stroop test. Although there were fitness-related differences in norepinephrine and epinephrine during the exercise stressor, there were no differences reported during the other three stressors. Claytor et al. (1988) also found no differences in either cardiovascular, catecholamine, or cold pressor test reactivity between high and low fit male college students following administration of four different psychosocial stressors. In an interesting deviation from conventional approaches to this subject, the authors reported initially screening subjects according to their heart rate reactivity to the reaction time-shock avoidance test, and subsequently assessed the VO_{2max} of the six highest and six lowest reactors. No differences in VO_{2max} were found between groups, although a significant association between reactivity and reported history of family hypertension was found. In a more recent study involving two randomly assigned groups of competitive sportsmen and inactive men, Steptoe, Kearsley, and Walters (1993) also found no fitness-related cardiovascular reactivity to a mental arithmetic and a public speaking task following either 20 minutes of exercise at high, moderate, or light intensity. This study also analyzed cardiac baroreflex sensitivity, a little reported measure of cardiovascular function. This variable was found to be much higher (i.e., more sensitive) at baseline in the active versus the inactive group, and was inhibited in both groups during the mental arithmetic task. However, as with other cardiovascular outcome measures in this study, no differences in reactivity were found between groups. Other studies have similarly reported no fitness-related differences in cardiovascular reactivity to a variety of psychosocial tasks, including easy and hard mental arithmetic tasks (Dorheim et al., 1984; Szabo, T. G. Brown, Gauvin, & Seraganian, 1993), reaction time, and cold pressor tasks (deGeus, Lorenz, & vanDoornan, 1993; Dorheim et al., 1984; Plante & Kospovitz, 1987).

In contrast to the aforementioned studies, other authors have noted fitness-related reactivity differences to particular cardiovascular and/or catecholamine outcome measures. Holmes and Roth (1985) divided 20 undergraduate females into low and high fit groups according to their estimated aerobic power following a submaximal cycle ergometer test. No catecholamine measures were taken in this study, but heart rate reactivity and subjective arousal were assessed during the administration of a mildly stressful memory task. High fit subjects evinced a smaller heart rate response to this task than low fit subjects, although there were no differences in subjective arousal. Other authors (Cantor, Zillman, & Day, 1978; J. P. Cox, Evans, & Jamieson, 1979; Light, Obrist, James, & Strogatz, 1987; Sinyor et al., 1983; VanDoornan & DeGeus, 1989) have also reported similar fitness-related differences in

heart rate reactivity, although these differences were obtained following, but not during, the application of the stressor. Claytor (1991) reported findings that suggest a fitness-related difference in cardiovascular reactivity according to the degree of familiarization to the stressor. In a series of studies comparing high versus low fit college-age males, the authors reported no differences in cardiovascular and catecholamine reactivity to novel psychosocial stressors. However, with repeated exposure to these tasks, fit individuals exhibited an attenuated mean arterial pressure and cardiac output responses. Sothmann, Horn, Hart, and Gustafson (1987) also investigated the cardiovascular reactivity to a well-learned stressor in a fit versus an unfit group. The stressor consisted of a modified version of the Stroop color-word conflict test immediately followed by the administration of nine scrambled anagrams with a time limited performance requirement. Two practice sessions were needed to establish familiarity with the anagram challenge (i.e., no differences in total reaction time). During the performance of the well-learned task, the authors found, in contrast to Claytor (1991), no differences in heart rate reactivity between the groups, but reported a lower norepinephrine response in the fit versus the unfit group. This suggests a fitness-related attenuation of sympathetic nervous system during psychosocial stress. However, a major limitation to this study was that no reactivity measurements of the novel presentation of this vigilance task are reported. Using an electrocardiographic index of sympathetic nervous system activity, Shulhan et al. (1986) also investigated the reactivity of fit versus unfit men categorized according to their performance on the Canadian Home Fitness Step Test (1986). No fitness-related differences in heart rate reactivity were noted during a hard and easy mental arithmetic task, but the authors reported a greater attenuation of electrocardiographic T-wave amplitude in the low versus the high fit group during the hard trials. The authors considered T-wave amplitude as being an "adequate though not perfect" index of cardiac sympathetic nervous system activity, although some controversy is attached to this notion (Schwartz & Weiss, 1983). Shulhan et al. suggested that sympathetic cardiac reactivity during the performance of a psychosocial stressor is attenuated by enhanced aerobic fitness. This is in contrast to the results of Claytor (1991), who found no differences in sympathetic nervous system reactivity between fit and unfit subjects as judged by catecholamine levels.

The central ethos of the reactivity literature is that of "high reactivity = high risk," and of fitness as modifying this risk by reducing reactivity. Paradoxically, however, deGeus et al. (1993) reported an association between high fitness and higher reactivity. In this study, the authors found that heart rate reactivity tended to be higher for all stressors in the more fit subjects and was significantly higher in the memory search task. Similarly, systolic blood pressure reactivity was higher in fitter subjects and there was a significant positive correlation between VO_{2max} and systolic blood pressure reactivity to the tone avoidance and memory search tasks, a relation in the opposite direction to conventional expectations. These relations were unchanged (and in some cases strengthened), even after adjustment for the lower baseline levels of the fitter sub-

jects. Diastolic blood pressure reactivity was also higher in fitter subjects for these same two tasks, although no significance level is reported. It would be tempting to dismiss this result as an experimental artifact except that such a finding is not unique in the reactivity literature. For example, Lake, Suarez, and Schneiderman (1985) reported that fit Type A males demonstrated higher blood pressure reactivity than their unfit counterparts only during competitive card games that also included harassment. A number of other studies have also reported results that do not fit the accepted concept of "high reactivity equals high risk" (Ahern, Gorkin, & Anderson, 1990; Kjaer & Galbo, 1988; Kvetnansky, 1980; Siegrist, 1990). Ahern et al. (1990) reported results suggesting that low rather than high reactivity to a psychomotor stressor (a video game) was predictive of cardiac arrest. Additionally, Siegrist (1990) reported that chronic occupational stress in blue collar workers was associated with reduced rather than increased cardiovascular reactivity to a mental arithmetic test presented at the end of a working day.

Although deGeus et al. (1993) found that fitness level was associated with higher cardiovascular reactivity, they found no training effects on these outcome measures in the same group of subjects even after an 8-month period. The authors, however, noted that some absolute measures of cardiovascular function (heart rate and diastolic blood pressure) were significantly improved following training and stated that such overall improvements "amply compensate" in health risk terms for the lack of improvement in cardiovascular reactivity. In a hypothesis contrary to conventional thinking on reactivity, the authors suggested that stress and exercise may independently exert separate and opposite effects on health.

Can the Reactivity of Unfit Persons Be Attenuated Following a Program of Regular Fitness Training?

The literature on aerobic training effects on reactivity is not extensive, but is equally as equivocal as that of the cross-sectional studies. Of the nine randomized controlled trials reviewed here, three report no posttraining differences in reactivity, five report posttraining reductions in reactivity and one recent study reports increases in posttraining reactivity to a variety of active and passive psychological and physical stressors.

Sinyor, Golden, Steinert, & Seraganian (1986) randomly assigned 38 healthy males to either aerobic exercise weight lifting or a wait list control. Training was conducted 3 to 4 times per week for 12 weeks. Pre- and posttest measures of fitness were assessed via a submaximal treadmill test based on time taken to attain 85% of maximal heart rate. Pre- and posttest anxiety were assessed using the Spielberger State-Trait Anxiety Inventory (Spielberger et al., 1983), and three psychosocial stressors were administered (a mental arithmetic task with exposure to white noise, a quiz, and the Stroop color-word task). Although significant differences in fitness were found in the aerobic versus the weight lifting and control groups, no group differences were found for any of the psychosocial stressors. In a similar study design, Roskies, Seraganian, & Oseasohn (1986) also reported no posttraining group differences in cardiovascular reactivity in 107 Type A

men randomly assigned to aerobic training, strength training, or a stress management control group. For these two previous studies, the lack of an adequate fitness measure could have contributed to the nonsignificant findings because fitness was estimated in the Sinyor et al. study and no fitness protocol was reported for the Roskies et al. study. Additionally, in both of these studies, strength training was used as one of the comparison groups, and this activity has been reported by some as a potent modulator of cardiovascular and sympathetic nervous system function even though aerobic fitness may remain unchanged (R. Cox, Claytor, & Howley, 1989). Because strength training is a component of fitness (see definitions earlier), and may exert a nonneutral effect on reactivity, it may not be an appropriate condition for a control group. In a longer term study, Albright, King, Taylor, and Haskell (1992) randomly assigned a group of healthy middle-aged men to a 6-month moderate intensity walking program or a nonexercise control. No group differences were found in cardiovascular reactivity following posttraining presentation of a mental arithmetic task. In a nonrandomized controlled trial, Cleroux, Peronnet, & deChamplain (1985) also reported no cardiovascular (heart rate) reactivity differences to playing a video game following 20 weeks of aerobic training. As in the Sinyor and Roskies studies, fitness in this study was also estimated from heart rate responses to a submaximal exercise bout rather than from the more precise measure of VO_{2max} via a graded treadmill exercise test.

In contrast to these studies a series of investigations by Blumenthal and associates (Blumenthal et al., 1988, 1990, 1991) report posttraining differences in response to a mental arithmetic, speech, and a cold pressor task. In the two earlier studies, a group of Type A men were randomly assigned to either aerobic training or a weight training control group. In the first of these studies (Blumenthal et al., 1988), heart rate and double product (the product of heart rate and systolic blood pressure) were reduced during and following the presentation of the mental arithmetic task, and systolic blood pressure was reduced during recovery. In the second study (Blumenthal et al., 1990) systolic blood pressure, diastolic blood pressure, double product, and heart rate were all reduced during the presentation of the mental arithmetic task. A similar protocol used in the third study (Blumenthal et al., 1991), however, yielded mixed results. Two different psychosocial stressors were used (a public speaking task and a cold pressor test) in a group of 46 postmenopausal women. The aerobically trained women demonstrated lower posttraining responses in blood pressure, whereas the resistance trained women showed significant differences in recovery heart rate. Interestingly, all of the Blumenthal studies utilized strength training as a control group and the aerobic fitness groups all showed posttraining reactivity differences versus the strength training, despite the evidence cited indicating that strength training may also affect reactivity.

Relevance of Reactivity Studies to the Stress of Daily Living It is important to note that all of the experiments have utilized very short-term psychosocial stressors and the ecological validity of such interventions remains to be estab-

lished. Logically, cardiovascular reactivity to real-life stressors should provide more relevant data on the etiology of cardiovascular disease (Pollack, 1994). For example, 24-hour ambulatory blood pressure has been proposed as a more reliable and accurate predictor of cardiovascular disease risk than the conventional doctor's office measurement (Weber, D.H.G. Smith, Neutel, & Cheung, 1991). A limited number of studies have assessed to what extent laboratory-based cardiovascular reactivity reflects "field-based" reactivity. A full discussion of this topic is outside the scope of this chapter and is addressed only briefly here.

The laboratory-field comparison literature has not, in general, reported significant relations either for heart rate or blood pressure (M. H. Pollack, 1994). It has been suggested (Manuck, Kasprowicz & Muldoon, 1990; Pickering & Gerin, 1990; Pollak, 1994) that such relations may have been obscured by methodological problems such as not controlling for baseline measures (M. H. Pollack, 1991), daily variations in lifestyle physical activity (Van Egeren & Sparrow, 1990), or comparisons with insufficiently stressful daily life periods (Manuck et al., 1990). M. H. Pollack (1994) attempted to address these three issues in a single experiment involving 26 male medical students. Subjects participated in one laboratory session and two 24-hour daily life monitoring days. One of the daily life monitoring days was spent in the classroom listening to lectures and the other day was spent participating in a clinical rotation in a general practice outpatient department. During both of these days, heart rate and physical activity were continuously monitored and stored, and later downloaded for analysis, using a solid state ambulatory monitor (Vitalog Instrument Co.). During the laboratory sessions, subjects were subjected to a series of stressors beginning with a 15-minute pretask baseline rest period. This was followed by a 5-minute reaction time task, a video game, and a mental arithmetic task. After controlling for baseline measures of heart rate and for daily physical activity level, heart rate levels were found to be significantly higher during clinic days as compared to classroom days. Additionally, heart rate responses to the laboratory tasks correlated significantly with clinic heart rate but not with lecture attendance heart rate. These findings indicate that laboratory-induced differences in heart rate responses generalize only to certain daily life settings. Individual differences in heart rate reactivity during daily life appears to depend on the nature of the daily life situation or on subjective or behavioral response in the daily life situation.

Summary

The adverse health consequences of higher sustained stress in daily life are now well established (Kobusa, Maddi, & Kahn, 1982; McEwen & Stellar, 1993; Spielberger, 1987). Heightened cardiovascular and catecholamine response to stress ("reactivity") has been linked with the development of cardiovascular disease process (Beere et al., 1984; McEwen & Stellar, 1993). Exercise has been proposed as a "stress inoculator," that is, as a means of reducing the responsivity to psychosocial stressors and thus, in turn, cardiovascular risk.

Evidence to support the hypotheses that exercise evokes a psychological training effect, however, is still equivocal. Methodological problems beset most of the published studies and replication studies are still rare. As an example, although aerobic fitness is one of the prime independent variables of concern in the reactivity literature, it has not been assessed consistently across studies. Fitness testing protocols have included self-report, step tests of different kinds, heart rate and blood pressure responses to submaximal bike and treadmill tests, or maximal time on treadmill at an absolute work load. Few studies investigating reactivity between fit and unfit groups have used maximal treadmill testing as a fitness measure. Additional points of methodological concern include no or inappropriate control groups, and lack of adjustment of baseline variables such as heart rate and BP, which would generally be lower for fit versus unfit subjects. The familiarity of the stressor should also be accounted for because differences in reactivity have been reported according to whether the stressor is novel or well practiced (Clayton, 1991; Sothmann et al., 1987). Existing research suggests that links between exercise, fitness, and cardiovascular reactivity may be tenable, but as yet too few consistent and reliable studies have been conducted to assert causality. More randomized controlled training studies utilizing direct measures of $\dot{V}O_2$ are needed, together with greater emphasis on replication of findings.

MECHANISMS

A wide range of hypotheses have been proposed to explain the mechanisms by which exercise may improve aspects of mental health. For example, Gleser and Mendelberg (1990) listed five physiological and eight psychologically based hypotheses. Most of these mechanisms remain speculative, however, with little support from the scientific literature. Because no conclusive evidence has differentiated any one mechanism or group of mechanisms, this section focuses on those hypotheses that appear to be the most tenable and/or have received the most attention in the literature.

The Monoamine Hypothesis

This hypothesis proposes that improvements in psychological health are associated with changes in levels of the major neurotransmitters of the brain, principally the biogenic amines, both catecholamines (norepinephrine, epinephrine and dopamine) and indolamines (serotonin). Early evidence of the role of the amines came from pharmacological studies of psychoactive drugs known to alter affective states, but that were also found to produce changes in the brain amines of experimental animals (Schildkraut, Orsulak, Schatzberg, & Rosenbaum, 1983). In humans, because catecholamines are not able to pass the blood-brain barrier, changes in monamines have been assessed by measuring the metabolite of norepinephrine (3-methoxy-4hydroxyphenylethylene glycol or MHPG) in either urine, plasma, or cerebrospinal fluid. It is assumed in these studies that increased MHPG reflects increased brain (central) noradrenergic responses. Studies of

the effects of physical activity on MHPG have not yielded consistent results either in depressed or normal subjects. Ebert, Post, and Goodwin (1972) assessed MHPG levels in six depressive patients following a day spent watching TV and reading as compared to an activity day consisting of outdoor walks, stair climbing, and table tennis. MHPG assessed from two 12-hour postsession urine collections were significantly greater following the activity day. DeLeon-Jones, Maas, Dekirmenjian, and Sanchez (1975), however, found no differences in MHPG levels between agitated subjects, exhibiting persistent pacing as compared to retarded patients exhibiting minimal physical movement. Other studies with depressed patients have reported both increases (Beckman, Ebert, Post, & Goodwin, 1979; Muscettola, Potter, Pickor, & Goodwin, 1984; Post, Kotin, & Goodwin, 1973) and no differences (Sweeney, Leckman, Maas, Hattox, & Heninger, 1980; Taube, Kerstein, Sweeney, Heninger, & Maas, 1978) in MHPG between acute physical activity of various kinds compared to an inactive period. These inconsistent results may be due in part to methodological problems and inconsistencies. Sample sizes were small, and the levels of physical activity used were very low and not well quantified or standardized. In addition, different types of depression were present in the same treatment group Sweeney et al. (1980), for example, assigned unipolar, bipolar, and schizophrenic patients to the same treatment group.

A small number of studies have examined the effect of acute exercise in nondepressed individuals (Chodakowska, Wocial, Skorka, Nazar, & Chwalbinska-Moneta, 1980; Goode, Sekermenjian, Meltzer, & Maas, 1973; Howlett & Jenner, 1978; Peyrin & Pequignot, 1983; Tang, Stancer, Takahashi, Shephard, & Warsh, 1981). Interpretation and comparison of results of these studies, however, are made difficult by the variety of designs utilized, which included treadmill walking at low and high intensity, bicycling at low and high intensity, a 5-minute step test and maximal isometric exercise over a range of muscle groups. Goode et al. (1973), comparing rest, isometric exercise, and bicycling, and Tang et al. (1981) comparing rest, treadmill walking, and bicycling, assessed plasma as well as urinary MHPG. Both studies found significant increases in plasma but not urinary MHPG. Other studies (Howlett & Jenner, 1978; Peyrin & Pequignot, 1983) found significant differences in subfractions of MHPG, but no differences in total MHPG.

No studies on the acute effects of exercise have been published, although in a series of studies with nondepressed subjects Sothmann and colleagues (Sothmann & Ismail, 1984, 1985; Sothmann, Ismail, & Chodzko-Zajko, 1984) reported no differences in MHPG levels between fitness groups based on $\dot{V}O_{2max}$. However, Lobstein et al. (1983) reported an inverse relation between $\dot{V}O_2$ peak and self-rated depression.

Summary

The monoamine hypothesis continues to be a promising focus of research attention from a neurobiological perspective of psychological health, particularly in the study of depression. No definite conclusions can be drawn from the existing re-

search, however, due to the wide variation in study methodology, exercise quantification, and patient diagnosis.

The Endorphin Hypothesis

Endorphins (from “endogenous morphine”) are one of the three classifications of endogenous opiates so far identified, the other two being “enkephalins” and “dynorphins.” A number of studies conducted in animals and humans have shown significant increases in endorphins during and following exercise and a reported morphinelike effect—that is, an ability to reduce the sensation of pain and even produce a state of euphoria (Morgan, 1985; Ransford, 1982). Exercise has also long been known to produce a “feel good” effect, so a small number studies (Mandell, 1979; Pargman & Baker, 1980; Sachs, 1984) combined with considerable media coverage led to the development of what became virtually an urban legend—the “runners high.” Despite the prevalence of this belief, however, scientific evidence supporting the role of endorphin/exercise connection to psychological health remains, at best, inconclusive.

In humans, the effects of exercise on endorphins has been conducted using two distinct approaches: (a) measurement of plasma levels of endorphins either with or without self-report of mood changes postexercise (Carr et al., 1981; Farrell, Gates, Maksud, & Morgan, 1982; Grossman et al., 1984), and (b) manipulation of endorphin levels by the administration of naloxone, an endogenous opiate receptor blocker (Farrell et al., 1986; Haier, Quaid, & Mills, 1981; Janal, Colt, Clark, & Glusman, 1984; Markoff, Ryan, & Young, 1982).

Carr et al. (1981) investigated effects of acute and chronic exercise on levels of endorphins in a group of women during stationary cycling. Significant increases in endorphin levels were found at power outputs between 70 and 100 Watts, and training was also reported as increasing this response. This work is frequently cited in support of exercise-induced endorphin secretion, but has been criticized by several authors on methodological deficiencies (Morgan, 1985). Farrell (1985), in a review of endorphin responses to exercise, listed 11 studies in humans reporting increases in post-run levels of endorphins of up to five times that of pre-run levels.

In studies investigating the correlations between exercise, endorphins, and mood changes, Farrell et al. (1982) assessed changes in plasma endorphin in six well-trained endurance athletes following treadmill running at 60%, 80% VO_{2max} , and a self-selected pace ($M = 75\% VO_{2max}$). The “right now” profile of mood states (POMS) was completed before and 5 to 10 minutes following each run, and perceived exertion via the Borg scale (Borg, 1970) was elicited every 5 minutes during all runs. Endorphin levels increased for each of the running conditions but, contrary to expectation, the greatest increase in endorphins occurred during the 60% condition, which produced the lowest Borg score. Farrell, Gates, Morgan, and Pert (1983) also investigated endorphin responses in male and female athletes immediately following a 10-mile road race. POMS was completed before and after the race and blood was drawn immediately following. Anxiety decreased by almost 50% ($p < .05$) and plasma endorphins increased by 17.6%, al-

though this was not significant. The large standard deviations in this study speak to a large interindividual variation in endorphin activity. In a third study, Farrell et al. (1986) investigated the effects of endorphins on postexercise tension and mood in eight males prior to 30 minutes of stationary biking at 70% of a previously determined VO_{2max} . The POMS was administered pre- and postexercise and prior to exercise subjects were given either a placebo or 50 mg of Naltrexone. Tension and mood enhancement were significantly increased for both placebo and naltrexone conditions, and this was interpreted by the authors as negating the effects of endorphins on exercise-induced mood changes.

Summary

The evidence surrounding the endorphin hypothesis is equivocal, able to be rejected or accepted depending on the series of investigators that are cited (Morgan, 1985). Although tenable, further investigation of this hypothesis is needed with more standardized methodology to allow for study comparisons and replication.

The Distraction Hypothesis

This hypothesis proposes that it is the distraction from stressful stimuli (or taking a “time out”) provided by an exercise session, rather than the exercise per se, that elicits the improved affect associated with exercise. This hypothesis was first proposed by Bahrke and Morgan (1978), who randomly assigned 75 adult males to an exercise, meditation, or distraction group. The exercise group walked on a treadmill at 70% of VO_{2max} , the meditation group practiced Benson’s relaxation response (Benson, 1975), whereas the distraction group rested quietly while seated in an easy chair in a sound-filtered room. All three groups experienced reductions in state anxiety with no differences between groups. A later study reported similar results, but found that anxiety reductions elicited by exercise persisted for a longer time than those elicited by distraction (Raglin & Morgan, 1987). In a recent meta-analysis, Petruzzello et al. (1991) found conflicting support for this hypothesis. For state anxiety, both exercise and cognitively based distraction therapies were equally effective in reducing anxiety. However, for trait anxiety, exercise had greater anxiolytic effects. This review also reported not only that exercise-related anxiolytic benefits lasted longer postexercise than cognitively based therapies, but that the long-term effects of such effects were also greater.

Summary

These results suggest that the distraction hypothesis, although tenable, cannot be regarded as the sole reason for postexercise reductions in anxiety.

The Thermogenic Hypothesis

This hypothesis proposes that elevations in body temperature will produce therapeutic effects. Early anecdotal evidence in support of this theory comes from Scandinavian countries

who have traditionally used sauna for its alleged health benefits. More objective evidence has reported that whole body warming techniques such as sauna or warm showers reduces somatic tension (deVries, Beckman, Huber, & Deickmeir, 1968) and self-reported state anxiety levels (Raglin & Morgan, 1985). Animal studies have reported a significant effect of whole body and direct brain warming on central and peripheral neuron activity (deVries et al., 1968). Gamma motor activity is inversely related to hypothalamic temperature (Von Euler & Soderberg, 1957), which contributes significantly to tonic muscle activity (deVries, Wiswell, Bulbulian, & Moritani, 1981). Deep body temperature is increased in proportion to the intensity of exercise (Haight & Keatinge, 1973), and decreased muscle tension has been reported following both exercise and a sauna bath (deVries et al., 1981). The anxiolytic benefits of exercise, therefore, may be due to a reduction in muscle tension secondary to an elevation in body temperature. However, one of the few studies that has measured body temperature concurrently with exercise (Reeves, Levinson, Justesen, & Lubin, 1985) conflicts with this theory. The authors measured body temperature directly during exercise with subjects wearing vapor barrier and thermogenic clothing. Following 20 minutes of jumping jacks, push ups, running in place, and stationary stair stepping, body temperature increased by 1.2° C. This increase in body temperature was accompanied by an increase in anxiety. A control group (exercise with no insulating clothing) showed no temperature increases. In this study, however, no attempt was made to control for the effects of clothing on body temperature.

Summary

More study designs using simultaneous measures of exercise, body temperature, and affect are needed to confirm or deny the tenability of this hypothesis.

PHYSICAL ACTIVITY: NEW GUIDELINES

Prevalence of Physical Activity and Sedentary Behavior

Despite the plethora of physical and psychological benefits described, the majority of the U.S. population (Centers for Disease Control and Prevention, 1991; Surgeon General's Report, 1996; U.S. Department of Health and Human Services, 1991) and other developed nations remain essentially sedentary (Stephens & Thomas, 1994). Data from several countries in which national physical activity surveys have been conducted indicate that only about 15% of the adult population engage in vigorous physical exercise according to American College of Sports Medicine (ACSM) guidelines, with the percentage of adults who are sedentary ranging from 15% to 40% (Phillips, Pruitt, & King, 1996). Indeed, in the United States, some 30% of adults are reported as being sedentary (Casperson & Merritt, 1992; Merritt & Casperson, 1992).

Part of the reason for this low level of activity has been attributed to a history of associating "health" with "fitness" and

a misperception that exercise-mediated health benefits can only be elicited with vigorous, sustained activity that is aerobic in nature. Such perceptions have been fostered by long-standing exercise guidelines (ACSM, 1978) based on the improvement of cardiovascular or cardiorespiratory fitness, and an inference that such guidelines also pertained to health (Haskell, 1994b). Recently, however, recommendations from several authoritative sources (Pate et al., 1995; Surgeon General's Report, 1996; U.S. Department of Health and Human Services, 1991) have significantly influenced traditional beliefs about the amount, intensity, and frequency of exercise necessary to elicit physical and psychological benefits. Guidelines from these authorities emphasize the importance of moderate intensity, intermittent physical activity, as well as the more traditional "fitness" activities, and suggest that the performance of more moderate intensity physical activities of daily living (ADL) may provide significant health benefits for persons who are initially sedentary. This dramatic shift to a "lifestyle activity" approach (Phillips et al., 1996) should have important implications for exercise participation and adherence by making health-related physical activity far more accessible to people of all ages.

From "Exercise Training-Fitness" to "Physical Activity-Health"

Data supportive of the health benefits of moderate intensity activities were evident from early epidemiological studies published even earlier than the 1978 ACSM guidelines (Morris & Crawford, 1958; Morris et al., 1953; Morris, Kagan, Pattison, Gardner, & Raffle, 1966). These studies reported beneficial effects of activities such as gardening, walking the dog, and stair climbing, but such "everyday" physical activities received little attention until some 20 to 30 years later, when interest gradually spread to exercises other than fitness training (Haskell, 1994b). In 1990 (ACSM, 1990) and again in 1998 (ACSM, 1998), the ACSM updated its 1978 position statement on exercise, and although the recommendations still focused predominantly on cardiovascular fitness, its authors recognized that the quantity and quality of exercise needed to obtain health-related benefits may differ from what was recommended for fitness benefits.

A major step toward promoting the concept of moderate intensity physical activity occurred in the following year when the U.S. Department of Health and Human Services published a comprehensive set of Health Promotion and Disease Prevention Objectives for the nation entitled *Healthy People 2000* (U.S. Department of Health and Human Services, 1991). Two of the eight health promotion topics identified were physical activity and fitness and mental health and mental disorders. The physical activity recommendations provided research justification for the stated objectives of reducing risk of cardiovascular disease via low, moderate, and vigorous physical activity in the general population (Objectives 1.3-1.7, pp. 97-101). The mental health recommendations included exercise as a related objective and proposed it as a potential mediator of stress-related disorders (Objective 6.5, pp. 214-215).

These general objectives laid the groundwork for more specific recommendations related to physical activity, and in February 1995 an expert panel (Pate et al., 1995) coordinated by the Centers for Disease Control and Prevention (CDC) and the American College of Sports Medicine (ACSM) published the following recommendation: "Every U.S. adult should accumulate 30 minutes or more of moderate-intensity physical activity on most, preferably all, days of the week."

This new recommendation differs from those previously published, which were based on an "exercise training-fitness" model advocating vigorous physical exercise (ACSM, 1978, 1990, 1998). The CDC/ACSM guidelines embraces a "physical activity-health" paradigm, which uniquely incorporates moderate intensity and intermittent physical activity (Table 38.6). Such a paradigm shift broadens the focus on health-related physical activity in four major areas.

First, the types and dose of physical activity thought to produce health benefits are more inclusive. Distinctions have been made between physical activity and exercise, as defined at the beginning of this chapter. In the physical activity-health paradigm, it is assumed that health benefits can be gained from participation in diverse types of moderate intensity physical activity. This is supported by studies reporting reduced coronary heart disease mortality and all-cause mortality rates among individuals who regularly engage in moderate physical activity (Blair et al., 1989; Leon et al., 1987; Morris et al., 1990; Paffenbarger et al., 1986; Shapiro et al., 1969). Most of the beneficial activities reported approximated an intensity of 4 to 7 kcal·min⁻¹ and included activities such as brisk walking, house cleaning, and lawn/garden care. Additional evidence comes from intervention studies (Duncan, Gordon, & Scott, 1991; Jennings, Nelson, Nestel, Esler, Korner, Burton, & Bazelmans, 1986; Nelson, Jennings, Elser, & Kover, 1986). For example, a 24-week moderate intensity (6.4 km·hr⁻¹) walking program with initially sedentary women was equally effective in increasing high density lipoprotein cholesterol (HDL-c) levels when compared to an equidistant but more vigorous (8.0 km·hr⁻¹) walking program

(Duncan et al., 1991). This suggests that health benefits derived from physical activity may be linked to exercise volume as well as exercise intensity.

Second, a unique aspect of the new paradigm is the concept that health benefits may be gained from multiple daily sessions of physical activity, as well as from one continuous daily session. Epidemiological research (Leon et al., 1987; Paffenbarger et al., 1986) identified activities associated with health benefits such as gardening, raking the lawn, and home repair. It is likely that many of these activities are performed in a discontinuous, rather than continuous, manner. In one intervention study (DeBusk, Stenestrand, Sheehan, & Haskell, 1990), 40 men approximately 50 years old were randomly assigned to one of two aerobic activity groups, the first performing moderate intensity physical activity for 30 minutes daily, and the second performing three 10-minute sessions of moderate physical activity daily. After 8 weeks of training, both groups demonstrated significant improvements in maximal oxygen uptake and exercise treadmill test duration. In addition, heart rate at submaximal workloads significantly decreased in both groups. These latter studies and others (Ebisu, 1985; Morris et al., 1990; Paffenbarger et al., 1993) support the contention that health benefits associated with improved fitness and increased physical activity are also possible with shorter, intermittent activity.

Third, the segment of the population most likely to benefit from the paradigm is increased. The new paradigm focuses on mobilizing the large segment of the population that is sedentary to become moderately active rather encouraging the small percentage of already active people to become highly active. This is because the gain in health benefits resulting from the increase in physical activity is hypothesized to be exponentially related to initial activity level, such that sedentary people who increase their physical activity to recommended moderate levels appear to achieve the greatest gain in physical health benefits (Fig. 38.1).

Fourth, the new guidelines assume that physical activity may affect a vast array of health outcomes. It is conceivable

TABLE 38.6
A Comparison of American College of Sports Medicine Position Statement 1998
with CDC/ACSM Physical Activity Recommendations

Activity Characteristics	ACSM Exercise Recommendations for Cardiorespiratory Fitness in Healthy Adults (ACSM, 1998)	CDC/ACSM Physical Activity Recommendations (Pate et al., 1995)
	(Exercise Training-Fitness Model)	(Physical Activity-Health Paradigm)
Frequency	3-5 days per week	4-7 ("Most, preferably all") days of the week
Intensity	55/65%-90% of maximum heart rate or 40/50%-85% maximum oxygen uptake reserve Lower intensities most applicable to unfit individuals	"Moderate" (3-6 METs or 4-7 kcal/min)
Duration	20-60 min of continuous aerobic activity Intermittent activity with bouts of at least 10 min is appropriate	Accumulation of ≥ 30 min of daily activity in bouts of at least 10 min
Type	Any activity that uses large muscle groups, can be maintained continuously, and is aerobic in nature (e.g., walking, running, cycling, swimming)	Any activity that can be performed at an intensity similar to that of brisk walking

FIG. 38.1. Theoretical dose-response curve demonstrating that the magnitude of increased benefit for any given increase in activity is greater for less active persons. Note: Persons exercising vigorously who increase their level of activity (Level C) accrue only small increases in health benefit. However, they elicit the greatest *absolute* health benefits compared to those performing lower intensity activity (Levels A and B). From "Health Consequences of Physical Activity: Understanding and Challenges Regarding Dose-Response" by W. L. Haskell, 1994, *Medicine and Science in Sports and Exercise*, 26, pp. 649-660.

that the mechanisms underlying the relationship between physical activity and health may include those other than increased physical fitness. Indeed, because increased physical fitness may not be the causal mechanism affecting all health outcomes, the prevailing assumption that a "training" response is necessary (i.e., one that increases physical fitness) has been challenged. Health outcomes may in fact be affected by acute bouts of physical activity, repeated acute bouts of activity, chronic (i.e., training) bouts, or interactions between acute and chronic bouts (Haskell, 1994a; Rejeski, 1994). This issue is addressed in more detail later.

Exercise Participation and Adherence

The history of low participation in leisure time activities has been partly attributed to the vigorous nature of prior recommendations (Haskell, 1994a; Pate et al., 1995; Phillips et al., 1996). The new guidelines serve as more realistic goals for the sedentary adult who wishes to adopt health-related lifestyle activity. Attempting to accrue more moderate intensity physical activity throughout the day may improve adherence to both exercise and weight loss prescriptions (Jakicic, Wing, Butler, & Robertson, 1995). Although there are advantages to these broader and lower intensity guidelines, they may also paradoxically present some unique challenges for those involved with their effective dissemination and interpretation. Such challenges include overcoming the inertia of an exercise history generated by more than two decades of "conventional wisdom" that emphasized only the exercise training-fitness model. As a result, there may be a credibility gap to bridge in promoting moderate exercise or customary daily activities as important health-related behaviors. It will be important,

therefore, for exercise professionals and lay public to recognize that the new recommendations complement, rather than replace previous guidelines.

The definition of "moderate activity" must also be clarified, because this is of paramount importance in the setting and achievement of goals. Although higher intensity activities are often relatively easy to recognize, "moderate intensity" activity is typically more difficult to identify, particularly given the influences of individual differences in perception of work effort. Additionally, many adults routinely engage in household chores, or take an occasional walk to the corner store, albeit at an intensity that may be more appropriately termed "light" rather than "moderate." Emphasis on such commonly performed physical activities may lead to a belief that one is already active enough and that further increases in activity are unnecessary. For example, being "too busy" is frequently cited as a barrier to being physically active (Dishman, 1990). It would indeed be a shame if "busy-ness" was mistakenly interpreted as health-related activity! The fact remains that most adults are not active enough and would benefit from an increase in physical activity (Surgeon General's Report, 1996; U.S. Department of Health and Human Services, 1991).

Practical Applications of the New Physical Activity Guidelines

In practical terms, the sedentary adult who wishes to become more active need not embark on a vigorous exercise program to realize health benefits. Suggested physical activity scenarios include: a brisk 10-minute walk in the morning, at lunch time, and after work; a brisk walk to the mail box, raking leaves, and stationary cycling while reading or watching television; or general house cleaning, actively playing with children, and home gardening that requires large muscle group involvement (i.e., raking and digging rather than pruning). The accumulated duration of these activities should be gradually increased toward 30 minutes per day. The key to obtaining positive health results will be to perform these activities at an intensity that at least approximates brisk walking. Because health benefits accrue in a dose-response fashion (Fig. 38.1), adults who currently engage in vigorous activity for 20 to 30 minutes or longer should continue to do so. Furthermore, the importance of muscular strength and flexibility should also not be overlooked. A growing body of data (Haskell & Phillips, 1995; Phillips & Haskell, 1995; Province et al., 1995) indicates that maintenance and/or improvement of these two components of fitness is associated with improved daily functioning and thus critical to a healthy aging process.

Implementation of Recommendations

Creative solutions will be needed to implement these recommendations for the population, including how physical activity prescriptions are administered and followed, whether the physical activity is performed in a class or home situation, and how effective is the physical activity-oriented approach as compared to the more traditional fitness-oriented approach.

King (1991) demonstrated that exercise adherence is generally better when individuals can participate in physical activity at home rather than in a class situation. Dunn et al. (1998) also reported a study comparing a "lifestyle" approach to physical activity (based on Surgeon General's Report recommendation of accumulating at least 30 minutes of daily moderate intensity physical activity) with that of a more conventional "exercise" regimen (based on ACSM fitness guidelines). In the first 6 months of a year-long randomized trial, both interventions were reported as being equally effective in increasing physical activity and physical fitness in previously sedentary men and women.

Effective implementation of these national guidelines will also require interventions and involvement at levels beyond the personal and interpersonal approaches that to date have characterized much of the nation's efforts (King, 1991). In accordance with the approach adopted by *Healthy People 2000* (U.S. Department of Health and Human Services, 1991), the authors of the CDC/ACSM guidelines issued a "call to action" aimed at increasing the joint cooperation and involvement of public health agencies, corporations, schools, communities, and health professionals, as well as individuals and families. Examples of the types of physical activity programs that could be delivered across four hierarchical levels of intervention are illustrated in Table 38.7. Within these levels, the utility of a developmental or life-span strategy should also be stressed, that is, one that takes account of life periods and transitions that may markedly affect physical activity behaviors (Table 38.8).

SUMMARY

From a public health viewpoint, the well-publicized and well-accepted links between fitness and health appear to have been both blessing and curse over last two decades. Whereas a majority of the population would undoubtedly agree that exercise is "good for me," it has become apparent that this is not enough to motivate people to commence and/or continue a regular fitness-based program. At least part of this has been attributed to an assumption that improvement of health was inextricably linked to improvement of fitness and the vigorous intensity exercise needed to improve fitness. The extensive research base underpinning the recommendations of the Surgeon General's Report on Physical Activity and Health has provided sufficient initial evidence to assert not only that physical and mental health benefits may be elicited with physical activity or exercise that is of far lower intensity than recommended by previous guidelines, but that such benefits may also be elicited by accumulating shorter bouts of physical activity or exercise throughout the day. This has resulted in what has been termed a "paradigm shift" from an "exercise training-fitness model" to a "physical activity-health paradigm." From a public health perspective, the fact that a wide range of mental and physical benefits may be elicited by commonly performed activities of daily living will bring far greater accessibility to, and hopefully increased participation in, health-related activity for the sedentary majority of the United States. This is an exciting new prospect for practitioners and health educators alike. Early reports on recent intervention studies incorporating this new paradigm

TABLE 38.7
Examples of Physical Activity Programs by Level of Intervention, Channel, Target, and Strategy

Level of Intervention	Channel	Target	Strategy
Personal	Face-to-face: Physician's office; health clinics; health spas and clubs. Mediated/not face to face: Telephone, mail (feedback systems, correspondence courses; self-help kits and booklets)	Patients, clients	Information on risk, health benefits; counselor support; personal monitoring and feedback; problem solving (relapse prevention)
Interpersonal	Classes: Telephone/mail systems; health spas and clubs; peer-led groups.	Patients, healthy individuals, families, peers	Information; peer, family, and counselor support; group affiliation; personal or public monitoring and feedback; group problem solving.
Organizational /Environmental	Schools; worksite; neighborhoods; community facilities (e.g., par course, walk/bike paths), churches, community organizations; sites for activities of daily living (public stairs; shopping malls, parking lots).	Student body; all employees; local residents; social norms or milieu	Curricula; point-of-choice education and prompts; organizational support; public feedback; incentives
Institutional /Legislative	Policies; laws; regulations	Broad spectrum of community or population	Standardization of exercise-related curricula; insurance incentives for regular exercisers; flexible work time to permit exercise; monetary incentives for the development of adequate public facilities for exercise; Surgeon General's report on physical activity and health

Note: These four levels are not mutually exclusive—a "mix" of strategies is most likely to have the greatest effect on targeted subgroups within a community. From "Community Intervention for Physical Activity and Fitness" by A. C. King, 1991, *Exercise and Sports Science Reviews*, 19, p. 247.

TABLE 38.8
Features and Examples of Physical Activity Programs for Several Major Lifestyle Developmental Milestones

Milestone (Critical Period)	Specific Features	Goals/Strategies
Adolescence	Rapid physical and emotional changes Increased concern with appearance and weight Need for independence Short-term perspective Increased peer influence	Exercise as part of a program of healthy weight regulation (both sexes) Noncompetitive activities that are fun, varied Emphasis on independence, choice Focus on proximal outcomes (e.g., body image, stress management) Peer involvement, support
Initial Work Entry	Increased time and scheduling constraints Short-term perspective Employer demands	Choice of activities that are convenient, enjoyable Focus on proximal outcomes Involvement of worksite (environmental prompts, incentives) Realistic goal-setting/injury prevention Coeducational noncompetitive activities
Parenting	Increased family demands and time constraints Family- directed focus Postpartum effects on weight, mood	Emphasis on benefits to self and family (e.g., stress management, wt. control, well-being) Activities appropriate with children (e.g., walking) Flexible, convenient, personalized regimen Inclusion of activities of daily living Neighborhood involvement, focus Family-based public monitoring, goal-setting Availability of child-related services (child care)
Retirement Age	Increased time availability and flexibility Longer term perspective on health Increased health concerns, "readiness" Caregiving duties, responsibilities (parents, spouse, children, or grandchildren)	Identification of current and previous enjoyable activities Matching of activities to current health status Emphasis on mild and moderate intensity activities, including activities of daily living Use of "life path point" information and prompts Emphasis on activities engendering independence Garnering support of family members, peers Availability of necessary services (e.g., caretaking services for significant others)

Note: From "Community Intervention for Physical Activity and Fitness" by A. C. King, 1991, *Exercise and Sports Science Reviews*, 19, p. 250.

have reported favorable improvements in various health-related measures comparable to that of the more traditional fitness-based approach. However, more widespread acceptance and adoption of the new paradigm will depend on the involvement of public health agencies, educational and corporate institutions, and communities. Finally, if a lifestyle approach to health-related physical activity is to be established, it will require the development and adoption of strategies taking account of transitional life periods that may affect physical activities and behaviors.

There was a time, not very long ago, when behavioral medicine researchers studying the effects of psychosocial factors on health and disease gathered themselves into guilds—not unlike those medieval guilds of armorers, goldsmiths, cobblers, and the like—each specializing in a rather narrow area of inquiry. In the early 1970s, for example, the Type A Behavior Pattern (TABP) guild was powerful and prominent at national meetings and in the research literature. By the early 1980s, however, the TABP guild was in decline, with negative studies leading to the formation of the hostility guild, the membership of which was drawn largely from the old TABP guild.

The hostility guild extended its hegemony in the 1980s (easily documented by a Medline search for papers with “hostility” in the keyword list), but it was soon under challenge from other guilds (i.e., the depression guild, the social support guild, the job strain guild), all with members who seemed to be engaged in a zero-sum game: There’s only a limited amount of psychosocial risk factor “capital” available, and to the extent your risk factor is up, mine is down. This competition among psychosocial risk factor guilds led to a kind of internecine warfare, with engagements taking the form of statements like, “It’s not hostility that’s responsible for increased coronary risk; it’s the low social support among hostile people that’s really doing the damage.”

I participated in this warfare, often with gusto, on both the giving and receiving ends of the zero-sum debate—often defending my favorite risk factor, hostility, against the encroachments of those carrying the banner of depression, social support, or job strain. It was not a very satisfying endeavor, however, when I so often found myself at odds with other investigators who were not only good friends but also respected colleagues. By nature a lumpier rather than a splitter, I began in the early 1990s to search for some means of reconciling, in my own mind if nowhere else, the competing factions. The initial phase of this search culminated in my 1993 presidential address to the American Psychosomatic Society (R. B. Williams, 1994), in which I hypothesized that the clustering of health damaging behavioral (smoking, high alcohol consumption, and dysregulated eating) and biological (increased sympathetic and HPA axis function, decreased parasympathetic function, and dysregulated immune system function) characteristics in persons with high hostility levels is mediated by reduced serotonergic function in the central nervous system.

The major advance here was to move away from the spurious notion that risk characteristics act independently of each other—“Is it hostility or the increased smoking (or sympathetic excess, higher cholesterol, etc.)?” Instead, I was beginning to realize, researchers need to look at the joint effects of clusters

of risk characteristics, and try to understand why risk characteristics show this tendency to co-occur. This insight was facilitated by G. Kaplan's (1995) description of the compounded effects on mortality of combinations of psychosocial risk factors—for example, in the Kuopio study where mortality was doubled when one or two psychosocial risk factors were present, but quadrupled when three were present.

Another insight came when I was invited by Johannes Siegrist to attend a satellite meeting in Utrecht before the 1994 Amsterdam International Congress of Behavioral Medicine. There I encountered Michael Marmot and learned about his pioneering research (Marmot et al., 1991) documenting the health damaging impact of lower socioeconomic status (SES) in British civil servants working in Whitehall. When recalling earlier research (Barefoot et al., 1991; Matthews, Kelsey, Meilahn, Kuller, & Wing, 1989) showing increased levels of psychosocial risk factors in lower SES groups, I was inspired to extend my earlier hypothesis (R. B. Williams, 1994) that the clustering of biobehavioral risk factors in hostile persons might be driven by reduced levels of CNS serotonergic function. This shift in my thinking was also influenced by realizing that the same biobehavioral risk factors found in hostile persons also tend to cluster in persons with the other psychosocial risk factors (e.g., smoking in persons with depression), as well as new findings from my own research showing that psychosocial risk factors themselves also cluster in the same persons (R. B. Williams et al., 1997).

The time had come to move away from the guild approach to psychosocial risk factors and look at the big picture. Now, rather than focusing on the single psychosocial risk factor of hostility and mechanisms responsible for its impact on health and disease, it is my view that there is a need to focus on the clustering of psychosocial risk factors, especially in lower SES groups, the biobehavioral mechanisms whereby such clusters damage health, and the possible utility of psychosocial and behavioral interventions in both primary and secondary prevention. This chapter reviews the current state of affairs in each of these areas.

PSYCHOSOCIAL RISK FACTORS: EPIDEMIOLOGIC EVIDENCE

Initial findings of an association between higher scores on the Cook and Medley Ho scale on the Minnesota Multiphasic Personality Inventory (MMPI) and coronary atherosclerosis severity in a cross-sectional study (R. B. Williams, Haney, Lee, Blumenthal, & Kong, 1980) and coronary heart disease (CHD) incidence and all-cause mortality in two prospective studies (Barefoot, Dahlstrom, & R. B. Williams, 1983; Shekelle, Gale, Ostfeld, & Paul, 1983) spawned a very large body of research on the role of hostility as a psychosocial risk factor. This research, recently reviewed by Miller, Smith, Turner, Guizarro, and Hallet (1996), has documented that the psychological characteristic of hostility, as measured with a wide array of instruments, is a risk factor, not only for CHD but for virtually any physical illness. It has become increasingly clear, however,

that hostility is not the only psychosocial characteristic that is "coronary prone," or health damaging in the broader sense.

Thus, *depression*, whether construed as a subsyndromal predisposition or a clinical disorder, has been shown to predispose to increased risk of CHD (Anda et al., 1993) or all-cause mortality (Barefoot & Schroll, 1997) in healthy people, as well as the risk of dying in post-MI patients (Frasure-Smith, Lesperance, & Talajic, 1994). Similarly, *social isolation* (or low social support) predicts increased risk of CHD and all-cause mortality (House, Landis, & Umberson, 1988), as well as a poor prognosis in CHD patients (R. B. Williams et al., 1992). *Job stress*, whether defined as high strain (high demands/low control) or effort-reward imbalance, has also been shown to increase risk of CHD (Bosma, Peter, Siegrist, & Marmot, 1998) in healthy people, although an impact on prognosis in CHD patients has not been confirmed (Hlatky et al., 1995). *Lower SES* also predisposes to increased risk of CHD and all-cause mortality in healthy people (Adler, Boyce, Chesney, Folkman, & Syme, 1993) and a poorer prognosis in CHD patients (R. B. Williams et al., 1992).

It is now evident that these psychosocial risk factors do not occur in isolation from one another, but tend to cluster in the same individuals and groups. Thus, working women who report high job strain are characterized by increased levels of hostility, anger, depression, anxiety, and social isolation (R. B. Williams et al., 1997). And when psychosocial risk factors do co-occur, their impact on mortality is compounded (Kaplan, 1995). A specific example of this dynamic interaction among psychosocial risk factors comes from a recent study that found a larger impact of an intense episode of anger on risk of having a myocardial infarction in lower as compared to higher SES individuals (Mittelman, Maclure, Nachnani, Sherwood, & Muller, 1997).

It is becoming increasingly evident that lower SES, rather than being simply one among a list of other psychosocial risk factors, may be, in fact, a "master" risk factor that contributes to increased levels of the other risk factors. As already noted, both psychosocial risk factors and risky health behaviors are increased in lower SES groups (Barefoot et al., 1991; Matthews et al., 1989). Whereas health behaviors like smoking, alcohol consumption, obesity, and sedentary lifestyle are all increased among lower SES individuals, these risky health behaviors account for no more than from 12% to 13% of the predictive effect of lower SES on mortality in a nationally representative sample containing both men and women (Lantz et al., 1998). However, when a broader set of risk factors, including representatives from behavioral, biological, and psychosocial domains are controlled for, the SES gradient in all-cause mortality becomes nonsignificant (Lynch, G. A., Kaplan, R. D., & Salonen, 1997), suggesting that SES effects on health are mediated by factors in these three domains.

This epidemiological evidence leads to the conclusion that hostility and other psychosocial risk factors do not occur in isolation from one another, but tend to cluster in the same individuals. Moreover, lower SES appears to be a driver of increased levels of the other psychosocial risk factors, perhaps even acting through them, somehow, to increase risk of devel-

oping a wide range of diseases. Pathogenesis is something that happens at the level of cells and molecules. Psychosocial risk factors do not themselves act directly on cells and molecules, however. There must be mediators between the psychosocial domain and the cellular/molecular domain.

PSYCHOSOCIAL RISK FACTORS: BIOBEHAVIORAL MECHANISMS

Both hostility and depression are associated with alterations in autonomic balance and HPA axis function that could account for at least some of their health-damaging effects. When anger is induced in laboratory studies (T. W. Smith & Allred, 1989; Suarez, Kuhn, Schanberg, R. B. Williams, & Zimmerman, 1998; Suarez & R. B. Williams, 1989), for example, persons who score high on the same hostility scale that predicts increased risk of CHD and all-cause mortality exhibit larger sympathetic nervous system (SNS)-mediated cardiovascular responses than low scorers. Hostile persons also show increased SNS activation during everyday life, as documented by larger increases in daytime urinary epinephrine excretion (Suarez, R. B. Williams, Peoples, Kuhn, & Schanberg, 1991) and down regulation of lymphocyte beta adrenergic receptors (Shiller et al., 1997). Veith and coworkers (1994) documented increased SNS outflow in patients with major depression.

There is also evidence that parasympathetic (PNS) function is reduced in both hostile and depressed persons. Laboratory research (Fukudo et al., 1992) has shown decreased PNS antagonism of SNS effects on myocardial function in high hostile subjects. Both hostility (Sloan et al., 1994) and depression (Carney et al., 1988) are associated with decreased PNS function during ambulatory ECG monitoring.

Increased and dysregulated HPA axis function has long been a known accompaniment of depression (Holsboer, van Bardeleben, Gerken, Stallag, & Muller, 1984). Persons with hostile personality have also been found in recent research to exhibit increased HPA activation, both in ambulatory (Pope & T. W. Smith, 1991) and laboratory (Suarez et al., 1998) conditions.

Biologic changes similar to those documented in depressed and hostile persons are also present in persons who are socially isolated and/or exposed to high demand/low control jobs or life situations. Increased urinary catecholamine excretion has been found (Fleming, Baum, Gisriel, & Gatchel, 1982), for example, in persons reporting low social support. Persons in high strain jobs exhibit (Schnall et al., 1990) increased ambulatory blood pressure and increased left ventricular mass index—both likely the result of chronically increased SNS function. Working women with young children living in the home—clearly a high demand/low control situation!—show greater 24-hour urinary cortisol excretion than working women without children at home (Luecken et al., 1997).

Psychosocial risk factors are also associated with increased behavioral/physical risk factor levels. Two large-scale studies, one prospective (Siegler, Peterson, Barefoot, & R. B. Williams, 1992) and one cross-sectional (Scherwitz et

al., 1992), and each involving over 5,000 subjects, found hostility to be associated with increased cigarette smoking, alcohol consumption, body mass index, 24-hour caloric intake, and cholesterol/HDL ratio. Hostility has also been found to predict increased incidence of hypertension (Barefoot, Dahlstrom, & Williams, 1983). Increased smoking (Glassman et al., 1990) and alcohol consumption (Hartka et al., 1991) are also well-documented in depression. Persons with low social support are less likely to succeed in smoking cessation (Mermelstein, S. Cohen, Lichtenstein, Baer, & Kamarck, 1986) or to adhere to a prescribed medical regimen (C. A. Williams et al., 1985).

How do the increased behavioral/physical risk factors, altered SNS/PNS balance, and increased HPA function among persons with psychosocial risk factors actually contribute to the development of CHD and other major diseases? Previous attempts (J. R. Kaplan, Petterson, Manuck, & Olsson, 1991) to answer this question have focused on the biological plausibility of these biobehavioral characteristics as contributors to possible pathogenic mechanisms—for example, via excessive cardiovascular arousals that promote atherogenesis via mechanical injury of arterial endothelium. Endothelial injury is only part of the story, however. An emerging consensus (Ross, 1993) sees chemical mediators like oxidatively modified low density lipoprotein (LDL) as modifying the cellular and molecular biology of the monocyte/macrophage system in ways that are critically involved in the events leading to the development of the atherosclerotic plaque. To understand how epidemiological associations between psychosocial factors and increased risk of major illnesses like CHD are mediated, it is necessary to identify the direct linkages between biobehavioral characteristics like increased SNS activity, smoking, and increased lipid levels and those events at the cellular and molecular levels that facilitate processes like atherogenesis and tumorigenesis that are responsible ultimately for the development of diseases like CHD and cancer.

Adams (1994) proposed that the search for such linkages can profitably focus on the effects of biobehavioral factors on the cellular and molecular biology of the monocyte/macrophage system. The combination of increased smoking and elevated lipids (including LDL) observed in hostile persons is likely to result in elevated circulating levels of oxidized LDL—recognized (Ross, 1993) as a key promotor of atherogenesis. Oxidized LDL causes a wide array of changes in murine macrophage gene expression and functions that are consistent with a phenotype—suppression of certain immediate early inflammatory genes and decreased macrophage mediated killing of tumor cells (Thai, J. G. Lewis, R. B. Williams, Johnson, & Adams, 1995)—that has the potential (Adams, 1994) to facilitate both atherogenesis and tumorigenesis. Ligation *in vitro* of the macrophage beta adrenergic receptor—a likely occurrence among hostile, depressed, and socially isolated persons, given their increased SNS function—appears to stimulate a similar phenotype (Adams, 1994). Based on these observations, Adams (1994) proposed that stress (e.g., associated with psychosocial risk factors) could potentiate the effects of oxidized lipids on monocyte/macrophage gene expression and functions in-

volved in both atherogenesis and tumorigenesis. Preliminary support for this hypothesis comes from human studies in the laboratory showing both anger (Suarez, Sasaki, J. G. Lewis, R. B. Williams, & Adams, 1996) and pharmacologically induced alterations in autonomic balance (R. B. Williams et al., 1998) to be associated with differential effects on monocyte gene expression in high as contrasted to low hostile persons.

I have dealt at some length with the monocyte/macrophage system because I believe it is a key area where specific data indicate a strong heuristic potential for extending to the cellular and molecular levels an understanding of mechanisms whereby psychosocial factors increase risk of disease. Prior research in psychoneuroimmunology is also helping to identify cellular/molecular mechanisms. Thus, studies showing decreased immune function in association with depression (Evans et al., 1992) and high demand/low control life situations (Kiecolt-Glaser & Glaser, 1992) provide further evidence of cellular mechanisms whereby the biologic and behavioral/physical accompaniments of psychosocial risk factors could affect health.

The foregoing review leads to this synthesis: Psychosocial risk factors do not themselves lead directly to increased risk of disease and death. Rather, their health damaging effects are probably mediated by the behavioral/physical and biological characteristics that co-occur with the psychosocial risk factors. These biobehavioral characteristics are the proximate contributors to pathophysiology, via an altered internal biochemical milieu that changes monocyte/macrophage gene expression and functions in ways that promote, at the cellular/molecular levels, the pathophysiological events (like atherogenesis and tumorigenesis) that are ultimately responsible for the development of life threatening diseases.

This scenario in no way minimizes the impact of *direct* pathogens—genetic predispositions (e.g., oncogenes), environmental toxins/carcinogens, infectious agents, and the like—on pathogenesis. Rather, it sees biobehavioral factors associated with psychosocial risk factors as contributing to disease by affecting the cellular and molecular processes whereby the body copes with these direct pathogens. An example of such an effect on cellular/molecular processes is preliminary observations of differential alterations in monocyte functions following behavioral and pharmacologic manipulations in high versus low hostile persons (Suarez et al., 1996; R. B. Williams et al., 1998).

In contrast to the progress just reviewed regarding the “downstream” biological mechanisms whereby low SES and other psychosocial risk factors contribute to pathogenesis, as Kaplan (1995) noted, relatively little attention has been given to the factors involved in the development of psychosocial (and associated biobehavioral) risk factors. To explore this issue, a developmental and neurobiological perspective must be taken.

Some time ago, a review of the extensive evidence linking a wide range of biological and behavioral characteristics to variations in brain serotonergic function led to the heuristic hypothesis (R. B. Williams, 1994) that the clustering of health-damaging biobehavioral characteristics observed in hostile persons (and persons with the other psychosocial risk factors that tend to cluster with hostility) is mediated by de-

creased function of the neurotransmitter serotonin in the brain. Research showing that children in lower SES groups hear fewer positive communications from their parents from birth to age 3 (Hart & Risley, 1995), and research showing that, compared to mother-reared monkeys, rhesus monkeys who are reared in peer groups from birth to age 6 months exhibit biobehavioral alterations that appear to be mediated by reduced brain serotonergic function (Higley, Suomi & Linnoila, 1992; Higley et al., 1993), have led to the expansion and extension of this hypothesis as follows: Reduced brain serotonergic function resulting from the experience of relatively harsh and adverse circumstances in early childhood is one important factor contributing to the clustering of health damaging psychosocial and biobehavioral characteristics in lower SES groups (R. B. Williams, 1998).

The foregoing review leads to these conclusions:

Hostility, depression, social isolation, stress at work (high job strain, effort–reward imbalance), and lower SES have been shown in prospective epidemiological studies to increase risk of developing CHD as well as a broad range of other medical illnesses in healthy populations.

In patients with clinical evidence of CHD, depression, social isolation, and lower SES have also been shown to confer a poorer prognosis.

A wide range of potentially health damaging behaviors and biological characteristics have been found in persons with psychosocial risk factors and are the likely mediators of the increased disease risk observed in such persons and groups.

Reduced brain serotonergic function, known to be influenced by both genetic and environmental factors, is an attractive candidate to account for the clustering of biobehavioral and psychosocial risk factors in certain individuals and groups (i.e., lower SES).

The purpose of doing the research leading to these conclusions is, ultimately, to be able to use the knowledge gained to develop effective interventions to ameliorate the health damaging effects of psychosocial risk factors and accompanying biobehavioral characteristics. Here also, there has been encouraging progress in recent years, especially with interventions aimed at improving prognosis in patients with disease already present.

PSYCHOSOCIAL RISK FACTORS: POTENTIAL FOR SUCCESSFUL PREVENTION AND TREATMENT

Group-based behavioral interventions targeting psychosocial factors have already been shown to improve prognosis in both CHD (Friedman et al., 1986; Blumenthal, Jiang, Babyak, et al., 1997) and cancer (F. I. Fawzy et al., 1993; Spiegel, Bloom, Kraemer, & Gottheil, 1989). Based on these encouraging observations, albeit with small sample sizes, R. B. Williams and Chesney (1993) asserted that enough is already known about the impact of psychosocial factors on prognosis in established CHD to proceed with randomized clinical trials

of behavioral interventions aimed at reducing the mortality associated with depression and social isolation in CHD patients. The National Heart, Lung, and Blood Institute is currently supporting just such a trial—the ENRICH study, the first large-scale, multicenter randomized clinical trial of a psychosocial intervention in any major illness (Blumenthal et al., 1997).

Another application for behavioral interventions is in patients with chronic medical conditions that, although not necessarily life threatening, are associated with much suffering and costly use of medical diagnostic and treatment services. In the Hawaii Medicaid study, Cummings, Pallak, Dorken, and Henke (1991) conducted a randomized clinical trial in which patients who were high utilizers of medical services were randomly assigned to three groups: no mental health treatment, traditional one-on-one psychotherapy for up to 50 sessions over a year, or a highly structured group-based intervention consisting of no more than 8 sessions of training in various coping skills. Compared to the other two groups, both of which showed increased medical costs during the year following randomization, the patients randomized to the structured group intervention showed a decrease of from 15% to 20% in costs for medical-surgical services.

These encouraging early intervention studies—especially when considered in the light of the extensive progress, reviewed earlier in this chapter, toward documenting the health damaging impact of psychosocial risk factors and the intervening biobehavioral mechanisms—make for considerable optimism that behavioral medicine and health psychology are on the threshold of an exciting new era. In this new era there will be an application of the knowledge and technology that emerges from the research reviewed herein in the day-to-day clinical care of patients with the widest conceivable range of medical disorders. As this technology transfer proceeds, there will be a time in the not distant future when behavioral interventions will be incorporated into the care of patients with heart disease and cancer with the expectation that both quality and quantity of life will be increased.

During this same time frame, the development of behavioral interventions will lead to decreased suffering and costs among patients in primary care medical settings, whether or not a chronic medical condition is present. In the more distant future, similar approaches will be developed and applied in a wide range of *primary prevention* programs, designed to keep healthy people well. After all, it is far more efficient and less costly to cut off toxic pollution at its source than it is to remove the pollutants from the water far downstream!

For this exciting potential to be fully realized, however, it will take more than the best of our research and good intentions. Until digitalis leaf was packaged into tablets with a more or less standard dose of digitalis glycosides for patients with the “dropsy” (congestive heart failure), the pharmacological promise contained in Sir William Withering’s 18th-century observations of the potential benefits of the foxglove plant could not be realized. Thus, it will be essential for health psychologists and others working in the field of behavioral medicine to package behavioral interventions into prod-

ucts that can be delivered in a standardized fashion with reasonable expectation that similar benefits will be achieved across settings and deliverers. Such products will be entities that can be bought and sold, leading to the development—analogue to the genesis of the pharmaceutical industry 200 years ago in the work leading to development of standardized digitalis leaf preparations—of a new “behavioro-tech” industry that will be essential to ensure that research is transferred to and regularly used in clinical practice.

It is already possible to discern key elements in the successful intervention programs described here:

Group settings are more efficient than one-on-one approaches, enable patients to learn from one another, and serve as a powerful source of social support.

Proven principles of *cognitive behavior therapy* and *behavior therapy*, along with *social skills training* enable patients to gain hands-on practice in the use of skills they can use to handle the stressful situations and resulting negative emotions they need to face in the here and now.

Treatment is limited to a fixed number of sessions, often no more than six to eight, during which each skill to be mastered is presented in a manualized, protocol-driven format that enables patients to learn to practice and apply the skill to actual problems they are currently encountering at work, home or play.

R. B. Williams and V. P. Williams (1993) developed a behavioral intervention program incorporating these elements that was aimed at reducing the impact of hostility and anger on health. This program has been refined to develop the “LifeSkills” system (V. P. Williams & R. B. Williams, 1997), a six-session workshop that targets not only hostility/anger but the other established psychosocial risk factors as well. Moreover, it aims to prevent stressful situations from occurring in the first place by providing training in skills that will enhance emotional competencies and the quality of interpersonal relationships. Rather than approaching people as broken and in need of fixing, the LifeSkills system takes a wellness focus based on the message that people can benefit from learning and practicing skills that will improve their ability to cope and introduce a more positive focus into their life and relationships. The LifeSkills Workshop trains people to use two sets of skills:

Learn to understand yourself and others by:

- Increasing your awareness of thoughts and feelings
- Evaluating and managing negative thoughts and feelings
- Communicating effectively using speaking and listening skills
- Empathizing with others

Learn to act effectively by:

- Using problem solving when it is the situation that bothers you
- Practicing assertion when it is another person’s behavior
- Keeping acceptance as an option when it will cause no one harm
- Increasing the positives in your life and relationships

Not unlike colleagues in basic biomedical sciences who partner with their academic institutions to form private corporations—"biotech spinoffs"—to facilitate technology transfer with respect to research findings in cellular and molecular biology, Virginia Williams and I have formed a "behavioro-tech" spinoff company, Williams LifeSkills, Inc., to further develop and market the LifeSkills system to both medical and corporate, as well as individual, buyers. Our corporate strategy is based on the premise, growing out of the research already reviewed, that psychosocial factors increase risk and costs of medical illness and that well-designed and implemented behavioral intervention packages have the potential to reduce these risks and costs. Preliminary analyses of data from corporate settings show significant decreases in hostility/anger, depression, and social isolation in persons following participation in the LifeSkills Workshop.

There has been one randomized clinical trial (Gidron, Davidson, & Bata, 1999) that used a group hostility-control intervention based on the earlier *Anger Kills* model and found decreases in both self-report and behaviorally assessed hostility levels, as well as diastolic blood pressure that were sustained over a 2-month follow-up period in post-MI patients randomized to the intervention as compared to patients receiving usual care. Although small in scale, this trial provides, along with the other clinical trials described earlier, encouraging evidence that structured group-based behavioral interventions that teach a set of key coping skills have real potential to improve prognosis once major illness is present. Only time will tell, but it is likely that such interventions have a role in primary prevention as well.

CONCLUSIONS

It is now possible to look back over the past quarter century and reflect with some pride on the accomplishments of behavioral medicine and health psychology during this exciting period. We are no longer gathered into guilds, each jealously defending its own particular psychosocial risk factor against the encroachments of other, competing guilds. Instead, we now realize that the psychosocial risk factors being studied separately do not occur in isolation from one another and associated biobehavioral characteristics, but tend to cluster in the same individuals and groups. It appears that, like the Vichy inspector played by Claude Rains in *Casablanca*, we have rounded up "the usual suspects" and find they belong to the same gang.

There has also been considerable progress toward identifying the biological and behavioral pathways whereby these psychosocial risk factors (including combinations of them, which are common) actually participate in the etiology of medical disease. We are just beginning to use the new tools of cellular and molecular biology in this endeavor. However, there are already exciting portents that we will be able to identify not only the basic mechanisms whereby clusters of psychosocial and biobehavioral risk characteristics participate in pathogenesis, but also the basic neurobiological mechanisms responsible for the clustering in the first place.

Finally, and most exciting and satisfying of all, in the not-too-distant future it appears increasingly likely that we will be able to apply what we have learned to reduce human suffering and disease and, at the same time, enhance well-being and quality of life.

ACKNOWLEDGMENTS

Preparation of this chapter was supported in part by grants P01-HL36587 and R01-HL44998 from the National Heart, Lung, and Blood Institute; grants 5P60-AG11268 and P02-AG12058 from the National Institute on Aging; grant K01-MH70482 from the National Institute of Mental Health; the Duke Clinical Research Unit grant M01-RR30; and research support from the Fetzer Institute and the John D. and Catherine T. McArthur Foundation.

Stress and Silent Ischemia

Willem J. Kop

David S. Krantz

Uniformed Services University of the Health Sciences

Evidence indicates that both chronic (Appels, 1990; Friedman & Rosenman, 1959; Kop, 1997; Williams et al., 1980) and acute (Krantz, Kop, Santiago, & Gottdiener, 1996) psychologically stressful circumstances can promote coronary artery disease (CAD) progression and its clinical manifestations such as chest pain, myocardial infarction, and sudden cardiac death. Current models of the effects of mental and physical stress on the heart suggest that behaviorally induced autonomic nervous system activation can produce clinical cardiovascular events at several levels: by promoting atherosclerosis and subsequent plaque formation in the coronary artery wall; by directly triggering disturbances in cardiac rhythm (arrhythmias) through alterations of the neural activation of the heart; and by producing intermediate pathologic or pathophysiologic processes causing ischemia in patients with CAD (Krantz et al., 1996b). This chapter addresses the third level, that is, mental and physical triggers of cardiac ischemia.

The characteristic symptom of coronary artery disease is stress-induced anginal pain. Angina is a consequence of myocardial ischemia, which may develop when the oxygen supply to the heart does not meet cardiac oxygen demand (Krantz et al., 1996b). Myocardial ischemia is commonly manifest in patients with CAD. However, many cardiac ischemic episodes are asymptomatic, or "silent" (Deanfield et al., 1983; Krantz et al., 1994; Nabel, Rocco, Barry, Campbell, & Selwyn, 1987). The absence of symptoms may interfere with patients' recognition of impending cardiac events as well as

the accuracy with which symptoms are described to medical professionals (Kenyon, Ketterer, Gheorghide, & Goldstein, 1992; Theisen et al., 1995). Moreover, the incidence of painless and undetected acute myocardial infarction is estimated to be approximately 10% (Kannel & Abbott, 1984). This chapter focuses on silent ischemia during episodes of mental stress in laboratory settings and activities of daily life and addresses possible biobehavioral mechanisms that may explain stress-induced silent ischemia. Specifically, it describes: the prevalence of mental stress-induced myocardial ischemia in the laboratory; the characteristics of (silent) ischemia in field studies; possible mechanisms for the onset of ischemia with mental stress and its characteristic absence of cardiac symptoms; and the predictive value of silent ischemia for adverse prognosis in patients with CAD.

MENTAL STRESS-INDUCED SILENT ISCHEMIA: LABORATORY STUDIES

Myocardial ischemia is a consequence of an imbalance between cardiac demand (the workload of the heart) and coronary blood supply (the delivery of oxygenated blood to the heart via the coronary arteries). As is discussed later, mental and physical stress may increase cardiac demand by increasing heart rate and blood pressure; and, in addition, other evidence indicates that mental stress may also reduce coronary blood supply to the heart. Thus, mental stress may cause car-

diac ischemia because it unfavorably effects the balance between cardiac demand and supply (Krantz et al., 1996b; Rozanski et al., 1988). Cardiac ischemia triggered by mental stress is generally transient and asymptomatic. Ischemia may, in rare circumstances, occur in the absence of atherosclerotic coronary disease; this often reflects cardiac pathology including aortic stenosis, cardiomyopathy, congenital abnormalities, and syndrome X (i.e., impaired perfusion of the coronary resistance vessels). This review of stress-induced ischemia is limited to patients with established CAD.

Myocardial ischemia can be objectified utilizing several procedures that are increasingly sensitive to detect cardiac changes indicative of cardiac ischemia (Fig. 40.1). For the purpose of this chapter, these procedures can broadly be divided into the electrocardiogram (ECG), and echocardiographic and/or radionuclide techniques to assess cardiac function and perfusion.

Electrocardiographic Measures of Ischemia

Because the cardiac muscle is electrically active, electrocardiographic recordings can be made to measure beat-by-beat electrical polarization and recovery of the cardiac muscle cells. Ischemia prolongs the duration of recovery, and the ischemic area is repolarized last (Braunwald, 1988). Ischemia during exercise testing and activities of daily life can be assessed using shifts in the ST-segment of the ECG, where a depression of > 0.10 mV for a duration of more than 1 minute is the critical index for diagnosis of ischemia (Fig. 40.2). To document episodes of ischemia during the activities of daily life, ambulatory Holter monitors have been developed that record continuous ECGs for 24 hours on tape.

Wall Motion Abnormalities, Decrease in Ejection Fraction, and Perfusion Defects

Under normal circumstances, the left ventricle of the heart muscle contracts in a rhythmic, coordinated pattern and ejects blood into the aorta to produce a pulsatile maintenance of systemic blood pressure. However, when the heart muscle becomes ischemic, this contraction pattern may become uneven. The occurrence of unevenness of left ventricular contraction pattern is referred to as *wall motion abnormalities*. In the absence of cardiac muscle damage due to prior myocardial infarction, these wall motion abnormalities are generally not present in resting conditions, but can be induced by procedures that increase cardiac demand, such as exercise testing. Stress-induced wall motion abnormalities occur at the specific regions where ischemia occurs. To objectify stress-induced wall motion abnormalities, baseline measures of cardiac wall motion are compared to wall motion during a stress task. Both echocardiographic and radionuclide techniques are available to detect changes in cardiac function and determine inducibility of cardiac ischemia.

A measure of stress-induced ischemia that is related to the pump function of the heart uses a $< 5\%$ increase in *ejection fraction* as diagnostic criterium. Normally, when cardiac demand is elevated, the ejection fraction (the relative output of the heart during systole) increases. However, if the heart becomes ischemic, this increase does not occur. Normal values for baseline ejection fractions range from 50% to 75%. Inducibility of ischemia during exercise is suspected when the increase in ejection fraction from baseline is less than 5%. Similar criteria (a 5% drop in ejection fraction) have been used to detect mental stress ischemia (Ironson et al., 1992), al-

FIG. 40.1. Chest pain reflects only the top of the iceberg of underlying cardiac disease. New cardiological tests are becoming increasingly sensitive in the detection of ischemic coronary artery disease.

FIG. 40.2. Characteristic electrocardiographic (ECG) pattern indicative of stress-induced ischemia. A. The baseline ECG shows a rhythm of 80 beats/min and the ST segment is marked by the circle. B. ST segment depression, which is indicative of stress-induced ischemia, can occur when cardiac demand increases (160 beats/min).

though recent studies indicate that a steeper decrease (8%) in ejection fraction is required to optimally determine ischemia with mental stress (Becker et al., 1996; Goldberg et al., 1996).

Alternatively, positron emission tomographic techniques can be used to objectify unevenness in the cardiac blood *perfusion* and stress-induced changes thereof. Deanfield and colleagues demonstrated that most (93 out of 95) episodes of ST segment depression during exercise co-occurred with cardiac perfusion deficits (Deanfield et al., 1984). As is discussed later, the correspondence between radionuclide and ECG measures of ischemia is less consistent with mental stress (Rozanski et al., 1988) and cold pressor (Deanfield et al., 1987).

The most commonly used clinical assessment methods for inducible cardiac ischemia, however, are infrequently used in mental stress studies. Generally, exercise or pharmacologically induced ischemia is assessed using echocardiographic or myocardial perfusion single-photon emission computed tomographic (SPECT) studies. SPECT studies may involve thallium and/or technetium (Tc) 99m methoxy isobutyl

isonitrile (sestamibi) isotopes. Evidence regarding the prevalence and severity of mental stress-induced ischemia using these standard assessment techniques (Giubbini et al., 1991; Gottdiener et al., 1994) has revealed similar results as studies using radionuclide ventriculography and PET scanning.

Prevalence of Silent Ischemia During Physical Exercise and Laboratory Mental Stress Tasks

Some of the early studies examining the effects of mental stress on myocardial ischemia have found stress-induced ST segment depression (Schiffer, Hartley, Schulman, & Abelmann, 1976; Taggart, Carruthers, & Somerville, 1973; Taggart, Gibbons, & Somerville, 1969). Later studies repeatedly demonstrated, however, that ST segment depression with mental stress is uncommon (Blumenthal et al., 1995; Rozanski et al., 1988; Specchia et al., 1984) and occurs in less than 20% of patients with stable CAD. ST depression during mental stress is especially rare in patients who do not have ST depression during physical exercise testing (Specchia et al., 1984).

As noted earlier, more sensitive methods are now being used in mental stress studies to detect cardiac ischemia, such as echocardiography, radionuclide ventriculography, and positron emission tomography. Indeed, these sensitive measures are indispensable if researchers are to reliably investigate mental stress-induced ischemia. One of the earliest studies in this area was performed by Deanfield and colleagues (Deanfield, Shea, & Kensett, 1984). Utilizing positron emission tomography, mental arithmetic caused ischemia in 12 of 16 (75%) CAD patients. In a study by Rozanski et al. (1988), ischemia was assessed using radionuclide ventriculography during a series of mental stress tasks (mental arithmetic, public speaking, and Stroop color-word test) and exercise testing. Of the 29 patients who had exercise-induced wall motion abnormalities, 21 (71%) had ischemia during mental stress. It was further noted that the speech task was the most potent trigger of ischemia. This finding is consistent with the observation of Ironson et al. (1992) where a speech task, specifically aimed to the recall of an anger provoking event, produced a steeper decrease in ejection fraction than either arithmetic with harassment or a nonanger speech task. Similar results have been reported by Gottdiener and colleagues (1994). These investigators further showed that there was a relation between the severity of exercise stress-induced left ventricular dysfunction and the extent to which mental tasks triggered ischemia, suggesting that mental stress-induced ischemia may in part reflect the severity of underlying CAD. La Veau et al. (1989) and Burg et al. (1993) showed that the onset of ischemia occurs rapidly on the start of mental stress (< 2 min). There are also studies using radionuclide techniques in more ambulatory settings in which it has been found that mental stress can trigger ischemia (Breisblatt et al., 1988; Legault, Langer, Armstrong, & Freeman, 1995) with an overall prevalence ranging from 30% to 70%, whereas ST segment depression was generally not observed.

Chest pain accompanies mental stress-induced ischemia at a very low prevalence (< 10%), whereas estimates of exercise-induced chest pain range from 35% to 70%. Various ex-

planations have been offered for this phenomenon, which is discussed in more detail later. In brief, it has been suggested that silent ischemia is less severe and occurs at lower cardiac demand than symptomatic cardiac ischemia and, in addition, that psychological factors and stress-induced changes in endogenous opioids, such as beta-endorphin, may mediate the relation between mental stress ischemia and chest pain (Deedwania, 1995).

Some evidence suggests that apparently paradoxical reductions in ejection fraction may occur, especially in healthy women, with no angiographic evidence of CAD (Becker et al., 1996). Moreover, even with ischemia of some portion of the left ventricle, compensating increases in contraction of nonischemic segments may serve to maintain or increase ejection fraction with stress. Therefore, the validity of mental stress-induced ischemia can be improved when changes in wall motion or myocardial perfusion are used, rather than either a drop in ejection fraction that would reveal false positives, or ST segment depression that would yield false negative findings.

Psychological Factors Associated With the Inducibility of Laboratory Mental Stress-Induced Ischemia

Based on the evidence that psychological traits such as the Type A behavior pattern, trait anger, and hostility are associated with an increased risk of myocardial infarction and sudden cardiac death (Friedman & Rosenman, 1959; Williams et al., 1980) and these traits are related to increased cardiovascular reactivity (Krantz et al., 1996b), research has examined whether this psychological profile affects the threshold for inducibility of ischemia with mental stress. In a group of 30 patients with coronary artery disease, Burg et al. demonstrated lower anger control and elevated hostility, aggressive responding during the Type A interview, and trait anger in patients with mental stress-induced ischemia ($N = 15$) as compared to nonischemic patients. Of note, the ischemic patients did not score higher on measures of anxiety or neuroticism than nonischemic patients, indicating that the antagonistic behavioral style is specific for a lower threshold for mental stress-induced ischemia. Moreover, no differences in hemodynamic response between ischemic versus nonischemic patients were found, which may suggest that the differences between high hostile patients versus patients without this profile may result from differences in stress-induced changes in coronary supply.

One study found that hostility was associated with more severe ischemia in women and middle-aged men (Helmert et al., 1993). In addition, the combination of both hostility and defensiveness was associated with more severe ischemia during laboratory tasks and demonstrated more frequent episodes of ischemia during the activities of daily life (Helmert et al., 1995). This study indicates that psychological traits, other than hostility may modulate the relation between mental stress and inducibility of cardiac ischemia.

In summary, mental stress tasks may cause ischemia in 30% to 70% of patients with stable CAD. Ischemia with men-

tal stress is generally silent and is commonly not accompanied by ST segment depression. Thus, sensitive measures of cardiac ischemia—such as alterations in wall motion, pump function, or cardiac perfusion—are needed to assess the ischemic effects of mental stress tasks in the laboratory. In addition, if patients do not have ischemia during provocative physical exercise testing, then the likelihood of ischemia with mental stress is small. Hostility is a psychological trait that may potentiate the effects of mental stress on ischemia by increased cardiovascular reactivity and/or exaggerated emotional responses to mental challenges.

MENTAL AND PHYSICAL TRIGGERS OF SILENT ISCHEMIA DURING ACTIVITIES OF DAILY LIFE

Using a methodology involving both ambulatory ECG monitors and structured diary assessments, episodes of ambulatory ischemia can be cross-tabulated with activities and symptoms that co-occur with these ischemic events. Several studies have indicated that mental stress can function as a trigger of ischemia during the activities of daily life. The majority of ambulatory ischemic episodes (> 75%) are silent (Cecchi et al., 1983; Gabbay et al., 1996; Schang & Pepine, 1977). For example, Schang and Pepine (1977) demonstrated that most ischemic events occur at relatively low levels of physical activity, such as slow walking or sitting. In addition, the heart rate at which ambulatory ischemic events occur is reported to be significantly lower than the ischemic heart rate of diagnostic exercise testing (Andrews et al., 1993; Mulcahy et al., 1989). These relatively low ambulatory ischemic heart rates may in part reflect peculiarities of the standard treadmill exercise test, where cardiac demand is increased much faster than what is generally observed during daily monitoring (Panza, Diodati, Callahan, Epstein, & Quyyumi, 1992). It is nonetheless accepted that the majority of ambulatory ischemic events occur at relatively low cardiac demand and are often symptomatically silent; a result that parallels the characteristics of mental stress-induced ischemia in the laboratory.

To examine specific mental and physical activities that trigger ambulatory ischemia, patients' activity ratings during ischemia have been correlated with concomitant ischemia. This procedure is especially worthwhile from a methodological perspective, because most ischemic events are asymptomatic, thereby preventing symptom-based report bias. In a study of patients who were "uncertain" while waiting for the result of their diagnostic coronary angiography, Freeman and colleagues (Freeman, Nixon, Sallabank, & Reavely, 1987) found that ischemia was more prevalent than in a nonstressed control period. Moreover, ambulatory ischemia was related to the extent of perceived distress and elevation of catecholamine levels. Several other studies have used structured diary systems to examine the relation between activities of daily life as triggers of ischemia.

Barry and colleagues (1988) asked patients to complete a diary page each time their activities changed and rate them as either "rest," "usual," or "stress." Most episodes of ischemia

occurred at “usual” levels of activity. However, by definition, activities that are labeled as “usual” are engaged in most frequently during daily life. Therefore, the duration of ischemia was divided by the total time spent in each activity category. When correcting for the duration of activities, a graded relation was found such that more intense physical and/or mental activities were associated with more ischemia.

In a similar study in 63 patients with CAD, using a more sophisticated diary system, Gabbay et al. (1996) confirmed that ambulatory ischemia occurred at relatively sedentary activities. Of note was that ischemia occurred in 5% of the time spent in either high physical or high mental activity, as compared to 0.2% of the low activity control episodes (Fig. 40.3). Of the emotions assessed (anger, anxiety, tension, happiness, depression), “anger” was a significant trigger of ischemic events. In addition, among smokers, it was found that ischemia occurred more than five times as often while patients were smoking than when they were not. Although coffee and alcohol consumption were related to ischemia as well, these associations disappeared after adjusting for concomitant smoking.

It is well-documented that cardiac events have an increased incidence in the early morning hours (6 AM to 9 AM). Similar to the pattern of occurrence of clinical manifestations of CAD, there is a circadian rhythm of transient ischemia. In an elegant experiment, Parker et al. (1994) demonstrated that the increases in activity after waking up contribute considerably to the early morning peak of ambulatory ischemia. When patients were instructed to stay in bed until noon, a corresponding delay

in the “morning” peak of ischemia was observed. A recent study (Krantz et al., 1996a) showed that physical and mental triggers of ischemia are more potent in the first 6 hours after waking up. In addition, there appears to be an additional underlying endogenous circadian variation in vulnerability for ischemia, independent of patients’ activities.

The aforementioned studies lead to the following conclusions: (a) ischemia during the activities of daily life is generally silent (75%–95%); (b) ambulatory ischemia occurs most frequently during patients’ usual activities, but when adjusting for the duration of activities, a graded relation is observed between the level of both physical and mental stressors and the likelihood of subsequent ischemia; (c) the ambulatory ischemic heart rate is often lower than with standard treadmill exercise testing. It has furthermore been shown that symptomatic ischemic events are more common during physical than during mental activities (Krantz et al., 1994). The evaluation of triggers of ambulatory ischemia are somewhat limited by the reliance on diaries. Patients generally complete diaries with a frequency of 2 to 3 assessments per hour awake. Because mental and physical activities are proximate triggers of ischemic events, this relatively low rate of assessment might be too infrequent, and therefore underestimate the importance of these triggers. Laboratory procedures are more adequate in this respect, but lack the opportunity to examine real-life stressors. Recent studies have nonetheless demonstrated correspondence between laboratory and field assessments of mental stress-induced ischemia.

FIG. 40.3. Relation between increasing levels of physical (left panel) and mental (right panel) activity during the activities of daily life and duration of ambulatory ischemia. The upper two panels show the ischemic time unadjusted for the time spent in that specific activity level, the lower panels show the time-adjusted ischemic duration. Adapted from “Triggers of Myocardial Ischemia During Daily Life in Patients With Coronary Artery Disease: Physical and Mental Activities, Anger and Smoking” by F. H. Gabbay et al., 1996, *Journal of the American College of Cardiology*, 27, 585–592.

Correspondence Between Laboratory and Field Assessments of Ischemia

To examine the relation between ischemia during mental stress in the laboratory with ischemia during the activities of daily life, Blumenthal and colleagues (Blumenthal et al., 1995) studied 132 patients with stable CAD in both settings. Mental stress-induced ischemia (during either arithmetic, speech, mirror trace, or the Type A interview) was observed in 45 patients (34%), and ambulatory ischemia occurred in 58 patients (44%). Mental stress-induced ischemia was significantly more present in patients with ambulatory ischemia (26/58; 45%) than in patients without ambulatory ischemia (19/74; 26%). Results with laboratory exercise showed that exercise-induced wall motion abnormalities were unrelated to ambulatory ischemia, whereas exercise-induced ST depression during exercise was significantly associated with ischemia during daily life. To further validate that emotions and mental activities are independent triggers of cardiac ischemia, the authors demonstrated that ambulatory ischemia occurred three times as often in patients with mental stress-induced ischemia in the laboratory, while statistically controlling for the presence of exercise-induced ST segment depression. Similar associations between laboratory mental stress-induced ischemia for ambulatory ischemia were demonstrated by Legoult et al. (1995).

In an earlier study, Gottdiener et al. (1994) reported ambulatory ischemia in 24 out of 45 (53%) CAD patients. Laboratory-field comparisons were possible in 41 patients, of whom 19 (46%) displayed ambulatory ischemia. In contrast to the previously described findings of Blumenthal, no overall association was found between ambulatory ischemia and the presence of mental stress-induced ischemia in the laboratory (10/19; 53%), as compared to patients who did not have ambulatory ischemia (12/22; 55%). However, when the analyses were restricted to ambulatory ischemic episodes that occurred at low physical activity, it was found that patients with evidence of mental stress-induced ischemia in the laboratory had longer (22.9 ± 24.5 min) and more (23) ischemic events than patients without an ischemic response to mental stress (2.4 ± 3.5 min and 8 episodes, respectively). Moreover, the heart rate during ambulatory ischemia was lower (105 ± 15 beats/min) in patients with mental stress-induced ischemia, than in patients lacking this response (114 ± 21 beats/min).

Another laboratory-field study indicated that mental stress-induced increases in heart rate but not blood pressure are predictive of ambulatory ischemia (Krittayaphong, Light, Biles, Ballenger, & Sheps, 1995). Although ischemia occurred in 50% of the 18 patients, the authors did not report its association with ambulatory ischemia. Other methodological problems regarding this study include the small sample size and use of anti-ischemic medication in some of the subjects.

In summary, ischemia during the activities of daily life can be observed with ambulatory ECG monitoring and occurs in 30% to 50% of patients with stable CAD. Typically these ischemic episodes are asymptomatic (approximately 85%) and occur at relatively low heart rates. These characteristics

of ambulatory ischemia are similar to the cardiac effects of mental stress in laboratory settings. There is some evidence that mental stress-induced ischemia in the laboratory is a better predictor of ambulatory ischemia than exercise-induced ischemia, especially if these ambulatory episodes occur at low cardiac demand. However, these laboratory-field associations are somewhat limited by the restrictions regarding patient inclusion. That is to say, it has generally been required that patients meet the criteria of a prior diagnostic exercise test indicative of inducibility of ischemia, which makes exercise-mental stress comparisons a complicated issue. The well-documented observation that mental stress-induced ischemia occurs at relatively low cardiac demand and generally occurs without cardiac symptoms, has led to specific studies regarding possible biobehavioral mechanisms that may account for this phenomenon. These mechanisms are discussed next.

PATHOPHYSIOLOGICAL MECHANISMS OF STRESS-INDUCED SILENT ISCHEMIA

In order to explain the occurrence of silent ischemia, studies have examined factors that affect cardiac demand as well as factors that might impair coronary supply. In addition, several explanations have been purported to specifically account for the absence of symptoms during stress-induced ischemia, including the severity of ischemia itself, increases in endogenous β -endorphins with mental stress, and psychological factors. The following sections address the issues of cardiac demand and supply and mediators of ischemic pain perception.

Increased Cardiac Demand; Effects of Hemodynamic Reactivity

The response to acute psychological challenges most often includes the release of catecholamines and corticosteroids, with concomitant elevations in blood pressure, heart rate, and cardiac contractility (Krantz & Manuck, 1984). This has led to the assumption that an increased physiological response to environmental stressors is the primary pathophysiological mechanism accounting for the relation between psychosocial factors and CAD (Engelbreton & Matthews, 1992; Lepore, 1995; Rumboldt et al., 1993; Suarez, Williams, Kuhn, Zimmerman, & Schanberg, 1991). Increased reactivity may enhance progression of CAD even at early stages of atherosclerosis by increasing vascular damage due to elevated blood pressure and arterial lipid deposition (Fuster, Badimon, Badimon, & Chesebro, 1992). At a later stage of coronary atherosclerosis, which is of relevance for this chapter, increased catecholamine responses may result in episodes of transient ischemia due to increased cardiac demand (Krantz & Manuck, 1984; blood pressure and heart rate) and/or impaired coronary supply related to coronary constriction (Muller, Abela, Nesto, & Tofler, 1994) and increased tendency toward blood clot formation (Markovitz & Matthews, 1991).

Although mental stress can elicit significant hemodynamic responses, the increase in heart rate during mental stress is rela-

tively small compared to exercise testing, whereas blood pressure elevations in CAD patients are comparable to those observed with exercise (Blumenthal et al., 1995; Rozanski et al., 1988). The systolic blood pressure response is probably the main determinant of the cardiac demand component of mental stress-induced ischemia in the laboratory (Blumenthal et al., 1995). Note also that ischemia in itself may cause elevations of heart rate and blood pressure. However, hemodynamic elevations precede rather than follow ischemia. In addition, because ischemia with mental stress is generally silent, it is not likely that symptom-mediated elevation of autonomic nervous system activity is a confounding factor in the observed relation between stress-induced increases in cardiac demand and inducibility of ischemia.

Decreased Coronary Supply; Endothelial Dysfunction and Modifying Risk Factors

Because ischemia triggered by mental stress develops at lower cardiac demand than exercise-induced ischemia, it has been suggested that impaired coronary supply is a crucial factor in this process. Yeung and colleagues (Yeung et al., 1991) demonstrated that mental stress during cardiac catheterization can produce paradoxical coronary constriction in patients with CAD (Fig. 40.4). Other studies since then have confirmed this observation (Boltwood et al., 1993; Lacy et al., 1995), although negative findings have been reported as well (Dakak, Quyyumi, Eisenhofer, Goldstein, & Cannon, 1995; L'Abbate, Simonetti, Carpeggiani, & Michelassi, 1991).

The study by Yeung et al. (1991) found a linear relation between the coronary effects of mental stress and the response to intracoronary acetylcholine ($r = 0.58$). This suggests impaired coronary endothelial function as a pathophysiological mechanism for stress-induced coronary constriction (Fuster et al., 1992; Krantz et al., 1996b; Muller et al., 1994). Moreover, mental stress and acetylcholine administration have been shown to reduce coronary diameter in normal coronary arteries of patients with CAD risk factors, such as hypertension and elevated cholesterol (Kuhn et al., 1991; Vita et al., 1990, 1992). Preliminary evidence is available showing that mental stress-induced coronary constriction in smooth arteries is more severe in male coronary patients with hypertension and/or elevated LDL cholesterol (Gottdiener et al., 1997). Stress-induced factors that affect endothelial function may include circulating catecholamines (Fuster et al., 1992) and possibly vagal withdrawal. Vagal withdrawal has been shown to precede silent myocardial ischemia during daily life (Goseki, Matsubara, Takahashi, Takeuchi, & Ibukiyama, 1994; Kop et al., 1995; Verdino et al., 1995), and in dogs it has been demonstrated that pharmacological or surgical blockade of cardiac vagal innervation results in coronary constriction (Kovach, Gottdiener, & Verrier, 1995).

Therefore, mental stress may cause (silent) ischemia by in part reducing coronary supply. This process results from en-

dothelial dysfunction and is most likely mediated by CAD risk factors and sympathovagal activation of the heart.

Physical and Psychological Factors Accounting for the Absence of Pain During Myocardial Ischemia

In many medical conditions, visceral pain is a very poor self-warning system for pathophysiological abnormalities. Mechanisms of cardiac pain perception have been disappointingly elusive (Malliani, 1986). There are no nerve endings in the myocardium that have a specific function in mediating pain perception. The uncoupling of cardiac ischemia and symptomatology has been documented by Krantz et al. (1994). Using Holter monitoring and structured diary techniques, 85% of the ischemic episodes were found to be silent. Moreover, as shown in Fig. 40.5, 66% of the reports of typical chest pain were not accompanied by ischemia. Furthermore, ischemia during physical activity was significantly more often symptomatic than ischemia occurring at high mental activity. Table 40.1 summarizes factors that have been found to be associated with the absence of anginal symptoms during cardiac ischemia.

Evidence has indicated that ischemia is less severe in asymptomatic episodes (Dellborg, Emanuelsson, & Swedberg, 1993; Hecht, DeBord, Sotomayor, Shaw, & Ryan, 1994; Hendler, Greyson, Robinson, & Freeman, 1992; Klein, Chao, Berman, & Rozanski, 1994; Marwick, 1995; Nihoyannopoulos, Marsonis, Joshi, Athanassopoulos, & Oakley, 1995). In part, the less severe ischemia could result from the effects of collateral coronary flow that may act as a natural bypass (Dellborg et al., 1993), or by more cardiac tis-

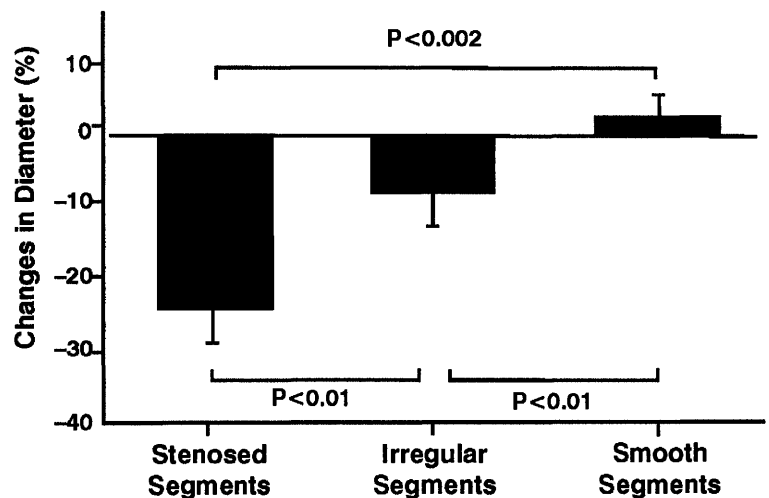

FIG. 40.4. Effects of mental stress on coronary diameter in stenosed segments, irregular segments, and smooth segments. Stenosed segments constricted significantly more (-24%) than irregular (-9%) and nondiseased (3%) segments. Adapted from "The Effect of Atherosclerosis on the Vasomotor Response of Coronary Arteries to Mental Stress" by Yeung et al., 1991, *New England Journal of Medicine*, 325, 1551-1556.

sue damage at rest as reflected by previous transmural (Q-wave) myocardial infarction (Titus & Sherman, 1991). It should be noted, however, that less severe ischemia during silent episodes has not been confirmed in several studies (Deanfield et al., 1984; Gasperetti, Burwell, & Beller, 1990; Light et al., 1991; Torosian, Lumley, Pickard, & Ketterer, 1997). Other studies have shown that cardiac demand is lower during asymptomatic ischemia (Deanfield et al., 1983; Schang & Pepine, 1977), but this is not an unchallenged position either (Carboni, Lahiri, Cashman, & Raftery, 1987). In addition, effective pharmacological treatment of documented ischemia is not necessarily accompanied by a reduction of anginal complaints (Borzak et al., 1993), which further supports the imperfect association between symptoms and underlying biological processes.

A second mechanism involves gradual decreases in autonomic nervous system functioning, which may result in impaired pain perception. Autonomic nervous system dysfunction may explain the increased prevalence of silent ischemia in diabetic patients due to peripheral neuropathy (Hikita et al., 1993; Langer, Freeman, Josse, Steiner, & Armstrong, 1991) and in the elderly (Ambepitiya, Roberts, Ranjadayalan, & Tallis, 1994).

Thirdly, it has been reported that patients with silent ischemia are characterized by a generalized higher threshold for pain stimuli (Droste & Roskamm, 1983). Light, Sheps, and colleagues demonstrated that mental stress may increase plasma β -endorphin concentrations (Light et al., 1991; Sheps

et al., 1995), thereby increasing the pain-sensitivity threshold. The importance of endogenous opioids is further supported by studies examining the effects of coronary angioplasty. This invasive procedure is used to remove obstructive coronary blockages by inflating a small balloon at the site of coronary obstruction, temporarily causing ischemia due to complete occlusion of a major coronary artery. Even in the setting of such a strong ischemic stimulus, approximately 30% of the patients remain free of symptoms (Dellborg et al., 1993; Falcone et al., 1993; Titus & Sherman, 1991). Higher plasma endorphin levels have been reported in patients without symptoms during angioplasty, whereas no difference in the severity or duration of ischemia has been noted between symptomatic and silent patients (Falcone et al., 1993). Biomedical predictors of "silent" ischemia may therefore include: lower cardiac demand and less severe ischemia; higher pain threshold due to autonomic nervous system dysfunction; and elevated endorphin levels. Nonetheless, the medical and biological predictors of absence of symptoms have as yet not revealed a consistent pattern of results and leaves room for psychological investigations regarding the nature of silent ischemia.

Recently, patterns of brain activity in symptomatic versus asymptomatic cardiac ischemia have been investigated using positron emission tomography (PET) studies assessing changes in cerebral blood flow (Rosen et al., 1996). Ischemia was induced using dobutamine, a β 1-agonist that does not pass the blood-brain barrier. Ischemia resulted in increased

FIG. 40.5. Association of cardiac ischemia (ST segment depression) and anginal pain. Thirty-one of 90 reports of chest pain (34%) were accompanied by ischemia (left), whereas only 31 of the 203 ischemic episodes were associated with chest pain (15%). Adapted from "Triggers of Angina and ST-Segment Depression in Ambulatory Patients With Coronary Artery Disease: Evidence for an Uncoupling of Angina and Ischemia, by Krantz et al., 1994, *American Heart Journal*, 128, 703-712.

activation of the brain stem, thalamus, and left hippocampal gyrus. Moreover, sustained alterations in brain activity were noted in the thalamus and dorsal frontal cortex until 13 minutes postischemia. Patients with painful ischemia ($N = 9$) displayed much more extended cerebral activation than patients with silent ischemia ($N = 9$), specifically in the ventral cingulate and dorsal frontal regions. Rosen et al. hypothesized that "gating" at the thalamic level may account for the altered central nervous system processing of cardiac ischemia. Alternatively, the perception of pain may induce cortical activation, and this study does not allow the differentiation of cause and effect of painful ischemia and concomitant cerebral activation.

Among the psychological factors that have been reported to predict the absence of ischemic symptoms is the observation that lower levels of depression are variably associated with silent ischemia (Davies et al., 1993; Light et al., 1991). In one study (Light et al., 1991) examining 45 CAD patients with ST depression during exercise testing, it was found that low scores on the Minnesota Multiphasic Personality Inventory (MMPI) depression subscale was associated with a lower frequency of anginal symptoms (28%) as compared to patients who had high depression scores (54%). Interestingly, these results were congruent with exercise-induced β -endorphins response, which was significantly higher in the nondepressed patients. Some evidence indicates that the Type A behavior pattern (Keefe, Castell, & Blumenthal, 1986; Siegel et al., 1989) and anger control (Torosian et al., 1997) are related to silent ischemia, but this has not been confirmed in other studies (Davies et al., 1993; Light et al., 1991). Type

A behavior may be related to the denial of physical and mental complaints. Denial has been found to predict absence of symptoms during ischemia (Freedland et al., 1991) and may be the general factor that accounts for the evidence supporting various symptom-based psychological constructs, such as low symptom awareness (Freedland et al., 1991), undercomplaining (Davies et al., 1993), and certain components of alexithymia (Torosian et al., 1997). In this respect, it is of relevance that alexithymia is related to myocardial infarction without symptoms and a delay in hospitalization for myocardial infarction (Kenyon et al., 1992; Theisen et al., 1995). This is in contrast, however, to the contention that alexithymia relates to symptom overreporting. To summarize, although the literature on psychological predictors of silent ischemia is still far from consistent, some evidence suggests that silent ischemia is related to lower depression scores and a tendency toward denial of symptoms.

PREDICTIVE VALUE OF SILENT AND MENTAL STRESS-INDUCED ISCHEMIA FOR FUTURE CARDIAC EVENTS

The prognostic importance of painless ischemia will be dependent on the method used for its detection. In general, most studies indicate that ischemic episodes during the activities of daily life are associated with an adverse risk of myocardial infarction and cardiac death, as is the presence of exercise-induced ischemia (e.g., Jain, Burg, Soufer, & Zaret, 1995; Pepine et al., 1994; Rocco et al., 1988). However, the presence or absence of ischemic pain has not added to the prediction of long-term outcome (Jain et al., 1995). For example, in a study of 406 post-MI patients, ambulatory ischemia was predictive of recurrent MI and unstable angina, independent of presence of anginal pain, physical exercise stress test results, cardiac function, and other clinical predictors.

Evidence accumulates that ischemia elicited by mental stress during laboratory tasks is predictive of adverse outcome (Jain et al., 1995; Jiang et al., 1996; Krantz et al., 1999). In a 2-year follow-up study in 30 patients with exercise inducible ischemia and coronary disease (Jain et al., 1995), mental stress was administered using the arithmetic task with harassment. Fifteen patients developed transient wall motion abnormalities with mental stress of whom 10 (67%) suffered a cardiac event during follow-up, as compared to 4 of 15 (27%) patients without mental stress-induced ischemia. In addition to the small sample size, this study is limited by the continued use of cardiac medication during mental stress testing and the use of suboptimal cardiac endpoints during follow-up such as episodes of unstable angina.

In a more recent study, Jiang et al. followed 126 patients with coronary disease for an average duration of 2 years and recorded the incidence of cardiac death, myocardial infarction, and coronary revascularization (Jiang et al., 1996). Ischemia was provoked in 67% of the patients using a series of five mental tasks. The investigators found that new cardiac events occurred in 27.4% of the patients with mental stress-induced ischemia, as compared to 11.9% of patients

TABLE 40.1

Possible Mediators Responsible for the Absence of Symptoms During Episodes of Myocardial Ischemia

Cardiovascular factors

- Low cardiac demand (mental stress, ambulatory ischemia)
- Ischemia less severe
- Collateral coronary flow
- Prior Q-wave infarction
- Peripheral Claudication
- Anti-anginal medication

Factors Affecting Autonomous and Central Nervous System Function

- Diabetes mellitus
- Age
- Inhibition of autonomic input at thalamic level

General Pain Threshold

- Elevated α -endorphins
- Stress-induced decrease in sensitivity

Psychological Factors

- Low depression
- Denial of symptoms

who did not develop ischemia during mental stress (Fig. 40.6). The most potent mental stress predictor of adverse outcome was the arithmetic task (OR = 3.9; $p < .001$). Exercise-induced ST segment depression was a marginally significant predictor of new events (OR = 1.8; $p = .07$), whereas ambulatory ischemia was unrelated to outcome. A recent follow-up study was consistent with this finding and showed that mental stress-induced ischemia was associated with a greater than twofold risk for an adverse long-term outcome. No such associations were found with exercise-induced ischemia (Krantz et al., in press).

At present it is not known whether the prognostic value of ischemia induced by mental stress reflects its association with ambulatory measures of ischemia, the severity of underlying CAD, or other cardiovascular risk factors. It is undoubtedly important to combine research from both behavioral and

medical disciplines to explain the absence of symptoms during cardiac ischemia and to clarify the prognostic value of silent ischemia for future cardiac events.

CONCLUSIONS

Mental stress is a potent trigger of cardiac ischemia in patients with coronary artery disease. Characteristic of mental stress-induced ischemia is the absence of symptoms such as chest pain and the lower cardiac demand at onset of ischemia. This has led to the hypothesis that impaired cardiac blood supply following paradoxical stress-induced constriction of the coronary arteries is a crucial factor in ischemia triggered by mental stress. Future studies are needed to examine whether psychological factors such as hostility are associated with increased coronary constriction to mental stress.

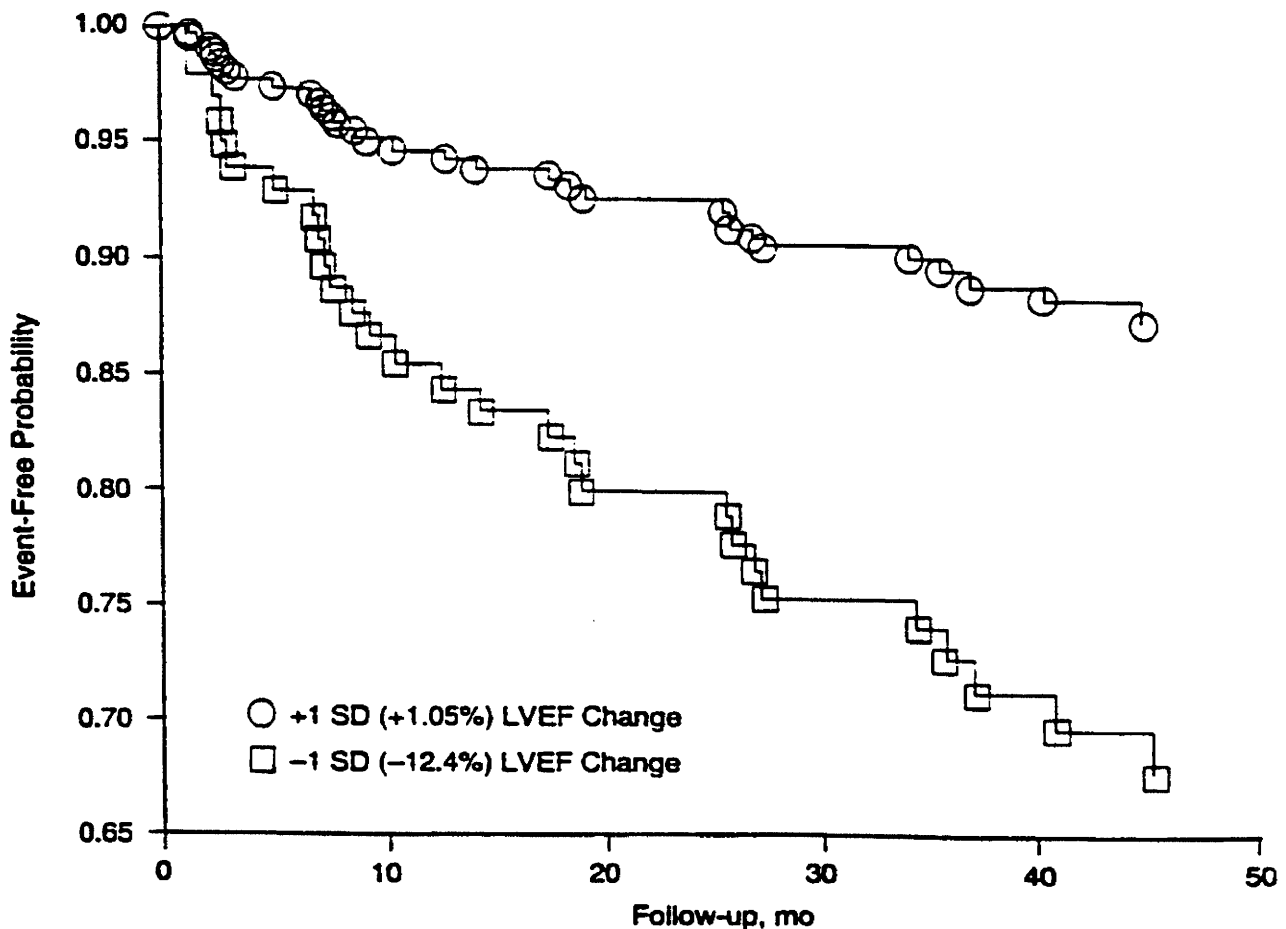

FIG. 40.6. Probability of an event-free survival as related to mental stress-induced ischemia. Patients who had less than 1 standard deviation decrease in ejection fraction (-12.4%) with mental stress had an adjusted relative risk of 2.4 ($p = .02$) for an adverse outcome during follow-up compared to patients with a > 1 standard deviation increase in ejection fraction ($+1\%$) with mental stress. Adapted from "Mental Stress-Induced Myocardial Ischemia and Cardiac Events" by Jiang et al., 1996, *Journal of the American Medical Association*, 275, 1651-1656.

An important and unresolved issue is the dissociation between chest pain and cardiac ischemia. Possible mechanisms of asymptomatic ischemia have been discussed, including cardiovascular factors such as lower cardiac demand and lesser severity of ischemia, the autonomous nervous system function, elevated endogenous opioids, and psychological factors such as lower depression scores and denial of symptoms. In addition, possible differences in cerebral processing may account for altered perception of pain in cardiac ischemia. Large studies will be needed to determine the individual and interactive contributions of biologic and psychological factors in silent ischemia.

Finally, a series of studies are now available in support of the predictive value of mental stress-induced ischemia for future cardiac events in patients with established coronary artery disease. Most studies were restricted to patients with a prior positive exercise test for ischemia. This limits the possibility to disentangle the predictive value of ischemia induced by mental versus physical stress. In addition, further research is needed to clarify the biobehavioral mechanisms accounting for the higher incidence of adverse events in patients with ischemia during mental stress in the laboratory. It could be that patients with mental stress-induced ischemia have a worse cardiac condition to start with, but it is also conceivable that increased cardiovascular reactivity and a higher prevalence of ischemic episodes during the activities of daily life account for the predictive value of mental stress ischemia. Given the specific hemodynamic characteristics of mental stress-induced ischemia, pharmacological treatments targeted to counteract coronary vasoconstriction combined with psychological interventions directed at reducing anger, hostility, and depressive symptoms may ultimately prove beneficial in the treatment of patients with coronary artery disease.

Psychoimmunology is the study of relations between behavioral factors, the central nervous system, the immune system, and health. To date, the human literature within this field has focused on a working model that stressful life events impact immune function, which in turn modifies host resistance to immune-related disease (S. Cohen & Herbert, 1996). Upper respiratory infections (URI) have served as the primary disease model in this literature and recent prospective studies support popular belief and provide compelling evidence that stressful life events and psychological distress predict biologically verified infectious illness (S. Cohen et al., 1998; S. Cohen, Tyrrell, & A. P. Smith, 1991, 1993; Stone et al., 1992). To date, however, the mechanism(s) of this effect remains unclear. Although there is substantial evidence that stress is associated with changes in immune function (Herbert & S. Cohen, 1993), the implications of stress-induced immune changes for susceptibility to disease have not been established. This chapter provides an overview of the human literature in psychoneuroimmunology, exploring evidence linking stress to immune function and susceptibility to infectious disease. Particular attention is given to individual differences in the magnitude of stress-related changes in immunity

as one plausible explanation for variability in susceptibility to infectious pathogens.

STRESS AND SUSCEPTIBILITY TO INFECTIOUS DISEASE

There is consistent evidence that persons under stress report more symptoms of URI, and that stress results in greater health care utilization for URI (S. Cohen & Williamson, 1991). For example, Stone, Reed, and Neale (1987) found that for 79 couples followed over 3 months, daily life events rated as undesirable increased 3 to 4 days prior to the onset of self-reported symptoms of URI. However, whereas self-reported symptoms of URI may tap underlying pathology, it is also possible that they reflect a biased interpretation of physical sensations without underlying illness. This possibility is supported by studies in which effects of stress are observed on symptom reporting, but not verified disease (S. Cohen & Williamson, 1991).

In support of a relation between stress and increased susceptibility to URI, epidemiological studies in which the pres-

ence of pathology was verified by physician diagnosis or biological methods, have found that major stressful life events, chronic family conflict, and disruptive daily events increase risk for upper respiratory disease (Graham, Douglas, & Ryan, 1986; Meyer & Haggerty, 1962; Turner Cobb & Steptoe, 1996). For example, Meyer and Haggerty followed 100 members of sixteen families for a 12-month period. Daily life events that disrupted family and personal life were four times more likely to precede than to follow new streptococcal and nonstreptococcal infections (as diagnosed by throat cultures and blood antibody levels) and associated symptomatology. Similarly, Turner Cobb and Steptoe (1996) found that among 107 adults followed for 15 weeks, individuals who developed clinically verified URI ($n = 29$) endorsed higher levels of life event stress than individuals who remained healthy. In another study, individuals who perceived their families as being more "chaotic" or "rigid" were found to be at greater risk of verified influenza B infection than individuals who described their families as more "balanced" (Clover, Abell, Becker, Crawford, & Ramsey, 1989). However, community studies like these do not control for the possible effects of stressful life events on exposure to infectious agents. Indeed, increased incidence of infection in these studies may be attributable to stress-induced increases in exposure to infectious agents rather than to stress-induced immunosuppression.

More recent studies provide control for exposure by experimentally inoculating healthy individuals with common cold or flu viruses (viral challenge studies). Here, volunteers are assessed for degree of stress and then experimentally exposed to a cold or influenza virus or placebo. They are then kept in quarantine and monitored for the development of infection and illness. Early viral inoculation studies were limited by a range of methodological weaknesses, including insufficient sample sizes and lack of control for factors known to influence susceptibility to viral infection (including preexisting antibodies to the infectious agent and age). Furthermore, the possible role of stress-elicited changes in health practices, such as smoking and alcohol consumption, was not considered. These limitations may account for initial failures to find consistent relations between stress and susceptibility to URI (S. Cohen & Williamson, 1991). In contrast, recent viral challenge studies have included multiple controls for factors known to be independently associated with susceptibility to viral infection (S. Cohen et al., 1991, 1993, 1998; Stone et al., 1992). These studies consistently find an association between stress and susceptibility to URI. For example, among 394 healthy adults, stressful life events, perceptions of current stress, and negative affect all predicted the probability of developing a biologically verified cold, with greater stress related linearly to susceptibility (S. Cohen et al., 1991, 1993). This dose-response relation was found across five different URI viruses. In addition, recent research suggests that the longer the duration of stressful life events, the greater the risk of becoming infected (S. Cohen et al., 1998). A large number of control factors (including, age, sex, allergic status, body weight, season, and virus-specific antibody status before challenge) have not been able to explain the increased risk for

colds among persons reporting greater stress. Smoking, alcohol consumption, diet, exercise, and sleep quality have also failed to account for the relation between stress and illness in these studies (S. Cohen et al., 1991). Similar results have been independently replicated by Stone et al. (1992).

In addition to episode onset, severity of infectious disease appears to be influenced by stress. For example, S. Cohen et al. (1995) found that negative mood measured prior to viral exposure was related to colds and influenza of greater severity, as determined by the amount of mucus produced over the course of illness. In sum, recent well-controlled studies corroborate prospective studies of community samples in indicating that psychological stress is associated with increased susceptibility to upper respiratory disease. In addition, there is consistent evidence for increased symptom reporting under stress.

MECHANISMS THAT MAY LINK STRESS TO DISEASE

A number of potential pathways exist through which an association between stress and infectious pathology might occur, including behavioral and immune mechanisms. In the first case, psychosocial factors could directly or indirectly influence health through changes in health-related behaviors. For example, poor nutritional status, smoking, drug and alcohol intake, lack of exercise, and poor sleep have all been shown to compromise immune status and health (Irwin, Lacher, & Caldwell, 1992; Kiecolt-Glaser & Glaser, 1988; Kronfol et al., 1989; Kusaka, Kondou, & Morimoto, 1992). However, as noted earlier, these behavioral factors do not account for much of the variability among individuals in infectious disease susceptibility. Hence, other mechanisms must also be operating.

The influence of stress on the immune system is considered the primary biological pathway through which stress can influence infectious pathology. Numerous neurochemicals released during stress are associated with modulation of immune function, including catecholamines (epinephrine and norepinephrine), corticosteroids, and opiates (e.g., Darko, Irwin, Risch, & Gillin, 1992; Herberman & Ortaldo, 1981; Irwin et al., 1992). In addition, direct anatomical links exist between the central nervous and immune systems, as evidenced by sympathetic and parasympathetic innervation of lymphoid organs (Felten & Olschowka, 1987; Livnat, Felten, Carlson, Bellinger, & Felten, 1985). Moreover, immune cells, which migrate between lymphoid organs and the peripheral bloodstream, have receptors for a variety of hormones and neurotransmitters that are released during stress (see Plaut, 1987). Thus, there is extensive evidence for direct anatomical and functional links between the central nervous and immune systems, providing a biological pathway for the influences of stress on susceptibility to infectious disease.

To date, the only study to examine whether the immune system mediates the association of chronic stressors and colds found little evidence for the role of either numbers of circulating white blood cell populations or NK cell activity (S. Cohen et al., 1998). However, the immune response to viral pathogens involves a complex cascade of events. Researchers measuring

immune function in humans are limited to a few basic markers that provide a poor overall estimate of the body's ability to resist disease. Hence, it remains likely that other immune components operate as pathways in the link between stress and susceptibility to disease. The remainder of this chapter focuses on evidence that stress is accompanied by changes in immune function, which may in turn render the individual more susceptible to infectious disease. First, however, a brief overview of measures of immune function is offered.

MEASUREMENTS OF IMMUNOCOMPETENCE

The immune system is a highly complex, interactive network and there is no single, adequate measure of its status (Cunnick, Lysle, Armfield, & Rabin, 1988). Human studies are limited to quantitative and functional assessments of immune parameters sampled from peripheral blood and saliva. These tests include assessment of the numbers and functional abilities of various subgroups of immune cells. In enumerative assays, the various populations of leukocytes are identified and counted by staining the unique surface molecules of each cell type with specific fluorescent reagents. Using this technique, the percentages or absolute numbers of circulating T-lymphocytes (and their subsets), B lymphocytes, macrophages, and NK cells can be determined.

With respect to functional assessments, lymphocyte proliferation assays are commonly used in human research. In this assay, leukocytes are incubated with experimental antigens called mitogens that nonspecifically stimulate T or B lymphocytes to divide. The rate of resultant proliferation is taken as a measure of immunocompetence, with greater cell division reflecting a more effective immune response. Commonly used mitogens include phytohemagglutinin (PHA) and concanavalin A (Con A), which stimulate the proliferation of T lymphocytes, and pokeweed mitogen (PWM), which activates T and B lymphocytes. Natural killer cell cytotoxicity is also frequently measured. NK cells are a subset of lymphoid cells with the ability to spontaneously kill some human tumor and virally infected cells. The ability of NK cells to destroy tumor cells (NK cell activity) is most commonly assessed by a chromium release assay. Enhanced NK cell activity may also be measured by incubating NK cells with stimulatory cytokines, such as interleukin-2 (IL-2) or gamma-interferon (IFN- γ). The ability of these cytokines to increase NK cell activity is then compared to cytotoxicity levels found in unstimulated samples. Finally, *in vitro* assays are also used to measure cytokine concentrations in the circulation or the production of cytokines by lymphocytes and monocytes following stimulation with mitogens.

In contrast to these laboratory measures, other indices of immunocompetence are performed *in vivo*, assessing immune function in the living organism. One such measure is antibody production in response to inoculation with an antigen (e.g., vaccination with recombinant hepatitis B vaccine or keyhole limpet hemocyanin). Here, individuals ingest or are inoculated with an antigen and the amount of antibody produced in response to that specific antigen is quantified in serum. Certain

antibody responses (e.g., salivary immunoglobulin A) can also be measured in saliva. In general, greater antibody response is thought to reflect better immunocompetence; however, elevated antibody levels to latent herpes virus may reflect a weakened ability of the immune system to keep such viruses in check. Therefore, higher antibody levels to herpes viruses (e.g., Epstein-Barr virus) are often interpreted as indicating poorer immunocompetence (Kiecolt-Glaser & Glaser, 1987).

CHRONIC STRESSORS AND IMMUNITY

Several reviews (Bachen, Marsland, Manuck, & S. Cohen, 1998; Kiecolt-Glaser & Glaser, 1991; O'Leary, 1990) and a meta-analysis of the literature on stress and immunity in humans (Herbert & S. Cohen, 1993) conclude that naturalistic stress (as measured by both self-report and objective life events) is reliably associated with modulation of functional and enumerative aspects of the immune system. The most consistent functional alterations include reduced NK cell activity and lymphocyte proliferation to PHA and Con A, and increased antibody levels to latent herpes viruses, suggesting decreases in the competence of the immune system to control latent virus activity. In terms of enumerative parameters, chronic stress is associated with decreases in percentages or absolute numbers of circulating B cells, T cells, T-helper cells, T suppressor/cytotoxic cells and NK cells. Stress has also been associated with decreases in total serum IgM (Herbert & S. Cohen, 1993) and in the concentration of total salivary IgA (Evans, Bristow, Hucklebridge, Clow, & Walters, 1993).

To date, the majority of studies in this literature has examined the influence of naturally occurring stressors on immune function. Numerous life event stressors and environmental demands have been associated with immune changes, including job stress (Arnetz et al., 1987), long-term unemployment (Arnetz et al., 1987; Dorian et al., 1985), loss of an intimate relationship due to death (Kemeny et al., 1995; Schleifer, Keller, Camerino, Thornton, & Stein, 1983) or separation/divorce (Kennedy, Kiecolt-Glaser, & Glaser, 1988), caring for a relative with Alzheimer's disease (Kiecolt-Glaser, Glaser, Shuttleworth, Dyer, Ogrocki, & Speicher, 1987), marital conflict (Kiecolt-Glaser et al., 1997), and natural disasters, such as earthquakes (Soloman, Segerstrom, Grohr, Kemeny, & Fahey, 1997) and hurricanes (Ironson et al., 1997), missile attacks during the 1991 Persian Gulf War (Weiss et al., 1996) and residing near a damaged nuclear power plant (McKinnon, Weisse, Reynolds, Bowles, & Baum, 1989). Interestingly, there is also evidence that alterations in immunity may persist (i.e., fail to habituate) with prolonged stressor exposure (e.g., Baum, 1990; Kiecolt-Glaser & Glaser, 1991; Kiecolt-Glaser, Glaser, et al., 1987).

Naturalistic Stressors

One stressor that has been associated consistently with altered immunity is the loss of a close personal relationship from either death or divorce. Early studies demonstrated that lymphocyte proliferative responses among bereaved subjects were lower after the death of a loved one than during the

pre-bereavement period (Schleifer et al., 1983), and were also lower than in nonbereaved controls (Bartrop, Lazarus, Luckhurst, Kiloh, & Penny, 1977). In these studies, immunologic alterations persisted from 2 to 14 months after the loss. Recent studies support these findings (e.g., Goodkin et al., 1996; Kemeny et al., 1995) and also demonstrate that the degree of immune change associated with bereavement may be related to the severity of concomitant depressed mood. For example, Irwin, Daniels, T. L. Smith, Bloom, and Weiner (1987) found that levels of depression among a group of bereaved women correlated inversely with NK cell activity ($r = .89$). Similarly, M. W. Linn, B. S. Linn, and Jensen (1984) found reduced lymphocyte proliferation to PHA in bereaved spouses, but only among those who also had depressive symptomatology.

Loss of a relationship from separation or divorce has also been associated reliably with immune alterations. In this regard, Kiecolt-Glaser, Fisher, et al. (1987) found decreased proliferative responses to PHA, higher antibodies to Epstein-Barr virus, and lower percentages of circulating NK and T-helper cells among 16 recently separated or divorced women than among a matched group of married women. Similarly, in a study of 32 men, individuals who had been separated or divorced for up to 3 years had higher antibody levels to latent viruses than matched, married controls (Kiecolt-Glaser et al., 1988). Other studies have demonstrated that poorer marital quality among married couples is related to greater distress, loneliness, and latent virus antibody response. For example, in a study of newlyweds, couples who expressed greater hostility during a discussion of marital problems showed the most pronounced suppression of immune function, as measured by natural killer cell activity and proliferative responses to PHA and Con A over a 24-hour period, and by higher antibody titers to latent Epstein-Barr virus. Similar findings were reported recently in a study of 31 older couples who had been married an average of 42 years. Here, men and women who showed greater suppression of lymphocyte proliferative response and higher antibodies to latent Epstein-Barr virus displayed more negative behavior during conflict, and described their usual marital disagreements as more negative, than individuals who showed better immune responses (Kiecolt-Glaser et al., 1997).

Several studies have also examined immune responses to the stress associated with caring for a family member with Alzheimer's disease (AD). Here, it has been demonstrated that caregivers frequently suffer higher levels of depression, more frequent health complaints, and decreased life satisfaction, due to the stressfulness of the caregiving experience (Light & Lebowitz, 1989; S. H. Zarit, Orr, & J. M. Zarit, 1985). Kiecolt-Glaser and colleagues published a series of studies examining immunologic alterations associated with caregiving for a family member with AD. To date, results indicate changes in several cellular immune components supportive of immunosuppression, including lower percentages of total lymphocytes and T-helper subsets, lower *in vitro* interleukin-1B responses to lipopolysaccharide stimulation, poorer NK cell response to stimulatory cytokines (IFN- γ and IL-2), and higher antibody titers to Epstein-Barr virus (Esterling,

Kiecolt-Glaser, Bodnar, & Glaser, 1994). Interestingly, caregivers also showed slower healing of a 3.5 mm punch biopsy wound (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995), making it possible that the decreases in immune function observed among caregivers leads to an impairment in wound healing. Taken together, then, there is a large body of evidence demonstrating that chronic naturalistic stressors, such as loss due to death or divorce, marital conflict, or caring for a relative with AD, modulate immune function.

Examination Stress

Numerous studies in the PNI literature have employed a quasi-experimental design, examining immune changes from before to after a naturally occurring event. Probably best known in this literature are the series of studies by Kiecolt-Glaser, Glaser and colleagues (e.g., Kiecolt-Glaser et al., 1986; Kiecolt-Glaser, Garner, Speicher, Penn, & Glaser, 1984) examining immune responses of medical students to examination stress. Compared to measures taken at less stressful times (e.g., just following a vacation), students demonstrate modulation of a number of immune components during examinations, including decreases in the total number of circulating T lymphocytes and NK cells, and in lymphocyte response to mitogen stimulation, lowered gamma interferon production and reduced NK cell activity (Dobbin, Harth, McCain, Martin, & Cousin, 1991; Glaser, Kiecolt-Glaser, Stout, Tarr, Speicher, Holliday, 1985; Glaser, Rice, Speicher, Stout, & Kiecolt-Glaser, 1986; Kiecolt-Glaser, & Glaser, 1987). During exams, students have also shown increased levels of circulating antibodies to Epstein Barr and other herpes viruses (Glaser et al., 1993; Glaser, Kiecolt-Glaser, Speicher, & Holliday, 1985) and slower healing of a punch biopsy wound (Kiecolt-Glaser, Page, Marucha, MacCallum, & Glaser, 1998).

Vaccination Responses

Other investigations have explored the impact of perceived stress on the ability to produce antibodies (develop immunity) to novel antigens. These *in vivo* immune measures may provide a more proximate mechanism of stress-infectious disease associations because they are directly related to host resistance. Results of early retrospective studies examining relations between life event stressors and antibody response to influenza viruses are inconclusive, possibly due to the memory distortion and bias inherent in recalling stressful events. For example, Green, Betts, and Ochitill (1978) found that higher perceived life change stress, during the 12 months preceding inoculation with an influenza virus, was associated with a lower antibody response; however, others reported no significant relations (Locke & Heisel, 1977; Locke, Hurst, & Heisel, 1979). Results of prospective studies are more consistent, indicating that higher levels of perceived stress around the time of influenza vaccination are associated with lower antibody responses (Bovbjerg, Manne, & Gross, 1990; Locke et al., 1979).

One limitation of using a common live virus, such as influenza vaccine, to examine development of immunity is the

likelihood that individuals have already been exposed to the virus. Consequently, antibody response is influenced by factors such as preexisting antibody levels, the amount of time since prior sensitization, and ongoing environmental exposure. In order to avoid these potential confounds, more recent prospective studies have examined antibody responses to novel antigens, to which the individual has not had prior exposure. Once again, results suggest that an individual's psychological "state" around the time of antigen challenge and antibody formation may influence their level of antibody response. For example, Snyder, Roghmann, and Sigal (1993) demonstrated that 3 weeks after inoculation with keyhole limpet hemocyanin (KLH), individuals reporting more psychological distress and "bad" life events mounted a lower lymphocyte proliferation response to KLH than individuals who reported "good" life events and social support. Similarly, Stone et al. (1994) had volunteers ingest a capsule containing an innocuous novel antigen daily for 12 weeks. During this period, volunteers also completed daily diaries, recording positive and negative daily events, and gave daily saliva samples to assess secretory immunoglobulin A (sIgA), an antibody to the novel antigen. Once again, more desirable daily events were associated with greater, and more undesirable events with less, antibody to the novel antigen.

Other research has explored the impact of perceived stress on antibody response to hepatitis B vaccination. To date, these studies have yielded inconsistent findings. Glaser et al. (1992) followed medical students who received each of three hepatitis B inoculations during an examination period. Those individuals who mounted an adequate immune response to the first dose of vaccine (25% of sample) reported less stress and anxiety to subsequent examinations than those who did not seroconvert until later. However, there was no prospective relation between perceived stress and antibody response to the first vaccination in the series. In another study, Jabaaij et al. (1993) demonstrated that greater perceived stress around the time of the initial vaccination was associated with lower final antibody levels, as assessed after a series of three vaccinations. In contrast, Petry, Weems, and Livingstone (1991) found a positive relation between negatively perceived stress, irascibility, depression, and anxiety and peak antibody titers.

Reasons for contradictory findings across studies are unclear. Comparisons are made difficult by variability in study design, including psychological constructs measured, and timing of psychological and immune measurements. In regard to the latter, it is possible that psychological stress influences antibody response to hepatitis B vaccination in a time-dependent fashion, with stress having a greater impact in the earlier phases of the immune response around the time of initial antibody formation. In support of this possibility, Jabaaij et al. (1993) demonstrated that whereas psychological distress at the time of the initial vaccination was associated with lower peak antibody responses following a complete vaccination series, levels of distress around the time of the final booster vaccination were unrelated to the final immune response. Other studies measuring stress later in the antibody response also failed to find an association or found opposite effects (Marsland et al., in press; Petry et al., 1991). In sum,

there is consistent evidence that high levels of perceived stress around the time of antigen challenge are associated with a decreased *in vivo* immune response. It remains to be determined whether a reduction in the magnitude of antibody response to vaccinations translates into increased susceptibility to infection; however, it has been demonstrated that individuals who mount lower antibody responses lose their protective status more quickly (Hollinger, 1989).

Individual Differences in Immune Responses to Naturalistic Stress

Not all individuals demonstrate immune changes following stressful life events. Indeed, there is marked variability among individuals in the magnitude of their immune responses to stress. In this regard, it is suggested that negative events only have an impact on immune function when they lead to negative affect or psychological distress. It is proposed that such distress is elicited when persons perceive that demands imposed by life events exceed their ability to cope (Lazarus & Folkman, 1984). In support of this model, a recent meta-analysis of the literature concluded that depressed mood states in clinical and nonclinical samples modulate various immune components, as evidenced by a down regulation of NK cell activity, lowered proliferative response of lymphocytes to the mitogens PHA, Con A, and PWM, and decreases in the total numbers of circulating lymphocytes, NK and B cells, and T-cell subpopulations (Herbert & S. Cohen, 1993). Furthermore, a number of studies have demonstrated that level of perceived distress moderates the impact of life event stress on immune function. For example, Locke and colleagues (1984) found that among students who reported high levels of life-change stress, those with many psychological symptoms of distress, including anxiety and depression, had lower NK cell activity than similarly stressed peers with few symptoms. Thus, there is some consensus that psychosocial adaptation to stress modulates immune function, with poor coping and emotional distress being associated with greater changes in immune components.

Interindividual variability in the magnitude of immune responses to stress may also be attributable to psychosocial buffers (e.g., interpersonal resources) that modulate the negative impact of adverse life events. For example, perceived inadequacy of interpersonal relationships, as measured by self-report, is related to distress and diminished immune function among medical students taking examinations (e.g., Kiecolt-Glaser & Glaser, 1991), caregivers of relatives with AD (Kiecolt-Glaser, Glaser et al., 1987), and psychiatric inpatients on the day of admission (Kiecolt-Glaser et al., 1984). There is also evidence that supportive interpersonal relationships buffer the adverse impact of negative life events on immune function (Kennedy et al., 1988). For example, Baron, Cutrona, Hicklin, Russell, and Lubaroff (1990) found that social support was associated with higher NK cell activity and greater proliferative responses to PHA (but not Con A) among 23 women whose husbands were being treated for urological cancer. Similarly, Glaser et al. (1992) showed that, when compared with individuals reporting low levels of social support,

medical students with more support mounted greater antibody responses to hepatitis B vaccination. In sum, although few studies examine individual differences in immune response to naturalistic stressors, there is some evidence that psychosocial adaptation modulates immune function, with distress (as measured by symptoms of anxiety or depression) being associated with greater immunosuppression.

Intervention Studies

Related to the stress-buffering hypothesis, studies have also examined whether interventions designed to lower emotional distress also reduce or prevent stress-related changes in immunity. These studies have used a diverse array of psychological interventions, including stress management training, relaxation, hypnosis, cognitive-behavioral strategies, exercise, and coping skills training. In general, results are consistent with improved immune function, or an amelioration of stress-related changes (Kiecolt-Glaser & Glaser, 1992). For example, Kiecolt-Glaser et al. (1985) demonstrated increases in NK cell activity and decreases in HSV antibody titers following progressive relaxation training in a group of older adults. One of the most widely cited studies in this literature evaluated the effects of a six-session group intervention for patients with malignant melanoma (R. I. Fawzy et al., 1993). When compared with patients who received routine medical care, the intervention, comprised of psychological support and training in relaxation, stress management, problem-solving and coping skills, effectively enhanced coping and reduced psychological distress, and was associated with an increase in the percentage of NK cells and NK cell activity, and a decrease in the percentage of T-helper cells. Other studies suggest that the down regulation of immune components known to accompany notification of positive HIV antibody status can be attenuated by aerobic exercise training (La Perriere et al., 1990, 1991) or by cognitive-behavioral stress management intervention (Antoni et al., 1991). However, not all findings are consistent. An 8-week stress reduction intervention was not associated with changes in immunological measures in HIV-seropositive men when compared with waiting list controls (Coates, McKusick, Kuno, & Stites, 1989). Similarly, Kiecolt-Glaser et al. (1986) found that a hypnotic/relaxation intervention did not attenuate the decline in NK cell activity associated with examination stress in medical students. Despite these negative findings, the majority of studies in this literature suggest that interventions designed to manage or reduce stress are associated with improved immune function or an amelioration of stress-related changes in immunity. Again, however, the health significance of these positive, but relatively small, immunologic changes remains unknown.

Persistence of Immunological Changes

Many studies suggest that chronic naturalistic stressors are capable of evoking psychological and immunological changes that continue long after a stressful event has ended. For example, extended stress responses were found in former

caregivers of AD relatives who had died at least 2 years earlier (Esterling et al., 1994). Similar ongoing responses were observed among residents of Three-Mile Island (TMI) more than 6 years after the nuclear plant accident occurred. In comparison to a group of demographically similar controls, many TMI-area residents continued to exhibit heightened levels of distress, elevated 24-hour urinary catecholamine excretion, increased latent herpes virus antibodies, and diminished numbers of B lymphocytes, T-suppressor/cytotoxic lymphocytes, and NK cells (Baum, 1990; McKinnon et al., 1989). These differences were not attributable to health behavior, because the two groups did not differ on diet, smoking, health, medications, or substance abuse.

It is unclear why stress-elicited changes in immune function persist over prolonged periods of time. As previously discussed (see Bachen et al., 1998), one possibility is that stressful life events may initiate a series of other related stressors, such as financial difficulties or social isolation, as well as behavioral or mood changes that could perpetuate immune alterations (Kasl, 1984; Kiecolt-Glaser & Glaser, 1988; Stone, Marco, Cruise, Cox, & Neal, 1996). In addition, cognitions, such as intrusive thoughts or images, may be important in sustaining stress reactions even when the initiating event no longer exists (Baum, 1990; Baum, L. Cohen, & Hall, 1993). For example, McKinnon et al. (1989) found that intrusive thoughts or imagery about the TMI accident and its health effects were related to elevated anxiety and immunologic changes in TMI-area residents. Similarly, intrusive thoughts about upcoming stressful events, such as a medical school examination (Workman & LaVia, 1987) or waiting for HIV test results (Antoni et al., 1990), have been shown to be related to poorer proliferative responses to PHA.

SUMMARY OF NATURALISTIC STRESS

In sum, it is well established that naturalistic stress modulates both functional and enumerative aspects of immunity. The most consistent alterations suggest that stress may suppress immune function over protracted intervals during particularly intense or prolonged stressors. Despite these central tendencies, not all individuals demonstrate immune changes following stressful life events. Indeed, there is marked variability among individuals in the magnitude of immune responses to stress. This interindividual variability has been attributed to a number of psychosocial buffers, including interpersonal resources and coping skills, which are thought to modulate the negative impact of adverse life events. To date, it remains unclear how stress may contribute to changes in the immune system. Potential pathways include the impact of stress on health practices (e.g., changes in diet, exercise or sleep) and/or the stress-induced activation of more physiological pathways (e.g., neuroendocrine parameters). Few naturalistic investigations have examined relations between health practices, neuroendocrine factors, and immune measures during stress (Herbert & S. Cohen, 1993). However, recent studies indicate that sleep disturbances may play an important role in the modulation of immune function during naturalistic stress. For example, Ironson et al. (1997) found evidence that the onset of

sleep problems following Hurricane Andrew partially mediated the relation between posttraumatic stress symptoms and lowered NK cell activity in a community sample affected by this disaster. Such findings are consistent with earlier reports that partial sleep deprivation is associated with reduced NK cell activity in humans (Irwin et al., 1992, 1994).

LABORATORY STRESSORS AND IMMUNITY

In order to examine whether psychological stress, independent of concomitant changes in health behaviors, alters immune components, investigators have recently begun to examine the effects of acute laboratory stress on immune functioning in healthy individuals. These controlled, experimental studies also provide a means to explore neuroendocrine pathways associated with stress and immunity. Findings from these studies reveal significant immunologic alterations following exposure to a range of standardized, short-term laboratory stressors that are generally perceived by subjects as aversive, demanding, or interpersonally challenging. Stressors employed in these studies include mental arithmetic, unsolvable puzzles, evaluative speech tasks, electric shocks and/or loud noise, marital discussions involving conflict and disturbing films depicting combat surgery (for a review, see Kiecolt-Glaser, Cacioppo, Malarkey, & Glaser, 1992). In contrast to some of the less common naturalistic stressors (e.g., bereavement or caring for a relative with AD), some of these challenges may more accurately characterize everyday hassles, and thus account for more observed interindividual variability in immune response to stress and susceptibility to disease.

The immediate effects of short-term laboratory challenge on immune function are not entirely consistent with longer term changes seen following chronic forms of naturalistic stress. In contrast to the chronic stress literature, acute stressors are usually associated with a transient increase in the number of circulating T-suppressor/cytotoxic lymphocytes and NK cells (Bachen et al., 1992; Brosschot, Benschop, Godaert, Heijnen, & Ballieux, 1992; Herbert et al., 1994; Manuck, S. Cohen, Rabin, Muldoon, & Bachen, 1991; Marsland et al., 1995; Naliboff et al., 1991; Zakowski, McCallister, Deal, & Baum, 1992). Decreases in the ratio of T-helper to T-suppressor lymphocytes (CD4:CD8 ratio) have also been reported (Bachen et al., 1992; Brosschot et al., 1992; Landmann et al., 1984). Less consistent findings include alterations in the number of T-helper and B-cell populations (Bachen et al., 1992; Caggiula et al., 1995; Gerritsen, Heijnen, Wiegant, Bermond, & Frijda, 1996; Marsland et al., 1995).

With regard to functional measures, both chronic naturalistic and acute laboratory stress have been associated with reduced lymphocyte mitogenesis on exposure to PHA, Con A, and PWM (Bachen et al., 1992; Caggiula et al., 1995; Gerritsen et al., 1996; Manuck et al., 1991; Marsland et al., 1995; Weisse et al., 1990; Zakowski, L. Cohen, Hall, Wollman, & Baum, 1994); however, not all results are consistent (Brosschot et al., 1992; Zakowski et al., 1994). In contrast to the decreases associated with chronic stress, a growing number of studies suggest that NK cell activity is increased following acute challenge (Cacioppo, 1994;

Naliboff et al., 1991; but not Sieber, Rodin, Larson, Ortega, & Cummings, 1992). Indeed, recent evidence suggests that the NK cell response to stress is biphasic, with an immediate increase in activity, followed by a later decrease to below baseline levels (Delahanty et al., 1996; Schedlowski et al., 1993).
